	3,3-Dichlorobenzidine
	4-Bromophenylphenylether
	4-Chlorophenylphenylether
	Benzidine
	Bis(2-chloroethoxy)methane
	Bis(2-chloroethyl)ether
	Bis(2-chloroisopropyl)ether
	Hexachlorobenzene
	Hexachlorobutadiene
SVOCs (continued)	Hexachlorocyclopentadiene
	Hexachloroethane
	Isophorone
	N-Nitrosodi-n-propylamine
	N-Nitrosodimethylamine
	N-Nitrosodiphenylamine
	Nitrobenzene
	2,4,6-Trichlorophenol
	2,4-Dichlorophenol
	2,4-Dimethylphenol
	2,4-Dinitrophenol
	2-Chlorophenol
	2-Methyl-4,6-dinitrophenol
	2-Methylphenol
	2-Nitrophenol
	3- and 4-Methylphenol
	4-Chloro-3-methylphenol
	4-Nitrophenol
	Pentachlorophenol
	Phenol
	Bis(2-ethylhexyl)phthalate
	Butylbenzylphthalate
	Di-n-butylphthalate
	Di-n-octylphthalate
	Diethylphthalate
	Dimethylphthalate
Pesticides	Aldrin
	alpha-BHC[c]
	beta-BHC
	Chlordane
	delta-BHC
	Dieldrin
	Endosulfan I
	Endosulfan II
	Endosulfan Sulfate
	Endrin
	Endrin Aldehyde
	Heptachlor
	Heptachlor Epoxide
	Lindane (gamma-BHC)
	Methoxychlor
	p,p'-DDD[d]
	p,p'-DDE[e]
	p,p'-DDT[f]
	Toxaphene
PCBs[g]	Aroclor 1016
	Aroclor 1221
	Aroclor 1232
	Aroclor 1242
	Aroclor 1248
	Aroclor 1254
	Aroclor 1260

Table 7-5
List of Analytes by Analytical Method for Fish Tissue Samples

Analyte Group	Analyte	Analyte Group	Analyte
Physical	Lipids	Pesticides	Aldrin
Metals	Antimony		alpha-BHC[b]
	Arsenic		beta-BHC
	Beryllium		Chlordane
	Cadmium		delta-BHC
	Chromium		Dieldrin
	Copper		Endosulfan I
	Lead		Endosulfan II
	Mercury		Endosulfan Sulfate
	Nickel		Endrin
	Selenium		Endrin Aldehyde
	Silver		Heptachlor
	Thallium		Heptachlor Epoxide
	Zinc		Lindane (gamma-BHC)
			Methoxychlor
Butyltins	Dibutyltin		p,p'-DDD[c]
	Monobutyltin		p,p'-DDE[d]
	Tributyltin		p,p'-DDT[e]
			Toxaphene
PAHs[a]	Benz(a)anthracene	PCBs[f]	Aroclor 1016
	Benzo(a)pyrene		Aroclor 1221
	Benzo(b)fluoranthene		Aroclor 1232
	Benzo(ghi)perylene		Aroclor 1242
	Benzo(k)fluoranthene		Aroclor 1248
	Chrysene		Aroclor 1254
	Dibenz(a,h)anthracene		Aroclor 1260
	Fluoranthene		
	Indeno(1,2,3-cd)pyrene		
	Pyrene		
	Acenaphthene		
	Acenaphthylene		
	Anthracene		
	Fluorene		
	Methylnaphthalenes		
	Naphthalene		
	Phenanthrene		

Notes:
[a] PAHs – polynuclear aromatic hydrocarbons
[b] BHC – hexachlorocyclohexane
[c] DDD – dichloro-diphenyl-dichloroethane
[d] DDE – dichloro-diphenyl-ethane
[e] DDT – Dichloro-diphenyl-trichloroethane
[f] PCBs – polychlorinated biphenyls

Table 9-1 (continued)

Data Qualification Note: Estimated data (J qualified) are presented along with validated data. Rejected data and undetected analytes are not shown. Sediment data are reported on a dry weight (dw) basis.

Notes:

[a] SEM/AVS – simultaneously extracted metals/acid volatile sulfides
[b] HPAH – high molecular weight polynuclear aromatic hydrocarbons
[c] LPAH – low molecular weight polynuclear aromatic hydrocarbons
[d] PCB – polychlorinated biphenyls
[e] BHC – hexachlorocyclohexane
[f] DDD – dichloro-diphenyl-dichloroethane
[g] DDE – dichloro-diphenyl-ethane
[h] DDT – Dichloro-dipher.yl-trichloroethane

HEALTH AND SAFETY ACTIVITIES

1.0 INTRODUCTION

From July through September 1994, a remedial investigation feasibility study (RI/FS) was conducted in the Long Beach Harbor West Basin (West Basin) of the Long Beach Naval Station (NAVSTA) located in Long Beach, California. Activities were conducted in response to the Installation Restoration Program RI/FS Work Plan issued April 1994 under Contract No. N68711-92-D-4670. On-site activities were designed to conform to federal, state and local environmental regulations All work was conducted under the Contract Task Order (CTO) No. 0026.

This report documents and summarizes the Health and Safety activities for CTO-0026 conducted in the West Basin (also referred to as Site 7 of the NAVSTA). Work operations included sediment sampling and fish bioassay conducted from the harbor piers and from water vessels. Field activities included fish collection by trolling operations, underwater diving, and sediment drilling from piers and Vibra-Core drilling from vessels.

2.0 PURPOSE/BACKGROUND

The purpose of Health and Safety is to support site activities, ensuring that project personnel and the immediate community are not exposed to harmful contaminants/materials from operations which have been recognized as potential sources of injury and illness. The overall objectives of the Remedial Investigation for marine sediments were to:

- identify chemicals of potential concern (COPCs),
- identify areas of potential concern (AOPCs),
- rank the AOPCs,
- assess which of the AOPCs need sediment remediation and identify appropriate cleanup levels; and
- assess whether further investigation is warranted for the remaining AOPCs.

The Comprehensive Long-Term Environmental Action Navy (CLEAN) II Project Health and Safety Procedures were used on a daily basis as guidelines to assess and correct/modify potential exposure sources and to promote safe and healthful work practices. This report documents the results of airborne contaminant monitoring, decontamination procedures, and other health and safety issues which were associated with Site 7 field activities

The Long Beach Harbor West Basin has been jointly used by both the NAVSTA and the Long Beach Naval Shipyard (LBNSY) since the early 1940s as a location to dock sea vessels. Both the NAVSTA and LBNSY have been selected as one of many military bases for closure in compliance with the Base Closure and Realignment Act of 1990.

0671

R0062606

3.0 SITE DESCRIPTION

The West Basin is located on the south side of Terminal Island within the Los Angeles and Long Beach Harbor districts. A Site Location Map is included in the Site-Specific Health and Safety Plan Supplement (Supplement).

CTO-0026 field work was conducted throughout the West Basin. Below is a brief description of Site 7. A Detailed Facility Map is included in the Supplement.

Site 7 has been defined as the sediments found in the West Basin. The main facilities of the Long Beach Naval Complex are located to the north while the NAVSTA Mole is located to the south and west. Storm sewers discharge into the harbor at 14 locations. A marina is located in the southwest corner of the harbor.

From the early 1940s to the mid-1970s, drainage from cleaning and processing tanks and from the various industrial areas were discharged into the West Basin through the storm sewer system and from flushing the drydocks. It is suspected that storm sewer discharges settled on the ocean floor and infiltrated into the harbor sediments. Previous reports have identified the following materials as being discharged into the West Basin:

- sodium nitrite,
- hydrazine,
- polychlorinated biphenyls (PCBs,)
- acids,
- solvents,
- oils, and
- greases.

4.0 SCOPE OF WORK

The scope of work for CTO-0026 involved surface and subsurface sediment sampling and biological testing/dissecting of West Basin fish. Tasks necessary to conduct these activities included the following:

- over water Vibra-Core subsurface sediment sampling,
- hollow stem drilling from Piers 2, 12 and 15,
- over water trolling,
- over water fish collection, and
- underwater (diving) surface sediment sampling.

5.0 HEALTH AND SAFETY COVERAGE

During non-intrusive activities, CTO-0026 field work was staffed by a member of Bechtel Safety and Health Services who conducted health and safety field operations and supervised members of

VOL 18
0672
R0062607

the CLEAN II Site Health and Safety Officer (SHSO) program. SHSOs are technical field personnel who have met the CLEAN II criteria for conducting collateral health and safety responsibilities.

When non-hazardous materials operations (i.e., non-intrusive) were conducted, field operations staffed a health and safety coordinator to document field activities to ensure that the specific health and safety guidelines provided by the Health and Safety Supervisor (HSS) were practiced. Health and Safety Coordinators are technical field personnel who, while not participating in the CLEAN II SHSO training Program, have been designated by the HSS to oversee health and safety for non-hazardous materials environments.

Health and Safety coverage was provided continuously during field activities and was focused on operations where there was the greatest potential exposure to safety and health hazards. These operations included work over water, extended time periods away from land, and exposure to airborne contaminants. During sediment sampling activities, airborne monitoring was conducted to assess potential airborne exposures. Minimum coverage (i.e., no airborne monitoring) was provided during non-intrusive operations, such as fish collection within the West Basin.

6.0 CHEMICALS OF POTENTIAL CONCERN

Using previous site investigation reports, various exposures for chemical and physical hazards have been identified. These include volatile and semivolatile organic hydrocarbons (VOCs and SVOCs), petroleum hydrocarbons, polynuclear aromatic hydrocarbons (PAHs), PCBs, pesticides and heavy metals.

At each location where airborne contaminants were a concern, real time air monitoring was conducted. Air monitoring was conducted during work operations and was documented according to the CLEAN II Site Health and Safety Plan, Section 10.2, 'Responsibility for Monitoring." Specific attention was given to employee exposures in the exclusion zones during intrusive operations.

Appropriate personal protective equipment (PPE) was required for all CTO-0026 locations where field personnel were expected to handle potentially contaminated sediments. In addition, airborne monitoring was conducted to assess personal exposure to COPCs.

The following subsections describe detailed monitoring and sampling methods that were used, or available for use, for site-specific contaminant assessments.

6.1 Airborne Hydrocarbons

Airborne monitoring for various solvents and oils was generally conducted using a photoionization detector (PID). This instrument is designed to detect various airborne materials by ionizing molecules, as they enter the instrument, using ultraviolet (UV) light. While the PID can detect many types of airborne hydrocarbons, it does not have the capability to speciate individual contaminants. Therefore, the PID was used as a principal screening device. The PID used for CTO-0026 field work, the ThermoEnvironmental Model 580 B, has a sensitivity of 0.1 part per million (ppm) and was calibrated daily with a known concentration of isobutylene.

VOL 18

0673

R0062608

In some cases, airborne contaminants were monitored with a flame ionization detector (FID). This instrument is designed to detect various airborne materials by ionizing molecules, particularly organic materials, as they enter the instrument, by a controlled burning hydrogen gas source. Similar to the PID, the FID was used as a screening device, as it cannot speciate specific airborne contaminants. The FID used for CTO-0026 field work, a Foxboro organic vapor analyzer (OVA) Model 128, has a sensitivity of 1 ppm. Calibration was conducted daily with a known concentration of methane.

Elevated FID/PID readings were further evaluated with a Drager bellows pump and detector tubes. This is a direct reading calorimetric method where the length of color change within a contaminant-specific detector tube correlates to the concentration of the specific contaminant in ppm. While this method yields a more specific quantification than the FID or PID, substantial errors can result from various sources, such as interferences from other contaminants and actual measurement of the length of color change.

6.2 Physical/Safety Hazards

Prior to conducting field activities, an assessment was made by noting appropriate accident control measures, such as verification of U.S. Coast Guard certifications for vessel specifications and personnel, first aid and rescue equipment, and appropriate communication devices. As a result of this assessment, appropriate health and safety supplies were documented in the Hazardous Work Permit (refer to Section 7.1). A checklist was developed by the HSS and approved by the Health and Safety Manager (HSM). This checklist was used prior to all work over water operations.

As a method to control accidental falling off vessels, personnel not directly involved with fish collection (trolling) were required to stay within a "safe-zone," established by the vessel captain (subcontractor health and safety coordinator) and approved by the HSS. Personnel conducting the fish collection were required to wear skid-resistant rubber boots. Rescue equipment and emergency medical supplies were available for the duration of all over water activities.

7.0 HEALTH AND SAFETY PROGRAM ELEMENTS

This section describes the program elements of the Site Health and Safety Plan implemented during CTO-0026 field activities.

7.1 Hazardous Work Permits

A Hazardous Work Permit (HWP) program was established to control all work and to specify the PPE and the monitoring and control requirements for each task. General HWPs were prepared for site reconnaissance, vessel operations, and sampling. Specific HWPs were prepared for each task that required specific health and safety requirements.

VOL 18
0674
R0062609

7.2 Personal Protective Equipment

Each HWP specifies appropriate protective equipment required for each task. Most field work for CTO-0026 required level D personal protective equipment (PPE). This ensemble consisted of sturdy work garments, work gloves, work boots with steel toe and shank, hard hat, and safety glasses. Personnel working within the exclusion zone during subsurface sediment sampling through the piers wore a modified level D ensemble, as specified in the CLEAN II Program Procedures, HS 3.2, 'Personal Protective Equipment."

Certain activities required specific PPE, such as underwater surface sampling (i.e., diving) and work on a vessel. Diving operations were required to comply with the following documents:

- USACE EM-385-1-1 Section 30, Contract Diving Operations,
- CFR 1910, Subpart T,
- US Navy Diving Manual, Volume 1, and
- CCR Subchapter 7, Article 152 & 153.

Work on vessels required a modification to Level D PPE, such as skid-resistant boots to replace steel toe boots. Hard hats were not required while working on the vessel; however, cloth hats were necessary for sun protection.

8.0 SITE CONTROL

All intrusive activities were performed according to the Site Specific Health and Safety Plan, which required an HWP, an applicable site configuration, decontamination, and site entry logs. Site configurations were designed to support personal decontamination and control hazardous materials from leaving the work area and reducing the threat of contamination to nearby people and areas. Refer to Section 7.1 (Hazardous Work Permit).

9.0 TRAINING PROGRAM

All personnel working at the project location were required to attend a CLEAN II Health and Safety Orientation, plus a Site Orientation. The CLEAN II Orientation was required only upon the initial visit to a CLEAN II Site. Hard hat stickers with individual CLEAN II employee numbers were issued to all field personnel. The Site Orientation was given to all personnel upon initial visit to a new CLEAN II location.

The purpose of the orientations were to brief the project personnel on project and site-specific elements of the CLEAN II Health and Safety Program, brief project personnel on the site-specific Health and Safety Plan requirements, and to provide site specific hazard communication information.

The briefing followed the standard CLEAN II Training Course Content. Respiratory protection training/fit testing was not required for this particular CTO, as field work was considered to be

VOL 18

0675

R0062610

'hon-hazardous" as defined by Federal and California Occupational Safety and Health Administration (OSHA) Hazardous Worker Operations and Emergency Response regulations.

Title 8 of the Code of California Regulations, Section 5192, and the project protocol require proof of completion of the 40-hour training and 8-hour refresher training courses for intrusive operations within sites that have been recognized as a hazardous cleanup site or emergency materials release area. Because the West Basin has not been identified as either of these scenarios, only drilling operations on Piers 2, 12, and 15 required compliance to these regulations.

10.0 HEALTH AND SAFETY PROGRAM FIELD RESULTS

The following is a description of the results of the program elements as implemented during CTO-0026 field activities.

10.1 Airborne Chemical Surveillance

10.1.1 SOLVENTS

Direct reading monitoring around employee breathing zones were recorded as nondetectable.

10.1.2 SAFETY HAZARDS

Daily inspections of PPE and HWPs were documented in the Daily Inspection Checklist. Health and safety equipment and supplies, such as fire extinguishers, life preservers, first aid kits, rubber boots, and sun protection, were checked prior to the start of site activities. If any hazard was identified which was not identified prior to the start of field activities, a procedure would have been developed and used as an established protocol to conduct field work.

10.2 Respiratory Protection

Respiratory protection was not utilized during this project.

11.0 UNUSUAL INCIDENTS

There were no unusual incidents, occurrences, or reportable injuries during the field work.

12.0 RECORDS

Health and Safety records generated during the field investigation are kept on file.

VOL 18
0676
R0062611

"non-hazardous" as defined by Federal and California Occupational Safety and Health Administration (OSHA) Hazardous Worker Operations and Emergency Response regulations.

Title 8 of the Code of California Regulations, Section 5192, and the project protocol require proof of completion of the 40-hour training and 8-hour refresher training courses for intrusive operations within sites that have been recognized as a hazardous cleanup site or emergency materials release area. Because the West Basin has not been identified as either of these scenarios, only drilling operations on Piers 2, 12, and 15 required compliance to these regulations.

10.0 HEALTH AND SAFETY PROGRAM FIELD RESULTS

The following is a description of the results of the program elements as implemented during CTO-0026 field activities.

10.1 Airborne Chemical Surveillance

10.1.1 SOLVENTS

Direct reading monitoring around employee breathing zones were recorded as nondetectable.

10.1.2 SAFETY HAZARDS

Daily inspections of PPE and HWPs were documented in the Daily Inspection Checklist. Health and safety equipment and supplies, such as fire extinguishers, life preservers, first aid kits, rubber boots, and sun protection, were checked prior to the start of site activities. If any hazard was identified which was not identified prior to the start of field activities, a procedure would have been developed and used as an established protocol to conduct field work.

10.2 Respiratory Protection

Respiratory protection was not utilized during this project.

11.0 UNUSUAL INCIDENTS

There were no unusual incidents, occurrences, or reportable injuries during the field work.

12.0 RECORDS

Health and Safety records generated during the field investigation are kept on file.

2 SUMMARY OF PREVIOUS INVESTIGATIONS AND IDENTIFICATION OF DISCHARGES

2.1 Summary of Previous Investigations 2-1
2.1.1 Studies Within the LBNC 2-1
2.1.1.1 1969 Industrial Waste Study 2-1
2.1.1.2 1983 Initial Assessment Study 2-1
2.1.1.3 1989 RCRA Facility Assessment 2-2
2.1.1.4 1991/1992 Site Inspection 2-2
2.1.1.5 1993 RI/FS Work Plan 2-3
2.1.2 Scientific Surveys 2-4
2.1.2.1 Physical Oceanographic Surveys 2-5
2.1.2.2 Chemical Surveys 2-6
2.1.2.3 Marine Biological Surveys 2-9
2.1.3 Dredging Activities 2-10
2.1.3.1 Los Angeles/Long Beach Harbor 2-11
2.1.3.2 West Basin 2-14
2.2 Identification of Discharges 2-16
2.2.1 Discharges to the LA/LB Harbor 2-16
2.2.2 Discharges to the West Basin 2-17
2.2.2.1 Land-Based Discharges 2-18
2.2.2.2 Ship-Related Discharges 2-25
2.2.2.3 Accidental Spills 2-29
2.2.2.4 Summary of Past Discharges to the West Basin 2-30
2.2.2.5 Non-LBNC Discharges to the West Basin 2-33

3 SITE CHARACTERIZATION

3.1 Data Quality Objectives 3-1
3.2 Sampling Design 3-3
3.2.1 West Basin Surface Sediment Sampling 3-4

EXECUTIVE SUMMARY

This report presents methods, data, and findings of a remedial investigation (RI) conducted at the Long Beach Naval Complex (LBNC) on behalf of the Department of the Navy (DON). The work was performed by Bechtel National, Inc. (BNI) at Site 7 under the Installation Restoration (IR) Program developed by the DON. For the purposes of implementing the IR program at the Long Beach Harbor West Basin (Site 7), the DON elected to follow the methodologies promulgated by the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA) of 1980, as amended by the Superfund Amendments and Reauthorization Act (SARA) of 1986.

The objective of this RI was to characterize the toxicity of West Basin sediments and fish. This objective was accomplished by acquiring chemical, physical, and biological measurements of, and assessing the extent of chemicals, their concentrations and toxicity in these media. This objective was outlined in the Remedial Investigation/Feasibility Study (RI/FS) Work Plan (JEG 1993a) and the Sampling and Analysis Plan (SAP) (JEG 1993b). These documents were approved by the DON and the United States Environmental Protection Agency (U.S. EPA), the Regional Water Quality Control Board (RWQCB), and the Department of Toxic Substances Control (DTSC).

At the onset of this RI and at the request of the technical oversight agencies, which included the U.S. EPA, RWQCB, and DTSC as well as the National Oceanic and Atmospheric Administration (NOAA), U.S. Fish and Wildlife Service (U.S. FWS) and the California Department of Fish and Game (CDFG), several addenda to the Work Plan and the SAP were developed, with the participation and acceptance of the technical oversight agencies. These addenda further defined specialized tasks and methodologies such as sample collection, laboratory analysis, data evaluation, and interpretation of results.

The LBNC, composed of the Naval Station (NAVSTA) Long Beach, the Long Beach Naval Shipyard (LBNSY), and the West Basin, is located on the south side of Terminal Island within the Los Angeles and Long Beach (LA/LB) Harbor districts. The LBNC was constructed in the early to mid-1940s. The West Basin is approximately 700 acres, with water depths on the order of 45 feet. Eleven piers, used for the purposes of ship docking for maintenance and loading, and a small-craft marina presently exist in the West Basin. Three dry docks are located at the LBNSY.

This RI addresses Operable Unit (OU) 3, which encompasses all of Site 7 under the IR Program. Site 7 designates the West Basin of Long Beach Harbor. The West Basin has been jointly used by the former Naval Station (NAVSTA) Long Beach, and the Long Beach Naval Shipyard (LBNSY) which will cease operations by September 1997.

Environmental investigations conducted within the LBNC, and regional scientific surveys were reviewed as part of this RI. Documents containing information of discharges into the LA/LB Harbor and the West Basin, and dredging plans were also reviewed and summarized in this RI. These documents indicate that most of the sources of discharge entering the West Basin are historical, whereas currently identifiable sources are generally

R0062633

under permit. Pollution control measures during the past years have been enacted to reduce or eliminate new contaminant sources into the West Basin.

SITE CHARACTERIZATION METHODOLOGIES

The findings of the site characterization were used in conducting a human health risk assessment which focused on ingestion of fish caught in West Basin by recreational and subsistence anglers. In addition, the site characterization findings were used in conducting an ecological risk assessment which focused primarily on West Basin sediments, as well as on ingestion of West Basin fish by an aquatic predator (harbor seal).

In support of these tasks, reference locations outside of West Basin, which were not impacted by the activities of LBNC, were selected and also characterized for the purposes of comparing West Basin data with local reference data. Fish and sediment samples were collected from both West Basin and reference locations. Fish samples included whole body, muscle tissue, and gall bladder bile. Two species dominated the catch and were used in this RI: California halibut and white croaker.

Both surface sediment (upper 10 cm) and subsurface sediment (up to 5 meters in depth) samples were collected. Benthic infaunal invertebrate samples were collected from the upper 10 cm at the locations of surface sediment samples. Sampling was generally conducted from a 40-foot scientific survey vessel; divers and land-based drill rigs were used to sample surface and subsurface sediments beneath piers.

Physical, chemical, and biological analyses were conducted on the sediment samples: grain size, total organic carbon (TOC), metals, polynuclear aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), pesticides, semivolatile organic compounds (SVOCs), and simultaneously extracted metals/acid volatile sulfide (SEM/AVS). In addition, laboratory clam bioaccumulation tests, and bioassays were performed using amphipods and polychaete worms (solid phase), and echinoderm larvae (pore water) as test organisms. Benthic community analysis was undertaken by specialists who identified and quantified the infaunal invertebrates in the samples. The results of laboratory chemical analyses were validated by a third-party laboratory.

Rigorous statistical methods and cluster analysis were used in evaluating West Basin and reference data. These evaluation methods clustered sampling stations on the basis of physical and chemical data, and allowed identification of sediment evaluation zones (SEZs) within West Basin. The individual SEZs were compared with the reference data for the purpose of establishing areas of potential concern (AOPCs) and chemicals of potential concern (COPCs).

RESULTS OF SITE CHARACTERIZATION

Surface sediment samples were collected from 7 reference stations, 34 basin stations representing the general basin area, and from 11 pier stations representing sediments beneath the piers, to characterize the distribution of physical, chemical, toxicity, and benthic infaunal properties of the surface sediments. Subsurface sediment core samples were collected from 2 reference stations, 5 basin stations and from 3 pier stations to describe the vertical distribution of the sediment physical and chemical properties.

Reference Station Data

Seven reference stations in the outer Los Angeles/Long Beach (LA/LB) Harbor were selected during the project planning stage with participation and acceptance of the U.S. EPA, RWQCB and DTSC. The reference stations represent sediments that were exposed to the normal port activities of the LA/LB Harbor, but were not affected by the activities of the LBNC. The sediments of the reference stations represented a wide range of sediment grain size and TOC distribution, similar to the range found in the West Basin sediments. Reference stations generally contained low levels of metals, DDT, and PAHs. No butyltins, PCBs, or SVOCs were found at the reference stations. Surface sediment toxicity at reference stations was very low. Only reference station toxicity data passing the performance criterion (i.e. comparison to laboratory control standard) were retained. Community indices at the reference stations suggest a healthy and normal benthic infaunal community. Mean and 95 percent predictive limits were calculated from the seven reference station sample data and used for comparison with data from West Basin stations.

Physical Properties of West Basin Sediments

West Basin sediments contained a wide range of sediment grain size distribution, probably influenced by earlier dredging activities, sediment sources (e.g. stormwater drains), and sediment depositional patterns within West Basin. The sediments collected from beneath piers contained substantial amounts of shell hash material that was not found in appreciable quantities at the basin stations. Sediments of the West Basin were primarily fines (sediment particles smaller than 62.5 μm), averaging 65 percent fines overall. Several surface sediment samples collected near the basin entrance contained a high percentage of sand-sized particles. West Basin stations located beneath piers, and along the seawall and Navy Mole contained a greater percentage of fines than the central areas of the West Basin. TOC was found in a distribution similar to the sediment fines, with greater concentrations along the seawall and Navy Mole, and beneath the piers.

West Basin Sediment Chemistry

Most of the detected metals, including arsenic, beryllium, cadmium, chromium, copper, lead, mercury, nickel, and zinc, were found in similar distributions among stations within West Basin. Metals concentrations were generally higher along the seawall and the Navy Mole, and between and beneath piers. In general, metals concentrations in West Basin sediments were not statistically significantly different than metals concentrations found at the reference stations, except for those stations beneath piers and adjacent to piers. Silver and selenium were detected in West Basin sediments but were not distributed in a recognizable pattern. PAH compounds were found at highest concentrations beneath the piers and adjacent to piers. Similar to patterns observed with the metals, the PAH concentrations exceeded the reference levels at the stations beneath the piers and adjacent to piers. Other chemical compounds were detected at many stations in West Basin, such as DDT derivatives, PCB, and di-n-octylphthalate, but displayed no clear distributional pattern. A few compounds were only detected at a few of the West Basin stations: dibutyltin, monobutyltin, aldrin, lindane, bis(2-ethylhexyl)phthalate, and phenol.

R0062635

VOL 18 00007

West Basin Biological Characteristics

Bioaccumulation tests included analyses of whole body samples from laboratory clams, California halibut, and white croaker, fillet samples from California halibut and white croaker, and gall bladder bile from California halibut. Mean values of chemical analytes detected in West Basin clam, fish tissue, and bile were compared to mean values found at the reference stations. No statistically significant differences were noted for concentrations of chemical analytes in the clam tissue between West Basin and reference stations. No statistically significant difference was noted between the West Basin and reference station values for California halibut whole body, fillet, or bile. A statistically significant difference was found between the West Basin and reference stations for chemical concentrations of mercury for white croaker fillet, and of arsenic, copper, and tributyltin for white croaker whole body. The chemical concentrations were higher in the samples collected from West Basin. However, mercury concentrations in fillet samples collected from the West Basin were within the range of values commonly measured in southern California harbors. Furthermore, based on the number of fish captured and their external physical appearance, there was no evidence of the elevated levels of chemicals having any detrimental effects on the white croaker population in the West Basin.

Toxicity results of the echinoderm, amphipod, and polychaete bioassays showed a wide range of response. Echinoderm larval development were more sensitive than the other bioassay tests with 67 percent of the West Basin stations exhibiting a response. The other bioassays showed a range of sensitivity: 27 percent of the West Basin stations showed a measurable response for echinoderm survival; 13 percent for amphipod survival, 11 percent for amphipod reburial; 2 percent for polychaete survival; and 0 percent for polychaete growth. Toxicity response for echinoderm larval development was observed at stations beneath the piers, adjacent to piers, near the entrance to the West Basin, and in the western area of the basin. No clear pattern of correlation to concentrations of detected chemicals was apparent in distribution of echinoderm toxicity results. Amphipod bioassay results showed toxicity response at three piers and at one sampling station. Polychaete bioassays showed only one location with a toxicity response beneath a pier.

Benthic infauna throughout the West Basin generally appeared abundant and diverse. No significant differences were noted between reference stations and West Basin stations for community indices. The most abundant West Basin benthic infauna species were recognized as indicators of healthy sediment conditions. A unique invertebrate assemblage was found in sediments collected from beneath the piers, attributed to the habitat diversity and abundance represented by hard substrate (shell hash). The community was very complex compared to communities from areas of soft mud. Therefore, comparisons among pier stations, basin stations and reference stations were difficult at best.

The infaunal community, the chief ecosystem of concern, for basin areas appears to be robust in terms of number of taxa, ecological function of different taxa (i.e., 'healthy', 'semihealthy' species), number of individuals, and total biomass. The infauna appears to have improved significantly since abatement of chemical discharges to the West Basin over the last 30 years, and there does not appear to be an ecological risk from surface sediment chemical concentrations. The invertebrate community beneath the piers exceeds basin and

R0062636

reference stations in number of taxa, number of total individuals, and total biomass and is also a mixture of healthy and semihealthy species.

Sediment Evaluation Zones

SEZs were established by grouping sampling stations of the West Basin that exhibited similar physical and chemical properties. Surface sediment physical and chemical data were evaluated with a cluster analysis procedure, a multivariate statistical technique that evaluates a similarity matrix for West Basin stations based on the physical and chemical variables. Stations presented as similar by the cluster analysis were considered members of a single SEZ. The cluster analysis presented eight SEZs in the West Basin. Because of the similar nature of physical and chemical properties of the stations within an SEZ, mean values were calculated for chemical, toxicity, and benthic infauna variables at each SEZ and compared to the mean values of reference stations for statistical differences.

The SEZs were labeled as follows: SEZ "A" located near the entrance to the West Basin; SEZs "B", "C", and "D" located in the central and western areas of West Basin; SEZs "E" and "F" located adjacent to the piers; and SEZs "G" and "H" located beneath the piers. Metals concentrations at SEZs F and H were found significantly higher than at reference stations. PAH concentrations were significantly higher than reference stations, primarily at SEZs E, F, G, and H. PCB was detected at concentrations greater than the reference stations at all SEZs except SEZ G. A few pesticides and SVOCs were detected at SEZs at concentrations exceeding the reference.

Chemicals of Potential Concern

Chemical analytes at each SEZ that statistically significantly exceeded the reference station concentrations, or that were not detected at the reference stations, were considered sediment chemicals of potential ecological concern (COPECs) for that SEZ. All SEZs contained sediment COPECs, although SEZs E, F, G, and H contained more sediment COPECs and at noticeably greater concentrations than the other SEZs.

Fish COPECs for hazard quotient calculations were comprised of analytes that were at significantly greater concentrations in West Basin fish samples than at reference station fish samples, or were only detected in West Basin fish samples and not in reference station fish samples.

Any chemical analyte detected in the fish tissue samples were considered COPHCs for the human health risk assessment. A list of COPHCs was prepared for the West Basin stations and for the reference stations for each fish species and each tissue sample type.

Areas of Potential Concern

Areas of potential ecological concern (AOPECs) were identified according to the preponderance-of-evidence evaluation matrix developed for this RI with participation and acceptance of the agencies. SEZs B, G, and H were shown as AOPECs upon application of data to the evaluation matrix because of chemical analyte concentrations and echinoderm toxicity. The remaining SEZs, although containing chemical concentrations

VOL 18
00008
R0062637

exceeding the reference stations showed no adverse toxicity response or benthic infauna patterns were not considered AOPECs.

HUMAN HEALTH RISK ASSESSMENT

Both cancer and noncancer risks to recreational and subsistence anglers consuming fish caught in West Basin were estimated for both California halibut and white croaker. The assessment of cancer risk did not show an appreciable difference in the cancer risks associated with consumption of California halibut and white croaker from the West Basin and the reference stations. The results indicate, however, that the upper-bound cancer risk associated with consumption of California halibut and white croaker, regardless of the source, is within the range considered to be unacceptable in accordance with criteria presented in the National Contingency Plan (NCP). Thus, concentrations of carcinogenic chemicals identified in some of the West Basin and reference California halibut and white croaker appear to be high enough to adversely affect individuals who consume these two species of fish. The fish consumption advisory recommended by the California EPA Office of Environmental Health Hazard Assessment (Cal-EPA OEHHA) supports this finding.

The results of the noncancer risk assessment suggest that, with the exception of arsenic, there appears to be no appreciable difference between the noncancer risk for the COPHCs in California halibut and white croaker from the West Basin and the reference stations. Noncancer risk associated with arsenic is probably overstated because a very conservative estimator was used. Generally, arsenic values found in the West Basin fish tissue samples are similar to results from other southern California harbors.

ECOLOGICAL RISK ASSESSMENT

The ERA focused on the assessment of risk that was related to contaminants existing in the West Basin sediment. Two methods were employed to assess the potential for risk: preponderance-of-evidence from sediment tests, and hazard quotient (HQ) calculations. The preponderance-of-evidence approach evaluated chemical analytes identified in sediment samples with the benthic biological systems, as indicated by benthic infauna composition, sediment toxicity, and bioaccumulation tests. The HQ approach evaluated the potential risk to an aquatic predator (harbor seal) exposed to chemical analytes in a benthic feeding prey species (white croaker).

Results of bioassays and the benthic infaunal study were evaluated for patterns related to the distribution of chemical analytes. Correlation analysis was used to evaluate relationships between individual chemical analytes and the biological response indicators (bioassays and benthic infauna indices). Principal component analysis and stepwise multiple regression were used to evaluate relationships between groups of co-occurring chemical analytes and the biological responses. The statistical analyses did not reveal any strong relationships between chemical analytes and biological responses. However, it appeared that a strong relationship existed between the biological responses and the location of the station. Biological responses were significantly different from reference at stations beneath the piers, although the responses were not consistent. Most bioassays

VOL 18
00099
R0062638

performed poorly beneath the piers except for the polychaete growth, while the benthic infaunal indices improved at stations beneath the piers.

Sulfide was detected at significant concentrations at pier stations. This appears to be a natural phenomenon resulting from reducing conditions in these sediments, which are probably poorly oxygenated and remain largely undisturbed beneath the piers. The high sulfide content at pier stations made the interpretation of bioassay results difficult, especially for echinoderm larvae development. The distribution of echinoderm larval development results were quite paradoxical when compared to concentrations of detected chemicals.

A review of the bioaccumulation data for biological significance did not reveal any adverse conditions for the fish, clam, or harbor seal. Tissue concentrations in the fish and clam were within the range reported from other studies in the area, and were not indicative of detrimental levels. Hazard quotients calculated for the harbor seal indicated that risk exists for the harbor seal feeding exclusively on West Basin fish, however, the risk appeared similar to the risk posed to the harbor seal feeding on fish from the reference stations.

Most of the SEZs contained sediment COPECs at concentrations that were less than those used to indicate levels of adverse conditions, such as ER-Ls, effects range-median (ER-Ms), and no-effect levels observed in this RI. Several of the metals and PAHs at SEZs F and H exceeded such guideline concentrations.

AOPECs were evaluated for levels of chemical analytes, toxicity responses, and benthic infauna data for consideration as areas of ecological concern (AOECs), an area containing demonstrable adverse conditions. None of the AOPECs appeared at risk due to the measured chemical analytes. The toxicity response observed at the AOPECs appeared to be more related to an unmeasured feature of the piers than to any other measured parameter. Benthic infaunal communities found at the AOPECs were abundant and diverse, although the invertebrates found beneath the piers were quite different from those found at other basin stations. The benthic community beneath the piers appears to have adjusted to the mixed habitat conditions found beneath the piers and apparently not adversely affected by the chemical concentration found in the sediments.

CONCLUSIONS AND RECOMMENDATIONS

Based on discussions related to, and the results of the human health risk assessment and the ecological risk assessment provided in this RI Report, no chemicals or areas of concern were identified for the West Basin which require remedial action or further characterization, such as water column investigations. Therefore, no further action is recommended for the West Basin.

R0062646

VOL 18

Section 1
INTRODUCTION

This report presents the methods, data, interpretations, and conclusions of a Remedial Investigation (RI) conducted at the Long Beach Harbor West Basin (West Basin). This site is located within the Long Beach Naval Complex (LBNC), and it is part of the Installation Restoration (IR) Program developed by the Department of the Navy (DON). The IR Program is designed, in part, to evaluate and remediate, if necessary, past contamination caused by hazardous substances, pollutants, or contaminants. To implement the IR Program at West Basin, the DON elected to follow the RI methodologies promulgated by the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA) of 1980, as amended by the Superfund Amendments and Reauthorization Act (SARA) of 1986.

The RI described herein was conducted and this RI Report was prepared by Bechtel National, Inc. (BNI) on behalf of the DON, Southwest Division Naval Facilities Engineering Command (SWDIV). The West Basin, which has been jointly used by the Long Beach Naval Shipyard (LBNSY) and the former Naval Station (NAVSTA) Long Beach, was the subject of this RI in accordance with Contract Task Order (CTO)-0026, under the Comprehensive Long-Term Environmental Action Navy (CLEAN) II Contract No. N68711-92D-4670.

1.1 PLANNING DOCUMENTS

At the onset of this RI, various plans were developed, describing the rationale, methodology, and details of the multitude of tasks to be implemented during the course of the work. These planning documents are listed below, with brief descriptions of their contents and objectives.

- Final Remedial Investigation/Feasibility Study Work Plan (JEG 1993a). This Work Plan provides an extensive program to conduct RI activities for West Basin, and includes discussions of background information related to West Basin.
- Final Sampling and Analysis Plan (SAP) (JEG 1993b). The SAP, which is a companion document to the Work Plan listed above, provides guidance on conducting a site investigation for West Basin. Guidelines are provided for sampling strategy, laboratory analyses, and data usage, and procedures are provided for sample handling and quality assurance(QA)/quality control (QC). The SAP also includes the following:
  - Quality Assurance Project Plan (QAPP). The objectives of the QAPP are to develop and implement procedures for acquiring data of known and appropriate quality.
  - Health and Safety Plan (HSP). The HSP contains procedures for implementation during field work activities. These procedures have been established to ensure that field staff are familiar with the hazards associated with their work and take reasonable precautions to provide a safe work environment in conformance with Occupational Safety and Health Administration (OSHA) requirements and applicable DON orders and directives.

0038

R0062647

- Final Community Relations Plan (CRP) (JEG 1993c). The CRP describes activities intended to keep the community informed and involved in the RI/Feasibility Study (FS) process.
- Final Risk Assessment Work Plan (BNI 1994a). This Work Plan describes methodologies for use in assessing human health and ecological risk posed by exposure to chemicals present in West Basin sediments.
- Final Fish Sampling and Analysis Plan (BNI 1994b). This plan describes procedures to be used in selecting fish sampling locations, collecting fish, and measuring concentrations of selected chemicals in fish tissue. It also provides the results of a creel census conducted at the LBNC and provides a list of fish species targeted for collection.
- Final Implementation of Final RI/FS Sampling and Analysis Plan - Technical Memorandum (TM) No. 4 (BNI 1994c). TM No. 4 provides clarification and, where appropriate, revisions to the strategies for sampling and characterizing West Basin sediments as initially described in the SAP (JEG 1993b). TM No. 4 also provides additional details of the rationale on implementing key elements of the SAP related to sediments, such as characterization of indigenous benthic infaunal communities and delineation of reference stations. Appendix A of this RI Report contains a copy of TM No. 4.
- Final Fish Sampling and Analysis Plan - Technical Memorandum No. 5 (BNI 1994d). TM No. 5 significantly expands the fish collection, analysis, and data usage strategies for this RI, thereby replacing in its entirety the Final Fish Sampling and Analysis Plan (BNI 1994b). TM No. 5 identifies the number of fish required, representative species of fish targeted for collection, and types of samples to be obtained (whole body, fillet and bile) and analyzed for each species to support both human health and ecological risk assessments; sample collection locations within the West Basin and at project reference area; target analytes; and laboratory analytical methods. In addition, TM No. 5 describes specific fish collection and sample handling methods. Appendix B of this RI Report contains a copy of TM No. 5.
- Final Addendum to RI/FS Work Plan and Risk Assessment Work Plan (RAWP), (BNI 1995a). The RAWP describes how the sediment and tissue data acquired during the course of this RI will be evaluated and used to support the assessment of ecological risk (focused on sediments) and human health risk (focused on fish). This RAWP is significantly expanded in scope when compared to the preceding Final Risk Assessment Work Plan (BNI 1994a). The RAWP also describes the statistical methods for use in evaluating physical, chemical and biological data; the preponderance-of-evidence approach for use in toxicity evaluation; and the evaluation matrix developed for characterization of ecological risk. Appendix C of this RI Report contains a copy of the RAWP.

1.2 OBJECTIVE AND SCOPE OF THE REMEDIAL INVESTIGATION

The overall objective of this RI was to characterize West Basin fish and sediment toxicity through assessment of human health and ecological risks. This objective was achieved by performing these major tasks:

- obtain samples of fish and sediments within West Basin and at reference stations;
- identify chemicals of potential concern (COPCs) associated with fish and sediments for purposes of human health and ecological risk assessments;
- identify areas of potential concern (AOPCs) within West Basin on the basis of sediment characterization;
- assess human health and ecological risks; and
- assess whether, on the basis of these findings, remedial action is warranted and, if so, identify remedial action objectives and potential remedial action alternatives.

At the onset of this RI, in agreement with the technical oversight agencies, reference stations outside of West Basin, at areas known not to have been affected by LBNC activities, were selected to provide a benchmark for this project. Subsequently, sediment and fish samples were collected both from within West Basin and from the reference stations. The sediment and fish samples were analyzed in the laboratory for selected chemicals. In addition, physical and biological tests were conducted on the sediment samples. The analytical data were evaluated using statistical methods. The results of the data evaluation were used in human health and ecological risk assessments.

The human health risk assessment focused on ingestion of fish by recreational and subsistence anglers. The ecological risk assessment focused on the sediments and an aquatic predator of West Basin fish. The human health and ecological risk assessments were conducted using available standardized procedures. The purpose of the risk assessments was to evaluate whether the COPCs found in West Basin fish could potentially pose a threat to human health and to an aquatic predator, and whether COPCs found in sediments could potentially present a hazard to the local ecology. For the purposes of this RI, the harbor seal was selected as the aquatic predator, as discussed in the RAWP (BNI 1995a) and in subsequent sections of this RI Report. The results of the risk assessments were used to assess whether the risks posed by human health or ecological exposures to the COPCs would warrant remedial action.

1.3 FACILITY LOCATION AND DESCRIPTION

This section describes the local and regional setting, and presents an overview of the geographical, physical, historical, meteorological, and oceanographic attributes of the West Basin.

VOL 18
0040
R0062649

VOL 18 0041

1.3.1 Location and Physical Attributes

The LBNC, composed of NAVSTA Long Beach, the LBNSY and the West Basin, is located on the south side of Terminal Island within the Los Angeles and Long Beach Harbor districts (Figure 1-1, Regional Setting), approximately 3 miles west of downtown Long Beach, California. The LBNC is bounded by oil fields and container yards of Terminal Island on the north, Los Angeles Harbor on the west, San Pedro Bay on the south, and Long Beach Harbor Channel on the east.

The Long Beach Harbor West Basin, which is the focus of this RI, has been jointly used by NAVSTA Long Beach and the LBNSY. It is bounded on the west by the former NAVSTA, on the south by the Navy Mole, on the north by the LBNSY, and on the east by the ship-turning basin, which is part of the Port of Long Beach (POLB) complex. Ships leaving the Inner Harbor and East Basin use the entrance to the West Basin as a turning basin. Figure 1-2, Facility Plan, shows the locations of these major Naval facilities relative to West Basin.

The West Basin is approximately 700 acres, with water depths on the order of 45 feet. Eleven piers, used for the purposes of ship docking for maintenance and loading, presently exist in the West Basin (Figure 1-3, Project Base Map). These piers, generally constructed with concrete pilings, range from approximately 30 to 125 feet in width and 250 to 1,200 feet in length. Piers 1, 2, and 3 are located at the LBNSY, along the northern seawall of the West Basin. The other eight piers, located at the NAVSTA Long Beach, include Piers 6 and 7 along the northern seawall of the West Basin; Pier 9 in the northwest corner of the West Basin; and Piers 10, 11, 12, 15, and 16 in the southern portion of the West Basin along the Navy Mole. A pipeline system delivers fuel to the Defense Fuels Support Point in San Pedro from Pier 12 at the Navy Mole. A small-craft marina is located near the southwest corner of the West Basin. There are three dry docks in West Basin, located at the LBNSY, in the general area of Piers 1, 2, and 3.

1.3.2 History

In 1935, the U.S. Navy negotiated a 30-year lease with the City of Los Angeles for property to be developed into a naval facility. The Navy purchased a strip of coastline along the southern portion of Terminal Island from the Cities of Long Beach and Los Angeles in 1938. LBNC land, in general, was reclaimed through hydraulic fill operations conducted between 1938 and the early 1940s. A review of past aerial photographs has shown that in the early 1940s, the seawall that currently forms the northern boundary of the West Basin was constructed, and the area between the seawall and the former shoreline was filled with dredged materials and imported fill materials. During this period, Piers 1 through 7, the dry docks, and a breakwater north of the present Pier 9 location were constructed. The Navy Mole, which forms the western and southern boundaries of the West Basin, was constructed of dredged material and imported rock in late 1944 through early 1945. Construction of NAVSTA Long Beach and the Navy Mole created the West Basin in its present form. Following the construction of the Navy Mole, Piers 10, 15, and 16 were constructed in the mid to late 1940s. Pier 9 was constructed in the

R0062650

1950s during which time the breakwater was removed. Piers 11 and 12 were constructed in the late 1960s and mid- to late 1980s, respectively. Piers 4 and 5 were removed and the marina was constructed in the 1970s to early 1980s (JEG 1993a, NEESA 1983).

Since the creation of the West Basin, dredging has been conducted for the purpose of construction or relocation of West Basin piers. Maintenance dredging has also been conducted between these piers. The piers and dry docks were constructed for ship maintenance activities and fueling (JEG 1993a).

By 1946, NAVSTA Long Beach began maintaining facilities for the operation and berthing of tugboats, barges, and similar vessels. In 1948, the U.S. Naval Base, Terminal Island changed its name to U.S. Naval Station Long Beach. At that time, NAVSTA Long Beach provided support for active service ships and inactive ships of the Reserve Fleet (SWDIV 1994a).

From the early 1940s to the mid-1970s, drainage from various industrial areas and from cleaning and process tanks was discharged into the West Basin. Wastes were discharged through the storm drain system and from flushing of the dry docks (JEG 1993a).

During the 1940s and 1950s, a subsidence depression developed as a result of reservoir pressure reduction caused by oil production activities. The compaction of poorly consolidated reservoir sand threatened the eastern portion of Terminal Island with inundation (Strehle 1987). Maximum total subsidence at the center of the depression exceeded 29 feet. Subsidence has been controlled by water-flooding of production zones and continued monitoring of production and injection volumes. During this period, the West Basin subsided from less than 2 feet in the southwest to over 14 feet in the northeast (Mayuga 1968).

Currently, the West Basin harbors an active berthing and repair shipyard. Its primary use is for naval and other activities, such as providing maintenance facilities for the berthing operations of tugboats, barges, and similar vessels. The LBNSY provides logistical support for assigned ships, performing work in connection with construction, conversion, overhaul, repair, alteration, dry-docking, and fitting out of ships. Manufacturing operations, research, development, and test work have also been conducted at the LBNSY (JEG 1993a).

The West Basin is not used for recreational swimming. The outboard side of the Navy Mole, as well as its tip and inboard side extending to Pier 16, was permitted for pole fishing while NAVSTA Long Beach was in operation. As this RI Report was being written, the fishing areas on the Navy Mole were closed and off limits to all but authorized personnel.

NAVSTA Long Beach, which closed 30 September 1994, was one of the 11 military installations in California scheduled for closure under the Base Realignment and Closure Act II (BRAC II). The LBNSY has been ordered to close by September 1997 under BRAC IV.

R0062651

VOL 18

0043

1.3.3 Operable Unit Designation

Thirteen sites suspected of being contaminated have been identified at the LBNC under the IR Program. These 13 sites have been grouped into three operable units (OUs) which define an installation's remediation strategy. Contamination within an installation may be ultimately addressed as one or several OUs or portions of OUs. OUs represent areas in which discrete investigations and remedial response actions may be implemented to manage migration of contaminants, or eliminate or mitigate releases of contaminants, as well as reduce or eliminate potential pathways of exposure. OUs are typically defined as:

- areas with similar media or with similar types of contaminants,
- areas that are geographically contiguous,
- areas that could be remediated using similar techniques,
- areas which could be remediated within a parallel time frame, and
- areas that are amenable to being managed in a single RI/FS.

The RI/FS Work Plan for LBNC (JEG 1993a) identified the West Basin of Long Beach Harbor as Site 7, and designated the site as OU-3. With the exception of Site 7, all IR Program sites at the LBNC are land-based sites, wherein the media of concern consist of soil and groundwater. For Site 7, on the other hand, the media of concern were defined as subtidal sediments. Since harbor sediments are unique among the 13 IR Program sites, Site 7 was designated as a single operable unit.

1.3.4 Regional Climate

The climate in the general region of West Basin is classified as Mediterranean, characterized by warm, dry summers and mild winters. The average high and low temperatures, recorded at the Long Beach Airport, are 83 degrees Fahrenheit (°F) and 63°F in July and 66°F and 44°F in January (Los Angeles/Long Beach [LA/LB] Harbor Departments and United States Army Corps of Engineers [U.S. ACOE] 1990). Most of the precipitation throughout the year occurs between November and March, with an average annual rainfall of about 12 inches. Heavy rains occasionally contribute to flooding and significant sediment discharge from adjoining streams and rivers. Because of the relatively arid climate, annual evaporation is 63.6 inches (National Weather Service 1982). The dominant wind direction is westerly, with prevailing winds blowing off the ocean. At night, air cooled from the surrounding hills typically produces a gentle offshore flow (JEG 1993a).

The Eastern Pacific High (EPH) pressure system and the moderating effect of the cool Pacific Ocean are the major influences on the regional climate (LA/LB Harbor Departments and U.S. ACOE 1990). In the summer, the EPH is at its strongest, most northerly position and is centered west of northern California. The EPH shelters southern California from polar storm systems. Descending air due to the EPH produces an elevated temperature inversion with a base of 1,000 to 3,000 feet. Marine air trapped within the

R0062652

inversion is condensed into fog and stratus clouds by the cool temperature of the ocean, which typifies summer weather in San Pedro Bay. Stratus clouds formed offshore move onshore during the evening hours, but retreat to the coastline during the morning hours when land temperatures rise. Summer tropical storms may also infrequently move in from the west coast of Mexico.

During winter, the EPH weakens and shifts to the south, allowing polar storm systems to pass through the region. The storms are characterized by strong, shifting winds and occasionally heavy precipitation. Winter storms are followed by low pressure troughs that are characterized by clear skies, cool temperatures, and gusty west to north winds as the systems move eastward. Simultaneously with the EPH, a thermal low persists in the interior desert region of southern California which results in a westerly, onshore flow of air for most of the year. Easterly winds are due to nocturnal and wintertime land breezes; daytime heating reverses the flow back onshore. During the fall and winter, the EPH often combines with high pressure over the continent resulting in extended periods of light winds and inversion conditions. Excessive buildup of high pressure can produce "Santa Ana" conditions characterized by warm, dry, northeasterly winds.

1.3.5 Sedimentology

Sediments in the West Basin can be mobilized and moved away from their existing locations to settle somewhere else, or to move out of the West Basin entirely. Conversely, sediments from outside could enter and settle in the West Basin. Redistribution of bottom sediments typically requires their initial mobilization, and subsequent transport by currents. The intensity of currents required to initiate sediment motion is far greater than that required for subsequent transport. The overall circulation (i.e., persistent currents) in the West Basin is not strong enough to mobilize bottom sediments. However, there are other mechanisms that can mobilize the bottom sediments and make them available for transport by relatively weak currents (JEG 1993a).

Induced turbulence from ship propellers as well as construction and dredging activities, which are relatively localized and of short duration, form the major mechanisms for suspension and mobilization of West Basin sediments. Once mobilized and suspended in the water column, currents caused by tides and wind are potentially capable of transporting the sediments. The suspended sediments susceptible to such transport generally consist of fine particulates such as clays, silts and fine sands (JEG 1993a).

Sediment particle size is a characteristic that determines the extent of sediment dispersion throughout the West Basin. Dispersion may be attributed to ship propeller disturbance, tides, currents, and other phenomena. Particle sizes have been observed to be highly variable, ranging from fine particulates in suspected depositional areas to coarse-grained sediments in open areas of the main channel where maintenance dredging has been conducted. Part of these sediments may have originated from the fill materials brought in during the 1930s and 1940s to construct the Navy Mole and other portions of the LBNC

VOL 18
0044
R0062653

VOL 18

The areas beneath the West Basin piers represent suspected depositional areas, with accumulated shell hash due to concentrated mussel populations colonizing pier pilings. These suspected depositional areas are characterized by fine particulates, the presence of shell hash, and a strong odor, probably caused by anaerobic degradation of organic matter. In general, sediments underneath the piers have been described as dark, micaceous silt with some sand, gravel, and shell fragments (JEG 1993a). It is possible also that to some extent, sediments beneath the piers at the LBNSY may be remnants of the historical beach which is known to have existed there before the seawall and piers were constructed.

1.3.6 Oceanography

The West Basin is located in the San Pedro Bay region of the Southern California Bight (Bight). This region, which lies southeast of Santa Monica Bay, is defined oceanographically as the submarine shelf bounded by the Palos Verdes peninsula to the north, the Newport Submarine Canyon to the south, and the mainland shelf break extending 18 miles seaward (south) of Long Beach. The Bight itself is a 100,000 square mile submerged continental borderland of the Pacific Ocean bounded on the north, east, and southeast by a large mountainous reach of the North American coastline. The Bight extends from Point Conception, California, 360 miles south of Cabo Colnett, Baja California, Mexico (Dailey et al. 1993). The Bight is bounded on the west by the inner border of the southward-flowing California Current and by the outer edge of the continental shelf. The prominent distinguishing feature of the Bight is the eastward indentation of the coastline that allows for a northward flowing return eddy, the Southern California Countercurrent. As a result of its unique circulation patterns and complex bathymetry, the Bight acts as an enclave of region-specific populations of marine life, a trap for warm, equatorial water, and a reservoir for chemical components entering from the land, air, and sea.

0045

Understanding the physical processes (e.g., currents, tides, and waves), chemical characteristics (e.g., naturally occurring chemical constituents in water and sediment), biological habitats, and indigenous organisms of the West Basin facilitates comprehending its specific oceanographic characteristics. Physical characteristics, such as water transparency and temperature, may reflect overall water quality. Currents, tides, and waves are responsible for water circulation patterns which, in turn, affect the concentration and distribution of chemicals within West Basin. Water chemistry, including dissolved oxygen (DO), pH, salinity, metals and organic compound concentrations, is also an indication of overall water quality and closely related to biological activity. Important marine biological components of West Basin include plankton, plant life, benthic invertebrates, fish, and marine birds.

1.3.6.1 PHYSICAL OCEANOGRAPHY

Aspects of physical oceanography considered in this section include tides, waves, currents, temperature, transparency, and bathymetry. Tidal, wave, current, and bathymetric data

R0062654

provide a basis for predicting sediment-bound contaminant transport dynamics. Water temperature and transparency provide a general measure of water quality.

Tidal currents generally create water circulation patterns. Southern California coastal tides are semidiurnal, with two low and two high tides of unequal height every 25 hours. Rising tides, which vary with the phase of the moon, enter Long Beach Harbor and flow up the various channels and basins; flows reverse during falling tides. The tidal range is greatest during spring tides (i.e., during new and full moons), resulting in the strongest currents. Tidal range is least during neap tides (i.e., during first and third quarter moons), resulting in the weakest currents.

The mean tide in the Long Beach Harbor has been determined to have a maximum range of 5.5 feet; a maximum tidal discharge of 23,333 cubic feet per second (ft^3/s) (flood flow discharge) and 19,444 ft^3/s (ebb flow discharge); an average flow volume of 278 x 10^6 ft^3/tidal cycle (flood flow) and 277 x 10^6 ft^3/tidal cycle (ebb flow); and a net flood flow volume per tidal cycle of 1 x 10^6 cubic feet (ft^3) (Seabergh and Outlaw 1984). The maximum velocity at the entrance to the LA/LB Harbor has been estimated at 0.54 feet per second (ft/s) for ebb tide and 0.46 ft/s for flood tide. Velocity magnitudes throughout the LA/LB Harbor, in general, are small, usually less than 1 ft/s. Water circulation patterns within West Basin are clockwise. The small differences in tidal elevations (5.5 feet for West Basin), which normally govern water flow patterns, indicate that other factors (e.g., wind) have a stronger influence on circulation within inner LA/LB Harbor areas such as West Basin (Seabergh and Outlaw 1984).

Waves and swells in the Long Beach Harbor are small due to abundant seawalls and breakwaters throughout the harbor complex, with wave periods of 1 to 3 seconds and swell periods of 10 to 20 seconds. Seiche waves occur in the Long Beach Harbor with periods of 30 seconds to greater than 1 hour. Regular seiching is estimated to occur at intervals of 1.25 hours and equals 5 percent of the total tidal exchange (LA/LB Harbor Departments and U.S. ACOE 1990).

The temperature within the West Basin water column varies spatially and by season. It is cooler in the winter and warms up during the spring and summer. In addition to climatic conditions, water temperature of the West Basin reflects the proximity of open ocean, port facilities, and surface water discharges. Temperatures measured in the West Basin during June 1988 indicate a water surface temperature of 61°F and a 20-foot depth temperature of 57°F (POLB 1988). Mean water temperatures, as measured by the POLB at two stations within West Basin between 1971 and 1991, were 64°F at the surface and 62°F at a 20-foot depth (JEG 1993a).

Water transparency, a measure of vertical visibility in depth below surface, is affected by suspended materials from runoff, dredging activities, and shipping operations. It is also affected seasonally by plankton blooms. As a representative data point for the West Basin, transparency was measured to be 12 feet during June 1988 (POLB 1988). Mean transparency, as recorded monthly by POLB between 1971 and 1991 in West Basin, was measured at 12.2 feet (JEG 1993a).

VOL 18
0046
R0062655

Depths within the West Basin range from 30 feet close to the seawall at LBNSY to 69 feet at the entrance to West Basin. This entrance also acts as a turning basin for Navy and POLB ships. Water depths at the piers within West Basin average about 46 feet, except at Pier 9, where the water depth averages 36 feet (JEG 1993a).

1.3.6.2 CHEMICAL OCEANOGRAPHY

Aspects of chemical oceanography considered in this section include DO, pH, salinity, nutrients, and metals. These measurements provide background levels with which to compare potentially adverse effects caused by discharges to the West Basin.

DO levels vary by area, water depth, and season. Low levels of DO may occur due to a number of factors, including eutrophication (e.g., localized phytoplankton blooms) as a result of various types of discharge. In June 1988, the DO concentration of West Basin surface waters was found to be 9.3 milligrams per liter (mg/L) and 7.0 mg/L at 20 feet below surface (POLB 1988). Mean DO levels within West Basin, as recorded monthly between 1971 and 1991 by POLB, have been reported as 8.4 mg/L at the surface and 8.1 mg/L at a depth of 20 feet. These DO levels are above the 5 mg/L level recommended for marine environments to maintain a healthy aquatic habitat (U.S. EPA 1986).

The pH of Long Beach Harbor waters ranges from 7.0 to 8.7 (LA/LB Harbor Departments and U.S. ACOE 1990). Higher values occur at the surface during warm weather periods and lower readings are found in deeper, cooler water. The measured pH levels in the Long Beach Harbor are within the pH range of 6.5 and 8.5 necessary in marine waters to maintain a healthy aquatic habitat (U.S. EPA 1986).

Salinity in harbors is influenced by the influx of ocean water, evaporation, precipitation, freshwater runoff, and wastewater discharges. The salinity of Long Beach Harbor waters ranges from 10 to 34.2 parts per thousand (‰) (LA/LB Harbor Departments and U.S. ACOE 1990). Mean salinity of the inner harbors of Los Angeles and Long Beach has been reported as 33.5 ‰ (Allan Hancock Foundation 1975), which is similar to the salinity of open ocean water. This is reflective of relatively little freshwater input into the receiving waters of the LA/LB Harbor.

Nutrient levels are highly variable in the LA/LB Harbor waters due to varying types of discharges and climatic conditions. Nutrient concentrations tend to increase dramatically during periods of heavy rainfall, and may provide a nutrient base for localized algal blooms. This phenomenon, in turn, may lead to eutrophication and severe pollution episodes. During a survey of nutrient concentrations conducted in 1978, concentrations in Long Beach Harbor ranged from 0.12 to 120 mg/L for ammonia, up to 5.4 mg/L for nitrite, up to 83 mg/L for nitrate, and 0.17 to 12 mg/L for phosphate (LA/LB Harbor Departments and U.S. ACOE 1990). Some of these concentrations could be problematic if sustained over a period of time, but no time-series measurements of nutrients in water are known to have been made for the LA/LB Harbor waters.

Concentrations of United States Environmental Protection Agency (U.S. EPA) priority pollutant metals have been measured in the past in association with different surveys

R0062656

VOL 18 0047

including the receiving waters of eastern Long Beach Harbor in support of the Pier J expansion project (LA/LB Harbor Departments and U.S. ACOE 1990). These measurements provide a backdrop for more current water column measurements, should they be taken at a later date. Values ranged from 1.9 to 16 micrograms per liter (µg/L) for chromium; 8.7 to 14 µg/L for copper; 0.21 to 0.26 µg/L for lead; up to 0.4 µg/L for nickel; up to 0.7 µg/L for silver; and 6.2 to 9.6 µg/L for zinc. Some of these metals concentrations, especially copper, exceed federal ambient water quality criteria (2.9 µg/L for copper). Without time-series measurements, however, it is difficult to determine whether the measured levels are relatively constant or variable over time.

1.4 DEMOGRAPHICS AND LAND USE

General land use in the vicinity of the LBNC and West Basin is primarily port-related, commercial or industrial. Facilities in the vicinity of the LBNC include tank farms, automobile terminals, a cement terminal, cargo handling, and storage terminals. The areas east and west of the LBNC on Terminal Island are used for commercial shipping, liquid bulk handling, heavy industrial activities, and commercial fishing activities. The area north of the LBNC on Terminal Island is used for oil production activities. Terminal Island comprises the western portion of POLB and the eastern portion of the Port of Los Angeles (POLA). These ports participate in heavy shipping traffic, container storage, cargo handling, dredging activities, and loading/offloading operations.

1.5 COMMUNITY RELATIONS

As part of the environmental investigation and cleanup effort at the LBNC under the IR Program, a CRP was prepared in August 1993 to be implemented concurrently with the RI/FS work being performed at West Basin. The CRP describes the public participation program designed to assure involvement by the local community.

A Technical Review Committee (TRC) was formed for the IR Program at the LBNC in April 1992. The TRC includes the DON and environmental regulatory agency representatives. The purpose of this TRC is to review IR Program documents and comment on the cleanup activities.

The LBNC formed a Restoration Advisory Board (RAB) in April 1994 to invite members of the public to become involved in the environmental restoration program. The RAB expanded the TRC by including members of the public in the existing committee of regulatory agency representatives and Navy personnel.

Since April 1994, the 20-member RAB has met regularly, and has participated in site tours and educational workshops. The LBNC RAB will be invited to review and comment on this RI Report at the Draft stage.

1.6 REGULATORY STATUS

The State Department of Health Services issued a Resource Conservation and Recovery Act (RCRA) hazardous waste facility permit to the LBNSY in September 1983 (U.S. EPA

VOL 18
0048
R0062657

VOL 18

ID No. CA6170023109) to operate a hazardous waste storage facility. The permit expired in August 1988 and the LBNSY applied for a RCRA Part B permit to modify its listed permit requirements. The permit authorized the LBNSY to receive, handle, and store hazardous wastes generated by the LBNSY and by two additional off-site facilities, the former NAVSTA Long Beach (closed 30 September 1994) and the former Naval Hospital Long Beach (closed 31 March 1994). In 1993 the LBNSY received the RCRA Part B modification for changes to the facility and changes to specific hazardous waste activities.

Although the West Basin (Site 7) is not listed on the U.S. EPA National Priorities List (NPL), the DON's current policy is that response actions at both NPL and non-NPL sites be accomplished in accordance with the National Contingency Plan (NCP) under CERCLA. The Department of Toxic Substances Control (DTSC) has agreed to accept CERCLA remedial action documents under the corrective action provisions of the LBNSY's RCRA permit (RCRA Corrective Action Program), since these provisions will be addressed in the environmental response actions taken at the West Basin. The DON is the lead federal agency for the implementation of these actions, and the DTSC is the lead state agency.

1.7 CONSIDERATION OF APPLICABLE OR RELEVANT AND APPROPRIATE REQUIREMENTS

The CERCLA Compliance Policy, as set forth in Section 121(d)(2)(A) of CERCLA, specifies that Superfund remedial actions meet any federal standards, requirements, criteria, or limitations that are determined to be legally applicable or relevant and appropriate requirements (ARARs). Federal statutes that are specifically cited in CERCLA include the Solid Waste Disposal Act (SWDA), the Toxic Substances Control Act (TSCA), the Safe Drinking Water Act (SDWA), the Clean Air Act (CAA), the Clean Water Act (CWA), and the Marine Protection Research and Sanctuaries Act (MPRSA) (U.S. EPA 1988a). The Compliance Policy also includes the provision that states ARARs must be met if they are more stringent than federal requirements. If no ARARs exist that address a particular circumstance at a site, or if existing ARARs do not provide for adequate protection of human health and the environment, then non-promulgated advisories, criteria, and guidelines are "to be considered" (TBC) in setting remedial action objectives.

0049

ARARs are those cleanup standards, standards of control, and other substantive environmental protection requirements, criteria, or limitations promulgated under federal or state law that:

- specifically address a hazardous substance, pollutant, contaminant, remedial action, location, or other circumstance at a CERCLA cleanup site (i.e., an applicable requirement), or
- address problems or situations sufficiently similar to those encountered at the site, that their use is suited to the particular site (i.e., a relevant requirement).

R0062658

In some circumstances, however, a requirement may be relevant but not necessarily appropriate for the site-specific situation; in such a case, the requirement is not considered an ARAR.

Section 121(d)(4) of CERCLA identifies six circumstances under which ARARs may be waived (U.S. EPA 1988a):

- The remedial action selected is only a part of a total remedial action (interim remedy) and the final remedy will attain the ARAR upon its completion.
- Compliance with the ARAR will result in a greater risk to human health and the environment than alternative options.
- Compliance with the ARAR is technically impracticable from an engineering perspective.
- An alternative remedial action will attain an equivalent standard of performance through the use of another method or approach.
- The ARAR is a state requirement that the state has not consistently applied (or demonstrated the intent to apply consistently) in similar circumstances.
- For Section 104 Superfund-financed remedial actions, compliance with the ARAR will not provide a balance between protecting human health and the environment and the availability of Superfund money for response at other facilities.

ARARs may be categorized as chemical-, location-, and action-specific (U.S. EPA 1988a). Chemical- and location-specific requirements provide the basis for determining the objectives and goals of remedial action by defining acceptable exposure levels and setting restrictions on activities within specific locations (e.g., floodplains or wetlands), respectively. Potential chemical- and location-specific ARARs are identified on the basis of the compilation and evaluation of existing site data. Action-specific requirements provide the basis for determining how the remedial action will be carried out during the feasibility study process by setting controls or restrictions for particular treatment and disposal activities.

The actual determination of which requirements are applicable or relevant and appropriate is made by the lead state agency in consultation with the support agency at a time when the lead state agency has had the opportunity to review data and interpretations. Upon completing its review of this Draft RI Report for the West Basin, it is expected that the lead state agency (DTSC) will provide to SWDIV federal and California state ARARs for West Basin sediments and fish. In the meantime, however, several principal potential chemical- and location-specific ARARs and TBCs were reviewed for the purpose of this RI. These ARARs and TBCs are described in the following paragraphs.

VOL 18
00050
R0062659

1.7.1 Water Quality Control Plan for Ocean Waters of California (California Ocean Plan)

The State Water Resources Control Board (SWRCB) adopted the Ocean Plan on 6 July 1972 and revised the plan in 1978, 1983, 1988, 1990, and 1995. The Ocean Plan requires the control of the discharge of waste to ocean waters to protect the quality of such waters for human use and enjoyment. The Ocean Plan is reviewed at least every 3 years to guarantee that the current standards are adequate and that they do not allow degradation of marine species or pose a threat to public health. Chapter II of the Ocean Plan currently contains three narrative sediment quality objectives, prohibiting deposition of 1) inert solids, 2) toxic chemicals, and 3) other organic materials in sediments to levels which would cause degradation of marine life (SWRCB 1990). However, no numerical objectives for sediment quality are included to define unacceptable levels of pollutants.

1.7.2 Water Quality Control Plan for Enclosed Bays and Estuaries of California (California Enclosed Bays and Estuaries Plan)

The SWRCB adopted the Enclosed Bays and Estuaries Plan on 11 April 1991 to protect the quality of enclosed bays and estuaries for use and enjoyment by the people of California. The plan was amended in 1993, and it is reviewed at least every 3 years to ensure that the water quality objectives defined within the plan are appropriate and that the plan does not allow degradation of beneficial uses. Chapter II of the Enclosed Bays and Estuaries Plan contains a narrative sediment quality objective stating that the concentrations of toxic pollutants in sediments shall not adversely affect beneficial uses (SWRCB 1993). However, no numerical objectives for sediment quality are included to define unacceptable levels of toxic pollutants.

1.7.3 Work Plan for the Development of Sediment Quality Objectives for Enclosed Bays and Estuaries in California

California Water Code Section 13392.6 requires the adoption of sediment quality objectives by the SWRCB. The Work Plan describes the activities to be undertaken in order to develop sediment quality objectives and contains the SWRCB's estimates of time and costs required for the development of such objectives for California's enclosed bays and estuaries (SWRCB 1991). Numerical sediment quality objectives, however, had not been finalized at the time of writing this RI Report.

1.7.4 National Sediment Quality Criteria and Guidelines

Sediment quality criteria and guidelines have been issued by the U.S. EPA (1993a) and Long et al. (1995). The U.S. EPA has issued final criteria documents for five chemicals: phenanthrene, acenaphthene, fluoranthene, endrin, and dieldrin. Long et al. have issued criteria (referred to as "effects range-low" [ER-L] and "effects range-median" [ER-M] values) for trace metals, polychlorinated biphenyls (PCBs), pesticides, and polynuclear aromatic hydrocarbons (PAHs). Although not official California State guidance, these

VOL 18
0051
R0062660

values can be used as guidelines to evaluate whether sediment at a site would possibly have toxic effects based on chemical concentrations.

1.8 REPORT ORGANIZATION

This RI Report is divided into eight sections of text, and includes figures, tables, and Appendices A through V. The report summary and a listing of acronyms and abbreviations used are presented at the beginning of this report.

Section 1 is the introduction to the RI Report, and describes the planning documents that were the basis of this RI, discusses the purposes and scope of the work of this RI, presents information on the location of West Basin and its history, and provides a general overview comprising regional climate, sedimentology, and oceanography. Section 1 also summarizes land use; presents an overview of the community relations strategy; and discusses the regulatory status of LBNC and West Basin. Section 1 concludes with an overview of this RI Report.

Section 2 summarizes previous investigations at and in the vicinity of West Basin, including environmental assessments and studies conducted at the LBNC; scientific surveys including physiochemical and biological investigations; and dredging activities. In addition, Section 2 provides a survey of documents describing the past and current discharges into West Basin waters.

Section 3 discusses the site characterization procedures beginning with the rationale for the overall sampling and analysis program. Also discussed are the field methods used to collect sediment and biological samples; sample documentation, storage, processing, and shipping procedures; sampling equipment decontamination procedures; and procedures on collection, storage, and disposal of investigation-derived waste.

Section 3 also provides descriptions of the laboratory methods, including descriptions of physical and chemical analyses, bioassay testing, and benthic community analysis, and provides a discussion of methods used to analyze clam and fish tissue. Other topics include QA/QC procedures used throughout the various field and laboratory analysis operations; the verification and validation measures taken to assess the quality of analytical and biological data; and database management issues. Section 3 closes with a description of the statistical methods used to analyze project data.

Section 4 presents the results of site characterization and describes general sediment characteristics, followed by discussions of project reference conditions, and chemical and biological site characteristics. Sediment evaluation zones are discussed in detail, followed by selection of COPCs and AOPCs for human health and ecological risk assessments.

Section 5 presents the human health risk assessment and its conclusions. The methods used and the exposure and toxicity assessments, as well as the risk characterization, are discussed in detail.

Section 6 presents the focused ecological risk assessment and its conclusions. An overview of the methods used, as well as the development of the conceptual framework,

VOL 18
00552
R0062661

are provided, followed by an assessment of ecological effects. Subsequently, risk characterization is presented, including estimation of risk and uncertainty analyses of risk characterization. Section 6 also identifies whether or not any portions of West Basin sediments are found to require remedial action.

Section 7 presents conclusions and recommendations.

Section 8 contains a listing of the references cited in this RI Report.

A Glossary of scientific and miscellaneous terms used throughout this RI Report follows the list of references. The subjects discussed in this report are of a scientifically complex nature. To provide clarity and a handy quick-reference resource, the Glossary was carefully prepared and contains a comprehensive collection of terms and their definitions.

The following appendices are attached in support of and for completeness of this RI Report:

VOL 18 0055

Section 2

SUMMARY OF PREVIOUS INVESTIGATIONS AND IDENTIFICATION OF DISCHARGES

This section summarizes environmental investigations conducted at the LBNC as well as regional scientific surveys conducted at or in the vicinity of the West Basin. In addition, documents containing information on discharges into the LA/LB Harbor and the West Basin that were reviewed as part of this RI are summarized herein, as well as dredging plans both within the West Basin and the LA/LB Harbor. Unless otherwise indicated, no attempt was made to perform independent verification of materials in the reports discussed herein.

2.1 SUMMARY OF PREVIOUS INVESTIGATIONS

This section provides a review of previous investigations relevant to the West Basin as well as a historical backdrop for the current understanding of site-specific and regional environmental conditions.

2.1.1 Studies Within the LBNC

Since the 1960s, several environmental investigations have been conducted at the LBNC. Few, however, have related specifically to West Basin sediments. An overview of the key investigations relevant to the IR Program and West Basin in general is provided below in chronological order.

2.1.1.1 1969 INDUSTRIAL WASTE STUDY

In December 1969, SWDIV conducted an Industrial Waste Study at LBNC (SWDIV 1969). One of the objectives of this study was to determine the nature and quantity of liquid and solid industrial wastes being discharged into the storm drain system, discharged directly into the West Basin, or buried underground. This was the first known environmental investigation of "industrial" (now generally referred to as "hazardous") waste at LBNC. This study reported the discharge of industrial wastewater into the West Basin, placement of industrial waste liquids and sludges into pits on the Navy Mole, and the use of solid waste and sandblast grit to enlarge the Navy Mole.

2.1.1.2 1983 INITIAL ASSESSMENT STUDY

An Initial Assessment Study (IAS) for the LBNC was completed in August 1983 (NEESA 1983). The IAS was similar to a Preliminary Assessment (PA) under the CERCLA process. The purpose of this IAS was to identify and assess potential threats to human health and the environment caused by past hazardous materials storage, handling, or disposal practices at Naval installations. As such, the IAS was the first comprehensive study by the DON to identify contaminated areas at LBNC resulting from past operations. The study included information on waste generating sources, waste handling practices, storage and transportation procedures, waste processing practices, and descriptions of disposal sites and potentially contaminated areas.

R0062664

The IAS included a review of available records, aerial photographs, surface and aerial surveys, and personnel interviews. Based on information obtained from the study, 12 potentially contaminated sites were identified at LBNC (JEG 1993a), one of which was Site 7, consisting of the West Basin sediments. Each of the 12 sites was assessed with regard to contamination characteristics, migration pathways, and potential receptors. The study concluded that none of the 12 sites posed a sufficient threat to human health or the environment to warrant a confirmation study, but recommended various precautionary measures (JEG 1993a).

2.1.1.3 1989 RCRA FACILITY ASSESSMENT

A RCRA Facility Assessment (RFA) of the LBNC was prepared in 1989 by the California Environmental Protection Agency (Cal-EPA) DTSC, formerly the Department of Health Services (DHS 1989). The RFA was performed to identify and evaluate solid waste management units (SWMUs) and other areas of concern at LBNC. A records review, evaluation of existing data, personnel interviews, and a visual site inspection were conducted to evaluate the potential for releases of hazardous constituents from identified SWMUs. The RFA recommended further action at the 12 sites identified in the IAS.

2.1.1.4 1991/1992 SITE INSPECTION

Site Inspections (SIs) were conducted concurrently in 1991 at the NAVSTA Long Beach and LBNSY; reports for these SIs were finalized in November 1992 (JEG 1992a and 1992b). The objectives of the SIs, which followed the PA in the CERCLA process, were to:

- verify the presence of hazardous substance contamination at the 12 sites identified in the IAS,
- assess whether contamination at these sites exists at concentrations which warrant further action, and
- evaluate potential contaminant migration pathways and potential targets for scoring under the U.S. EPA Hazard Ranking System (HRS).

The NAVSTA Long Beach SI addressed Sites 1 through 7, which lie within the NAVSTA Long Beach boundaries, and the LBNSY SI addressed Sites 7 through 12, which lie within the LBNSY's boundaries. Site 7 is shared by both the NAVSTA Long Beach and LBNSY; therefore, portions of the site contiguous with the NAVSTA Long Beach and the LBNSY were designated as Sites 7A and 7B, respectively, and were addressed in separate SI reports.

To accomplish the SI objectives at Site 7, a total of 15 sediment core samples were collected as part of the field effort. No surface sediment collections (uppermost 10 cm or less) or biological samples were collected as part of this effort. No sediment sampling was conducted under the piers in the West Basin. Fourteen of the sampling locations were targeted to be as close to the storm water outfalls as possible (along the northern seawall), and a background sample was taken just off the tip of the Navy Mole near the entrance to

VOL 18
0056
R0062665

West Basin. The results of the laboratory analyses conducted on these samples were used to evaluate contaminant releases via various pathways in accordance with U.S. EPA guidance. Analytical data for sediments, excerpted from the SIs, are presented in Appendix D. Field data indicated the presence of numerous organic contaminants in sediments, in particular PAHs, at moderate to high levels, and several metals in sediments at low to moderate levels. Because of the limited number of samples collected and the restricted spatial coverage, further investigation was recommended for Site 7.

2.1.1.5 1993 RI/FS WORK PLAN

The RI/FS Work Plan (JEG 1993a) is a facilitywide document that outlines a program for evaluating potentially contaminated areas at the LBNC as part of this RI/FS process. The following tasks were performed to develop work plans for each of the sites identified within the LBNC:

- review of existing data,
- development of a conceptual model representing site conditions and potential exposure pathways,
- performance of a screening-level assessment to identify where risk-based or regulatory-based protectiveness criteria may have been exceeded, and
- determination of whether the site required further investigation or warranted a removal action.

Existing sediment chemistry data specific to West Basin (JEG 1992b and 1993a) were reviewed as part of the Work Plan development process. Field work, conducted as part of the SI, resulted in the identification of chemicals of potential concern, such as PAHs, PCBs, pesticides (e.g., dichloro-diphenyl-trichloroethane [DDT]), arsenic, copper, lead, mercury, and zinc. The SI results indicated that measured concentrations of these chemicals in sediment exceeded sediment screening-level criteria. The screening levels (SLs) included ER-L, ER-M, and equilibrium partitioning (EP) (Long and Morgan 1990); and the Puget Sound Standards (WSDOE 1991) of minimum cleanup levels and SLs. As a result of this screening evaluation, it was determined that further evaluation of sediment toxicity would be required prior to specifying remediation of sediment.

The conceptual site model prepared for West Basin sediments identified potential exposure pathways via bottom sediments and surface water. Potential human receptors were identified as those individuals who consume fish caught in West Basin. Significant aquatic receptors were identified as invertebrates (including polychaete worms and crustaceans) and fish. A sediment transport conceptual model was also developed to describe sediment mobilization and transport within West Basin.

The Work Plan also presented an approach to characterize risk associated with contaminated sediments. This approach was based on evaluation of sediment analytical data, bioassay results, and tissue bioaccumulation test results to determine the need for sediment remediation. Potential remedial action alternatives proposed in the Work Plan included capping, dredging and disposal, and natural recovery.

2.1.2 Scientific Surveys

This section presents an overview of some of the key physicochemical and biological investigations conducted specifically within the West Basin as well as those conducted within the LA/LB Harbor and the Bight. Areas within the Bight, outside the LA/LB Harbor, are appropriately comparable to West Basin, especially those areas with similar land/water use and contaminant sources/inputs (e.g., San Diego Bay). The Bight's unique geography and hydrography results in a regionally specific marine ecosystem that extends from Point Conception, Santa Barbara County, California to Cabo Colnett, Baja California, Mexico.

Dailey et al. (1993) report that the LA/LB Harbor may have been studied and characterized more thoroughly and for a longer time than any other similar body of water in the world. The first comprehensive survey of environmental conditions in the LA/LB Harbor was performed in 1951 (Anon. 1952) and included analyses of water, sediment, and benthic populations. A more detailed seasonal study was conducted in 1954 (Reish 1959) using bottom conditions, species composition, and water characteristics as a basis for documenting environmental quality at the time. This survey distinguished "polluted" zones and "very polluted" zones through identification of specific benthic organisms inhabiting the bottom. Generally, the most "polluted" zones occurred between piers located along the seawall of West Basin shared by the NAVSTA Long Beach and the LBNSY, as well as other locations within the LA/LB Harbor.

Various pollution abatement programs were initiated by the state of California, beginning in Dominguez Channel in 1968, which extended throughout the LA/LB Harbor during the 1970s. Complying with these orders, the improvement in biological conditions was immediate (Dailey et al. 1993). One factor contributing to the recovery was that many of the local benthic invertebrate species have extended reproductive periods throughout the year as a result of the mild climate, and such reproductive capability undoubtedly played an important role in the rapid recovery of the polluted harbor. Benthic species which were formerly dominant and known to be resistant to pollution gave way to more sensitive species; species diversity increased dramatically as well during this time. This improvement has been documented by a series of publications edited by Soule and Oguri (Soule and Oguri 1974; 1975; 1976; 1978a; 1978b; 1979; 1980; 1986; 1987; 1990). Improvements in biological conditions were accompanied by decreases in chemical and total organic carbon (TOC) concentrations in sediment as a result of discontinuing waste discharges into LA/LB Harbor receiving waters and sediment. Investigations conducted between 1973 and 1978 have chronicled changes over time in the LA/LB Harbor, with decreases in cadmium, nickel, lead, and total PCB concentrations. Other contaminants remained about the same, although arsenic concentrations were shown to increase to a small extent.

Regional chemical concentrations in sediment and fish tissue, and West Basin benthic biological data, most recently characterized in 1978, are presented in Appendix E. Data deemed appropriate to describe regional ambient conditions for the West Basin are those which have been obtained from the West Basin itself, LA/LB Harbor, and certain areas of

R0062667

the Bight (i.e., areas with similar land/water use and contaminant sources/inputs like San Diego Bay). Appendix E also provides an overview of contaminant concentrations measured in surface sediment, white croaker tissue, and California halibut tissue, respectively, which provide a basis for comparison with project-specific sediment and tissue data.

2.1.2.1 PHYSICAL OCEANOGRAPHIC SURVEYS

Few investigations of physical oceanography have been conducted within the West Basin and its environs. The principal studies include the POLB water quality monitoring program and the hydrodynamics investigations conducted by the U.S. ACOE.

The POLB has collected monthly water quality data at 16 stations throughout the Long Beach Harbor and its channels over the last 20 years (JEG 1993a). Physical water quality measurements included water temperature and transparency. A comparison of the mean values for these parameters, as measured between 1971 and 1991, between the two stations located in West Basin and all 16 stations was documented in the CLEAN I RI/FS Work Plan (JEG 1993a). The data indicate that water quality in the West Basin is comparable to that in other parts of Long Beach Harbor and may even be slightly better in terms of transparency.

The most extensive investigations of LA/LB Harbor hydrodynamics have been conducted by the U.S. ACOE Waterways Experiment Station (McAnally, Jr. 1975; Seabergh and Outlaw 1984; Sargent 1989; Vemulakonda et al. 1991). These studies were conducted to determine tide- and wind-driven circulation patterns and flushing rates of the LA/LB Harbor's inner basins. In general, these studies found that water circulation in the West Basin is restricted; its configuration and location results in less mixing of water than in the outer harbor.

Tidal circulation patterns for spring, mean, and neap tidal conditions were determined using a two-dimensional, depth-averaged, second order finite-difference model by Seabergh and Outlaw (1984); tidal verification was previously conducted by McAnally, Jr. (1975). The fluid flow equations used in the numerical tidal circulation model, titled the Waterways Experiment Station Implicit Flooding Model (WIFM), were derived from the Navier-Stokes equations. The WIFM predictions were verified using dye tests conducted in the outer LA/LB Harbor Complex (Seabergh and Outlaw 1984).

The U.S. ACOE also investigated harbor oscillations caused by long waves using a finite element numerical model (Sargent 1989) and determined where ship motion problems were most likely to develop. Numerical modeling of tide- and wind-driven circulation of LA/LB Harbor was conducted by applying a three-dimensional, hydrodynamic model called CH3D (Vemulakonda et al. 1991), the results of which were used to drive a water quality model. Flushing rates, water circulation, and DO levels were compared at various stations throughout the LA/LB Harbor. The CH3D model was calibrated and verified using field data collected in 1987 (surface elevation data, current measurements, current velocities, drogue study) (McGehee et al. 1989). Comparison of the CH3D model results with the 1987 observed surface elevation and currents indicated that the model reproduced

VOL 18
00059
R0062668

prototype behavior (i.e., the calibration and verification proved successful [U.S. ACOE 1990]).

Tracer studies of the LA/LB Harbor were conducted by the U.S. ACOE to determine flushing rates of the inner basins. The flushing studies consisted of inserting a tracer and observing its movement and dilution with time. Results of the tracer simulation for West Basin indicated that dilution to 20 percent of the initial tracer concentration was achieved in 16 days (Hall 1990). This moderate level of dilution is suggestive of the flushing rates predicted by the models summarized above. Tracer simulations for the East Basin channel of LA Harbor, which is more restricted by land than West Basin, and Seaplane Anchorage (the area between West Basin of Middle Harbor and Fish Harbor) of LA Harbor, which is less restricted by land than West Basin, were conducted. Results revealed 20 percent of initial tracer concentration remained after 25 days in the LA Harbor East Basin channel; the tracer was diluted to 20 percent of initial concentration after 10 days in Seaplane Anchorage.

2.1.2.2 CHEMICAL SURVEYS

The following section provides an overview of water column chemical surveys and sediment and marine fish tissue contaminant monitoring studies conducted both within and in areas surrounding West Basin.

Water Column Surveys

The literature review conducted for water column data indicated that the POLA and POLB, with their corresponding Harbor Departments, have most frequently taken measurements of DO, pH, salinity, nutrient levels, and trace metals concentrations in surface water, although most were taken outside of the immediate West Basin area. It is difficult to apply historical water column data to the understanding of current conditions in the West Basin due to its dynamic state, and because most of the contaminant inputs have changed over time as well.

Sediment Surveys

In 1973, Chen and Lu (1974) analyzed surface sediment samples for trace metals and organochlorine compounds (DDT, PCBs, and dieldrin) within the LA/LB Harbor as part of the Harbors' Environmental Projects sponsored by the University of Southern California's Allan Hancock Foundation. More sampling and analysis within the LA/LB Harbor was conducted for trace metals, DDT, and PCBs in 1974 (Allan Hancock Foundation 1975). Soule and Oguri (1980) produced analytical data for metals, DDT, and PCBs from the LA/LB Harbor in 1978. The general trend, as documented by the Allan Hancock studies, in sediment chemical concentrations over time is that while arsenic and zinc concentrations seemed to be increasing, cadmium, chromium, lead, total PCBs, and total DDT concentrations have actually decreased within the LA/LB Harbor. Copper and mercury levels remained the same throughout the 1970s, according to these studies.

VOL 18
00600
R0062669

The Southern California Coastal Water Research Project (SCCWRP), a scientific body established to study the effects of pollution in the Southern California marine environment, has conducted several major surveys of chemical and biological conditions in reference areas off the coast of Southern California in the last 15 years (1977, 1985, and 1990). The objectives of these surveys were to determine distribution of marine pollutants within the Bight, to evaluate potential biological effects, and to evaluate potential sources of these problems. Sampling stations were located along the 30-, 60-, and 150-meter isobaths of the mainland shelf and bracketed the major ocean municipal wastewater discharges (Woodland Mearns 1979, Thompson et al. 1987, and Thompson 1992). As a result of these surveys, SCCWRP has found that trace metal concentrations were at or near background levels and similar among the different depths sampled. Concentrations of total DDT, as measured in 1990, were highest at the northern 60-meter and 150-meter isobath sites. Total PCB (Aroclor 1254 and Aroclor 1260) concentrations were highest off Point Dume and Dana Point. Total PAH concentrations resulting from the 1990 survey were highest off Oxnard (Thompson 1992).

The SWRCB, through its Bay Protection and Toxic Cleanup Program (BPTCP), including the National Oceanic and Atmospheric Administration (NOAA) and the California Department of Fish and Game (CDFG) undertook a 3-year cooperative study effort to characterize the magnitude and extent of potential contaminant-induced biological effects in LA/LB Harbor and other areas of Southern California (SWRCB and NOAA 1994). The BPTCP used the results of sediment chemistry and bioassay testing from 35 replicated sampling sites to determine which areas could be potentially impacted by chemical contaminants. The concentrations of several sediment contaminants were correlated with amphipod mortality and abnormal abalone development using a sediment pore water test. Part of the significance of this study is that three of the established study sites (Sites 40010, 40018, 40032) in the BPTCP were adopted as reference stations for this RI. These stations are situated in the outer portion of San Pedro Bay, outside of the West Basin.

The BPTCP observed that PAH concentrations were higher in samples from the LA/LB Harbor than in samples collected from other Southern California areas when compared to the state of Florida threshold exposure limit (TEL) and permissible exposure limit (PEL) screening levels. The highest levels of PAHs were measured in samples from Los Angeles and Long Beach inner harbors and Fish Harbor (Station 40019); Long Beach outer harbor (Station 40018) had lower levels of PAHs (Figure 2-1). Significant amphipod toxicity was also observed at many LA/LB inner harbor sampling sites as well as some stations inside the San Pedro Breakwater (Figure 2-2). Undiluted pore water toxicity was widespread throughout the 35 sampling stations (Figure 2-3). Pore water toxicity at 50 percent dilution was observed to be also widespread throughout the sampling sites with several exceptions, notably Station 40009 located at the entrance to the West Basin, and off Cabrillo Beach (Station 40010) (Figure 2-4). The amphipod and undiluted pore water bioassays collectively identified Huntington Harbor, Consolidated Slip, and portions of Alamitos Bay as areas that were most toxic (SWRCB and NOAA 1994).

VOL 18
0061
R0062670

NOAA is currently monitoring a surface sediment station in Long Beach Harbor as part of its National Status & Trends (NS&T) Mussel Watch Project. The NS&T program's objectives include defining the geographic distribution of contaminant concentrations in tissues of marine organisms and sediments, and evaluating potential biological responses to contamination. Samples have been collected since 1984 under the Benthic Surveillance Project and, since 1986, under the Mussel Watch Project, the two components of the NS&T program. Chemicals and related parameters measured in sediment include chlorinated pesticides, PCBs, PAHs, trace elements, grain size, and TOC (NOAA 1991). The NS&T program concentrates considerable effort in Southern California, with 20 of its approximately 200 sampling sites nationwide located within the Bight (Mearns et al. 1991).

As a result of data gathered during 1986 through 1988, NOAA found 14 chemicals, sampled from stations located within the Bight, whose mean concentrations were at the "high" end of the overall, national log-normal distribution (i.e., greater than one standard deviation above the geometric mean). West Santa Monica Bay had the greatest number of chemicals with "high" concentrations (11), with South San Diego Bay having 10 chemicals and Palos Verdes having 9 chemicals exhibiting "high" concentrations in surface sediments. The Long Beach station had "high" concentrations of lead, total DDT, and total PCB (NOAA 1991).

Fish Tissue Surveys

Several investigators have surveyed and continue to survey fish tissue concentrations within the LA/LB Harbor and the Bight in general. This extensive database is expected to provide a viable means of comparing project-specific data and evaluating ecological conditions within the West Basin. In 1972, as part of a nationwide program, Butler and Schutzmann (1978) began a 4-year analysis of organochlorines (PCBs and DDT) in whole juvenile estuarine fish from three Southern California sites including LA/LB Harbor. Species collected included California halibut (*Paralichthys californicus*), queenfish (*Seriphus politus*), white croaker (*Genyonemus lineatus*), walleye surfperch (*Hyperprosopon argenteum*), and northern anchovy (*Engraulis mordax*). In 1978, SCCWRP launched the first of several studies to examine the potential for biomagnification of organochlorine compounds, trace elements, and other chemicals in various marine ecosystems of the Bight. Kelp, clam, and three fish species from LA Harbor were sampled and analyzed for metals and benzo(a)pyrene in 1979, as part of the Harbor Ecosystem Survey (Mearns and Young 1980; Goeders 1982). At the same time, Gadbois and Maney (1983) analyzed PCBs in fin fish muscle collected by the University of Southern California within and outside of LA Harbor as part of the nationwide NOAA Microconstituents Survey. Organic contaminants in Los Angeles area fish muscle and liver were analyzed for PCBs, DDT, other pesticides, and metals by the Los Angeles Regional Water Quality Control Board (LARWQCB) in 1985 (Risebrough 1987).

More recently, the U.S. EPA's National Study of Chemical Residues in Fish (previously referred to as the National Bioaccumulation Study) was initiated in 1986 as an outgrowth of U.S. EPA's National Dioxin Study. Composite fish samples were collected primarily in

VOL 18
0062
R0062671

1987 from approximately seven sites along the Southern California coast, including the LA/LB Harbor. The fish were analyzed for dioxins, furans, PCBs, pesticides, and mercury (U.S. EPA 1992b). Cal-EPA's Office of Environmental Health Hazard Assessment (OEHHA) conducted a comprehensive study and risk assessment of chemical contaminants (PCBs, DDT, chlordane, mercury, and tributyltin) in fish species, including California halibut and white croaker, in Southern California (Cal-EPA 1991). Fish were collected in 1987 from numerous sampling sites along the Southern California coast, with several sites located within the LA/LB Harbor. California halibut contained very low levels of chemical contaminants; few composite samples had quantifiable levels of DDT or PCBs (Aroclor 1254 and Aroclor 1260). The highest levels of DDT or PCB in white croaker were found at White's Point, Point Vicente, and Malibu. White croaker sampled from Belmont Pier and Pier J of Long Beach Harbor had the lowest DDT and PCB concentrations. Concentrations of chlordane in white croaker were relatively high at Point Dume, Malibu, White's Point, Point Vicente, and Cabrillo Pier. Mercury concentrations in California halibut were low. Tributyltin was detected in white croaker tissues collected from Marina Del Rey. NOAA currently surveys fish liver for metals, PAHs, PCBs, and pesticides from six sampling sites located between Santa Monica Bay and San Diego Harbor as part of its NS&T Benthic Surveillance program.

2.1.2.3 MARINE BIOLOGICAL SURVEYS

Numerous marine biological investigations have been conducted in LA/LB Harbor and surrounding areas. This section focuses on those surveys which evaluate potential biological effects in benthic biota and demersal (bottom-dwelling) fish rather than those inhabiting the upper water column. As noted earlier, the University of Southern California's Allan Hancock Foundation published a series of comprehensive studies on LA/LB Harbor biota, called the Harbors Environmental Projects, including a detailed 1971-1974 biological baseline assessment of LA/LB Harbor (Allan Hancock Foundation 1976). This assessment was supplemented and updated by Soule and Oguri in 1980.

A number of investigators have conducted fish surveys as part of biological studies, including Chamberlain (1973), Long Beach Harbor Consultants (1976), and Horn and Allen (1981). Specific harbor development projects were frequently preceded by biological studies, including those by Reish (1971), Environmental Quality Analysts and MBC (1978), Hill and Reish (1975), Loi (1981), and MBC (1984). In addition to summarizing earlier studies of the two harbors, the biological baseline surveys of Long Beach outer harbor and Queensway Bay by MBC Applied Environmental Sciences (1984) and of Los Angeles Harbor and adjacent waters by MEC Analytical Systems (1988a) included sampling methods and quantitatively described biological communities found in the LA/LB Harbor.

SCCWRP has conducted three surveys of biological conditions in reference areas off the coast of Southern California during the years 1977, 1985, and 1990. The results of the biological component of these studies indicate that the macrobenthic communities (organisms greater than 1 mm in length) of the Southern California mainland shelf are

VOL 18
0063
R0062672

VOL 18 0064

dominated by variations of the *Amphiodia urtica-Spiophanes missionensis* assemblage. Megabenthic invertebrates (large, motile invertebrates) are dominated by asteroids (*Astropecten verrilli*), sea urchins (*Lytechinus pictus* and *Allocentrotus fragilis*), and prawns (*Sicyonia ingentis*). Speckled, longfin, and Pacific sanddabs (*Citharichthys sp.*) represent the majority of demersal fish at the 30-meter and 60-meter isobaths. The species composition of macro- and megabenthic invertebrates and demersal fishes collected in 1990 were similar to those collected in the 1977 and 1985 reference surveys (Thompson 1992).

Benthic samples have been collected throughout the LA/LB Harbor from 1951 through 1968, and benthic data specific to West Basin have been collected in 1970-1971. At that time, these and other environmental studies concluded that the inner LA/LB Harbor waters, including West Basin, were polluted since benthic communities were either absent or stressed (e.g , dominated by the polychaete *Capitella capitata*), and there was little to no available DO. Figure 2-5 illustrates the findings of these studies. The information depicted on Figure 2-5 was prepared by combining data reported in 1954 for the LA/LB Harbor with data reported in 1971 for the West Basin. The outer LA/LB Harbor, however, indicated adequate DO levels, and benthic communities were rich, diverse, and healthy. These general benthic conditions remained static until the late 1960s.

In 1968, a pollution abatement program was initiated by the State of California to control industrial, domestic, and storm water wastes; this program was implemented within the LBNC during the mid-1970s. Benthic studies of the LA/LB Harbor began again in 1971 and continued on a regular basis throughout the 1970s (Soule and Oguri 1975, 1976, 1978a, 1978b, 1979). As a result of the pollution abatement program, benthic conditions greatly improved except for the West Basin, Dominguez Channel, Fish Harbor, and a few blind-ending slips in the LA/LB Harbor. West Basin was resampled in 1978 and was found to support a healthy benthic community more in common with the relatively unpolluted outer LA/LB Harbor than those associated with traditional polluted marine harbor areas (WESTDIV 1986). Figure 2-6 illustrates the findings of these studies. The information depicted on Figure 2-6 was prepared by combining data reported in 1973 for the LA/LB Harbor with data reported in 1978 for the West Basin. Benthic conditions of this post-pollution abatement period may be considered a more recent basis for defining baseline conditions and evaluating possible environmental changes within the LA/LB Harbor, including West Basin.

2.1.3 Dredging Activities

Dredging of sediments are typically associated with temporary increases in turbidity, resuspension, and migration of contaminated sediment, and decreases in DO. The type of dredging equipment used would affect the amount of resuspension of sediments. Contaminated sediments mobilized during dredging activities are capable of migrating and settling elsewhere, including settling in unimpacted areas. In addition, resuspension of such sediments could affect the water column in the event that the chemicals desorb from sediment particles (U.S. ACOE 1983).

R0062673

Dredging activities in the LA/LB Harbor are generally conducted in accordance with monitoring requirements dictated by the particular dredging permit. During dredging activities, water column samples are collected and analyzed for various chemicals in accordance with U.S. EPA, U.S. ACOE, and the Regional Water Quality Control Board (RWQCB) requirements. The appropriate regulatory agency is notified if specific chemical concentrations exceed the permit requirements (LARWQCB 1994). As a result of such monitoring, significant quantities of sediments are not expected to be resuspended and mobilized during dredging activities if equipment and methods that minimize resuspension are used.

Prior to 1979, dredging activities were conducted in West Basin fairly regularly. Since 1979, dredging has been conducted every 2 to 3 years. Sediment samples reportedly have been collected and analyzed for pesticides, heavy metals, and organohalides. In addition, bioassay tests have been conducted using sediment samples collected from West Basin. No record of chemical analysis of West Basin sediments was found during a review of available Western Division (WESTDIV) files conducted as part of the IR Program. No relevant information was available from the Los Angeles office of the U.S. ACOE (JEG 1992b).

The following section describes dredging plans and associated sampling both within the LA/LB Harbor and within the West Basin. Information was obtained mainly through a review of documents describing studies in the LA/LB Harbor.

2.1.3.1 LOS ANGELES/LONG BEACH HARBOR

During recent years, numerous dredging activities have been conducted by the POLA and POLB within the LA/LB Harbor. These dredging activities have been related to development of harbor facilities (e.g., construction of new piers), maintenance of harbor facilities which requires deepening of channels, or sampling investigations conducted in support of development or maintenance activities.

The steady growth of the POLA over the past 100 years to the present complex of several thousand acres of docks, piers, channels, basins, and anchorages has changed the character of the natural environment. Dredging and filling have converted former wetlands and shallow open water areas to deep channels and slips. Breakwater construction has converted the San Pedro Bay from exposed coastline to a protected embayment with restricted circulation. In addition to these physical changes, the increased urbanization and industrialization of the area and, consequently, the increased discharges of various contaminants, have altered sediment and water quality in the LA/LB Harbor (MEC 1988a).

Harbor development activities conducted during the 1980s have substantially altered the Los Angeles Harbor. These development activities included deepening of the Main Channel in the Inner and Outer Harbors, filling (approximately 190 acres) of shallow water on the south side of Terminal Island, relocating the Terminal Island Treatment Plant (TITP) outfall within the Outer Harbor, constructing a marina complex near Cabrillo

VOL 18
0065
R0062674

Beach, creating a salt marsh near Cabrillo Beach, and establishing a kelp bed directly inboard of the San Pedro Breakwater (MEC 1988a).

Very large development projects, collectively known as the POLA 2020 Plan, are currently being planned and implemented to meet anticipated future cargo demands. New terminals are being constructed on land created by dredging and filling areas within the LA/LB Harbor. The channels, basins, and slips are routinely dredged to promote navigation of larger ships.

In general, sediment sampling and analysis are conducted prior to dredging activities, according to POLA. Some of the dredged materials are expected to be disposed of in open water at LA-2, a dredge material disposal site located 4.7 nautical miles south of the San Pedro Breakwater. Before dredging begins, these materials undergo chemical and biological testing in accordance with guidance criteria in the "Green Book" (U.S. EPA/U.S. ACOE 1991) (Smith, pers. com. 1994).

The following paragraphs summarize a number of dredging plans, associated sampling, and planned disposition of the dredged materials, to be conducted in the LA/LB Harbor.

Pier E, Berth 121-122 (Planned Relocation of ARCO Tanker Terminal) (1981)

The planned relocation of the ARCO tanker terminal on Pier E from Berth 118 to the vicinity of Berths 121 and 122, located in the Back Channel of Long Beach Harbor, included dredging and disposal of dredged material. Under this plan, the berthing area would be dredged to a depth of -66 feet mean lower low water (MLLW), thereby providing more vessel clearance and increasing available maneuvering room in the Back Channel. Approximately 150,000 cubic yards of dredged material would be used as fill material at the project site and approximately 400,000 cubic yards of dredged material would be disposed of at the LA-2 ocean disposal site.

Coal Terminal Project, POLB (1982)

Sediment samples were collected at three areas planned to be dredged adjacent to the proposed coal terminal facility along the north shore of Cerritos Channel by the POLB. The three sampling areas consisted of the Cerritos Channel (north side), the Turning Basin, and the Back Channel. Samples were collected and bioassays conducted to assess potential impacts of the disposal of dredged materials derived from construction dredging for a berthing slip adjacent to the proposed coal terminal facility. The bioassays were performed on the three phases of dredge material (liquid phase, suspended particulate, and solid phase), as well as chemical analyses of the liquid and solid phases, and assessment of bioaccumulation potential. A control sediment sample was also collected along the perimeter of the LA-2 ocean disposal site. Trace metals, petroleum hydrocarbons, and halogenated hydrocarbons (pesticides and PCBs) were detected in the samples. Bioassays conducted using the three phases of dredge materials demonstrated little statistically significant evidence of mortality or other toxic effects. The sediment samples demonstrated statistically significant bioaccumulation potential for specific trace metals and petroleum hydrocarbons (MBC 1982).

VOL 18
0066
R0062675

Proposed Pier 400, POLA (1990)

An environmental study in support of the POLA 2020 Plan was conducted to identify regions within the potential dredge areas harboring contaminated sediment or sediment with significant acute or chronic toxicity to marine organisms. Sediment samples were collected at various locations in the vicinity of the proposed Pier 400 for analysis. Metals detected included chromium, copper, lead, mercury, nickel, silver, and zinc. Organics detected included PCBs, PAHs, and DDT. Test results indicated that concentrations were above action thresholds but the sediments would not pose a problem if disposed of (capped) in a landfill (Kinnetic Laboratories, Inc. 1991).

Pier J Expansion Site, POLB (1991)

Sediment samples were collected from the East Channel and the area east of Pier J. Sediment and elutriate chemical analyses, grain-size analyses, liquid and suspended particulate phase bioassays, solid phase bioassays, and an evaluation of the bioaccumulation potential were conducted according to "Green Book" methods (U.S. ACOE/U.S. EPA 1991). The sediment samples were similar in chemical constituent composition and concentration to other sites within the LA/LB Harbor. Elutriate chemistry analyses indicated no substantial leaching of chemical constituents from sediments to water, and no dissolved concentrations that exceeded water quality standards. Based on these results, the dredge materials were deemed to present no long-term degradation potential if disposed of at the LA-2 ocean disposal site (MEC 1992).

Pier 400 Maintenance Dredging and Design Program, POLA (1993)

Sediment samples were collected at various locations within Los Angeles Harbor and its adjoining basins where future maintenance dredging would be required in relation to the Pier 400 design program. Sample analysis results indicated that no single area was highest for all constituents measured. Test results indicated no consistent horizontal trend in the distribution of contaminants between areas or within an area, or vertically throughout the length of the core. This was attributed to the different sources of inputs each of the areas has received and historical deposition of contaminants each has accumulated. No biological testing was conducted as part of this sampling program. Metals detected in the samples included arsenic, cadmium, chromium, copper, lead, mercury, and nickel. Organics detected included total PAHs, DDTs, and PCBs (Kinnetic Laboratories, Inc. 1993).

Construction of Pier 400, POLA (1994)

The POLA current expansion project involves the construction of Pier 400, south of Pier 300. Dredging activities and associated sampling and analysis for this construction started in September 1994 and were ongoing at the time of writing this RI report. During dredging, the water quality is monitored on a weekly basis for DO, light transmittance, temperature, and pH at 2-meter increments throughout the water column. Suspended solids are monitored on a bimonthly basis at the water surface, mid-depth, and bottom. Quarterly monitoring of the water column is conducted at three sampling locations, at

VOL 18
0067
R0062676

mid-depth of the water column. The samples are collected at 30.5 meters up-current, and 30.5 and 91.5 meters down-current of the dredge operation. Samples are analyzed for trace metals (arsenic, chromium, copper, lead, mercury, nickel, silver, selenium, and zinc) and organics (p,p'-dichloro-diphenyl-ethane [DDE], PCBs, PAHs, phthalates, tributyltin, and oil and grease). As part of Pier 400 construction activities and as mitigation for project-related impacts to the existing shallow water habitat site, a permanent shallow water habitat is planned to be constructed adjacent to the San Pedro Breakwater using contaminated sediments which, in turn, will be capped with uncontaminated sediments (LARWQCB 1994).

2.1.3.2 WEST BASIN

Records of dredging plans in the West Basin are summarized in this section. A review of historical files pertaining to each of these dredging plans was conducted. These files were obtained from NAVSTA Long Beach, the LBNSY, the POLB, the U.S. Coast Guard, the U.S. ACOE, and the CLEAN I contractor. However, records of the dredging activities were not found. Most dredging plans were associated with the construction or maintenance of LBNC piers supporting vessel operations within the West Basin. Some of the dredging activities may have impacted bottom conditions of sediments through changes in depth or resuspension, and resettlement of particulates.

Maintenance Dredging at Piers 7 and 9 (1982)

In 1982, approximately 400,000 cubic yards of sediments were to be dredged from the West Basin at Piers 7 and 9 as part of a periodic removal of accumulated sediment from the berthing areas. Bioassay results indicated that the dredged material between Piers 7 and 9 would not have a significantly adverse effect on the marine environment after ocean disposal. The dredged material would be disposed of at the LA-2 ocean disposal site. The project would deepen the area between Piers 7 and 9 to -30 to -35 feet MLLW, plus 2 feet overdredge.

Fuel Pier Relocation (Pier 12) (1984)

This project included the construction of both a new fuel pier (Pier 12) extending into the West Basin from the Navy Mole at the LBNC, and a pipeline system to deliver fuel from the new fuel pier to the Defense Fuels Support Point in San Pedro. The pipeline system presently crosses the Los Angeles Main Channel in a trench. Dredging was to be conducted at the location of Pier 12 and in the Main Channel.

Maintenance Dredging at Pier 6 (1986)

This project, known as Project MI-85, involved the maintenance dredging of certain areas on both sides of Pier 6 to accommodate operational schedules and required berthing for deep-draft vessels. Dredging to a depth of -45 feet MLLW was found to be necessary to prevent fouling of battleships and amphibious landing ships. Bioassay tests were conducted as required by U.S. EPA and U.S. ACOE (1977) regulations to assess the potential toxicity associated with ocean disposal. These tests indicated that the dredged

VOL 18
0068
R0062677

material was acceptable for ocean disposal. Approximately 46,000 cubic yards of dredged material were to be removed and disposed of at the LA-2 ocean disposal site. The project was planned to be completed in the spring of 1987.

Maintenance Dredging at the South Face of Pier E (1991)

This LBNSY project, conducted in 1991, is referred to as Project MI-87 by the DON. This project involved maintenance dredging along the south face of Pier E to prevent the fouling or grounding of battleships and oiler class vessels. The harbor bottom along the south face of Pier E was to be dredged to an elevation of -47 feet MLLW (-45 feet plus 2 feet over depth). The total volume of dredged material would be approximately 18,300 cubic yards. The planned dredging project area extended for about 1,400 feet in the east-west direction along the south face of Pier E, and for a distance of 200 feet in the north-south direction (WESTDIV 1989).

Activities conducted in conjunction with this dredging project included a geotechnical investigation as well as sediment sampling and analysis (chemical, physical, and bioassay testing). These pre-dredging activities were required under the Ocean Disposal Program to provide results for submittal to the U.S. ACOE and the U.S. EPA to determine whether the dredged material was suitable for open water disposal.

The geotechnical investigation at Pier E showed that the bottom sediment strata between -5 and -18 feet MLLW depth consisted of very loose to loose sandy/clay soils with some shell hash, and very soft clay layers. These loose and soft sediments were found beneath the east end of the pier; they were underlain below the 18-foot depth by medium dense to very dense sands with shell hash. On the basis of developing and evaluating a geotechnical model for this project, it was concluded that the maintenance dredging project would not significantly affect the stability of the pier (WESTDIV 1989).

Results of the sediment sampling and analysis indicated that sediments were contaminated with moderately elevated levels of heavy metals and petroleum hydrocarbons. PAH concentrations ranged from moderate to high. Bioassay and bioaccumulation results indicated that sediments caused a reduction in sea urchin (echinoderm) development, affected mortality of worms and mysids, and were associated with elevated concentrations of zinc, PAHs, and chromium in clam tissue (WESTDIV 1990). Based on a review of these data, the CDFG and the U.S. EPA determined that the dredged materials were not suitable for ocean disposal. Upon comparing the sampling results with U.S. EPA ocean dumping criteria in 40 *Code of Federal Regulations* (CFR) Part 227, it was determined that the top 7-foot layer of the harbor bottom represented the zone of contamination, and the contaminated sediments would have to be removed and transported to a suitable disposal site.

As a result, the project involved dredging at two different locations within the project area and disposal of the dredged materials in the POLB Ford/Melamed Landfill. According to the dredging permit application filed with the U.S. ACOE, the dredged material that was unsuitable for ocean disposal (3,000 cubic yards) would be removed by clam-shell dredge to a depth of -47 feet MLLW, placed on a barge, and disposed of at the landfill. The

VOL 18
0069
R0062678

3,000 cubic yards of unsuitable material would be capped at the landfill with the addition of 15,300 cubic yards of uncontaminated dredged material from the project area. The dredged material was further capped by 50,000 cubic yards of material suitable for open water disposal.

2.2 IDENTIFICATION OF DISCHARGES

Identification of discharges to surface waters is an attempt to identify sources of discharge into the LA/LB Harbor in general, and the West Basin in particular. This task included researching possible points of origin, facility operations, discharge generators, and locations of discharge points into the receiving waters of the West Basin. This information was utilized in characterizing and delineating the nature and extent of COPCs in West Basin sediments.

Various historical documents were reviewed and Navy personnel interviews were conducted to identify potential discharge sources to the West Basin. The types of records reviewed and data collected included:

- records relating to waste characteristics, to the extent possible, such as the types and quantities of chemicals or materials that may have been released to the LA/LB Harbor;
- water quality conditions in the LA/LB Harbor with respect to the various industries operating in the area; and
- the physical or chemical characteristics of chemicals discharged or spilled into the LA/LB Harbor.

References reviewed included:

- CLEAN I RI/FS Work Plan and Sampling and Analysis Plan (JEG 1993a and b);
- Site Inspection Report (JEG 1992a and b;
- Initial Assessment Study (NEESA 1983);
- Storm Water Pollution Prevention Plan (Brown and Caldwell 1992b);
- Storm Water Discharge Management Plan (WWC 1993);
- Historical and Recent Water Quality Conditions in the Port of Long Beach (MBC 1992); and
- various records of LBNC operations, land-based or ship-based, that described the source location and potential releases.

2.2.1 Discharges to the LA/LB Harbor

Southern California's large, diverse urban population has facilitated input of many types of chemicals into the Bight. Chemical inputs have resulted through spills, sewage discharges, power plant cooling water discharges, various industrial discharges, atmospheric deposition, and runoff from flood control channels (Mearns et al. 1991).

VOL 18
00710
R0062679

Various point and nonpoint sources of discharges present in areas surrounding the LBNC have the potential of adversely affecting the water quality as well as the biological community of the LA/LB Harbor. Potential point sources would include industries such as: 1) the TITP, located approximately 1 mile west of the LBNC; 2) Southern California Edison Company's Long Beach Generating Station, located to the north of the LBNSY on Terminal Island; 3) petroleum refineries as well as petroleum shipping, receiving, and storage facilities in the South Bay area; and 4) manufacturing plants that may affect the LA/LB Harbor area. Nonpoint sources would include aerial fallout, advective transport, ocean dumping, and boating and shipping activities (MBC 1992).

Specifically, the sources that could potentially impact the LA/LB Harbor waters were identified (MBC 1992) as follows:

- surface runoff from piers and docks;
- surface runoff from storm drains which drain the Los Angeles basin, drainage channels of the Los Angeles and San Gabriel rivers and the Dominguez Channel;
- industrial wastes that have been discharged into San Pedro Bay; and
- ballast water and other wastes that may be introduced into the LA/LB Harbor by marine traffic (recreational, commercial, and naval) operating in the LA/LB Harbor.

Historically, sewage outfalls have been considered the principal sources of contaminants to the Bight. Sewage discharges have significantly decreased over the past two decades, however, as a result of enforcement of the 1972 Clean Water Act and its statewide counterpart, the Porter-Cologne Act by the California SWRCB and the U.S. EPA Region IX. This enforcement has resulted in much greater regulation of effluent discharge into the receiving waters of the Bight. Consequently, sources such as dredge material disposal, atmospheric deposition, and surface runoff have surpassed those of sewage outfalls, and they are currently considered of greater importance to Bight water quality (Mearns et al. 1991).

Bioassay tests of TITP effluent conducted in the early 1980s indicated no evidence of toxicity or bioaccumulation. Adverse effects to the biological community in the LA/LB Harbor receiving waters, due to potential contaminants in the TITP effluent, have not been found. Monitoring surveys, conducted and reported since 1979 under the National Pollutant Discharge Elimination System (NPDES) program, do not indicate adverse impacts to the receiving waters or associated biota as a result of cooling water being discharged by the Long Beach Generating Station (MBC 1992).

2.2.2 Discharges to the West Basin

Primary sources of discharges into the West Basin waters were found to occur from numerous land- and ship-based activities, such as lead caulking, painting or paint removal, boiler cleaning, and pipe-flushing operations (JEG 1992b and 1993a). Storm water

VOL 18
0071
R0062680

VOL 18

discharge and flushing of dry docks represent historical primary release mechanisms and potential sources of chemicals in West Basin sediments.

As a result of disposal and accidental releases of hazardous substances used in support of the LBNC operations, some areas of the West Basin may have been contaminated from approximately the mid-1930s to 1980. Types of major activities which supported the overall LBNC and their locations are illustrated on Figure 2-7, Land Use Map. Hazardous substances have, in the past, been discharged to the West Basin via the outfalls of the storm drain system. These past practices, together with leaks and spills, may have resulted in some areas of contamination that may potentially pose some level of risk to human health or the environment (WESTDIV 1991a).

Most of the sources of discharge entering the West Basin are historical, whereas currently identifiable sources are generally under permit. Pollution control measures during the past years, including the California Porter-Cologne Act and federal Clean Water Act, have been enacted to reduce or eliminate new contaminant sources into the marine environment.

The identified sources of discharge to the West Basin, discussed within this section, are presented according to the following general categories:

- land-based discharges,
- ship-related discharges, and
- accidental spills.

2.2.2.1 LAND-BASED DISCHARGES

Land-based discharges are identified herein as sanitary wastewater discharges, storm water discharges, industrial wastewater discharges, and indirect discharge sources. Both point and nonpoint sources are included in land-based sources. This investigation included long-term and short-term sources, as well as historical and current sources, as discussed below.

The single largest source of wastes discharged to the West Basin has been from the blowdown and flushing of utility shop boilers, water softeners, and cooling systems. The majority of chemicals in these waste streams, which are expected to have contained disinfectants (e.g., chlorine) to prevent algal growth, are easily dispersed, soluble in water, and considered nonhazardous at low concentrations (WESTDIV 1991b).

Sanitary Wastewater Discharges

A 1969 industrial waste study (IWS) indicated that sanitary wastewaters originating from activities on the Navy Mole were discharged directly to the West Basin or to septic tanks. Effluent from the septic tanks was disposed of by the use of leaching fields or discharged directly to the West Basin. Sanitary wastewaters from ships in floating dry docks or moored at the complex were discharged untreated directly to the West Basin (SWDIV 1969).

00712

R0062681

Raw sewage has been bypassed to the storm water system at LBNSY when the NAVSTA Long Beach sewerage system could not handle the peak sewage flows or when repairs were being conducted to the force main system. During sewage bypassing periods, the average flow was estimated to be 50,000 to 75,000 gallons per day (gpd). Bypassing NAVSTA Long Beach sewage to the West Basin has occurred during major power failures or when mechanical difficulties were encountered at the pumping stations (SWDIV 1969).

As part of the 1969 IWS, a composite sample of 32 wastewater samples, collected every 15 minutes while sewage was being bypassed into the storm sewer system, was analyzed for specific constituents. Results of this analysis indicated the presence of hexavalent chromium, possibly as a result of discharge from a process or cleaning tank. The specific conductance of the wastewater sample indicated the presence of seawater, possibly from seawater utilized aboard ships in the dry docks. It was estimated that 50,000 gallons of sewage was bypassed to the West Basin on the day samples were collected (SWDIV 1969).

According to an Environmental Engineering Survey (EES) conducted in 1976 at NAVSTA Long Beach, untreated sanitary and industrial wastewaters from the Navy Mole were disposed of into the West Basin at that time under a U.S. EPA permit, or into the ground by means of septic tanks and leach fields. Wastewater discharges into the West Basin were discontinued when facilities were constructed in late 1976 to collect and transport sanitary, industrial, and shipboard wastewater from the Navy Mole and the piers northerly for disposal through the pumping facilities located on the mainland. These construction projects (P-122 - Navy Mole Sewer, and P-131 - Ship Wastewater Collection Ashore, Piers 9, 11, and 15) extended the sewage collection system to include the Navy Mole and adjoining piers (Toups 1976).

On 31 December 1973, and in accordance with provisions of the Water Pollution Control Act, the DON was granted a conditional permit (CA0002356) by the U.S. EPA, authorizing temporary discharge of untreated sewage from 12 individual installations located at the LBNC and the Navy Mole to the waters of the United States at the Long Beach Harbor. Based on the permit conditions, the cessation of all untreated sewage discharge into Long Beach Harbor was required by 30 September 1975. Elimination of discharge from locations associated with the Navy Mole was delayed due to unforeseen site conditions and difficulties in obtaining timely delivery of equipment during the construction of the sewer improvements on the Navy Mole (Toups 1976). According to an EES conducted in 1975 at the LBNSY, LBNC sanitary wastewaters were being discharged to the City of Los Angeles TITP (CDM 1977).

Storm Water Discharges

The LBNSY has been separated into nine major drainage basins and 34 subbasins based on drainage patterns and discharge locations, as indicated in a 1992 Storm Water Management Plan (SWMP). Based on the site topography, storm water runoff generally flows toward the center of the facility and it is collected in the storm water conveyance

VOL 18
0073
R0062682

VOL 18 0074

system for discharge to the West Basin. Nine point-source outfalls and their corresponding storm drain systems were identified. Significant materials exposed to storm water at LBNSY were also identified in the SWMP. In-line video surveys of the storm drainage system throughout the LBNSY indicated that parts of the system were clogged with sediments (Brown and Caldwell 1992b).

As part of this RI, in October 1995 BNI obtained from the LBNSY video tapes of the insides of storm drains open to the West Basin waters. The NAVSTA Long Beach video tape had been made in May 1995, and the LBNSY video tape had been made in August 1995. It was observed, upon viewing the recordings on these tapes, that conditions of the storm water drain pipes ranged from containing little or no water or sediments to being flooded or containing gravel and sediments.

According to an EES conducted in 1975 at the LBNSY, a number of composite samples were collected from the storm water system at the LBNSY and analyzed. Results indicated elevated zinc, copper, and iron concentrations, which may be attributed to the crane cleaning operations that were carried out at various locations throughout the LBNSY facilities (CDM 1977).

In 1992, a storm water discharge survey was conducted for the LBNSY to identify illicit connections and discharges to the storm water drainage system. Sixty-two illicit surface and subsurface discharge connections were identified at the LBNSY. The majority of these discharges were aboveground and often involved steam condensate from leaking plumbing, or inappropriate releases to the ground surface. All subsurface discharges were reportedly of a steam/water nature, and did not appear to be potentially significant in terms of introducing pollutants to storm water runoff (Brown and Caldwell 1992a). Some of these illicit discharges were related to Dry Dock No. 1 operations (SWDIV 1992a). The location of Dry Dock No. 1 is illustrated on Figure 1-3.

Other nonstorm water discharges to the storm water drainage system included vehicle washing, direct discharge of bulk water to the storm drain system, cooling water discharges to the ground surface, and equipment washing near a storm drain inlet (SWDIV 1992a). Visually observed nonstorm water discharge data at LBNSY were presented in the LBNSY Storm Water Pollution Prevention Plan (SWPPP) (Brown and Caldwell 1992b).

An investigation of storm water outfalls conducted in 1992-93 at NAVSTA Long Beach detected nonstorm water discharges at six outfalls and the presence of possible illicit connections to the storm drain system and/or nonstorm water in the storm drain system. This Storm Water Discharge Management Plan (SWDMP) included illustrations showing the locations of outfalls into the West Basin and nonstorm water discharge screening results. The size and type of the various outfalls, visual observations (flow rate, presence of standing water, odor), and water quality data such as temperature, pH, and chemical constituents were included as part of the screening results (WWC 1993).

Since 1992, storm water from the LBNSY facility, discharged to the West Basin, has been regulated by the Statewide General Industrial Activities Storm Water Discharge Permit

R0062683

(Identification No. 4B19S005526), administered by the SWRCB (1992). A review of three Annual Storm Water Reports indicated that LBNSY storm water discharges were in compliance with all applicable standards except for a pH level below 6.5 in 1994-95 (SWDIV 1993a, 1994b, and 1995).

The 1994-95 Annual Storm Water Report included findings of the field survey conducted on the LBNSY storm drain connections and recommended remedial actions to eliminate illicit connections. The report also stated that the overall effectiveness of the facility's SWPPP was good. A comparative analysis of sample results with previous years' results indicated steady improvement in the area of storm water pollution prevention (SWDIV 1995). According to the LBNSY, the illicit storm water connections were eliminated by 30 September 1995.

Industrial Wastewater Discharges

This section describes industrial wastewater discharges generated by activities conducted at NAVSTA Long Beach and LBNSY. From the early 1940s until the mid-1970s, unregulated drainage from the various industrial areas and from cleaning and process tanks were discharged to the West Basin, directly through the storm water system and from flushing of the dry docks. The storm water outfalls released wastes, such as PCBs, acids, solvents, oil and grease, in unknown quantities from various industrial areas directly into the West Basin. Much of the waste discharged from these storm water system outfalls may have sorbed onto the harbor sediments (SWDIV 1969 and NEESA 1983).

During the early 1970s, after passage and implementation of the Federal Water Pollution Control Act, the DON began connecting some of these industrial discharges to the sanitary sewer system. By 1975, industrial discharge outfalls to the West Basin were connected to sanitary sewer lines, thus reducing or eliminating the discharge of industrial waste to the West Basin. However, a 1976 WESTDIV report estimated that a 15,000 gpd industrial discharge still found its way to the West Basin (NEESA 1983).

Characteristics and locations of industrial wastes discharged into the West Basin from storm drain outlets and rinse areas were described in the August 1983 IAS Report (NEESA 1983). Part of the information presented in the IAS Report was compiled from previous studies: the IWS conducted by Brown and Caldwell, the NAVSTA Long Beach EES conducted by Toups Corporation, and the LBNSY EES conducted by CDM, Inc.

Industrial wastewater sources were identified as part of the IWS (SWDIV 1969). A listing of the industrial wastewater sources, and an illustration showing the locations of these sources are presented in the IWS. An illustration of the sanitary and storm sewer systems and the outfalls to the West Basin is also presented in the IWS. Information pertaining to the characteristics and locations of industrial wastes generated at LBNC was also compiled as part of the LBNSY EES (CDM 1977). Information presented in these studies is summarized in the following paragraphs. Locations of buildings referenced in this section are indicated on Figure 2-8.

VOL 18
0075
R0062684

NAVSTA Long Beach Activities. Up until the late 1960s, waste oils and greases generated by the marine service station and the harbor craft service shops conducting mechanical repair and maintenance work on mine sweepers and small craft were discharged directly into the West Basin. This infrequent method of disposal involved quantities of less than 200 gallons. These activities were conducted in the area where Buildings 143, 144, and 145 are presently located, and along Pier 9 (NEESA 1983).

In 1964, a wet paper destructor was moved from the Navy's Old Reeves Field property to near where Building 819 presently exists at the shore end of Pier 9. The pulp generated by the wet paper destructor was disposed of by commercial refuse haulers. The ink and carbon-stained effluent from the process was discharged to the West Basin just south of the shore end of Pier 9. Unknown quantities of these wastes were discharged, on the average, every 6 months. This process was discontinued in the late 1960s when the wet paper destructor was replaced by an effluent-free hammermill machine (NEESA 1983).

Various maintenance and cleaning operations were conducted in Building 8, the former Naval Station Public Works Department. Paint buckets were cleaned in a 980-gallon hot caustic cleaning solution tank. This tank was emptied to the storm sewer approximately on a monthly basis (SWDIV 1969). This method of disposal was practiced between the start of operations in the 1940s until the early 1970s.

LBNSY Activities. The Public Works Department has been responsible for the operation of the air conditioning system in Building 210 since its construction in 1970. Until around 1980, cooling water blowdown was discharged to the storm drains. This practice reportedly caused the discharge of less than 1 pound of chromium in 10 years (NEESA 1983).

Prior to the early 1970s, wastewaters from boiler and once-through seawater for air compressor operations, and brines from the regeneration cycle of water softener units were reportedly discharged by the Utilities Shop (Shop 3) to the storm sewer system that discharged to the West Basin. In 1969, the monthly volume of seawater used by this process was estimated at 39,420,000 gallons. The discharge was reported to contain the chemical Nalco 201 (NEESA 1983). Currently, this discharge is regulated by a NPDES permit, as described in a subsequent section of this RI Report.

One interviewee reported that in the 1960s until the early 1970s, the Utilities Shop sometimes disposed of transformer fluids in storm drains (SWDIV 1969 and NEESA 1983).

The Maintenance Shop (Shop 7) has been responsible for a wide range of activities, including painting, plumbing, carpentry, machine maintenance, pest control, custodial services, and hazardous waste pick-up. Until the late 1970s, waste paints, solvents and acids generated by this shop were discharged to the storm drains. These discharges were estimated to be less than 50 gallons per month (NEESA 1983). Wastes generated by Shop 7 also included small amounts of pesticide residues. Pesticide container disposal has, for many years, been controlled by regulatory procedures. Pesticide containers have been rinsed and crushed prior to disposal with general refuse to prevent reuse. However,

VOL 18
0076
R0062685

the rinseate containing pesticide and herbicide residues has been disposed of by discharging to the ground and sanitary sewers (NEESA 1983). According to the Facilities and Maintenance Department of the Naval Shipyard, no pesticides or herbicides are stored at NAVSTA Long Beach. The Long Beach Installation Pest Management Plan identified specific rodenticides and pesticides that could be used on these properties, but quantities could not be determined (SWDIV 1994a).

Since 1945, the Shipfitter Shop (Shop 11) has been located in Building 128 and was responsible for fabrication, assembly, and installation of all structural parts of the ships. This shop generated small metal chips, pieces, grindings, turnings, and slag which were put into the dry dock waste piles and deposited into the Industrial Waste Disposal Pits (Site 3), located at the eastern bend on the Navy Mole. Up to the mid-1960s, "Red Lead" caulking was used on ships and between 15 and 60 gallons of caulking wastes were disposed of as dry dock waste from this operation. Approximately 15 gallons each of waste rust preventative and waste oils per ship were disposed of as dry dock waste. Previously, at infrequent intervals, this material was flushed to the West Basin (NEESA 1983).

As much as 350,000 gallons annually (from 1963 through 1978) of sodium nitrite, hydrazine, morpholine, solvents, and other chemicals were discharged to the storm water system. These discharges originated from flush pipe operations in Shop 56 (Building 131) and boiler cleaning operations in Shop 41 (Building 128). Until the early 1970s, approximately 800 gallons of rinse water generated by Shop 56 was drained daily into the storm sewer. The rinse water reportedly contained caustic and muriatic acid solutions, and metals (NEESA 1983 and JEG 1992b).

In the 1960s, motor blocks were cleaned with kerosene and then rinsed with steam and water at Shop 31 (Heavy Tools, Building 132). Varying quantities of wastewaters were discharged to the storm sewer. Annually, 2,000 to 3,000 gallons of wastewaters generated from the test boiler facility, which contained sodium nitrite and flushing water, were discharged into the storm sewer (NEESA 1983).

Rinse water from the diesel engine parts cleaning work area and metal parts paint stripping cleaning area at Shop 38 (Machinist, Warehouse A) was drained directly into storm drains (NEESA 1983).

Approximately 9,600 gpd of wastewater generated by Shop 71 (Painting and Abrasive Blasting; Buildings 109, 129, 130, and 132) from the sandblasting facility air cleaning system were drained to the storm sewer. The 1,100-gallon rinse tank of the aluminum cleaning operation was drained to the storm sewer every 3 months. These discharges to the storm sewer probably ended in the mid-1970s when industrial wastes were connected to the sanitary sewer system (NEESA 1983).

In the 1960s, Shop 72 (Equipment Cleaners) provided pump and hose cleaning services in Building 102. Rinse water was drained to the storm sewer (NEESA 1983).

Shop 99 provided ship support services. Water hoses used aboard ship were removed and taken to an open area outside Building 303 where they were filled with highly chlorinated

VOL 18
0077
R0062686

(100 parts per million [ppm]) water. After disinfection, the chlorine solution was discharged into a storm sewer. In 1980, this discharge method was abolished (NEESA 1983).

Indirect Contamination Sources

Indirect sources of potential contamination, such as soil and groundwater posing a potential risk of releasing chemicals to the West Basin waters, are discussed in this section. From the late 1940s to the early 1970s, industrial wastes and trash were transported by truck to the Industrial Waste Disposal Pits (Site 3), located at the eastern bend on the Navy Mole (NEESA 1983). The location of Site 3 is indicated on Figure 2-8. The volumes of industrial wastes deposited into Site 3 were estimated to be as follows:

Wastes Disposed of by NAVSTA

- Small quantities of acid (up to 50 gallons) discharged biweekly;
- Water and oil mixture (1,000 to 2,000 gallons) discharged semiannually; and
- Sludges from storage tanks on piers or shops (100 to 150 gallons) weekly.

Wastes Disposed of by LBNSY

- Sludges from bilge, fuel, lube, and other tanks on board ships in dry dock and moored at piers (up to 600 gallons) biweekly;
- Industrial process tanks, both liquid and sludge from tanks (800 to 1,500 gallons) biweekly; and
- Nonpetroleum contaminated hydraulic fluid from ships (up to 15,000 gallons) annually.

Analysis of groundwater samples, collected from the monitoring wells installed along the periphery of the West Basin (including at Site 3 on the Navy Mole) as part of the RIs currently being prepared for NAVSTA Long Beach and LBNSY, indicate that groundwater generally does not contain high levels of chemicals. Modeling of groundwater flow within the Navy Mole predicted that chemicals in groundwater would not migrate at levels that may significantly impact the harbor, i.e., exceed California ocean plan criteria (BNI 1995b). In addition, groundwater flow direction at the LBNSY has been preliminarily reported to be in a northeasterly direction, away from the West Basin, inferring that chemicals entering the groundwater regime beneath LBNSY would be expected to move in a direction away from the West Basin.

Surface soils, eroded from unpaved areas or entrained from paved areas around the West Basin, may constitute a potential source of chemicals entering the West Basin waters. Based on the Navy Mole underwater inspection conducted as part of the RI for NAVSTA Long Beach, there is no evidence that sediments, contaminated or otherwise, have been or are being transported through a breach in the Navy Mole riprap since no breaches were identified in this structure (BNI 1995b).

R0062687

2.2.2.2 SHIP-RELATED DISCHARGES

Ship-related sources are identified herein as resulting from dry dock operations and ship-related activities conducted at the piers, including welding, painting, loading, and other operations. The sources reviewed included long-term and short-term sources, as well as historical and current sources, as discussed in the following paragraphs.

Discharges from Dry Dock Operations

Dry-docking operations are conducted at LBNSY in three dry docks as part of routine and emergency operations on Naval vessels. These operations involve the flooding and dewatering of the dry docks to perform maintenance below the water line of ships. To flood the dry dock and allow vessels to enter or leave, the dry dock is opened to the West Basin waters by removing a caisson positioned at the entrance to the dry dock, between the dry dock and the West Basin waters. The caisson forms a sealed gate and prevents the waters of the West Basin from entering the dry dock. After the vessel enters or leaves the dry dock, the caisson is put back into place, and the water in the dry dock is pumped out. (SWDIV 1992b). In addition to the three dry docks at LBNSY, three floating dry docks, placed off the end of Pier 6, were in operation between 1960 and 1980 (JEG 1992b).

Hydrostatic relief well systems operate in conjunction with Dry Dock No. 1 to relieve hydrostatic pressure, thereby protecting the structural integrity and preventing buoyancy and floating of the dry dock (Moffatt and Nichol 1975).

The dry docks at the LBNSY are potentially major long-term sources of chemical discharges. The dry docks are used to repair and paint vessels. Paint chip fragments, as well as chemicals and solvents used in the maintenance and decommissioning of vessels, may have a direct path to West Basin sediments as the water level in the dry dock is lowered and raised during flooding and deflooding operations. Chemical products used at the dry docks, including a wide range of organic compounds and metals, may potentially be evident in the sediments found near these areas. During repair operations, incline tests, rolling tests, and other operations that do not require deflooding of the dry dock, raw sewage is discharged into the dry dock waters (Moffatt and Nichol 1975).

Before 1975, discharges to the West Basin included hydrostatic leakage, cooling tower blowdowns, sanitary wastewater, and industrial waste associated with maintenance of vessels. Hydrostatic leakage is infiltration of water through dry dock walls and floor; this water drains to a sump and it is discharged to the West Basin. Hose-down and general cleanup of the dry dock floor results in significant amounts of wastewater. Analyses conducted in 1975 on the hydrostatic leakage, hose-downs, and cleaning of the dry docks indicated high concentrations of copper and zinc. Concentrations of copper and zinc may be a result of leaching from the copper slag sandblast and zinc-containing paint residue. Samples from various locations on Dry Dock Nos. 1, 2, and 3 taken in 1975 also indicated concentrations of biochemical oxygen demand (BOD), total suspended solids, settleable solids, oil and grease, and fecal coliform, possibly caused by discharge of sanitary wastes onto the dry dock floor (Chan and Saam 1975). Locations of Dry Docks 1, 2, and 3 are shown on Figure 2-8.

VOL 18
0079
R0062688

Studies conducted by the Naval environmental support office confirm that significant amounts of zinc and copper leach from the sandblast residue in contact with seawater. Two possible sources for the sandblast residue are the paint chips from sandblasting operation and the sandblast material itself. The volume of water in contact with the sandblast residue appears to have little effect on leaching rate. Heavy metals are more readily leached out in seawater than in freshwater. Relatively high concentrations occur when small amounts of seawater are exposed to residue (Chan and Saam 1975).

NPDES Permit. The NPDES program, administered through the LARWQCB, manages the discharge of wastewater related to the industrial activity at the LBNSY. Since 15 March 1974, direct ocean discharges at 14 discharge locations have been regulated under NPDES Permit No. CA0003786. Concentration limits on certain discharge constituents became effective 1 July 1977 (CDM 1977).

In the early 1990s, the LBNSY reduced its discharge from a maximum of 8 million gallons per day (mgd) to a maximum of 6.2 mgd by eliminating some discharges. As a result, a number of outfalls have been eliminated or re-routed. As of July 1993, only seven outfalls into the West Basin remained. The current LBNSY NPDES permit (No. CA0003786), reissued on 19 July 1993, specifies that up to 6.2 mgd of wastes, associated with dry dock operations, can be discharged into the West Basin. The discharged wastes consist of single-pass, noncontact cooling seawater from air compressors, single-pass cooling water from docked ships, groundwater and seawater seepage from hydrostatic pressure relief wells, and caisson seawater leakage from dry docks. The seawater used for cooling is drawn from the shipyard's fire protection system which contains zinc plumbing fixtures for corrosion prevention (LARWQCB 1993).

Individual NPDES outfalls serve the following systems or operations (SWDIV 1989, LARWQCB 1993, and Brown and Caldwell 1980):

- Outfall No. 004: discharges single-pass, noncontact cooling seawater from air compressor heat exchangers at Building 104 via subsurface drains to the slip just east of Pier No. 3.
- Outfall No. 006: discharges single-pass, noncontact cooling seawater from air compressor heat exchangers at Building 196 via subsurface drains to the slip just west of Pier No. 2.
- Outfall No. 009: discharges single-pass, noncontact cooling seawater from air compressor heat exchangers at Building 150, dry dock drainage, and caisson seawater leakage from Dry Dock No. 1 to the adjacent slip, east of Dry Dock No. 1.
- Outfall No. 010: discharges single-pass, noncontact cooling water from docked ships, dry dock drainage, and caisson seawater leakage from Dry Dock No. 2 to the adjacent slip between Piers No. 2 and 3.
- Outfall No. 011: discharges single-pass, noncontact cooling water from docked ships, dry dock drainage, and caisson seawater leakage from Dry Dock No. 3 to the slip just west of Pier No. 3.

VOL 18
00800
R0062689

- Outfall No. 015: discharges single-pass, noncontact cooling seawater from air compressor heat exchangers at Building 162, Pier E to the West Basin east of Dry Dock No. 1.
- Outfall No. 016: discharges single-pass, noncontact cooling seawater from a boiler plant steam condenser at Building 132 to the slip just west of Pier No. 1.

Figure 2-8 illustrates the approximate locations of these outfalls.

NPDES Monitoring and Reporting Program. In compliance with the RWQCB Order No. 93-045, Monitoring and Reporting Program No. 6431, the DON conducts effluent sampling and analysis to monitor chemical constituents in the wastewater discharged to the West Basin. The receiving waters are also monitored annually through sediment sampling and analysis at five stations, and monthly through visual observations of the receiving waters. The NPDES sediment sampling stations are located as follows:

- R1 - in front of Dry Dock No. 1, east of Pier 1;
- R2 - in front of Building 132, west of Pier 1;
- R3 - in front of Dry Dock No. 2, east of Pier 3;
- R4 - in front of Dry Dock No. 3, west of Pier 3; and
- R5 - on the Navy Mole, in the vicinity of Building 800.

In addition to monitoring the receiving waters, bioaccumulation monitoring in mussel tissue is conducted annually at two stations in the West Basin. The bioaccumulation stations are located at the inland end of Pier 3 and in the vicinity of Building 800 on the Navy Mole. Results of the 1994 annual sampling and analysis were included in the September 1994 monthly NPDES monitoring report. Results indicated elevated levels of PAHs in sediments. Metals, PCBs, oil and grease, extractable fuel hydrocarbons, pesticides, and tributyltin were also detected. Results of the sediment analysis at the five stations are summarized in Table 2-1 (LARWQCB 1993 and SWDIV 1994c).

Discharges from Pier Activities

Historically, maintenance and repair operations were conducted on ships while docked at various piers at the LBNC. According to information provided by representatives of NAVSTA Long Beach, industrial activities conducted onboard U.S. Naval vessels (with exception of repair ships or tenders) reportedly were limited to minor repairs of ship facilities. Industrial activities conducted on ships docked at piers occurred mostly at the industrial piers (Piers 1, 2, and 3) (JEG 1992b).

Typical activities conducted on the ships included chipping and painting, valve maintenance, electrical motor repair, pipe and pump repair, and welding. Wastes generated during the repair activities primarily consisted of bilge water, which was removed from ships by barge or waste oil raft for appropriate treatment or recycling (WESTDIV 1991b).

VOL 18
0081
R0062690

The fuel pier (Pier 12) is used to off-load fuel from carriers or for fueling ships and barges at the pier. The main types of fuel currently handled at Pier 12 include jet fuels JP-5 and JP-8, and Navy Distillate (diesel). During its history of operation, jet fuel JP-4 and Diesel Fuel Marine were also handled at Pier 12 (Trani, pers. com. 1995).

Industrial wastewater, generated by maintenance and repair operations conducted on ships at the LBNC, is removed from ships by barge or waste oil raft for appropriate treatment or recycling. Sanitary wastewater is transferred from the ship's holding and collection tanks to the pier through a flexible hose to a pier riser, where it flows into the sanitary sewer collection system. A 1991 industrial wastewater discharge report, prepared by SCS Engineers, found that the wastewater generated from ships contained elevated concentrations of total metals, copper, zinc, and dissolved sulfide. These concentrations, however, fall below the City of Los Angeles Bureau of Sanitation specific limitations for discharges to Publicly Owned Treatment Works (POTWs). It has been suggested that the source of elevated concentrations of copper and zinc in ship wastewater may be from natural deterioration of shipboard piping, or seawater carrying elevated concentrations of copper and zinc which is introduced into the ship's wastewater stream through flushing (toilet) water (WESTDIV 1991b).

Bilge Water and Oily Wastes. When a ship arrives in port, the oily waste holding tank, the contaminated oil storage tank, the waste oil tank, and the ship's bilges (tanks used for collecting liquid wastes) typically contain substantial volumes of waste oil and oily waste. Upon berthing, these tanks are off-loaded, usually within the first 24 hours in port. During the period of time the vessel remains docked, oily wastes continue to be produced from daily ship operations. Leaky seals, accidental oil spills, and ship washdown waters all eventually drain to the bilge. The bilges are pumped out daily (WESTDIV 1984).

In the 1950s, bilge water was reportedly discharged both on the Navy Mole and into the West Basin, as there was no set policy guiding when and where bilge waters could be discharged. A 1971 Naval Shipyard report estimated a total of 300,000 gpd of sewage and industrial wastewater was discharged from an average of 20 ships berthed or dry-docked at any one time. Studies have indicated that bilge waters have high concentrations of oil (0.1 percent by volume) and hexavalent chromium (up to 500 ppm) which was used as a corrosion prevention solution (NEESA 1983).

Before July 1991, the oily wastes and the bilge water were pumped directly into a "donut" (oil disposal raft) on a daily basis (WESTDIV 1984). After July 1991, the use of donuts was eliminated, and the oily wastes and bilge water were removed by submersible or diaphragm pump through a piping system which transfers the wastes to a holding facility. The quality of the liquid wastes is tested in this facility prior to disposal.

Two types of donuts, with open and closed bottoms, were used at the LBNSY. The open-bottom donut was a 15-foot deep oval-shaped steel raft that floated, and it was open to the West Basin waters through 18-inch diameter holes in its bottom plate. These rafts always contained liquid and floated at a constant 12-foot draft. As the oily waste was discharged into the open-bottom donut, it mixed with seawater partially filling the donut.

VOL 18
0082
R0062691

The oil separated from the wastewater and floated to the top while emulsified and dissolved oily wastes escaped through the bottom of the donut. The donut was considered full when the depth of water below the floating oil was 4 feet. The capacity of the donut above this level was 15,000 gallons (SWDIV 1969 and WESTDIV 1984).

Closed-bottom donuts generally operated on the same principle as open-bottom donuts. However, water was accumulated inside the donut and discharged through a collector pipe extending to the bottom of the donut, whereas oily waste floating on top of the water was discharged through separate piping. Once the donut was filled, it was towed to Pier 6 where an oil barge was permanently moored. The oily waste in the donut was then pumped into an oil/water separator, with the oil being discharged to an oil storage compartment on the barge, and the water separated from the oily waste being discharged to another donut and ultimately to the West Basin. The use of the donuts, whether open- or closed-bottom, may have been a pathway of hydrocarbons and soluble chemicals into the West Basin sediments, via West Basin waters.

Boiler and Tank Cleaning Wastes. Another type of waste that is generated by ships and that may have been historically discharged into the harbor is boiler cleaning and tank cleaning waste. When a ship comes into port for servicing, repair, or overhaul, its tanks and boilers are drained, repaired, and cleaned prior to the ship leaving the harbor. This type of waste is normally generated shoreside by an outside contractor who is responsible for the removal of the waste from the LBNSY. When the boilers of the ships become heavily scaled, highly acidic solutions are used to remove the scale and the residues are removed off-site by contractors (WESTDIV 1984).

2.2.2.3 ACCIDENTAL SPILLS

The piers at the NAVSTA Long Beach and LBNSY are used primarily for ship moorage and minor repair and fabrication. Based on the various types of activities conducted on the piers, incidental spills, such as fuel spills or oil spillage associated with filling or emptying the donuts, may have occurred over the years. Based on the review of documents listed in the reference section, no reports of major accidental spills in the West Basin were found.

Historically, spills or leaks of toxic or hazardous pollutants may have entered the waters of the West Basin by discharge through the storm water system. Significant spills or leaks of toxic pollutants in areas exposed to storm water at NAVSTA Long Beach since 19 November 1988 were identified in the NAVSTA SWDMP. A listing of significant spills or leaks of toxic pollutants such as various types of fuels, oils, waxes, acids, and miscellaneous fluids is presented in the NAVSTA SWDMP (WWC 1993).

Information on significant releases, spills, or leaks of potentially toxic or hazardous pollutants at LBNSY was compiled for the period between March 1989 and October 1991 by the LBNSY SWMP. A listing of the LBNSY spill history, which includes various types of fuels, oils, waxes, acids, and miscellaneous fluids, is presented in the SWMP (Brown and Caldwell 1992b).

R0062692

2.2.2.4 SUMMARY OF PAST DISCHARGES TO THE WEST BASIN

Information on potential past discharges into the West Basin waters was obtained through a review of various reports and publications (NEESA 1983, SWDIV 1969, and CDM 1977). For the purposes of this RI Report, the locations of these discharges were grouped as illustrated on Figure 2-8, wherein discharge locations along the LBNSY seawall and the Navy Mole are referred to as Discharge Locations 1 through 8, and direct discharges from the piers or ships to the West Basin are referred to as Discharge Locations 9 through 12. Various discharges with unidentified locations are also listed on Figure 2-8. A description of the types of discharges by discharge location, including approximate dates when the discharge was discontinued, is presented below.

Discharge Location 1

- Chlorinated water used in cleaning ship's water hoses (to 1980).
- Wastewater, containing elevated zinc, copper, and iron concentrations, from crane cleaning operations.
- Wastewater, containing elevated copper and zinc concentrations, from dry dock operations: copper slag, sandblasting wastes, zinc-containing paint residue, oil and grease, and raw sewage.
- Noncontact cooling seawater used in air compressor heat exchanger, wastewater from boilers, and brines from the regeneration cycle of water softener units (to early 1970s).
- Wastewater from sandblasting operations (to mid-1970s).
- Wastewater from rinsing motor blocks cleaned in kerosene (1960s).

Discharge Location 2

- Wastewater, containing elevated zinc, copper, and iron concentrations, from crane cleaning operations.
- Wastewater from sandblasting and aluminum cleaning operations (to mid-1970s).
- Noncontact cooling seawater used in air compressor heat exchanger, wastewater from boilers, and brines from the regeneration cycle of water softener units (to early 1970s).
- Wastewater from rinsing motor blocks cleaned in kerosene (1960s).
- Sodium nitrite, hydrazine, morpholine, solvents, acids, and metals from flush pipe and boiler cleaning operations (1963 to 1978).

Discharge Location 3

- Wastewater, containing elevated zinc, copper, and iron concentrations, from crane cleaning operations.
- Wastewater from sandblasting and aluminum cleaning operations (to mid-1970s).

VOL 18
0084
R0062693

- Wastewater, containing elevated copper and zinc concentrations, from dry dock operations: copper slag sandblasting wastes, zinc-containing paint residue, oil and grease, and raw sewage.
- Air conditioning cooling water blowdown, containing chromium (1970 to 1980).
- Noncontact cooling seawater used in air compressor heat exchanger, wastewater from boilers, and brines from the regeneration cycle of water softener units (to early 1970s).
- Sodium nitrite, hydrazine, morpholine, solvents, acids, and metals from flush pipe and boiler cleaning operations (1963 to 1978).

Discharge Location 4

- Sanitary wastewater (to mid-1970s)
- Wastewater, containing elevated zinc, copper, and iron concentrations, from crane cleaning operations.
- Wastewater, containing elevated copper and zinc concentrations, from dry dock operations: copper slag sandblasting wastes, zinc-containing paint residue, and oil and grease.
- Air conditioning cooling water blowdown, containing chromium (1970 to 1980).
- Noncontact cooling seawater used in air compressor heat exchanger, wastewater from boilers, and brines from the regeneration cycle of water softener units (to early 1970s).
- Wastes from diesel engine parts cleaning and metal parts paint stripping.

Discharge Location 5

- Wastewater, containing elevated zinc, copper, and iron concentrations, from crane cleaning operations.

Discharge Location 6

- Sanitary wastewater (to mid-1970s)
- Wastewater from pump and hose cleaning (1960s).
- Waste oils and greases from mechanical repair and maintenance work on mine sweepers and small craft (to late 1960s).
- Wastewater from cleaning of paint buckets in caustic solution (to early 1970s).

Discharge Location 7

- Sanitary wastewater (to mid-1970s)
- Wastewater from cleaning of paint buckets in caustic solution (to early 1970s).
- Wastewater containing ink and carbon from wet paper destructor (to late 1960s).

VOL 18
0085
R0062694

- Waste oils and greases from mechanical repair and maintenance work on mine sweepers and small craft (to late 1960s).

Discharge Location 8

- Sanitary wastewater (to mid-1970s)

Discharge Location 9

- Sanitary wastewater (to mid-1970s)
- Discharges from pier activities: chipping and painting, valve maintenance, electrical motor repair, pipe and pump repair, and welding.
- Oily wastes removed by barge or waste oil raft (donuts).
- Wastewater containing elevated copper and zinc.
- Bilge water containing oil and hexavalent chromium (to 1991).

Discharge Location 10

- Sanitary wastewater (to mid-1970s)
- Discharges from pier activities: chipping and painting, valve maintenance, electrical motor repair, pipe and pump repair, and welding.
- Oily wastes removed by barge/waste oil raft.
- Wastewater containing elevated copper and zinc.
- Bilge water containing oil and hexavalent chromium.

Discharge Location 11

- Sanitary wastewater (to mid-1970s)
- Wastewater and various discharges from operation of three floating dry docks.

Discharge Location 12

- Diesel and jet fuel leaks due to off-loading fuel from carriers, fueling ships and barges (1984 to present).

Unidentified locations

- Transformer fluids (1960s to early 1970s).
- Pesticide residues and rust preventative.
- Accidental spills of various chemical substances.

VOL 18

2.2.2.5 NON-LBNC DISCHARGES TO THE WEST BASIN

This section describes discharges of chemicals into the West Basin waters that were not a direct result of LBNC activities. These sources of discharge include oil production activities conducted on Pier E, and use of refined products for dust suppression, as well as placement of fill material on Pier E to elevate subsided areas.

Petroleum-like materials were described in various boring logs from previous investigations conducted on land at the LBNSY, and total recoverable petroleum hydrocarbon (TRPH) concentrations were reported in soil samples analyzed during those investigations (Earth Tech 1989, JEG 1993d, and MTA 1994). Potential sources of the petroleum hydrocarbons include crude oil production and use of refined products such as waste motor oil for dust suppression of parking lots/roadway surfaces. Wastes generated by crude oil production activities may have been accidentally discharged to the surface waters, thereby into the West Basin waters. In addition, surface runoff from the oil production areas may have mobilized soils contaminated with petroleum hydrocarbons; these contaminated soils could have been discharged to the surface waters and possibly the West Basin.

In the early 1950s, subsided areas on the east side of Terminal Island (Pier E) have been elevated with fill material. Most of the fill material (approximately 6.5 million cubic yards) consisted of dredged material obtained from south of the Navy Mole (U.S. ACOE 1953a, 1953b, and 1955). The dredged material is likely to have contained compounds from both crude oil production in the area and refined products from harbor activities. Placement of the fill material on Pier E would have resulted in the liquid phase of the dredged material to drain to the surface waters surrounding Pier E, which would include West Basin. Thus, petroleum hydrocarbon contaminated fines present in the discharged liquid may have settled in the West Basin.

Section 3
SITE CHARACTERIZATION

West Basin sediments and fish were the target media for this RI. A comprehensive sampling and analysis program was designed and implemented with the objective of characterizing the toxicity of West Basin sediments and fish. This objective was accomplished by acquiring chemical, physical, and biological measurements of, and assessing the extent of chemicals, their concentrations, and toxicity in the target media.

Significant site characterization activities included:

- conducting a field investigation and obtaining sediment, fish, and benthic infaunal invertebrate samples;
- obtaining laboratory analyses of sediments, fish tissue and bile, clam tissue, and benthic infauna;
- performing statistical calculations and analysis of data;
- evaluating the results of statistical analyses; and
- identifying COPCs and AOPCs.

For the purposes of this RI Report, the discussion of site characterization was divided into two major components: rationale, methods, and design of site characterization, and the results of site characterization.

Section 3 describes the rationale and methods used in designing and implementing the site characterization program. This section begins with a discussion of data quality objectives, and an explanation of the rationale behind the design of the sampling and analysis plan. These discussions are followed by a narrative description of the methods used in conducting the field investigation, laboratory analyses, data management, and data evaluation.

3.1 DATA QUALITY OBJECTIVES

Clearly defined objectives for data acquisition are necessary to effectively support data evaluations and assessments that will ultimately lead to conclusions as to whether a site or medium is contaminated, and whether it requires remedial action. These objectives, referred to as Data Quality Objectives (DQOs), are essentially specifications which establish the quality of data to be collected for each specified type of planned data use. DQO development is based on the premise that data users may have different requirements of data quality, and that the quality of data obtained needs to be sufficient to meet all intended uses.

According to the SAP (JEG 1993b), the data collected during the West Basin RI was to be used for site characterization, risk assessment, and evaluation of remedial alternatives. The Final RI/FS Work Plan (JEG 1993a) explains that the general approach used in developing DQOs for West Basin comprises a three-step process: 1) AOPCs at West Basin would be identified, and decisions to be made regarding the need for remediation would be specified (the Work Plan defines an AOPC as having similar means and types of potential contamination, or similar remedial actions), 2) data uses and needs to achieve the

R0062698

objective of identifying AOPCs would be identified, and data quality needs specified in terms of COPCs, detection limits, and concentrations of concern; and 3) the methods of acquiring data of acceptable quality and quantity would be specified.

The Final RI/FS Work Plan (JEG 1993a) divides West Basin into two main AOPCs: general harbor area where sediments are subject to disturbance due to factors such as vessel operations and currents, and suspected depositional areas such as under piers. In addition, data uses are identified as characterization of sediment toxicity; human health and ecological risk assessment; and evaluation of remedial alternatives. Human health risk assessment would evaluate health risks to recreational anglers through ingestion of chemicals in fish. Ecological risk assessment would include the potential impacts of chemicals in fish or aquatic predators which consume West Basin fish. For the purposes of these risk assessments, fish samples would be collected from the dry docks at LBNSY. The Work Plan also includes water column analysis, chemical analysis of sediment samples, sediment bioassays, and bioconcentration tests. Screening levels and a matrix listing possible actions resulting from the sediment toxicity evaluation are also provided.

At the onset of this RI, a series of discussions and workshops held with the technical oversight agencies to review the work to be done culminated in significant modifications to the rationale and methods outlined in the Final RI/FS Work Plan (JEG 1993a) and the SAP (JEG 1993b). The technical oversight agencies include Cal-EPA/DTSC, U.S. EPA Region IX, United States Fish and Wildlife Service (U.S. FWS), and NOAA. One of the key developments of these discussions was the agreement that the focus of this RI would be the West Basin sediments and fish, and that the water column in the West Basin need not be evaluated as yet. The oversight agencies agreed to the concept of "triggering" water column investigations based on the findings from the sediment investigation. "Triggering" in this context meant that a certain task, water column investigations in this case, would be deemed to be required and would be conducted only if certain pre-established requisites were found to have been encountered at a pre-determined point in the project schedule. Other significant issues agreed upon included location and number of sediment samples to be collected; selection of reference stations; statistical methods to be used for analysis of data; number, type, and species of fish samples to be collected (tissue, bile, whole body) as well as fish collection methods; and the specific details of the bioassay and bioaccumulation tests. It was also agreed that benthic infaunal samples would be collected at the time of sediment sampling and archived; benthic community analysis would be conducted if found to be "triggered." Human health risk assessment would be expanded to include assessment of risk posed by ingestion of fish to the subsistence as well as the recreational angler. Ecological risk assessment would be focused on the sediments, in addition, risk to the harbor seal posed by ingestion of fish would be assessed. It was agreed that West Basin data would be statistically analyzed using clustering techniques, thereby developing sediment evaluation zones (SEZs). The results of that task would then allow assessing whether any particular SEZ could be identified as an AOPC or an AOC, as well as identifying and evaluating potential remedial action alternatives.

VOL 18 0090

R0062699

It was also agreed that the ecological risk assessment would be based on a preponderance-of-evidence approach. For this purpose, an evaluation matrix, significantly more detailed and expanded than the matrix presented in the RI/FS Work Plan (JEG 1993a), was developed. This new evaluation matrix included, as decision-making elements, the individual SEZs, sediment chemistry, sediment bioassay (solid phase and pore water), sediment bioaccumulation, and benthic community analysis. This matrix also contained pre-established, possible interpretations of the numerous combinations of elements to be collectively considered as part of the preponderance-of-evidence approach, and which would allow bringing to a decision-making point the voluminous data acquired, and the extensive statistical analyses conducted on the database. Interpretations of the significance of the various combinations of elements, as obtained from this evaluation matrix, formed the basis for the conclusions presented in this RI Report.

Details of the expanded DQOs, and modifications to the rationale and methods provided in CLEAN I documents, referenced earlier, for site characterization and risk assessments are voluminous and have not been repeated herein. However, these subjects are discussed in three documents: TM No. 4 (BNI 1994c), TM No. 5 (BNI 1994d), and RAWP (BNI 1995a), copies of which are contained in Appendices A, B, and C, respectively, for reference. These documents reflect the most current agreements and understandings with the technical oversight agencies, and essentially formed the basis of this RI.

DQOs for the West Basin RI are summarized in Table 3-1. The sampling and analysis rationale and methods used to achieve these objectives are described in the subsequent parts of Section 3.

3.2 SAMPLING DESIGN

The overall sampling program was designed to collect sediment, benthic invertebrate, and fish tissue and bile samples from the West Basin and from the reference stations. The program was designed on the basis of using statistical methods to enhance the usability and effectiveness of data. To accomplish these objectives, three major elements of statistical representativeness were taken into consideration: randomness, adequate representation of reference conditions, and sample replication. The discussion below provides a summary of the rationale for each of these elements which were intended to strengthen the overall statistical basis of the sampling design.

Randomness is a statistical element that enhances the representativeness of conditions encountered in the field and reduces sampling bias. The West Basin sampling program was composed of a stratified random design. Two key examples of this design include the randomly placed point of origin for the sediment sampling grid and the selection of locations of sampling transects used to collect fish within the West Basin. The locations of surface sediment sampling stations beneath the West Basin piers were also selected using a stratified random design.

Adequate representation of reference conditions yields reference data that provide a regional perspective for comparing West Basin data to a local benchmark not impacted by

VOL 18
0091
R0062700

the operations of the LBNC. The sampling program was designed for the purposes of performing statistical comparisons between the data acquired from the West Basin sampling stations and the data acquired from the reference stations, providing a site-specific evaluation of potential impact. Accordingly, reference conditions were characterized by collecting samples from three reference stations (seven total sites for chemistry and biological analyses, nine total sites for TOC and grain size analyses) located at various areas within San Pedro Bay. Section 3.2.6 discusses reference stations in greater detail.

Replication in an environmental sampling program provides for a measure of variability inherent in physical and biological systems. Therefore, although West Basin stations were generally sampled only once for chemical and biological measurements, two field measures were implemented to assess variability between West Basin stations and reference stations. These measures included: 1) replicating, in triplicate, all chemical measurements at one of the West Basin stations (Station 1); and 2) replicating, in triplicate, chemical and biological measurements at all three substations of Reference Station 40010 and at one of three substations of Reference Station 40018. The more intensive sampling, conducted at Station 1 and at the reference locations referred to above, provided greater insight into the natural variability of physical and biological conditions in sediments at these sampling stations.

Additional replication of West Basin sediment data was achieved by treating individual West Basin stations as field replicates within each SEZ. The evaluation of data by SEZs implements replication as an element of statistical representativeness. Detailed discussions of SEZs are presented in Section 4.6 of this RI Report.

The following paragraphs describe the procedures used in selecting the number and location of surface sediment, subsurface sediment, and fish samples within West Basin and at reference stations.

3.2.1 West Basin Surface Sediment Sampling

The objective of surface sediment sampling was to characterize the toxicity and ecological impact of surface sediments in West Basin. Overall, 44 surface sediment samples were collected from the West Basin to achieve this objective. In addition, data from a West Basin sediment sample (Station 41), collected as part of the Site 3 (Mole Industrial Waste Disposal Pits) RI/FS, were also used for the purposes of this RI Report.

The conceptual model of the West Basin, developed as part of the CLEAN I Work Plan (JEG 1993a), divides the West Basin into two main areas of study for purposes of conducting this RI: the general harbor area of the West Basin (herein referred to as "basin" for the purposes of this RI Report - basin area excludes areas beneath piers) where sediments are subject to the effects of vessel operations, tidal currents, and wind-driven currents; and suspected depositional areas such as under piers of the West Basin (herein referenced to as "piers") where sediments are less affected by vessel operations, tidal currents, or wind-driven currents. The suspected depositional areas were further

VOL 18
00092
R0062701

subdivided into areas of like operations which would be expected to have similar types and concentrations of chemicals, as described below:

- sediments beneath the grouping of Piers 1, 2, and 3, which experience less disturbance from ship traffic and are next to the LBNSY, where higher levels of contamination have been observed in previous investigations;
- sediments beneath the grouping of Piers 6, 7, 9, 15, and 16, which experience more disturbance from ship traffic and are away from the LBNSY;
- sediments beneath Pier 12 (Fuel Pier), since it is a newer pier and may have significantly less sediment accumulation;
- the northwest basin, where there is little ship disturbance; and
- the marina area, where the smaller crafts are likely to cause less sediment disturbance.

The CLEAN I conceptual model of West Basin is illustrated on Figure 3-1 (JEG 1993a). The CLEAN I SAP provides surface sediment sampling locations determined on the basis of random selection (JEG 1993b). These sampling stations were, in general, adopted for this RI. In cases where additional sampling stations were desired, the random selection method described in the SAP (JEG 1993b) was used in establishing the additional sampling locations. West Basin surface sediment sampling locations established for this RI are shown on Figure 3-2; the coordinates of these sampling stations are listed in Table 3-2.

The surface sediment sampling design for the piers, the northwest basin and marina areas, and the remaining portions of the basin are discussed in the subsequent sections.

3.2.1.1 PIERS

At least one surface sediment sampling location was selected beneath each pier within each of the three groupings of piers suspected to be depositional areas (Piers 1, 2, 3; Piers 6, 7, 9, 15, 16; and Fuel Pier [12]). Therefore, for the grouping of Piers 1, 2, and 3, one sample was collected beneath each pier for a total of three samples. One sample was collected beneath each pier in the grouping of Piers 6, 7, 9, 15, and 16 for a total of five samples. Three samples were collected beneath the Fuel Pier (Pier 12). Analysis of these number of samples for the individual pier groupings is expected to provide the following level of confidence that the maximum value observed within each defined area is greater than the median concentration within the study area:

- Piers 1, 2, 3: greater than 85 percent.
- Piers 6, 7, 9, 15, 16: greater than 95 percent.
- Fuel Pier (Pier 12): greater than 85 percent.

VOL 18
00993
R0062702

3.2.1.2 NORTHWEST BASIN AND MARINA AREAS

The CLEAN I SAP (JEG 1993b) specifies three surface sediment sample locations to be selected for each of the northwest basin and marina areas. Collection and analysis of three samples from each suspected depositional area would provide an 85 percent probability that the highest value from the three samples is greater than the median value from the study area. In addition to the three samples for the northwest basin area, five marina area sample locations were selected to provide a more complete characterization of the sediments within that region of West Basin. The additional two sampling stations were deemed to be of significance due to the greater areal extent from the marina area compared to the northwest basin area (please refer to Figure 3-1) (BNI 1994d).

3.2.1.3 THE BASIN

Sampling points within the basin (excluding the piers, northwest basin, and marina areas, as discussed above) were established by the CLEAN I SAP (JEG 1993b), using a grid of approximately 300 by 300 meters. The x-axis and y-axis coordinates of the point of origin for this sampling grid have been randomly generated, and the overall grid developed using this point of origin. Each sample point along the grid that fell within the basin was then selected as a sampling location. A total of 27 sampling locations were originally selected within the basin using this method. However, because two additional sampling locations had already been selected within the marina area (described in Section 3.2.1.2), 25 samples were actually collected within the basin to maintain the original total of 44 surface sediment samples established by the CLEAN I SAP (JEG 1993b).

3.2.2 West Basin Subsurface Sediment Sampling

The objective of West Basin subsurface sediment sampling was to characterize the vertical distribution of chemicals in sediments, and to assess whether adverse effects associated with potential remedial actions, such as dredging, should be expected. Four 3-meter deep subsurface sediment cores and four 5-meter deep subsurface sediment cores were planned to be collected from the West Basin to achieve this objective. Locations of the subsurface samples are shown on Figure 3-2, and their coordinates are listed in Table 3-2.

The methods of determining subsurface sediment sample locations provided in the CLEAN I SAP (JEG 1993b) were adopted for this RI. Planned locations of individual sediment subsamples within each of the subsurface sediment cores were as follows:

- two subsamples (one from 0 to 1 meter and another from 1 to 2 meters) from each of the four 3-meter cores (total of 8 samples), and
- five subsamples (one per 1-meter interval) from each of the four 5-meter cores (total of 18 samples because one of the cores yielded only 3 samples).

3.2.3 West Basin Fish Tissue and Bile Sampling

To achieve the purposes of fish tissue and bile sampling (BNI 1994d, 1995a), it was first necessary to identify appropriate fish species that could be collected in the required

VOL 18
0094
R0062703

numbers. Several key selection criteria were used to select fish species to be evaluated in order to reduce the chances that some species could contribute to underestimation of risk. Potential fish species to be collected were pre-selected based on the following criteria (U.S. EPA 1993f): (1) are commonly caught within West Basin and consumed by humans or aquatic predators; (2) have recreational or subsistence fishing value; (3) are at least partially bottom feeders in relatively close contact with sediments and, therefore, are more likely to uptake chemical residues directly from bed sediments; (4) have a propensity to bioaccumulate chemicals (i.e., have a relatively high tissue lipid content); and (5) are relatively localized rather than highly mobile or seasonally migratory.

BNI and the DON held a workshop with the U.S. EPA Region IX, DTSC, NOAA, and LARWQCB on July 18, 1994 to obtain concurrence on the fish species to be collected. It was jointly agreed to collect demersal, or bottom-dwelling species, (i.e., species more closely connected to potential sediment contamination) for ecological risk assessment purposes, and pelagic fish for human health risk assessment purposes.

Initially, the Fish SAP (1994b) called for only two species to be collected, which raised the difficulty of being able to collect the requisite number of fish within a reasonable period of time. The July 1994 workshop resulted in a list of target fish species for collection, which provided for flexible decision-making in the field by providing a wide range of species to select from for collection at the time of field sampling. This list, along with the specific rationale for each species selected, is shown in Table 3-3; fish are grouped by data use and listed by relative priority. Once in the field, however, the fish species selection criteria was driven by the actual fish catch, which was dominated by white croaker (*Genyonemus lineatus*) and California halibut (*Paralichthys californicus*).

Eighty-one samples were collected as planned from 30 white croaker and 44 California halibut to support the evaluation of human health and ecological risk assessment. The 81 samples consisted of the following:

- 45 whole body samples, to assess potential contaminant ingestion by subsistence anglers and by aquatic predators;
- 18 muscle filet samples, to assess potential contaminant ingestion by recreational anglers; and
- 18 bile samples (collected from California halibut only), to assess the potential for the effects of chemicals of potential concern to the fish themselves.

An attempt was made to collect both fish species in groups of three so that the fish could be used as field replicates in statistical analysis. Table 3-4 provides a summary of the numbers of fish samples analyzed by species and sample type.

Locations of fish sampling transects within West Basin were selected using a stratified random approach. The West Basin was first subdivided into three areas: NAVSTA Long Beach, LBNSY, and the entrance to West Basin. Each of these subareas represented distinct areas of land-based and ship activities as well as distinct physicochemical characteristics. For example, circulation within the innermost portions of the West Basin has been reported to be limited (JEG 1993a) and, therefore, particle size distributions

VOL 18
0095
R0062704

would be expected to be markedly different from other areas of the West Basin, thereby affecting the biological habitat. Sampling transects were selected randomly within these subareas without regard to the chemicals that may be present in bottom sediments. Selection of transects were, however, made in partial consideration of logistics (e.g., where space was available adjacent to piers or other structures). Two transects were selected and sampled in the entrance to West Basin, two at the LBNSY, and three at NAVSTA Long Beach (see Figure 3-2). Table 3-5 provides the latitudes and longitudes of the fish collection transects.

Additional transect locations were selected off the inboard side of the Navy Mole near the entrance to the West Basin. These transects were selected based on the Navy Creel Census (BNI 1994b) and area accessibility to anglers. Recreational and subsistence anglers have been allowed to fish regularly from the riprap along the Navy Mole.

3.2.4 Benthic Infauna Sampling

At the onset of the field investigations, and in view of the DQOs established earlier in Section 3, it became apparent that the possibility of "triggering" benthic community analysis (BCA) existed. If triggered, BCA would be one of the major components of the preponderance-of-evidence approach adopted for this RI as part of the ecological risk assessment procedures (BNI 1995a). For this purpose, samples of benthic infaunal invertebrates were collected at the same time and at the same locations as surface sediment samples inside West Basin. The organisms were preserved and archived for use at a later date in case BCA was triggered. Collecting BCA samples along with surface sediment samples provided a large number of BCA samples, allowing for robust statistical analyses and completeness of spatial sampling distribution. This large sample number also provided the opportunity to assess the qualities of the benthic community throughout West Basin, including beneath the piers. Sampling the benthic infauna at each surface sediment sampling location would also provide levels of confidence similar to those expected to be obtained under the rationale for surface sediment sampling, described in a preceding paragraph. Further, taking benthic infaunal samples at surface sediment locations would benefit from the random selection procedure applied to the surface sediment sampling locations.

3.2.5 West Basin Sediment Sampling for Laboratory Clam Bioaccumulation Tests

Another component of the preponderance-of-evidence approach for this RI was laboratory clam bioaccumulation testing. It was not deemed to be necessary to conduct bioaccumulation testing using every surface sediment sample, because bioaccumulation integrates contamination across time and area. Sediments for bedded sediment bioaccumulation testing were taken from nine surface sediment sampling stations within West Basin (see Figure 3-2). Specifically, one station from each of the suspected depositional areas was selected (except for the area consisting of Piers 6, 7, 9, 15, 16, within which two stations were chosen) and three surface sediment sampling stations were

VOL 18
00966
R0062705

selected from the basin. Specific surface sediment sampling stations, from which additional sediment samples would be obtained for bioaccumulation testing, were selected based on the following criteria:

- frequency and intensity of ship traffic to determine whether constant sediment resuspension could have contributed to bioaccumulation;
- stations located beneath piers, where little or no dredging has occurred;
- stations located near the shore, where contaminated surface water or groundwater, if discharged into West Basin, could have contaminated the sediments;
- nature and extent of chemicals found in the sediments based on existing information (bioaccumulation tests from areas of low and high concentrations of chemicals may help determine whether contaminants are bioavailable);
- flushing potential of West Basin waters due to forces such as tides;
- whether subsurface coring was also conducted at the surface sediment sampling station for the purposes of assessing whether chemicals, if found in the subsurface sediments, could be taken up by epibenthic or other organisms;
- measurement at selected reference areas; and
- whether the area is suspected to be depositional.

3.2.6 Reference Stations Sampling

Three reference stations within San Pedro Bay were sampled to assess the effects of regional background. The reference stations were intended to show background conditions and to assist in evaluating whether chemical concentrations in sediments collected from West Basin stations were in excess of those normally found in the San Pedro Bay area. Reference stations for this RI were selected with three primary objectives in mind:

1. Suitability for comparison to West Basin sediments based on physical parameters, such as water depth, TOC, and grain size. These parameters not only determine the nature of the benthic habitat (e.g., through mechanisms of oxidation/reduction, sunlight, currents, and tidal action), but also play a significant role in determining sediment toxicity through mediation of contaminant bioavailability in sediment.
2. Statistical defensibility and consistency with the design for the West Basin RI and risk assessment.
3. Consistency with other existing programs (e.g., the SWRCB's Bay Protection and Toxic Cleanup Program).

BNI and the DON held a series of meetings with the LARWQCB and telephone conversations with the SWRCB and the CDFG to identify reference stations in less urbanized settings within San Pedro Bay. Prior to start of field activities, and in light of

VOL 18
0097
R0062706

the meetings and objectives described above, it was jointly agreed to choose Stations 40010 (off Cabrillo Beach in Los Angeles Outer Harbor) and 40018 (Long Beach Outer Harbor) of the BPTCP as reference stations. During the past 2 years, these stations have been sampled by the SWRCB several times, using a sampling and analysis program similar to that implemented as part of this RI. Data from Stations 40010 and 40018 were compared with West Basin data collected during the SI. Sediment was determined to be of representative grain size, TOC content, and benthic habitat to those of West Basin, with acceptable survival rate of bioassay test organisms, and with low levels of sediment contamination present. The fact that synoptic data have been collected from these BPTCP stations lends substantial confidence to their selection as reference locations.

During the course of sediment sampling in West Basin, visual observations showed that sediments from several West Basin sampling stations had higher sand content and coarser grain size than other West Basin stations. To maintain the suitability of reference conditions for comparison with West Basin sediments based on physical characteristics, it became apparent that a reference station having grain size coarser than sediments found at Reference Stations 40010 and 40018 would be needed. Several other BPTCP stations were sampled on a trial basis, and the grain size of sediments from these stations were visually inspected and compared to the coarser grain size sediments sampled in West Basin. Subsequently, and while field sampling was still in progress, a conference call was held between BNI, the DON, and the technical oversight agencies on 23 June 1994. During this call, it was jointly agreed to add BPTCP Station 40032 in Los Angeles Outer Harbor as a third reference station because it was found to have predominantly coarse grain sediments. The three reference stations (40010, 40018, and 40032) together more thoroughly encompass the range of physical characteristics found in sediment samples taken from within West Basin.

Surface sediment samples were collected from three substations at each of the three reference stations, spaced 200 m apart in a triangular formation. The substations were identified with additional notation. Using Station 40010 as an example, its substations were identified as 40010.1, 40010.2, and 40010.3.

Subsurface sediment samples were collected from Reference Stations 40010 and 40018. These two reference stations were designated for subsurface sediment sampling prior to field activities, as set forth in the sampling and analysis plans (JEG 1993b; BNI 1994d).

Two 5-meter core samples were intended to be taken at Reference Stations 40010 and 40018 for subsurface sediment sampling. However, as a result of encountering refusal to penetration of corer because of dense sediment at Station 40010, one 5-meter and one 3-meter core were actually collected.

Surface and subsurface sediment locations at reference stations are illustrated on Figure 3-3. The coordinates of the sampling locations are listed in Table 3-2.

Benthic infaunal invertebrate samples were collected at each reference substation to represent reference conditions at the same locations as the surface sediment samples.

R0062707

VOL 18

00988

Surface sediment samples for laboratory clam bioaccumulation testing were collected from five reference substations (Stations 40010.1, 40010.2, 40010.3, 40018.3, and 40032.1).

One fish sampling transect at each of the Reference Stations 40010 and 40018 was selected with the intent of representing reference conditions at the same locations from which sediments were collected. The fish collection transects are illustrated on Figure 3-3. The coordinates of the transects are listed in Table 3-5.

3.3 ANALYTICAL DESIGN

The assessment of West Basin and reference sediment toxicity relied on chemical analyses, bioassays, bioaccumulation tests, and benthic community analysis. The results of these tests were then used to assess ecological risk and whether West Basin sediments would require remediation. In addition, fish tissue and bile samples were subjected to laboratory analyses to measure the concentrations of selected analytes in these samples. The analytical data were used in the human health and ecological risk assessments. Table 3-6 summarizes the analyses conducted on specific samples and sample types, along with the numbers and locations of samples collected within the West Basin and at the reference stations. The rationale for selecting specific target analytes is described in Table 3-7. Acquisition of analytical data both from West Basin and reference stations included:

- chemical and physical data obtained from surface sediment samples, intended for use in the interpretation of the bioassay, tissue bioaccumulation, and benthic community tests;
- sediment solid and aqueous (pore water) phase bioassay data obtained to assist in assessment of whether toxicity was associated with sediments;
- chemical residue data obtained from clam tissue analyses to assist in assessment of whether chemicals in sediment samples have a significant bioaccumulation potential (evaluation of long-term effects);
- benthic community analysis performed to provide a direct index of *in situ* effects of chemicals in sediment samples to native benthic biological communities; and
- chemical and physical data obtained from subsurface sediment samples to assess possible effects associated with potential remedial actions involving dredging.

3.4 FIELD METHODS

This section describes the field equipment and procedures used to collect sediment and fish samples within the West Basin and at the reference stations. Discussions also include sample documentation procedures, sample storage, processing and shipping procedures, decontamination procedures, and handling of investigation-derived waste (IDW).

VOL 18
00999
R0062708

3.4.1 Mobilization

Activities conducted to facilitate the commencement of field operations included obtaining site clearance and developing site-specific Health and Safety procedures. These activities are described in subsequent sections.

3.4.1.1 SITE CLEARANCE

As part of mobilization for sampling, clearance was obtained from Naval authorities to assure that Naval activities would not conflict with those planned for sampling, and that known physical obstructions which could prevent the collection of sediment and fish samples would be identified. Authorities at LBNC were contacted to obtain clearance to sample both sediment and fish within the West Basin, whether by sampling vessel, land-based drilling rig, or by divers. Clearance was obtained through the SWDIV Remedial Project Manager, the Environmental Coordinators for both NAVSTA Long Beach and LBNSY, the Naval Diving unit at LBNSY, the Operator of the Fuel Pier, and the Shipyard Control Tower which monitors and directs all ship movements within West Basin. The planned sampling activities were cleared with appropriate officials prior to undertaking of any sampling effort.

3.4.1.2 HEALTH AND SAFETY

Field activities were conducted in accordance with the site-specific HSP and the BNI CLEAN II Health and Safety Standard Operating Procedures. The Health and Safety Close-Out Summary Report is included as Appendix F to this RI report. Health and Safety coverage was provided continuously during field activities, focusing on areas of greatest potential hazards to safety and health such as working on water, extended time periods away from land, heat stress, and exposure to airborne contaminants. Personnel involved in field operations attended a mandatory Health and Safety briefing at the onset of field work. A Health and Safety representative accompanied the field team in its work.

Air monitoring was conducted to assess potential airborne exposures during subsurface sediment sampling activities. No air monitoring was deemed necessary during fish collection and therefore not conducted. Use of appropriate personal protective equipment was required where personnel were expected to handle potentially contaminated sediments.

3.4.2 Navigation and Positioning

The RV Crusader, a 40-foot scientific survey ship provided and operated by MEC Analytical Systems, Inc. (MEC), was used to sample sediments and fish. The vessel was equipped with a Magnavox MX 200 differential global positioning system (GPS) unit, and a six-channel receiver/navigator augmented with the Pinpoint AccuPoint differential GPS FM radio band correction for continual tracking. Accuracy was improved with real-time differential correction signal by AccuPoint, which provided ± 2 meter accuracy. A few sampling station locations were slightly shifted during sampling at the request of the field sampling manager (e.g., when moored ships blocked access to stations along piers). To

VOL 18
0100
R0062709

assure a higher degree of accuracy, the antenna receiving the GPS signal was located at the apex of an A-frame mounted on the stern of the survey vessel, directly above the point from which the sediment sampler was suspended during sample collection. GPS readings were recorded at each sampling location. The latitudes and longitudes of the sediment sampling locations are listed in Table 3-2. Readings from the GPS system were recorded at both the beginning and end of each sampling day at the same location (point of departure and arrival at the dock) to serve as a point of calibration for the system.

3.4.3 Sample Collection

Both sediment and fish samples were collected from within West Basin and at reference stations during several sampling events. The exact dates of each sampling event, along with the types of samples collected, are listed in Table 3-8. This section describes the equipment used and the procedures followed while collecting surface sediment, subsurface sediment, and fish samples.

3.4.3.1 SURFACE SEDIMENT

Surface sediment samples were collected using two different procedures as dictated by site conditions. A box corer, deployed from the RV Crusader, was used in open waters, and divers were used for sampling under piers. The following discussion describes in further detail the equipment and procedures used to sample surface sediment.

Sample Collection Using the Box Corer

A box corer sampling device, having a surface area of 0.1 m^2, was used to collect surface sediment samples from the survey vessel. Box corers are acknowledged to provide an excellent means of yielding undisturbed sediment samples (Murdoch and MacKnight 1991). The box corer was deployed from the A-frame at the stern of the RV Crusader using a hydraulic winch. The box corer operated mechanically and was pre-coated with Teflon® inserts to eliminate potential contamination from the metal sampler surfaces.

Surface sediment samples were collected from the top 10 centimeters (cm) at each of the sampling locations within the West Basin and at reference stations. The upper 10 cm was selected because it is characteristic of the biologically active zone (i.e., the depth zone most likely to be inhabited and mixed by benthic animals). After collection, surface sediment samples were packaged aboard the vessel for future chemical, physical, and biological analysis.

Sampling procedures using the box corer are summarized below:

- The vessel first deployed a marker buoy at the sampling location, using pre-established GPS coordinates for positioning.
- The vessel was then maneuvered as close to the marker buoy as practical, typically within a 3-meter radius of the marker buoy, and the box corer was deployed using an on-board winch and stern-mounted A-frame.

VOL 18
0101
R0062710

- The GPS coordinates were recorded upon deployment of the sampler, along with the water depth at the sampling location.
- Deployment procedures included first dropping the box corer through the water column, to the surface of the sediments. Upon reaching the sediment surface, the box corer penetrated into the sediment due to its weight, causing a surface sediment sample to be entrapped within the box corer. As the sampler retrieval mechanism was activated and the box corer began to lift from the bottom, the physical constraint of sediments trapped inside the box corer forced its jaw mechanism to close, thereby extracting the sediment trapped within the sampler from the sediment bed. The box corer was then lifted to the vessel and placed in a frame mounted on the deck to facilitate sample processing.
- Water overlying the sample was siphoned off from the box corer and discarded overboard.
- The first sediment sample obtained with the box corer at each sampling location was always used for collection of benthic infaunal invertebrates. The surface of sediment samples in the box corer was photographed and the field log annotated with the film roll number and frame number. Visual observations concerning the presence of items, such as detritus, larger organisms, and seaweed, were recorded in the field logbook at the time of sampling. A Teflon© corer insert, used to sieve benthic invertebrates and to provide a sample of 0.06 square meters (m^2) in surface area and 10 cm in depth, was then pressed into the sediment to assure a standard sample size and depth.
- The sediment sample selected for collection of benthic infaunal invertebrates was placed on a wash table after its removal from the box corer and washed with a hose through both 1 and 0.5 millimeter (mm) mesh stainless steel sieves, using seawater, to extract the organisms. The 1 mm sieve was placed on top of the 0.5 mm sieve and the sediment sample was washed through both sieves, and the benthic infaunal invertebrates retained on the sieves were processed as described further below. A review of the sieving procedures soon after the start of field activities showed that sieving performed during the first 2 days of sampling (21 and 22 June 1994) was faulty. It was discovered during this review that the 0.5 mm sieve, while being placed into position beneath the 1 mm sieve, had been secured, inadvertently, with a slight offset, leaving a minute gap between the two sieves. Since a portion of the sediment sample, along with the benthic infauna, being washed through the 1 mm sieve could very likely bypass the 0.5 mm sieve beneath because of this offset, the 0.5 mm sieve samples obtained during these 2 days, on which the offset of sieves occurred, were voided. The sampling stations impacted were resampled and resieved on 23 and 24 June 1994.
- Once the sediments were thoroughly washed through both sieves, the benthic organisms retained on each sieve were collected with forceps and placed in separate jars with 7 percent magnesium chloride solution for approximately 30 minutes to promote relaxation of the organisms. A 10 percent formalin solution was then added to the sample jars to preserve the organisms. The jars were double labeled, inside the jar and on the lid (e.g., station location, time of

VOL 18
0102
R0062711

VOL 18

sampling, date, sampler, and sieve mesh size), and placed in storage until transferred to the benthic laboratory. The benthic organism samples retained on the 1 mm sieve were later analyzed in the laboratory, as it is typically the current practice in the industry to analyze the 1 mm sieve samples; the samples retained on the 0.5 mm sieve were preserved for archival purposes.

- Both the box corer and the insert were then rinsed clean with seawater prior to redeployment; the rinse water was discarded overboard.
- The box corer was then dropped as many times as needed to achieve the specific sample volumes of sediment samples required for physical, chemical, and bioassay analyses. The Teflon® insert was used to measure the amount of sediment sample collected (top 10 cm, 0.06 m^2 surface area) at each sampling location. A sediment volume of 1,250 milliliter (mL) was collected at each station for chemistry, 1,000 mL for TOC and grain size, and 21 liter (L) for bioassay testing. Sediment collected for the solid phase bioassay (approximately 19 L) was placed in a clean plastic sample bag inside a calibrated bucket on the deck. Upon measuring the requisite volume, the plastic bag with the sediment sample was removed from the bucket, sealed, labeled, and placed in a sample cooler. Sediments collected for the pore water bioassay (approximately 2 L) were sealed in an airtight plastic bucket following nitrogen purging to assure that samples were maintained in an oxygen-free environment.
- An additional 19 L of sediment was collected in the same manner as above from stations selected for bioaccumulation testing.
- At the completion of sampling at each station, personnel washed their boots and gloves with seawater. Sampling implements were decontaminated following the procedures described in Section 3.4.6.

Sample Collection Using Divers

Surface sediments located under the piers (eleven stations from beneath nine piers, shown on Figure 3-2) were sampled manually by divers, as outlined below. These sampling stations were located visually using shore-based landmarks. Hand-held rectangular plastic scoops, 10 cm deep with a surface area of 0.06 m^2, were used by the divers for surface sediment collection. The hand-held samplers were designed to collect sediment samples with minimal disturbance and were fitted with lids to reduce disturbance of sediment samples as the divers ascended to the water surface after collecting a sample.

The sediment samples were collected by pressing the scoop into the sediment bed to a pre-measured 10 cm mark on the scoop, gently removing the full scoop from the sediment bed and covering it with a fitted cap. The diver then brought the filled and capped scoop to the surface. Each sample was inspected at the surface by field personnel to assure that an undisturbed sample was retrieved and that adequate volume had been collected. As with sediment samples collected from the survey vessel, sediment samples to be used for collecting benthic infauna were taken first. All samples were processed in the same manner as described above for samples collected from the survey vessel to minimize or

0103

R0062712

VOL 18 0104

eliminate differences that can be caused if different sediment sample collection methods were employed instead.

3.4.3.2 SUBSURFACE SEDIMENT

Subsurface sediment cores were collected in the basin and at reference stations using a vibratory coring system deployed from the RV Crusader. A similar vibratory coring system operating from a land-based drilling rig was used to sample sediments underneath piers selected for subsurface sediment sampling (Piers 2, 12, 15) because the sampling points located beneath the piers were inaccessible to the survey vessel. The following discussion describes in further detail the equipment and procedures used to sample subsurface sediments.

Sample Collection from the Survey Vessel

The vibratory coring system deployed from the survey vessel for subsurface sediment sampling was a hydraulically operated sediment sampling system with a uniquely designed hammer to drive an aluminum core tube assembly into the sediment bed. The core tube assembly was driven incrementally into the sediment bed with high instantaneous velocity. During the coring operation, the penetration of the core tube was continuously monitored and recorded. The percentage of material recovered for each penetration interval was also directly available from the acquired data.

The impact-generating hammer was mounted on a lightweight guide/support assembly. An integral, hydraulically operated core-extraction winch was mounted in the base of the guide/support assembly. This winch generated up to 15,000 pounds of pull-out force after the core tube assembly was driven to the desired depth within the sediment bed. The integral core-extraction winch allowed extraction of the core tube without bending, prior to lifting the coring system off the sediment bed with the vessel-mounted winch. The sampler was equipped with a core-retention device at its leading edge to aid in sample recovery.

Procedures for collecting subsurface sediment samples using the survey vessel are summarized below:

- A marker buoy was deployed at the sampling location and the vessel positioned at the buoy in a manner similar to that used for surface sediment sampling described in the previous section.
- The GPS coordinates were recorded.
- The hydraulic system on the vessel was connected to the corer with hydraulic hose and safety rope, and the corer was driven into the sediment bed to the appropriate depth (either 3 meters or 5 meters as planned for that particular sampling point).
- When the appropriate depth of penetration into the sediment bed was reached, coring was stopped, and the core sleeve assembly, made of disposable aluminum, was extracted using the guide-assembly-mounted extraction winch.

R0062713

- After the core tube was retrieved, the sediment inside the core tube was extruded into pre-prepared troughs on board the vessel, the length of the core carefully measured using a tape measure to assist in discerning the depth intervals from which each subsample was to be taken, and cut into the individual horizons. The core was cut using decontaminated equipment to avoid cross-contamination. Boring logs were continuously maintained, wherein visual observations of the core by depth were recorded.
- Each horizon sample was placed in a clean 19 L plastic bag and homogenized by hand, using sterile gloves. The homogenized samples were then placed into appropriate sample containers for shipment to the analytical laboratory. No subsample was combined or composited with each other

Initially, it was planned to homogenize cores on the basis of five 1-meter intervals (for the 5-meter cores), or the upper two 1-meter intervals (for the 3-meter cores) (JEG 1993a). However, upon reviewing the cores as they were actually recovered during the subsurface sediment sampling activities, it was observed that multiple horizons with varying thickness existed in the sediment subsurface, and it became apparent that a global 1-meter interval was not suitable. Homogenizing 1-meter intervals, as initially planned, would have caused different horizons with different characterizations to have been mixed and composited (such as mixing and homogenizing shell hash with underlying silt or sand). The issue was resolved in the field by homogenizing discrete subsurface sediment horizons, using the entire sample from each horizon as a discrete subsample.

Homogenized sediment samples were used for physical and chemical analyses only; no biological analyses were conducted on them because of the naturally occurring toxicity associated with anaerobic conditions in deep sediments. Observations of sediment physical properties, such as texture, color, and odor, were recorded during sampling. Measurements and descriptions of each sediment horizon depth interval used in homogenizing and preparing core samples for laboratory analysis were also recorded in the field log books.

Sample Collection from the Piers

The coring system used for sampling sediments located beneath piers consisted of a vibratory coring system operated from a Mobile B-61 drill rig. At each pier designated for subsurface sediment sampling, access through the pier deck was cleared with proper Naval authorities and the drill rig positioned over the opening. The access openings at the piers included a stillwell for a former tide gauge, a manhole, and an expansion joint. The use of these existing deck openings eliminated coring through the pier decks.

Stainless steel casing was passed through the deck opening and advanced into the sediments below by a vibrating hammer operating at 80 to 150 Hertz. The hammer and the deployment of the casing were hydraulically operated from the drill rig. Upon completion of the desired depth of penetration into the sediment bed, the casing containing the sediment sample was retrieved.

VOL 18
0105
R0062714

Sediment samples were then uniformly homogenized for each sample horizon in the manner described above for vessel-based coring operations. These samples were retained for physical and chemical analyses only; no biological analyses were conducted. Observations of sediment physical properties, such as texture, color, and odor, were recorded and logs of the cores were maintained during sampling.

Procedures for sampling of subsurface sediments using the land-based drilling rig were, in general, similar to the procedures used for subsurface sediment sampling in open waters from a survey vessel, except that the drill rig replaced the survey vessel, and the GPS or other navigational system was not used. Initially, sample locations at the three piers requiring subsurface sediment sampling had been intended to be the same locations at which the divers had previously collected surface samples from beneath the same piers. However, using the available openings for access through the pier decks resulted in subsurface sediment sample locations not coinciding with the surface sediment sample locations as initially planned. Figure 3-2 shows the surface and subsurface sediment sampling locations.

Prior to commencement of drilling activities, piers were inspected from both above and below for discernible evidence of piping, structural supports, or other obstructions potentially impeding sampling or which could result in unsafe conditions. None were found.

Upon completion of inserting the corer into the sediment bed, the casing containing the sediment sample was retrieved and placed on a Visqueen*-covered surface on the pier deck. The sediment inside the casing was extruded, using compressed nitrogen at a pressure of 10 pounds per square inch (psi), directly into an aluminum foil-covered trough. The trough had an inside diameter of approximately 4 inches and was slightly longer than the core was expected to be inside the casing. The use of a trough allowed observation of the complete sediment core for purposes such as photography, measurements, and visual description. Following these tasks, sediment samples were extracted from the core and prepared in the same manner as described aboye for vessel-based operation.

Core sections were scooped into a 19 L bucket lined with a disposable plastic bag. The sediment sample was homogenized using disposable trowels and by hand using sterile gloves. The homogenized sample was then placed into the appropriate sample container for shipment to the analytical laboratory.

Some difficulty was encountered in sample collection at Stations 43 (Pier 15) and 51 (Pier 2) on 26 and 27 July 1994. Insufficient recovery of core samples were initially experienced, apparently due to the presence of a high density of mussel shell hash overlying the unconsolidated sediments beneath the piers. The sediment samples in the tip of the core barrel were consistently intact upon retrieval, suggesting that the corer had, in fact, penetrated to depths below the soft sediments and into the underlying harder stratum. However, mussel shells covering the surface of the sediments were apparently large enough to obstruct the opening at the tip of the small diameter core barrel (2.5 inches OD) initially used for the sampling event and acted as a plug, pushing aside the soft sediments

VOL 18
0106
R0062715

until firmer material was encountered. Stations 43 and 51 were successfully resampled within a distance of several feet of the initial sampling location on 03 August 1994 using a larger diameter (4 inches OD) core barrel.

3.4.3.3 FISH TISSUE AND BILE

All fish samples were collected using an otter trawl deployed from the RV Crusader via hydraulic winch. The otter trawl used was a 4.9-meter headrope trawl net with a 2.5 cm body mesh and a 1.3 cm mesh cod-end liner.

Pre-established transects within the West Basin were trawled for 5 minutes of bottom time (timed from the end of cable payout to start of retrieval) at a speed of approximately 2 knots. Wire scope was set according to water depth and the guidelines of Mearns and Allen (1978). Bottom distances trawled were approximately 300 to 380 meters in length, plus the distance covered to let out winch wire and retrieve the net. Thus, an overall distance of about 500 to 700 meters was needed for each trawl, which, within the West Basin, required extensive maneuvering of the survey vessel. Planning of trawl paths included considerations of the desired sampling area, bathymetry, and the total distance required to deploy, trawl, and recover the net. GPS coordinates and times were recorded for initial net deployment, where the net began to "fish" along the bottom, and where the net recovery was started. In several cases, significant debris was collected by the net, but slight variations in the subsequent trawl tracks permitted valid sampling.

The trawl sample was emptied into a large tray placed on the deck of the vessel upon retrieval of the net and individual fish were identified and enumerated. After the fish were identified by species (a listing of species caught is presented in Section 4), California halibut and white croaker, which were in abundance compared to other species caught, larger than 19 cm and 14 cm standard length, respectively, were retained and targeted for analysis. The larger (i.e., older) fish were targeted for analysis because such fish are more likely to be retained by anglers for consumption and more likely to have potentially bioaccumulated detectable levels of chemicals than younger (i.e., smaller) fish. Fish ultimately selected for analysis were then weighed, and their length was measured as standard length. In addition, the selected fish were visually inspected by an on-board specialist for the presence of lesions, parasites, or deformities. These visual observations were recorded in the field logbook.

Whole body fish samples were taken by sacrificing the animal using impact to the head to avoid blood loss, and muscle fillet samples were taken using sterile, disposable scalpels. Both types of samples were wrapped in clean aluminum foil, bagged in Ziplock® baggies, appropriately labeled, and immediately cooled on blue ice in coolers. One California halibut filet sample collected from Reference Station 40010 was inadvertently lost some time between being packaged in the field on 30 August 1994 and arrival at the laboratory. Another California halibut was successfully collected on 16 September 1994 to replace the lost sample.

Nine of the 18 California halibut used to obtain samples of bile were used to obtain samples of fish fillet as well (Table 3-4). This reduced the numbers of fish sacrificed and

VOL 18
0107
R0062716

improved the database by providing additional information (muscle tissue body burden and bile concentrations) from the same nine fish. Prior to collection of bile sample, fish were carefully resected in the field using a sterile, disposable scalpel and a visual determination made by inspection of the gall bladder to determine whether a minimum of 50 microliters (μL) of bile appeared to reside within the gall bladder. If so, the bile was extracted from the gall bladder of the live fish using a sterile, disposable syringe and transferred into 3 mL amber vials for chemical analysis of PAH metabolites. Sample vials were immediately labeled and frozen in preparation for immediate shipment to the analytical laboratory.

In addition to using the otter trawl, two additional fish collection methods were unsuccessfully attempted for purposes of the human health risk assessment. The first method involved the use of set lines placed on the inboard side of the Navy Mole and near Cabrillo Pier (adjacent to reference Station 40010). The lines, baited with fish and squid, were left out for approximately 3 hours. Although the bait was taken from the hooks, no fish were caught. An attempt was also made to purchase fish from anglers on Cabrillo Pier. However, only two fish listed on the target species list (Table 3-3) were found (two small white croaker). The majority of the fish catch by anglers on the pier was made up of mackerel (about 300 fish) along with some lizard fish and bonito (three fish each). However, sufficient number of white croaker and California halibut were collected at West Basin and reference stations using the otter trawl method to satisfy the objectives of both the human health and ecological risk assessments.

3.4.4 Sample Documentation

This section describes the field logs and chain-of-custody (COC).forms used to document sample collection, description, and shipment.

3.4.4.1 FIELD LOGS

Relevant sampling information was documented in the field logbooks, including detailed visual observations. Field logs included:

- date and time of sampling;
- sampling conditions;
- visual observations of the sediment collected (both surface and subsurface), including the presence of detritus, detectable odors, and physical characteristics such as texture, color, cohesiveness, and presence and nature of obvious strata;
- obstructions, such as logs, ships, or buoys, affecting sampling equipment placement or retrieval;
- detailed boring logs for the sediment cores collected, including core number, sample interval, vertical distribution of visible contamination (if discernible), description of layering, description of sediment (following American Society for Testing and Materials [ASTM] Method D2488-84), lithology, sorting, structure,

VOL 18
0108
R0062717

relative density or consistency, relative moisture content, remarks, and the name of the observer;

- activities at or adjacent to the piers where sampling was conducted;
- water depth, turbidity, the presence of sheens or other characteristics;
- Naval or other ship traffic;
- the number of fish trawl attempts;
- types and numbers of fish collected per trawl;
- the distance the trawl traveled on the harbor bottom; and
- physical characteristics of fish retained.

3.4.4.2 CHAIN-OF-CUSTODY FORMS

COC forms were filled out at the time of sampling for every sample taken. These forms accompanied the samples from the sampling location to the analytical laboratory. BNI retained a copy of the COC forms for completeness of records. Separately, the analytical laboratory maintained its internal Chain of Custody. Therefore, two sets of COC forms exist for many of the samples: 1) the COC forms completed and relinquished by BNI, and received by the laboratory representative in the field, and 2) the analytical laboratory COC forms relinquished by the laboratory representative and received by the subcontract laboratory that actually conducted the analysis requested for the sample. Appendix G contains copies of the COC forms used in this RI.

3.4.4.3 CORRECTIONS TO SAMPLE DOCUMENTATION

Any errors made on sample documentation forms, such as field logbooks or COC forms, were corrected by crossing a line through the error, entering the correct information, initializing, and dating the change. The erroneous information was not obliterated. In cases where errors were discovered on COC forms, corrections were made either on an attached copy of the COC form or to the second page of the original COC itself. The corrections to COC forms were recorded via memoranda addressed to the project files.

3.4.5 Sample Storage, Processing, and Shipping

Table 3-9 presents the sample preservation, packaging, and shipping methods by analysis type for sediment and fish samples. Preservation of samples was conducted in the field. Samples were packaged for shipping in the following manner:

1. Glass sample containers were individually wrapped with bubble wrap prior to being placed in coolers.
2. Sample containers were placed on end inside coolers. Blue ice packages were placed in the coolers with the containers; voids were filled with packing material.
3. COC forms were sealed inside Ziplock® plastic bags and placed inside coolers that were shipped to the laboratory via overnight carrier (e.g., Federal Express).

VOL 18
0109
R0062718

Once the COC forms were placed inside the coolers, the lids were closed and secured by wrapping strapping tape around the cooler at both ends. The COC forms indicate the time and date the cooler was relinquished to the shipping agent. A shipping bill was attached to the cooler.

4. Step 3 was not necessary for those coolers delivered to the laboratory by courier. The COC form in these cases was relinquished to the courier for review and signing.

5. A mailing label with the laboratory address was placed on the coolers and covered with wide clear plastic tape.

6. The temperature of sample coolers was measured and recorded upon arrival at the laboratory to ensure that 4 degrees Centigrade (°C) was maintained.

3.4.6 Sampling Equipment Decontamination

Disposable equipment was used whenever possible because this practice precluded the need for decontamination and because the chances for cross-contamination were significantly reduced. Disposable equipment was used for vessel-deployed subsurface sediment sampling (disposable core barrel) and for fish sampling (disposable scalpels and syringes). The remainder of the surface and subsurface sampling required decontamination of implements used for handling and packaging samples designed for chemical analyses. Minimal decontamination was required for biological samples; it was necessary only to remove visible sediment particles from the implements that could affect the results of biological testing.

Decontamination was conducted on the survey vessel while out at sea. The typical decontamination sequence for surface and subsurface sediment sampling equipment (for samples intended for chemical analysis only) was as follows:

1. Seawater rinse of all visible residual sediment (rinse discarded overboard).
2. Wash with nonphosphate detergent (i.e., Liquinox, discarded overboard).
3. Tap water rinse of all exposed surfaces (rinse discarded overboard).
4. Deionized/distilled water rinse (rinse discarded overboard).
5. Pesticide grade methanol rinse of all surfaces for organic chemical scans only, rinseate retained onboard in carboy and delivered to the project IDW storage area by the field activities manager at the conclusion of the sampling activities.
6. Organic-free water (high performance liquid chromatography [HPLC] grade) deionized/distilled water rinse (twice, rinse discarded overboard).

After decontamination, implements were wrapped with oil-free aluminum foil to prevent contamination prior to their further use. Two project decontamination pads, one established at the NAVSTA Long Beach and another at the LBNSY in support of the CLEAN II field activities being conducted at the LBNC, were used to decontaminate coring sleeves used by the land-based drilling/sampling system.

VOL 1 8
0 1 1 0
R0062719

3.4.7 Collection, Storage, and Disposal of IDW

IDW obtained during sampling activities consisted of methanol-based rinseate from decontamination of sediment sampling equipment, and sediment cuttings obtained during drilling and sampling operations performed from Piers 2, 12, and 15. Because the latter was classified as a hazardous waste activity in the site-specific Health and Safety Plan, gloves, Tyvek® outerwear, Visqueen® tarpaulins, and miscellaneous sampling detritus were also discarded as IDW. The fish sampling effort exclusively utilized disposable equipment and, therefore, no decontamination was required. IDW from West Basin sampling operations was stored in 50-gallon capacity steel drums, and disposed of after analysis of contents. Appendix H contains copies of the IDW Management Plan and Removal Report.

3.5 LABORATORY METHODS

Laboratory analyses included physical, chemical, and biological tests performed on sediment, fish tissue, and fish bile samples. Laboratory bioaccumulation tests were conducted using clams. The laboratory program also included benthic community analysis.

Tests for sediment physical and general chemistry properties included grain size, TOC, total sulfide, and acid volatile sulfides/simultaneously extracted metals (AVS/SEM) determinations. Concentrations of semivolatile organic compounds (SVOCs), pesticides and PCBs, butyltin compounds, U.S. EPA priority pollutant metals, and percent moisture were also measured in sediment samples. Fish tissue samples (whole body homogenate and muscle fillet) were analyzed for lipid content, PAHs, pesticides and PCBs, butyltin compounds, and U.S. EPA priority pollutant metals. Fish bile samples were analyzed for equivalent concentrations of selected PAH compounds. Clams that were exposed to sediment samples in the laboratory during bioaccumulation tests were analyzed for lipid content, PAHs, pesticides and PCBs, butyltin compounds, and U.S. EPA priority pollutant metals.

In addition, biological tests were conducted on surface sediment samples, which included acute and chronic bioassays using pore water and solid phase sediment samples, and invertebrate organisms. Benthic community analysis was performed using benthic infaunal invertebrates sieved from sediment samples at the time of surface sediment sample collection.

This section summarizes the procedures used to conduct laboratory analyses. Analytical methods described in Test Methods for Evaluating Solid Wastes (SW-846; U.S. EPA 1990) were used where applicable. Other test methods not described in SW-846 were also used for specialized analyses. Types of laboratory analyses and laboratory methods used are summarized in this section and listed in Tables 3-10 and 3-11 for sediment and fish tissue testing, respectively. Analytes and analytical methods used for surface and subsurface sediments, as well as fish tissue and bile, are listed in Table 3-12. Appendix I contains copies of the laboratory procedures for test methods not included in SW-846.

VOL 18
0111
R0062720

VOL 18 0112

3.5.1 Surface Sediment Sample Analyses

Sediment grain size, TOC, and benthic community analyses were performed by MEC located in Carlsbad, California, under subcontract to BNI. Sediment bioassay and bioaccumulation testing was conducted by MEC at its Tiburon, California, laboratory. Sediment total sulfide, AVS/SEM, and chemical analyses were performed by Pace Environmental Laboratories, Inc. (Pace), located in Camarillo, California, under subcontract to MEC. Both MEC and Pace are environmental testing laboratories that are state-certified by the California Department of Health Services.

3.5.1.1 PHYSICAL ANALYSES

Following are summaries of analytical protocols used to measure physical parameter distributions in surface sediment samples from West Basin and reference stations.

Grain Size

Methods developed by Plumb (1981) were used for grain size analysis. A 30 to 40 grams (g) wet weight (ww) subsample was transferred to a 240 mL bottle, mixed with 150 mL of deflocculent (sodium hexametaphosphate), and allowed to stand overnight. The deflocculated sediment sample was passed through a 62.5 micron (µm) sieve (U.S.A. Standard Testing Sieve No. 230) to separate the sand size fraction from the silt/clay size fraction. The sand size fraction was dried and shaken through a series of eleven U.S.A. Standard Testing Sieves, which ranged from 2,000 to 62.5 µm. The fraction of the sample retained on each sieve was weighed on a digital electronic balance. The silt/clay size fraction, particles smaller than 62.5 µm, was measured for various intervals by standard pipette timed-withdrawal methods, and weights for each grain size interval were calculated. These two methods provided fractional weights for each interval measured.

Total Organic Carbon

Sediment samples were analyzed for TOC following the method described by Menzel and Vaccaro (1964). Homogenized sediment samples (0.018 to 0.020 g) were digested in concentrated phosphoric acid at room temperature and diluted with distilled water followed by potassium persulfate. Samples were then heated to 259°F at 17 to 19 psi for 6 hours after purging with purified oxygen and cooled overnight in a sealed ampoule. Ampoules were then broken, releasing carbon dioxide. The remaining organic carbon was measured with an infrared detector.

3.5.1.2 CHEMICAL ANALYSES

Following are brief summaries of the analytical protocols used to measure concentrations of analytes in surface sediment samples from West Basin and reference stations.

SVOCs, Pesticides, and PCBs

Sediment samples were prepared for SVOC analyses (U.S. EPA Method 8270) and pesticide and PCB analysis (U.S. EPA Method 8080) by ultrasonic extraction using U.S.

R0062721

EPA Method 3550. Forty to 100 g of sample sediment were extracted with methylene chloride. The extracts were concentrated in a Kuderna-Danish apparatus. The pesticides/PCBs extract was then solvent-exchanged into hexane.

Sediment samples were analyzed for 19 chlorinated pesticides and seven PCB Aroclors using a gas chromatograph (GC) equipped with an electron capture detector (ECD), following U.S. EPA Method 8080. Compound confirmation was performed using second column GC/ECD. U.S. EPA priority pollutant SVOCs (59 analytes) were analyzed by gas chromatography/mass spectrometry (GC/MS) following U.S. EPA Method 8270. Tentatively identified compounds (TICs) were not reported with the SVOC results.

Priority Pollutant Trace Metals

Sediments were analyzed for the standard U.S. EPA suite of 13 priority pollutant metals. Approximately 40 g of sediment were acid-digested prior to analysis using U.S. EPA Method 3050A. Beryllium, cadmium, chromium, copper, lead, nickel, and zinc were analyzed using inductively coupled plasma (ICP) emission spectrometry following U.S. EPA Method 6010. Antimony, arsenic, selenium, and thallium were analyzed using atomic absorption spectrophotometry with a graphite furnace (AA/GF). Mercury was analyzed using the cold-vapor extraction technique following U.S. EPA Method 7470. Silver was analyzed using U.S. EPA Methods 6010 and 7760.

Total Sulfide and Acid Volatile Sulfides/Simultaneously Extracted Metals

Total sulfide extracts were prepared following U.S. EPA Method 9030. The impingate collected using this method was quantitated following U.S. EPA Method 376.2 on a Lachat Flow Injection Analyzer Model 80.

AVSs were analyzed following a U.S. EPA draft method (Allen et al. 1993) to determine their presence in sediment. The AVS in sediment was first converted to hydrogen sulfide (H_2S) by acidification with concentrated hydrochloric acid at room temperature. The H_2S was purged from the sample and trapped in an aqueous sodium hydroxide solution. Once in solution, the sulfide reacted with n-n-dimethyl-p-phenylenediamine to form methylene blue. Quantification of AVS was performed by measuring the spectrophotometric determination of methylene blue.

Sediment samples were analyzed for five divalent priority pollutant trace metals (cadmium, copper, lead, mercury, and zinc) following simultaneous extraction via the AVS procedure. Metal analysis was performed on the acid digest from the AVS procedure, referred to as the SEM fraction. After release of the H_2S, the acidified sediment sample was membrane-filtered. The sample digest was then analyzed for the trace metals using the same method as summarized in the preceding paragraph for the analysis of total metals.

Butyltins

Sediment extraction procedures followed a modification of U.S. EPA Method 3550. After extraction by sonication in hexane-tropolone chelation, the sample was filtered and

VOL 18
0113
R0062722

the filtrate concentrated in a Kuderna-Danish apparatus. The concentrate was then spiked with the surrogate, tripentyltin chloride, and derivatized with a Grignard reagent. The Grignard reaction was quenched after 15 to 20 minutes using acidified water. The organic layer containing the derivatized organotins was collected in a 30 mL screw-topped vial and concentrated using a nitrogen blow-down apparatus. The sample was then subjected to gel permeation chromatography (GPC) or florisil column chromatography cleanup using hexane as the extraction solvent. The sample was concentrated to 0.20 mL prior to analysis. Butyltins were analyzed using a GC equipped with a flame photometric detector (FPD) following the method of Uhler and Durell (1989).

3.5.1.3 BIOASSAYS AND BIOACCUMULATION TESTS

Following is a brief summary of the bioassay test protocols used to measure toxicity caused by both solid phase and pore water components of surface sediment samples. Four different organisms were used in conducting the laboratory bioassays and bioaccumulation test. The echinoderms, amphipods, and clams, as well as the control sediments were provided by Brezina & Associates. The polychaetes were provided by Dr. Donald Reish.

Pore Water Acute Test

The purpose of this test was to determine the percent of abnormally developed echinoderms, in this case sand dollar larvae (*Dendraster excentricus*), over a 72-hour test period. Pore water was extracted from collected sediment within 24 hours of collection using centrifugation, and prepared in five test concentrations (6.25, 12.5, 25, 50, and 100 percent) of 5 mL aliquots each. Three replicates of each dilution were analyzed. Seawater was used for sample dilutions. The passing performance criterion for each test was greater than or equal to 70 percent normal development in the laboratory control sample. Survival and development data were used to estimate LC_{50} values (lethal concentration for 50 percent of test organisms), IC_{50} (inhibitory concentration for 50 percent of test organisms), and NOEC (no observable effects concentration) for each level of dilution.

Solid Phase Acute Test

The purpose of this test was to determine the percent mortality in marine amphipods (a shrimp-like organism) over a 10-day test period, using the standard sediment test amphipod, *Rhepoxynius abronius*, as the test organism. The solid phase sediment was used as collected, with five laboratory replicates run per sample, using 2 cm of test sediment per container. The passing performance criterion for each test was greater than or equal to 90 percent survival in the laboratory negative control sample. The percentage of organisms surviving was averaged over the five laboratory replicates. As an additional endpoint, the percentage of surviving organisms that were capable of reburying in the sediment was also reported as a measure of the vigor of the surviving organisms. Reburial is often considered to be a viable toxicological endpoint for assessing sediment toxicity to benthic infaunal organisms.

VOL 18
0114
R0062723

VOL 18 0115

Solid Phase Chronic Test

The purpose of this test was to determine the percent mortality in polychaete worms and their growth rates over a chronic (28-day) exposure period. This test was conducted using the standard sediment test polychaete worm, *Neanthes arenaceodentata*, as the test organism. The solid phase sediment was used as collected, with five laboratory replicates run per sample. The passing performance criterion for each test was greater than or equal to 90 percent survival in the laboratory negative control sample. The percentage of organisms surviving was averaged for the five laboratory replicates. As an additional endpoint, somatic growth rates were also reported by averaging the weights of dried organisms at the conclusion of the 28-day exposure period. Growth is considered to be a viable toxicological endpoint for assessing the health and viability of sediment infaunal organisms.

Clam Bioaccumulation Test

The purpose of this test was to determine the tissue residues of select chemical analytes in clams that have been exposed to West Basin sediments for a 28-day exposure period. This test was conducted using the standard sediment test clam, *Macoma nasuta*, as the test organism. The solid phase sediment was used as collected, with three laboratory replicates run per sample. Although the primary purpose of the test was to conduct chemical analyses, the test was a bioassay and included a measurement of the toxicological response of the clams as well. The passing performance criterion for each test was greater than or equal to 90 percent survival in the laboratory negative control sample. The percentage of organisms surviving was averaged over the five laboratory replicates. At the end of the exposure period, the clams were allowed to depurate (purged) then sacrificed, the tissue extracted, and subjected to chemical residue analysis (chemical methods described in Section 3.5.3).

3.5.1.4 BENTHIC INFAUNA ANALYSES

MEC analyzed 60 benthic infaunal samples, consisting of 15 samples obtained from reference stations, and an additional 45 samples which were collected within the West Basin. Organisms retained on the 1 mm sieve were counted and identified to the lowest possible taxon.

Data analysis by station and station groupings for the infaunal data included the following community parameters: number of species, abundance, diversity indices (Margalef's Species Richness, Shannon Wiener diversity, Dominance index, and Pielou's J or Evenness), and biomass.

These parameters are defined as follows.

Margalef's Species Richness	(Number of Species - 1)/ln (Total Abundance)
Shannon-Wiener Diversity	$-1 * \Sigma p_i * \ln(p_i)$ where p_i = abundance of species i / Total Abundance

R0062724

Evenness	(-1 * Shannon-Wiener)/ln(Number of Species)
Dominance	Number of species accounting for 75% of the Total Abundance (species abundances are added together starting with the most abundant species).

3.5.2 Subsurface Sediment Analyses

In general, the procedures followed for surface sediment chemical analyses, described in Section 3.5.1.2, were also followed for the subsurface sediment samples. However, biological tests, total sulfides, and AVS/SEM analyses were not conducted on subsurface sediments because of the naturally occurring toxicity associated with anaerobic conditions.

3.5.3 Fish and Clam Analyses

Fish tissue (whole body and fillet) and clam tissue samples were analyzed for bioaccumulation of chlorinated pesticides, PCB Aroclors, PAHs, butyltins, priority pollutant trace metals, and lipid content. Analyses were also performed on fish bile for parent PAH metabolite compounds. The procedures followed in performing these analyses are described in subsequent sections.

3.5.3.1 FISH TISSUE ANALYSES

Chemical analyses were performed on fish tissue by Pace. Analyses consisted of the following suite of organic and inorganic analytes: chlorinated pesticides, PCB Aroclors, PAHs, butyltins, priority pollutant trace metals and percent lipids. Extraction and analytical methodologies followed the methods criteria specified in SW-846 (U.S. EPA 1990) with appropriate modifications for tissue, as mentioned in the following subsections. While these modifications successfully allowed for the lowering of method detection limits, they did prevent the identification of TICs.

Lipid Analysis

Lipid analysis in fish was conducted using a Soxhlet extractor with freon to digest the tissue, following U.S. EPA Method 9071. This method specifies 20 g of tissue, but this amount was not always available. A gravimetric determination was used to calculate percent lipids for fish.

SVOCs, Pesticides, and PCBs

The methods for tissue extraction and analysis generally followed those used for sediment, except that additional cleanup methods and changes in instrumentation were made to minimize interferences from salts and nonpolar fatty acids. Tissue samples were prepared for SVOC, pesticide, and PCB analyses by Soxhlet extraction using U.S. EPA Method 3540. Ten to 100 g of tissue mixed with anhydrous sodium sulfate were extracted with a 1:1 mixture of methylene chloride and acetone. The extracts were then passed through a large anhydrous sodium sulfate column and concentrated in a Kuderna-Danish apparatus.

VOL 18
0116
R0062725

The sample extracts were then subjected to alumina column using U.S. EPA Method 3610 and GPC cleanup using U.S. EPA Method 3640.

Chlorinated pesticides and seven PCB Aroclors were analyzed in tissue samples, using the same U.S. EPA method for sediment samples (U.S. EPA Method 8080). Analysis of PAHs was performed using GC/MS (U.S. EPA Method 8270), modified by operating the GC/MS in the selective ion monitoring mode. The SW-846 methods were modified to include use of the Soxhlet extraction, alumina cleanup, and GPC cleanup with the tissue sample matrix (Tetra Tech 1986).

Priority Pollutant Trace Metals

Tissue samples were analyzed for the same 13 priority pollutant metals quantified in sediment samples. The U.S. EPA methods described in Section 3.5.1.2 for surface sediments were utilized for tissue except for lead. Lead was analyzed using AA/GF following U.S. EPA Method 7421. A 5 to 10 g tissue subsample was homogenized and digested with concentrated nitric and perchloric acids prior to analysis by ICP or AA/GF (Tetra Tech 1986).

Butyltins

Tissue samples were analyzed for organotins using the GC/FPD method described in Section 3.5.1.2. In addition, a GPC or florisil cleanup was performed to achieve the practical quantitation limit of 1 µg/kg and reduce viscosity of the extract for injection into the GC.

3.5.3.2 FISH BILE ANALYSES

Fish bile analysis was performed by Battelle Ocean Sciences (Batelle) located in Duxbury, Massachusetts. All PAH metabolite analyses were performed in accordance with Battelle Standard Operating Procedure (SOP) 5-199 (Polynuclear Aromatic Hydrocarbon Metabolite Analysis of Bile and Tissue Samples using an HPLC). This method is based on Krahn et al. (1986), and has been applied in a series of PAH metabolite investigations over the past several years.

Following extraction from halibut gall bladders in the field, bile samples were placed in 2 mL amber glass sample vials. Once the samples arrived at Battelle, they were logged into the laboratory according to standard protocols (Battelle SOP 5-199). Samples were stored in a freezer at approximately -20°C until the day they were removed for analysis. Residual samples are currently stored at -20°C at Battelle.

The bile samples required minimal preparation prior to instrumental analysis. The samples were simply vortexed and a subsample transferred to a 200 microliters (µL) autosampler vial. An average density of the bile was determined, which was used to convert the data to a weight basis by accurately weighing a 50 or 100 µL subsample from four separate bile samples.

VOL 18
01177
R0062726

The PAH metabolite analysis was performed using an HPLC. The method employs a gradient HPLC separation on a 25-cm long, 4.6-mm inner diameter, octadecylsilane (i.e., C-18), reverse-phase column with acetic acid/water and methanol as the mobile phases (Battelle SOP 5-199, Krahn et al. 1986a, 1986b, 1987). A Hewlett-Packard 1050 series quaternary gradient HPLC system, coupled with a Hewlett-Packard 1046A fluorescence detector, was used for the analysis. A sample injection volume of 5 µL was used. The instrument was calibrated with multilevel calibration. Two-, three-, four-, and five-ring metabolites, represented by naphthalene, phenanthrene, pyrene, and benzo(a)pyrene, were determined using detector wavelength settings applicable to the four target PAHs.

Detector excitation and emission wavelengths were pre-selected to levels of high sensitivity and specificity on the fluorescence detector, each optimized specifically for the four parent PAH homologues. The analysis of primarily two-ring metabolites, expressed as naphthalene equivalents, was performed with a detector wavelength pair setting of 286/328 nanometer (nm; excitation/emission). The analysis of primarily three-, four-, and five-ring metabolites, as phenanthrene, pyrene, and benzo(a)pyrene equivalents was accomplished with detector wavelength pair settings of 258/359 nm, 318/378 nm, and 364/430 nm, respectively.

PAH metabolites were quantified by an external standard method, using the response of the parent PAH for quantification. The detection limit was approximately 0.01 to 0.05 micrograms per milliliter (µg/mL) for the unresolved PAH metabolite component. The total PAH metabolite concentrations determined and reported in this study are based on the total resolved and unresolved area in the applicable chromatographic region.

3.5.3.3 CLAM TISSUE ANALYSES

The procedures followed for fish tissue chemistry analyses, described previously in Section 3.5.3.1, were also followed for the clam tissue samples.

3.6 QUALITY ASSURANCE / QUALITY CONTROL

QA/QC were consistently emphasized throughout every phase of this RI, including data collection in the field, transmittal of samples to laboratories, and verification of procedures and findings. Physical and chemical data were subjected to validation using the NEESA procedures. An overview of the QA/QC procedures employed as part of this RI are presented in this section.

3.6.1 Field Sampling

Field QA/QC procedures followed those specified in the SAP (JEG 1993b) and the QAPP (JEG 1993b). These procedures included taking field replicates for surface and subsurface sediment samples, and rinseate and field blanks for subsurface sediment samples. Field replicates were collected at a rate of 1 in 10 samples collected per matrix; the matrices included surface sediment, subsurface sediment, and bioassay samples. The following field QA/QC samples were collected:

VOL 18 018

R0062727

- Surface sediment triplicate samples were collected at West Basin Station 1 and at Reference Stations 40010.1, 40010.2, 40010.3, and 40018.3 for TOC and grain size analyses. Each of the field triplicates was acquired by separate collection efforts in order to obtain sufficient sample volumes.
- Surface sediment triplicate samples were collected at West Basin Station 1 and at Reference Station 40010.3 for chemical analyses. Each of the field triplicates was acquired by separate collection efforts in order to obtain sufficient sample volumes.
- Surface sediment triplicate samples were collected at Reference Stations 40010.1, 40010.2, 40010.3, and 40018.3 for purposes of bioassay and benthic community analyses. Each of the field triplicates was acquired by separate collection efforts in order to obtain sufficient sample volumes.
- One subsurface field duplicate was collected during the sampling of subsurface sediments beneath piers using a drill rig.
- One equipment rinseate blank was collected daily during the sampling of subsurface sediments beneath piers; two days of sampling resulted in two rinseate blanks collected. The SAP did not require collection of rinseate blanks for surface sediment or tissue sampling.
- One field blank was collected per source of deionized water during sampling of subsurface sediments beneath piers, resulting in two field blanks actually collected. The SAP did not require collection of field blanks for surface sediment or tissue sampling.
- One matrix spike/matrix spike duplicate (MS/MSD) sample was collected daily during the sampling of subsurface sediments beneath piers; two days of sampling resulted in two MS/MSD samples actually collected. MS/MSD samples were not collected in the field during surface sediment sampling because Pace generated these samples in the laboratory by splitting original field samples.

Other field QA/QC procedures included appropriate decontamination of sampling equipment and following proper COC procedures. All samples were assigned a unique identifying number, and containers were labeled with information identifying sample location, date and time of sample collection, and preservative. Field notebooks were maintained by the sampling team leader to provide a daily record of significant events, observations, and measurements taken during the field investigation. Field quality control procedures specific to fish sampling included: 1) visual examination of the net and the samples, in particular, checking for invertebrates in the net (i.e., benthic invertebrates which could only be collected by appropriate trawling practices); and 2) ensuring that proper scope of trawl line to depth ratio (5:1) was used.

3.6.2 Laboratory Analyses

Laboratory QA was performed as specified in the QAPP (JEG 1993b). In addition to internal laboratory-specific QA procedures for physical, chemical, and biological tests, each of the laboratories (MEC, Pace, and Battelle) reported that they implemented and

VOL 18
0119
R0062728

followed standard protocols which specified laboratory QA procedures to improve precision and accuracy from these analyses. These procedures addressed:

- detection and quantification limits,
- instrument calibration,
- internal quality control checks and corrective actions,
- data calculations and reporting units, and
- documentation and deliverables.

The chemical analyses of surface and subsurface sediment and tissue were performed using protocols and quality control criteria specified in SW-846 (U.S. EPA 1990). Procedural blanks, MS/MSDs, and standard reference materials were also analyzed in the laboratory at a frequency of 1 per 20 samples. Deuterated surrogates and internal standards were analyzed for every sample as well.

QA requirements specified in Battelle's SOP 5-199 were followed throughout the fish bile testing procedure. The initial instrument calibration was established and the correlation coefficient of the calibration was determined by analyzing a continuing calibration check standard approximately every 12 samples. Pure methanol was analyzed as method blanks to monitor background signal. The methanol blank was considered acceptable if no resolved analytes, or unresolved components, were detected at greater than three times the detection limit in the chromatographic region of interest. A set of MS/MSD samples were also analyzed along with the field samples.

3.6.3 Physical and Chemical Data Verification / Validation

Verification of physical and chemical data was conducted by both MEC and BNI. The verification procedure included checking hard copies of the data as reported by the laboratories against the electronic database for accurate transcription or other errors which could affect data quality. MEC, who prepared an electronic database for this project, verified 100 percent of the physical and chemical data during preparation of the electronic database; BNI conducted a 10 percent acceptance review of such data and did not find errors. In addition, verification of calibration curves, where appropriate, and evaluation of matrix spikes (surrogate recoveries) were conducted by the individual contract laboratories to assess that data met project DQOs, as specified in the Data Management Plan (BNI 1994e).

Physical and chemical test results were also subjected to formal data validation following NEESA guidelines. This validation procedure was conducted by an independent contractor (Laboratory Data Consultants [LDC] in Carlsbad, California) to assure objectivity in evaluating laboratory-generated data.

The project QAPP (JEG 1993b) notes that both NEESA Level C and Level D (U.S. EPA Level III and Level IV, respectively) data support packages would be prepared for harbor sediments, although it is not possible to report both levels for the same data. Because it

VOL 18
0120
R0062729

was inappropriate to report Level D for sediments, due in part to the use of certain non-standard analytical methods, Level C was used as a reporting level for all sediment chemistry data. This is consistent with U.S. EPA guidelines (1992b), which state that Level C is adequate to support baseline risk assessment and define remedial action objectives. Nevertheless, 10 percent of the data were subjected to Level D validation and the remaining 90 percent were subjected to Level C validation. This level of validation provided an additional rigorous check for laboratory data. Validation included a check of the adequacy of sensitivity for individual testing sequences (i.e., whether analytical detection limits were acceptable).

Analyses of AVS metals, total sulfide, and butyltin in sediment were also reviewed by LDC using NEESA Level C and Level D guidelines, as appropriate. The results were validated following generally accepted methodology for conducting data validation, as documented in NEESA (1988), U.S. EPA (1988b; 1991), and Allen et al. (1993).

After the data were validated by LDC, BNI compared the concentrations of analytes in laboratory and field blanks to the concentrations of the same analytes detected in West Basin and reference station samples. This comparison served the purpose of excluding nonsite-related chemicals from the data evaluation process (i.e., chemicals that might have entered the samples after the samples have been collected and packaged were removed from the list of chemicals to be evaluated). According to the U.S. EPA (1989a), a chemical is treated as having been introduced into a sample after the sample has been collected if the concentration of the chemical in the sample is less than 10 times (for common laboratory contaminants only) or 5 times (for other chemicals) the concentration in the associated field or laboratory blank sample. Acetone, 2-butanone (methyl ethyl ketone), methylene chloride, toluene, and phthalate esters are considered by the U.S. EPA to be common laboratory contaminants. Accordingly, samples with less than 10 times the concentration of common laboratory contaminants or 5 times the concentration of other chemicals in any blank were treated as "non-detects" and the chemical concentration measured in the blank was considered to be the quantitation limit value for the chemical in that sample (U.S. EPA 1989a).

3.6.4 Bioassay Data Verification

Bioassay test data were verified using a project-specific, multi-step approach designed to identify potential data inaccuracies or inconsistencies. The verification approach included:

- a 10 percent check to verify that raw electronic data were accurately transferred to the electronic data summaries (mean of laboratory replicate results per sampling station);
- a 10 percent check of raw hard copy data against raw electronic data;
- a check of test water quality data (e.g., DO levels, temperature, salinity, ammonia, sulfides);
- a check of exposure conditions, including acclimation of the organisms, length of exposure, feeding protocols, and

VOL 18
0121
R0062730

- a check of the survival data for test organisms, using both negative and positive control tests, to assure the viability of each test.

All appropriate data qualifiers were assigned by MEC to laboratory sample replicates (e.g., replicates that were contaminated, double inoculated, not inoculated). Minor deviations were observed in test protocols such as variation in temperature and salinity, although recorded values were within the industry standard. However, two pore water samples (representing 1 percent of the data set) experienced reduced DO levels during testing, DO levels fell to less than 60 percent of saturation. The depressed DO levels for these samples (Stations 24 and 51) were taken into consideration during the interpretation of the pore water toxicity tests.

3.6.5 Benthic Community Data Verification

MEC provided standard internal verification of benthic indices counts after transferring the data from hard copy to an electronic database, which was used in subsequent statistical analyses.

3.6.6 Data Usability

Guidance for overall data usability in risk assessment was based on U.S. EPA's Final Guidance for Data Usability in Risk Assessment (1992a). This guidance document, designed to address analytical data, identifies several data quality issues which are frequently encountered and need to be addressed in risk assessments. Five criteria, defined by the U.S. EPA and used to evaluate data usability for risk assessment, include:

- data sources,
- documentation,
- analytical methods and adequate detection limits,
- data review, and
- reports to the risk assessor.

The manual provides guidance on interpreting the impact of sample collection, analytical techniques, and data review procedures on the usability of analytical data in risk assessment.

These data usability criteria were applied during the RI planning process to guide the design of sampling plans and select analytical methods for the data collection effort. This included guidance concerning how to determine the degree of confidence in the risk assessment based on the level of uncertainty of the analytical data. For the data generated and validated for West Basin, data usability criteria extended to:

- whether measured parameters were within method-specified QC limits,
- accuracy and reliability of the data estimates,
- adherence to detection limits during analysis, and

VOL 18
0122
R0062731

- whether data precision goals were met (e.g., a relative percent difference [RPD] between matrix spike and matrix spike duplicates of less than or equal to 35 percent).

Specifically, biological performance criteria were established for bioassays, and closely scrutinized for purposes of data usability determination as described below. Data usability criteria, described in TM No. 4 (BNI 1994c), included negative controls to determine whether individual laboratory tests were valid, positive controls (reference toxicants) to establish the sensitivity of test animals, and reference sediment performance criteria to determine whether reference locations used were appropriate for statistical comparisons with test stations.

Negative Control Performance Criterion. Table 3-13 shows that mean survival in control amphipod and polychaete organisms less than 90 percent or mean normal echinoderm development less than 70 percent constitutes a bioassay test failure. In addition, individual laboratory replicate survival in control polychaete organisms must be greater than 80 percent.

Positive Control Performance Criterion. Control organisms were exposed to a standard reference toxicant for 96 hours and concentration-response data (LC_{50} for amphipod and polychaete and EC_{50} for echinoderm) evaluated and compared to the overall laboratory mean for that particular species. The reference toxicants used for the purposes of this project were cadmium chloride ($CdCl_2$) for amphipod and polychaete bioassays and Cu^{2+} for pore water bioassays. The LC_{50}/EC_{50} results for each control batch must fall within two standard deviations of the overall laboratory mean in order for the bioassay test to be considered valid.

Reference Sediment Performance Criterion. Table 3-13 shows that the relative difference between mean survival and normal development (echinoderm) in reference station and laboratory controls must be less than or equal to 20 percent; the RPD between mean individual weight (polychaete) in reference station and laboratory controls must be less than or equal to 30 percent. Relative percent differences greater than 20 percent or 30 percent, as appropriate, constitute a reference failure. Data that did not pass this criterion were considered outliers and, therefore, were excluded from the reference data set.

3.6.7 Database Management

Following verification and validation, the data generated during the course of this RI were entered, stored, organized, and secured into a centralized database, Bechtel Environmental Integrated Data Management System (BEIDMS), maintained by BNI. This database houses physical, chemical, and biological data in an ORACLE® relational database.

The BEIDMS database system is designed to protect against unauthorized data access and corruption of data. User access is controlled by the use of passwords, and users are provided "read-only" access to verified and validated data. Preliminary data are available for limited specific modifications, such as the entry of data quality codes. However, once

VOL 18
0123
R0062732

the data are declared to be validated and verified by authorized personnel, they are placed in production database tables. Modifications to production tables are performed only by data management staff and only when required database change request forms have been approved by appropriate project managers and technical specialists. Modifications to validated data are tracked electronically as separate fields within all environmental database tables. Tracking fields include the user identification of the person making the change to the database, the date of the change, and the program number of the database change request. Completed field review/correction forms accompany transmittal of all raw data files, reports, and field logs to the data management staff for inclusion in the BEIDMS database.

3.7 DATA ANALYSIS METHODS

Data collected from the analyses of the West Basin sediment and tissue samples were evaluated for descriptive statistics, significant differences from the reference data, spatial patterns, and data correlation patterns as described below:

- The descriptive statistics provide conventional measures of the data set such as mean and standard deviation.
- West Basin station data were compared to the 95 percent predictive interval of the reference station data. The data from groups of stations (sediment evaluation zones [SEZs]) were tested for significant differences from reference data using analysis of variance (ANOVA) with Tukey's multiple comparison test.
- Sediment quality spatial patterns were examined by plotting contour intervals of data values on site maps.
- Sediment data correlation patterns were examined using correlation coefficients, cluster analysis, and principal component analyses with multiple regression.
  - The correlation coefficients reflected the patterns that existed among all the data parameters (i.e., grain size, TOC, chemical analytes, toxicity, and benthic infauna indices).
  - The cluster analysis procedure grouped stations together according to similar physical and chemical characteristics; such groups were treated as SEZs.
  - The principal component and multiple regression analyses evaluated the relationships between the toxicity and benthic infauna data and variables developed by grouping similarly distributed sediment chemistry data.

3.7.1 West Basin Descriptive Statistics

General descriptive statistics were calculated for each basin and pier station for physical, chemical, and toxicity parameters for each individual data set. These data sets included clam tissue (bioaccumulation test), fish bile (California halibut), fish tissue (California halibut fillet, white croaker fillet, California halibut whole body, white croaker whole body), and surface and subsurface sediment. Data used for this analysis included the

VOL 18
0124
R0062733

reported concentrations of detected compounds, and one-half the practical quantitation limit (PQL) if the concentration of the compound was reported as below its detectable concentration. The following descriptive statistics were calculated, as applicable:

- Number of available data values. A data value was defined as the concentration at which a compound was detected; when the compound was not found at detectable levels, one-half of the PQL was the data value. The number of data values may differ from the total number of actual analyses due to the results of data validation (i.e., some data values were rejected).
- Number of detectable values. Number of data values reported at a detectable concentration.
- Percent frequency of detection. Calculated as number of detectable values divided by the number of available data values.
- Minimum value. Minimum concentration in the data set. In many cases, this value was one-half the PQL.
- Minimum detectable value. Minimum concentration in the data set where a compound was found at a detectable level.
- Maximum value. Maximum concentration in the data set. When a compound was not detected, this value was one-half of the PQL.
- Mean value. Arithmetic average of available data values for each compound.
- Standard deviation. Standard deviation of the mean of available data values for each compound.
- 95% upper confidence limit (UCL). Upper 95 percent confidence limit of available data values for each compound using a 2-tail t statistic ($t_{(0.05, n-1)}$).

3.7.2 Reference Stations Descriptive Statistics

General descriptive statistics for physical, chemical, and toxicity parameters were calculated for each individual reference station data set including clam tissue (bioaccumulation test), fish bile (California halibut), fish tissue (California halibut fillet, white croaker fillet, California halibut whole body, white croaker whole body), and surface and subsurface sediment. Data were included for this analysis as the detectable concentration for detectable compounds, and as one-half the PQL when the compound was not found at detectable levels. The descriptive statistics calculated using the reference station data were the same statistical analyses used for the West Basin data, except for several additional analyses. These additional analyses included testing for normality of data to asses the suitability of using 95% upper predictive limit (UPL) interval; and calculation of the 95 % UPL. The 95% lower predictive limit (LPL) was used to compare the toxicity and benthic infaunal data. Brief descriptions of the additional analyses are provided below:

- Shapiro-Wilks Statistic. Shapiro-Wilks test for normality (performed for sediment and fish tissue only). The Shapiro-Wilks W statistic was calculated both for untransformed and log-transformed ($\log_{10}$ (value+1)) data values for

VOL 18
0125
R0062734

each analyte. The value was not calculated when the standard deviation of the mean was not greater than 0. When the probability was less than 0.05, then the null hypothesis of a normal distribution of the reference data was rejected.

- 95% UPL of available data values for each compound using a 1-tail *t* statistic ($t_{(0.05*2, n-1)}$) for reference stations (Hahn 1970). This statistic was not calculated when the number of values was less than n=2. The following formula was used to calculate the 1-tail statistic:

$$95\% \text{ Predictive Limit} = \text{mean} \pm t * \sigma(1+1/n)^{(1/2)}$$

3.7.3 Comparison of West Basin Data to Reference Data

Results of single analyses at each of the West Basin stations were compared to the reference stations' results for sediment physical, chemical, benthic infaunal, and toxicity data using the 95% predictive limit (see Section 3.7.2). Mean values of pooled analytical data from the West Basin were compared to the reference station mean values using analysis of variance (ANOVA). Results of the fish tissue, halibut bile, and clam bioaccumulation data from the West Basin were pooled and treated as replicates for comparing to the reference data. In addition, results of sediment analyses from the stations within each SEZ were pooled to represent replicate samples of the SEZ.

The data were prepared for the ANOVA by using one half PQL values when the analytical results indicated that analyte concentrations were less than the reporting limit. Each data set was tested for the ANOVA assumption of homogeneity of variances (equal variances among the groups) using Levene's test ($\alpha = 0.05$). Levene's test is also sensitive to non-normally distributed data; therefore, a separate test for normality was omitted. If the raw (untransformed) data passed Levene's test, the ANOVA was applied. If the raw data did not pass Levene's test, the data were log-transformed (arcsine-transformed for percentage data) and tested again. If the transformed data passed Levene's test, the ANOVA was applied. If the transformed data did not pass Levene's test, the data were rank-transformed and the ANOVA applied. The ANOVA with rank-transformed data is equivalent to the non-parametric Kruskal-Wallis test.

ANOVA results were considered significant when the probability associated with the calculated *F* statistic was less than an alpha of 0.05. Tukey's multiple range test was performed to evaluate differences between the ANOVA cases. ANOVA were performed on each data set using the SAS® statistical program (version 6.07).

ANOVA represents a standard, highly accepted procedure to determine whether any observed differences among groups are statistically significant. If the test is not statistically significant ($P > 0.05$), it can be concluded that the test groups are the same as the reference. If the F-test is significant, all groups are compared with the reference data by using a multiple comparison test (e.g., Tukey's multiple range test), which is specifically designed to compare several experimental samples to the reference, and accounts for several simultaneous comparisons (Sokal and Rohlf 1969).

R0062735

VOL 18
0126

3.7.3.1 FISH TISSUE AND BILE

An individual one-way unbalanced ANOVA was performed for each analyte for each analysis matrix (whole body, fillet, and bile) for both species of fish (California halibut and white croaker) collected from the West Basin and the reference stations. Individual fish were treated as separate samples and the mean and variance of all fish samples of a similar type were combined for the West Basin and reference stations.

3.7.3.2 BIOACCUMULATION - CLAM TISSUE

Individual one-way unbalanced ANOVA was performed for each analyte for the clams grown in West Basin and reference station sediment samples. Clams were grouped according to sediment type: pier stations, basin stations, and reference stations.

3.7.3.3 SURFACE SEDIMENT CHEMISTRY AND PHYSICAL PARAMETERS

Two methods of comparison of West Basin data to reference station data were performed for the surface sediments. The first method compared every individual station chemical parameter value with the 95% UPL value for the pooled reference station data. A simple examination of the data indicated which West Basin station values exceeded reference station values. Any analyte which was found in the West Basin but not in the reference station samples was assumed to exceed the reference station value. The second method consisted of performing individual ANOVAs for each chemical analyte and physical parameter for the West Basin stations after they were grouped into SEZs, and the reference station data.

3.7.3.4 SEDIMENT TOXICITY - BIOASSAY

Specific performance criteria for comparing West Basin bioassay data to reference station bioassay data for the purposes of assessing whether West Basin data were statistically different from reference data, included:

- a relative mean numerical difference between West Basin and reference station bioassay results of less than or equal to 20 percent for survival, 20 percent for normal development (echinoderm only), and 30 percent for growth (polychaete only) endpoints; and
- a statistically significant difference in a measured biological endpoint between West Basin and reference station organisms based on a comparison of biological response at West Basin stations to biological response at reference stations.

Table 3-13 shows specific biological performance criteria for each test organism. These criteria are valid assuming a laboratory control organism survival rate greater than 90 percent. Exceeding both of the above performance criteria constitutes a definitive "hit" for bioassay tests, implying that natural variability is screened out as a potential "cause" or indicator of toxicity. Table 3-14 is designed to show specific biological performance criteria for an example organism and how results would be evaluated as a series of yes and no questions to ultimately lead to a "hit" or "no hit" result.

VOL 18
0127
R0062736

VOL 18

0128

Table 3-13 shows that evaluation of the West Basin sediment data involves two interpretation performance criteria for each bioassay endpoint. First, the RPD must be less than or equal to 20 percent for survival and normal development (echinoderm) and less than or equal to 30 percent for mean individual weight (polychaete) in order for the West Basin sediment to have "passed" the bioassay, i.e., relatively little difference between West Basin and reference station toxicity. Second, West Basin and reference station results were statistically compared at the $\alpha = 0.05$ level. The results of these two analyses (RPD and statistical comparisons) were then evaluated for each West Basin station or SEZ to determine the ultimate bioassay test result, i.e., either "hit" or "no hit."

West Basin bioassay data were compared to reference station values both on a station-by-station and on a SEZ basis. Station-by-station statistical analyses were conducted by comparing the biological response observed at each individual West Basin station with the pooled reference 95% lower predictive limit (LPL) for same biological response using SAS®. This technique is normally applied for the analysis of a single test observation as compared to a reference mean. Statistical analyses of bioassay data grouped into SEZs proceeded with ANOVAs and Tukey's multiple comparison test.

3.7.3.5 BENTHIC INFAUNA

Several unique statistics were calculated for the benthic infauna community results at each station, including the number of species, abundance, diversity indices (Margalef's Species Richness, Shannon-Wiener diversity, Dominance Index, and Pielou's J or Evenness), and biomass. Data were also classified by cluster analysis using the Bray-Curtis dissimilarity index. Individual ANOVA for each benthic infauna community result was performed for the West Basin SEZs and the pooled reference stations.

3.7.4 Data Patterns

Three approaches - cluster analysis, data mapping (spatial plots), and correlation and regression analysis - were used to investigate patterns among the extensive sediment quality data, which consisted of 45 West Basin stations and nearly 140 sample analysis determinations. These data analyses and presentation methods are briefly described below.

Cluster analysis is a statistical technique that evaluates patterns among the station data by summarizing the results of many tests. The analytical results are summarized onto a matrix table that describes theoretical similarity between sampling stations. The matrix is then used to construct a diagram illustrating which stations are similar to each other.

Spatial plots are contour lines of equal data values presented on a site plan of the sampling stations. Contour lines are plotted for selected test results. The illustrations generated in this manner aid in the identification of areas containing low or high values for a certain parameter.

Relationships between the sediment chemistry data and the biological data (benthic infauna and toxicity) were investigated using correlation and regression analysis. Results of the

R0062737

correlation analysis described the association between results of one test and results of another test. High correlation values between two tests may indicate similar distributions or potential cause and effect relationships. The regression analysis evaluated the dependence of one test's results on another test's results. A strong dependence between two sets of test results can potentially indicate a cause and effect relationship.

The following sections provide more detailed descriptions of these data pattern analysis methods. The descriptions provide a thorough technical discussion of the mathematical and statistical procedures, with references to computer programs used for this RI.

3.7.4.1 CLUSTER ANALYSIS

Cluster analysis, a classification type of multivariate statistical test, was used to identify groups of data with similar characteristics (i.e., stations with similar chemical analytes). Cluster analysis involves a hierarchical classification of entities (or groups) according to a resemblance measure (sometimes called a dissimilarity index). A normal (Q-mode) agglomerative hierarchical clustering technique was used from the SAS® statistical analyses software. The clustering method (grouping strategy) used was the flexible sorting strategy with the clustering intensity coefficient, Beta, set at the standard -0.25.

Stations were evaluated as a group of all 52 together (basin, pier, and reference), and as a group of the 45 West Basin stations (basin and pier). Both of these groups of stations were evaluated with three variable groups: 1) chemical and physical data combined, 2) physical data, and 3) chemical data. For the purposes of this evaluation, chemicals included all compounds that were analyzed (except TOC) that were found at least at 50 percent of the stations. Variations in detection limits (due to complex sample matrices) for compounds that were detected at a frequency less than 50 percent caused interference in pattern recognition and, therefore, were not included in this process. The physical data group for this analysis included grain size as percent fines (sum of clay and silt) and TOC.

The clustering algorithm used a Bray-Curtis dissimilarity matrix (the inverse is similarity), from which distance measures between units (stations) were computed. This index takes a matrix of 'r' rows and 'c' columns (matrix D), and produces a square matrix of 'r' rows and columns (matrix BC). The value of BC_{ij} is the dissimilarity between the ith and jth rows of matrix D with each row containing data for one station, and each column containing data for one analyte (chemical/physical). The resulting matrix BC shows all possible pair-wise stations, as calculated from the relative concentration of each analyte at those stations.

The formula for each element is:

$$BC_{ik} = \Sigma \mid D_{kj}-D_{ij} \mid / \Sigma (D_{kj}+D_{ij})$$

where i = 1 to maximum number of rows, k = 1 to maximum number of rows, and j = 1 to maximum number of columns.

VOL 18
0129
R0062738

The matrix is symmetrical around the diagonal, so only one-half of the matrix was calculated. Analyte concentrations were transformed to the mean value (i.e., D_{ij} = (concentration of analyte j at station i) / (mean concentration per station of analyte j). See Bray and Curtis, 1957 for a complete explanation of the technique.

Results of the cluster analysis are displayed as a two-dimensional hierarchical structure called a dendrogram (tree diagram). The dendrogram shows the level at which entities or groups of entities are grouped along the hierarchical agglomerative process, according to a dissimilarity index (e.g., Bray-Curtis) scale. The dendrogram of stations illustrates which stations show similarity, while the dendrogram of physical and chemical data show which parameters are similarly associated. The associations among the stations as well as among the parameters are illustrated in two-way tables that display the relative distribution of parameters among the stations in a matrix format.

Clusters of stations were then used to construct SEZs, discussed in the following Section 4.

3.7.4.2 SPATIAL PLOTS

Chemical data were grouped according to logical sets (PAHs, metals, etc.) and spatial plots were produced to illustrate possible variations in chemical concentration gradients using SURFER© for Windows Version 6.0 software. SURFER© interpolated data from irregularly spaced stations and produced contour maps of possible distribution and concentration of analytes according to the specific interpolation technique used by the software.

3.7.4.3 CORRELATION ANALYSIS AND MULTIVARIATE TECHNIQUES

All of the following analyses were performed using the SAS® statistical program (Version 6.07) on a VAX computer.

Pearson correlation analyses were performed using all physical, chemical, and bioassay sediment values. The following benthic community variables also were included: number of individuals (to lowest possible taxon), abundance, biomass, Shannon-Wiener diversity, and Margalef diversity. Correlation coefficients (r) $\geq$ 0.04 and number of observations (n) were recorded for all pairwise comparisons. Correlations were not performed for fish tissue data or clam bioaccumulation data. X - Y plots were prepared for all biological-chemical correlation pairs that met the r $\geq$ 0.04 criterion.

Principal component analyses (PCA) were performed using sediment physical/chemical data for all stations for values $\geq$ 50% for the entire data set. The SAS® procedure FACTOR was used with the following settings: method = principal simple; n = 30 (allows maximum of 30 eigenvectors); rotate = varimax. Output included data used in the PCA, eigenvalues for each analyte (for a total of 10 eigenvectors), total and cumulative variance explained for each eigenvector, and eigenvector scores for each station. Output was generated for both rotated and nonrotated eigenvectors

VOL 18
0130
R0062739

Step-wise multiple regressions were performed using the five dominant eigenvectors produced in the PCA. The regression analysis was run using SAS® procedure REG, selection = stepwise, and stay level = 0.15 (correlation criterion for inclusion into the model). Output included degrees of freedom, sum of squares (SS), mean square, correlation coefficient squared (r^2), F value, probability > F, mean standard error, and type II SS. Regression plots were prepared for each biological variable (bioassay and select benthic community measures) versus each eigenvector included in the model.

3.7.5 Sediment Quality Guidelines

Sediment chemical data were screened against quality guidelines by comparing individual analytes for each West Basin station to the reference stations (see Section 3.7.3). Chemical data were also compared to ER-L or ER-M values reported in Long, et al. 1995 and shown in Table 3-15. The effects on aquatic organisms of several trace metals and PAHs, total PCBs, and two pesticides were evaluated by Long et al. by examining the results of numerous modeling, laboratory, and field studies performed in marine and estuarine sediments. The incidence of adverse effects has been quantified and the ER-L and ER-M values have been determined to provide reliable guidelines for use in sediment quality assessments. ER-L levels generally correspond to chemical concentrations in sediments that do not demonstrate any adverse effects on aquatic organisms and ER-M levels correspond to chemical concentrations in sediments that demonstrate a moderate amount of adverse effects on aquatic organisms.

VOL 18

SECTION 4

RESULTS OF SITE CHARACTERIZATION

0132

VOL 18

Section 4
RESULTS OF SITE CHARACTERIZATION

This section presents the results of the site characterization efforts and includes a discussion of the distribution and spatial patterns of the physical, chemical, and biological data found at West Basin. The results presented herein are based on final verified and validated laboratory data. All results of sediment analyses are presented in this RI Report as dw units, and all results of tissue analyses are presented as ww units.

The physical, chemical, and toxicological parameters of surface sediments obtained in this RI were used to describe the nature and extent of chemicals measured in the sediments. Physical measurements (i.e., TOC and grain size), which are known to influence both sediment toxicity and chemical distribution in sediments, provided an understanding of the general character of the sediments at West Basin and the reference stations. While chemical analytes provided direct measures of chemical distribution, bioassay toxicity tests were used to assess the potential toxicological effect of chemicals in sediments. Benthic community analysis assessed the infaunal invertebrates found in sediments, which are sensitive to and useful indicators of various disturbances to the benthic environment. Tissue bioaccumulation tests of fish and laboratory clams were useful in evaluating the potential for chemical uptake in the tissues of marine organisms from the sediments.

West Basin surface sediments were analyzed for areas of similar physical and chemical nature to establish SEZs. The data for each SEZ were compared to reference station values and to sediment quality guidelines (ER-Ls). COPCs were identified as those analytes exceeding the reference station values, and AOPCs were identified as those SEZs containing at least one COPC. Fish tissue data were also compared to the reference station values. COPCs detected in fish tissue were evaluated using human health risk assessment (Section 5) and ecological risk assessment (Section 6). AOPCs and COPCs for sediments were evaluated using ecological risk assessment methods described in Section 6.

Throughout this RI Report, four major groups of sediment sampling stations are discussed: 1) Reference Stations - those stations located in the outer LA/LB Harbor used to describe background levels of sediment characteristics, 2) West Basin Stations - all stations located within the West Basin, 3) Basin Stations - those stations located within the West Basin but not beneath piers, and 4) Pier Stations - those stations located beneath piers within the West Basin.

Complete data reports from the analytical laboratories are provided as appendices to this RI Report for sediment particle size distribution (Appendix J); sediment TOC (Appendix K); sediment, tissue, and fish bile chemical analyses (Appendix L); sediment and pore water toxicity bioassay (Appendix M); and benthic community analysis (Appendix N). The data validation reports are included as Appendix O. A complete listing of the West Basin electronic database is provided in Appendix P. This database is the culmination of data verification and validation efforts, and provides the complete set of data used for this RI.

The borehole logs for subsurface sediment samples are included in Appendix Q. Appendix R contains the results of grain size distribution tests, and presents the data in graphical form as grain size distribution curves.

R0062742

4.1 GENERAL DESCRIPTION OF PROJECT DATA QUALITY AND USABILITY

Chemical data, bioassay performance criteria assessment, and benthic infauna assessment for each sample were reviewed under a data validation program. The results of data validation are presented in this section. The methods used for data validation were identified in planning documents referenced earlier (BNI 1994c, BNI 1994d, BNI 1995a) and summarized in Section 3.

4.1.1 Chemistry Data

The analytical chemistry data were compared to U.S. EPA data validation guidelines (U.S. EPA 1988b, 1991). Table 4-1 lists the number of analytical data values reported by the laboratory, and the percentage of these data values retained after data validation. Some of the chemical data values were assigned a "J" data validation code indicating the value is considered an estimate. The "J" code was assigned because of various conditions, including sample holding times that were exceeded, inconsistencies with initial and subsequent calibrations, and spiked sample recoveries. A few of the data values were assigned an "R" validation code indicating rejected data. Upon completion of data validation, none of the data that the analytical laboratory reported as detectable concentrations were found to require the classification of "rejected."

Evaluation of laboratory and field blank data revealed no detectable levels of common laboratory contaminants. Other chemicals (e.g., zinc, tributylin, and dibutyltin), however, were detected in some of the blank samples. Zinc was found in the field and rinseate blanks associated with the subsurface sediment core taken at Station 46. Concentrations of zinc in the Station 46 samples were greater than 5 times the blank contamination level; therefore, the levels of zinc detected in the Station 46 samples were considered positive results. Zinc was also found in laboratory blanks associated with 14 fish tissue samples. Zinc concentrations in these fish samples did not exceed 5 times the zinc concentrations detected in the blanks and were thus considered false positive results.

Likewise, tributyltin was found in laboratory blanks and 70 associated surface and subsurface sediment samples; dibutyltin was found in both a laboratory blank and one associated surface sediment sample. Tributyltin and dibutyltin concentrations in these sediment samples did not exceed 5 times the associated blank concentrations and therefore were considered false positive results.

False positive results were treated as "non-detects," and 5 times the blank chemical concentration (i.e., zinc, tributyltin, or dibutyltin) was considered the quantitation limit for such a chemical in the affected sample. Comparison of concentrations of chemicals detected in blanks to the associated West Basin and reference samples are contained in Appendix O.

VOL 18
0134
R0062743

4.1.2 Toxicity Data

Bioassay test results were compared to project-specific performance criteria (BNI 1994c). These criteria assessed the acceptability of bioassay tests and the suitability of project reference station data for comparison with West Basin data.

4.1.2.1 NEGATIVE CONTROL PERFORMANCE CRITERION

Individual laboratory replicates of percent normal development data in echinoderm bioassay test controls were averaged to determine mean percent normal development. Individual laboratory replicates of percent survival data in amphipod and polychaete bioassay test controls were averaged to determine mean percent survival. These mean percent responses for the test controls were compared to the appropriate performance criteria, specified in Table 3-13. In addition, individual laboratory replicate percent survival in the control polychaete bioassay tests were compared against the 20 percent performance criterion previously specified in Section 3.

All laboratory control samples passed this performance criterion when mean survival and normal development were evaluated. However, two of the six polychaete method control samples did not meet the negative control performance criterion in its entirety. The negative control performance criterion for the polychaete bioassay included both a replicate criterion and a mean replicate criterion. Although the mean replicate criterion was met, one replicate each from polychaete control samples mentioned above failed the 20 percent replicate specification: mortality was 40 percent and 60 percent for the two replicates, respectively. Because the mean replicate criterion is a better estimate of test performance than the replicate criterion, and because only one of the ten replicates from each of these two control samples did not meet the replicate criterion, the data were ultimately considered acceptable for further analyses.

4.1.2.2 POSITIVE CONTROL PERFORMANCE CRITERION

The reference toxicant LC_{50} (amphipod and polychaete) and EC_{50} (echinoderm) results were evaluated for each control batch for the three bioassay tests to assess whether the results fell within two standard deviations of the overall laboratory mean. All bioassay tests passed this performance criterion.

4.1.3 Benthic Infauna Data

Benthic infaunal analysis was performed on samples collected from all of the 45 stations in the West Basin and from seven reference stations. Single samples were collected at each of the West Basin Stations, and at Reference Stations 40018.1, 40018.2, and 40032.1. Three field replicates were collected at Reference Stations 40010.1, 40010.2, 40010.3, and 40018.3. The community index values calculated from the benthic infauna results for each field replicate were averaged for subsequent data analysis. Analysis of Reference Station 40010.3 Replicate 1 was terminated as an invalid sample after it was found that only two animals were present in the sample. All other benthic infaunal results were considered valid.

VOL 18

R0062744

4.2 ESTABLISHING THE PROJECT REFERENCE

This section describes and compares general sediment characteristics, including visual observations, grain size distribution, and TOC of West Basin and reference station surface sediments for the purposes of providing the basis for the reference station values established for this RI. The rationale and methods of selecting the reference stations are provided in Section 3.

Seven locations in the outer LA/LB Harbor were selected as project reference stations. For the purposes of this RI report, the project reference stations were considered to represent sediment conditions of the LA/LB Harbor which have not been influenced by activities associated with the LBNC.

Three reference stations, 40010.1, 40010.2, and 40010.3, were located near Cabrillo Beach in outer Los Angeles Harbor, collectively referred to herein as Station 40010. Three other reference stations, 40018.1, 40018.2, and 40018.3, collectively referred to herein as Station 40018, were located near the eastern boundary of outer Long Beach Harbor. One additional reference station, 40032.1, was located in outer Long Beach Harbor near the Angel's Gate opening in the breakwater, referred to as Station 40032.

4.2.1 Visual Observations

Detailed visual observations of surface sediments were documented in field logbooks during the sampling event. These observations, shown in Table 4-2, included detectable odors and physical characteristics such as texture, color, and cohesiveness. Sediments collected from basin stations in the West Basin were generally similar in texture, color, and cohesiveness, and differed considerably from sediments collected from beneath the piers. Reference station sediments represented a relatively wide range in texture and color, and appeared to be favorably comparable with West Basin sediments.

Basin surface sediments generally had fine texture, high cohesiveness, and no odor, except for Stations 1, 4, 12, and 41 which had detectable odors. The basin sediments were composed of mostly a silt/clay mixture and dark brown to black in color, with Stations 27, 28, and 41 exhibiting a greenish tint in color. In addition, benthic organisms were visible at most of the sampling stations. The characteristics of sediments from Station 24 differed from the rest of West Basin in that the sediments at Station 24 were composed primarily of sand, coarse in texture, and gray in color.

Surface sediments underneath the piers were mostly composed of silt with a significant amount of shell hash, especially beneath Piers 3, 7, and 12, and ranged from dark brown to black in color. The pier sediments were generally fine in texture with low cohesiveness, indicating a high moisture content. Odors were detectable from samples collected underneath each pier. In addition, crabs were present in most samples and an oily sheen was ubiquitous in sediment samples collected from underneath Piers 1, 9, and 15.

Surface sediments from the three reference stations were generally fine in texture (except for Station 40032, which was coarse in texture), high in cohesiveness, and ranged from light brown to brown in color (except for Station 40010, which was dark brown to black

VOL 18
0136
R0062745

in color). Odors were not detected at any reference station and benthic organisms were observed in most samples. The reference stations differed between each other in texture, with Station 40010 being composed primarily of clay, Station 40018 having a silty-clay texture, and Station 40032 being primarily composed of sand.

4.2.2 Grain Size

West Basin surface sediment particle size (used interchangeably with "grain size" herein) ranged widely from fine-grained sediments (94 percent fines) to coarse-grained sediments (79 percent sand). Figures 4-1 and 4-2 show the range of particle size distribution curves for the basin stations and for the pier stations, respectively. Individual particle size distribution curves by station are presented in Appendix R.

For the purposes of this RI Report, "fine-grained sediment" as well as "clay" and "silt" are used herein to mean sediment particles smaller than 62.5 µm. Particles greater than 62.5 µm in size are referred to herein as "coarse-grained sediments" or "sand." Grain size data for surface sediments are presented in Table 4-3, including mean and median grain size as microns, and percent clay, silt, sand, and gravel size, as well as fines (the sum of percent clay and silt sizes). The percent gravel value represents all sediment particles larger than sand size particles.

Grain size data were evaluated to identify areas of similar sediment physical characteristics. Because events such as historical dredging activities have likely altered the distribution of sediment grain size, median and mean grain size values are not assumed to be consistently representative of West Basin sediments.

Sediments from sampling stations along the seawall of the LBNSY and the eastern section of the Navy Mole (Figure 4-3) showed higher levels of percent fines, ranging from 80 to 93 percent. The coarsest sediment grain size within the West Basin was found near the entrance to the West Basin (Stations 24, 25, and 32). In general, clay content was highest, greater than 40 percent, in sediment samples from stations along the LBNSY seawall (Figure 4-4). Silt content was generally highest, greater than 50 percent, in sediment samples from stations in the southeast area of the West Basin (Figure 4-5).

The measured sediment grain size of samples collected from sampling stations beneath the piers is expected to have been influenced by the amount of debris and shell hash present in the sample. The grain size of sediments beneath the piers was generally fine, exceeding 70 percent fines. However, sediments at Piers 3, 9, and 12 (Stations 44, 47, and 50) showed fine grain size values ranging from 38 to 54 percent. The grain size data at Stations 44 and 50 appear to have been influenced by the content of debris and shell hash, having a gravel size fraction content of greater than 29 percent. Sediment grain size at Station 47 was different than the other pier stations by having a large sand content (47 percent).

Grain size characteristics of the reference stations ranged from sediments dominated by fines (silt and clay size) to sediments dominated by sand size materials (see Table 4-3). Figure 4-6 shows the range of grain size distribution curves for the reference stations. Sediments at Stations 40010.1, 40010.2, and 40010.3 were predominantly silt size particles. Sediments at Stations 40018.1, 40018.2, and 40018.3 were almost evenly

VOL 18
0137
R0062746

composed of clay, silt, and sand size particles. Sand was the predominant grain size at Station 40032.1.

4.2.3 Total Organic Carbon

Surface sediments from 34 basin stations and 11 pier stations within the West Basin, as well as from seven reference stations, were analyzed for TOC (Table 4-3).

Results of analyses for TOC in surface sediments from the basin stations ranged from 0.070 to 1.8 percent. Concentrations of TOC in sediments from beneath the piers ranged from 1.3 to 2.3 percent. The highest concentrations of TOC were detected at stations beneath piers and at stations near the LBNSY seawall (Stations 10, 17, and 27) and along the eastern Navy Mole (Station 21). The lowest concentration of TOC was reported from Station 24, near the mouth of the West Basin. The spatial distribution of TOC among the basin stations is shown on Figure 4-7.

4.2.4 Evaluation of Project Reference Suitability

The grain size distribution data for the surface sediments of West Basin and reference stations represented a wide range of values. Figure 4-8 shows the confidence interval for grain size distribution curves from the reference stations. Stations 40010 and 40018 appear to have overlapping confidence intervals, indicating some similarity in sediment grain size. When these confidence intervals are compared to the range of particle size curves shown on Figures 4-1 and 4-2 for basin and pier stations, it is apparent that while sediments at many West Basin stations consist of a grain size distribution similar to Reference Stations 40010 and 40018, a few West Basin stations do not. It is also apparent that the range of grain size distributions is continuous (i.e., there is no appreciable separation between distinct groups of grain size distribution curves). Therefore, the grain size data from Reference Station 40032 on Figure 4-8 was included with the reference station data from Stations 40010 and 40018. Comparison of the grain size distribution curves from the basin and pier stations (Figures 4-1 and 4-2) with the range of grain size distribution confidence intervals for the reference stations (Figure 4-8) shows a large amount of overlap.

Similar to the grain size distribution within the West Basin, the TOC distribution among the West Basin stations showed a wide range. Reference Stations 40010 and 40018 had TOC values similar to many of the West Basin stations, but not to all of the stations. Figure 4-9 shows the distribution of sediment fines and TOC for the West Basin and for the reference stations. Data presented in Figure 4-9 indicate that the West Basin stations show a continuous range of grain size and TOC values, and that no apparent separation is discernible between distinct groups of stations. The wide range of grain size and TOC distributions among the West Basin stations is well represented by the range of grain size and TOC at Reference Stations 40010, 40018, and 40032.

Because of the continuous range and lack of distinct patterns in the West Basin sediment grain size and TOC data, and similar grain size and TOC ranges in the three reference stations, data from the reference stations were pooled to develop a mean reference station

VOL 18
0138
R0062747

value. As described in Section 3, Stations 40010 and 40018 included three substations each (40010.1, 40010.2, 40010.3, 40018.1, 40018.2, and 40018.3). When pooled, data from these stations, along with Station 40032.1, provided seven data values (n=7) for mean, standard deviation, and other statistical estimates provided in Section 4.

4.2.5 Subsurface Grain Size and TOC Data

Laboratory tests for grain size and TOC determinations of subsurface sediments were also performed, separately from surface sediment data, as discussed below. Subsurface sediment data were not a part of the criteria established in selecting reference stations; the data are provided and discussed below for purposes of clarity and completeness.

Subsurface sediment samples were collected at Basin Stations 6, 8, 14, 24, and 29, Pier Stations 43 (Pier 15), 46 (Pier 12), and 51 (Pier 2); and Reference Stations 40010 and 40018. The recovered sediments were visually inspected and, based on identified sediment horizons and field judgment, separated into the various sediment samples. Sample 1 indicates the sample sequence beginning at the harbor bottom. Deeper samples are sequentially numbered as Samples 2 through 5 with increasing depth. This sample identification method was used particularly for pier sediment samples where sediment recovery was less than 100 percent of the maximum depth of penetration. These pier station core samples are identified in Table 4-4. The subsurface sediment samples collected at non-pier stations generally had 100 percent recovery. The borehole logs for subsurface sediment samples are included in Appendix Q.

Basin subsurface sediment samples collected at Stations 6, 8, 14, 24, and 29 generally had fine texture, high cohesiveness, and no odor, except for Station 6 at which a strong odor was detected in the Sample 2. The sediment in each core was mostly composed of a silt/clay mixture in Sample 1, becoming sandy in Samples 2 and 3. Clay and sand layers were observed in Samples 3 to 5 at Station 6. Sediment samples were generally dark gray to black in color. Shell hash was observed in Sample 4 at Station 6, all three samples at Station 14, and Samples 2 and 3 at Station 24.

Subsurface sediment samples collected from underneath the piers (Stations 43, 46, and 51) predominantly consisted of mud with abundant shell hash of up to 2 inches in size, especially in Sample 1. A slight oily sheen was observed in Sample 1 at Station 43, whereas oily sludge was observed in Samples 1 through 4 at Station 51. Strong hydrogen sulfide odor was detected in most of the sediment samples from beneath piers. The sediments were generally composed of a silt/clay mixture with varying degrees of sand. Mica flakes were observed in Sample 5 at Stations 43 and 51. The sediments were fine in texture and very soft, grading to denser material at greater depths. Samples varied in color between dark gray and black.

Subsurface sediments collected from Reference Station 40010 consisted of dark brown, cohesive clay, where sampling device refusal was encountered at 2 meters below sea bottom. Subsurface sediments collected from Reference Station 40018 consisted of interbedded sand and clay, varying in color between light gray and black. Shell hash was

VOL 18
0139
R0062748

encountered in Sample 2. Sample 5 consisted of very dense, partially cemented sand. Odors were not detected in the reference station samples.

Subsurface sediment core samples were also analyzed for grain size distribution (Table 4-5). Subsurface sediments in Sample 1 ranged from 8 percent fines at Station 8 to 66 percent fines at Station 24 in West Basin. In Sample 2, sediment fines ranged from 6 percent at Station 8 to 70 percent at Station 14. Sediments at Station 8 had higher sand size particle content in the upper two samples than the other West Basin stations. Station 6, which was sampled to a depth of five horizons, showed a high percentage of sand size particles in Sample 2 and a low percentage of sand size particles in Sample 3. Subsurface sediment grain size data did not show a consistent pattern of change with increasing sample depth.

Subsurface sediments beneath the piers in West Basin had a higher percent of fine grain size than sediments from other West Basin areas. Percent fines ranged from 29 to 62 percent at Station 43 (Pier 16), 32 to 34 percent at Station 46 (Pier 12), and 62 to 87 percent at Station 51 (Pier 2). Sediment core samples taken from Station 46 generally had higher percentages of sand size particles than did the core samples from Stations 43 and 51. Subsurface sediments from beneath the piers had a higher content of gravel size particles than did the subsurface sediments taken from the other West Basin areas, probably due to debris and shell hash present in the samples. Gravel size particle content was higher in Sample 3 than in the upper two or the lower two samples. Gravel size particle content in Sample 3 was 25 percent at Station 43 and 21 percent at Station 51.

Subsurface sediment grain size in West Basin samples showed more variation with increasing sample depth than those from the reference stations. Sediment fines content in core samples ranged from 83 to 99 percent at Reference Station 40010, and from 50 to 65 percent at Reference Station 40018. Grain size distribution at the project reference stations appears to change little with increasing depth of the sample.

Appendix R contains the results of grain size distribution tests, and presents the data in graphical form, as grain size distribution curves.

Subsurface sediment samples were analyzed for TOC (Table 4-5). Results of subsurface sediment TOC analysis in West Basin samples ranged from 0.060 percent for Sample 2 at Station 29 to 0.43 percent for Sample 1 at Station 24. TOC was higher in Sample 1 than Sample 2 at all stations. TOC levels in the top two core samples were lowest at Station 29. At Station 6, TOC percentage decreased with depth of sample, except that Sample 3 had a higher TOC percentage than the other core samples at this station.

Subsurface sediments from beneath the piers showed TOC levels ranging from 0.20 percent for Sample 5 at Station 46 (Pier 12) to 2.4 percent for Sample 3 at Station 51 (Pier 2). Sediment core samples at stations beneath the piers showed a general trend of decreasing TOC with increasing depth of the sample.

TOC levels in surface sediments at the reference stations were 2 percent at Stations 40010.1, 40010.2, and 40010.3; 1 percent at Stations 40018.1, 40018.2, and 40018.3; and 0.4 percent at Station 40032.1. Subsurface sediment levels of TOC ranged from 0.050 percent in Sample 5 at Station 40018 to 3.6 percent in Sample 1 at Station 40010

VOL 18

R0062749

4.3 PROJECT REFERENCE VALUES

The project reference values were calculated from the data collected from the reference stations as presented in this section. Generally, the upper 95 percent predictive limit was used as the project reference value for chemical analytes, while the lower 95 percent predictive limit was used as the project reference value for the toxicity and benthic community data.

4.3.1 Chemical Characteristics

Metals, butyltins, PAHs, pesticides, phthalates, and total sulfide were detected in surface sediment samples collected from the reference stations (Table 4-6). A summary of descriptive statistics for the project reference data is presented in Table 4-7 for chemical analytes that were detected in reference station surface sediment samples. The mean values and 95 percent predictive limits of the chemical analyte concentrations for the reference stations are also listed in Table 4-7.

Maximum levels of arsenic, cadmium, copper, lead, mercury, nickel, silver, and zinc in surface sediment samples from the reference stations exceeded the ER-L values but not the ER-M values. Concentrations of DDE and total DDTs exceeded both the ER-L and the ER-M values. Levels of butyltin, PAH, phthalates, and total sulfide were less than both the ER-L and ER-M values.

Subsurface sediments at Reference Stations 40010.1 and 40018.3 were sampled and analyzed for the chemical compounds listed in Table 3-12. Station 40010.1 had samples from two core horizons, and Station 40018.3 had samples from five core horizons. Concentrations of metals were found in most of these samples (Table 4-8). Higher concentrations of metals generally occurred in Sample 1 compared to the deeper core samples. PAH compounds detected at Station 40010.1 were at higher concentrations in Sample 2 than in Sample 1. No PAH compounds were detected in the Station 40018 core samples. Di-n-octylphthalate and DDE were detected in core samples from Station 40018.3, with highest concentrations in Sample 5. Concentrations of DDE were detected at Station 40010.1 with the highest level in Sample 1.

4.3.2 Toxicity Characteristics

Surface sediments from reference stations were compared to a project-specific reference sediment performance criterion (BNI 1994c, 1995a). This section presents the results of this performance evaluation and then describes the toxicity found at the reference stations.

4.3.2.1 REFERENCE SEDIMENT PERFORMANCE CRITERION

Tables 4-9 through 4-11 present the results of the reference sediment performance criterion evaluation for each of the three bioassays performed for this RI (using echinoderm, amphipod, and polychaete, respectively). Four of the reference stations (40018.1, two field replicates from 40018.3, and 40032.1) equaled or exceeded the 20 percent RPD performance criterion for echinoderm normal development as compared to laboratory control sediment (see Table 4-9). Data from these four samples were excluded

VOL 18
0141
R0062750

from calculating both the mean and 95 percent lower predictive limit of echinoderm normal development in reference samples. All other reference station data were accepted for the echinoderm test.

Two reference station samples (one field replicate from 40010.2 and 40018.1) failed the amphipod bioassay test by exceeding the 20 percent RPD performance criterion for survival as compared to the laboratory control sediment (see Table 4-10). Survival data from these two samples were excluded from further mathematical and statistical evaluation of amphipod bioassay data. All other reference station data were accepted for the amphipod test.

None of the results from the reference station polychaete growth tests met the project-specific RPD performance criterion for reference stations (see Table 4-11). Growth measurements were uniformly greater for polychaetes exposed to the laboratory control sediment than those polychaetes exposed to project reference sediment.

The purpose of comparing the reference station toxicity data to the laboratory control results was to detect "outlier" values within the reference data set. It was expected that such an evaluation would result in the identification of possibly two or three extreme values (outliers). However, it is unusual that the performance at every reference station for a particular bioassay would be greater than 20 percent different from the laboratory control performance. Therefore, the reference sediment performance check for the polychaete growth bioassay clearly did not meet the objectives of the performance criterion. However, the results of the polychaete growth test met other quality control objectives specified in the laboratory SOP. Therefore, the data were retained for evaluation of sediment quality and comparison to West Basin data.

4.3.2.2 TOXICITY DATA

Results of the reference station surface sediment sample bioassay tests are shown in Table 4-12. Mean echinoderm survival ranged from 70.5 percent (Station 40018.3) to 97.7 percent (Station 40018.1). Percent normal development ranged from 80.3 percent (Station 40018.2) to 86.2 percent (Station 40010.3).

Mean survival for the amphipod bioassay ranged from 79.7 percent (Station 40010.1) to 88.5 percent (Station 40010.2). Of those amphipods which survived, percentages of test animals able to rebury in sediment ranged from 93.1 percent (Station 40018.1) to 98.9 percent (Station 40032.1).

Mean polychaete survival ranged from 92 percent (Station 40018.2) to 100 percent (Station 40018.3). Mean growth ranged from 0.056 mg/d (Station 40018.2) to 0.108 mg/d (Station 40010.3). Growth was measured at less than 0.08 mg/d in samples taken from Stations 40018.1, 40018.2, and 40032.1.

4.3.3 Benthic Infaunal Characteristics

The abundance of benthic infaunal organisms was greater at Station 40010 than at the other reference stations (Table 4-13). Numbers of infaunal species were similar at Stations 40010 and 40018, but less than the number of species at Station 40032. Biomass

VOL 18
0142
R0062751

VOL 18

estimates were higher at Stations 40010 and 40032 than at Station 40018. The four diversity indices, Evenness, Dominance, Margalef's Species Richness, and Shannon-Wiener, showed similar patterns where diversity values were lower at Station 40010 and higher at Station 40032.

The predominant species of the benthic infaunal community at Station 40010 were composed primarily of two polychaete worms, *Cossura* sp. A and *Pseudopolydora paucibranchiata*, and two crustaceans, *Euphilomedes carcharodonta* and *Amphideutopus oculatus* (Table 4-14). *Cossura* sp. A and *P. paucibranchiata* are considered indicators of healthy and semi-healthy benthic environments, respectively (Reish et al. 1980). The highest ranking species at Station 40018 were *Cossura* sp. A and *Phoronida*, both indicators of healthy conditions (Reish et al. 1980, Word 1978). Predominant species at Station 40032 included *Metamysidopsis elongata, A. oculatus, Paraprionospio pinnata*, and *Monticellina tesselata*.

The benthic infaunal community indices representing the reference conditions were generally similar to values reported by other studies conducted in the outer LA/LB Harbor (MEC 1995). A summary of benthic infauna community indices for the reference stations is presented in Table 4-15.

4.4 WEST BASIN CHEMISTRY DATA

This section reviews the chemical data collected from within the West Basin during this RI, and provides an assessment of the magnitude and distribution (nature and extent) of chemicals in West Basin sediments. This evaluation was conducted both by general location in the West Basin and also by matrix type (surface sediment, subsurface sediment, fish tissue, clam tissue), and it was intended to provide direct support for the risk assessment process.

The distribution of chemical characteristics of sediments in the West Basin generally appeared to follow a predictable pattern, based on factors such as particle size, as well as possible sediment deposition patterns and proximity to specific shore-based features such as piers, seawalls, ship moorings, and storm water outfalls. Sediments beneath the piers, which were generally composed of fine-grained particles (consisting of higher percent silt and clay), contained greater levels of sulfides, and were higher in organic content than sediments from remaining areas of the West Basin.

4.4.1 Sediment Chemistry

Surface and subsurface sediment samples were analyzed for metals, butyltins, PAHs, PCBs, pesticides, and SVOCs. Surface sediment samples were also analyzed for total sulfide and acid volatile sulfides with simultaneously extracted metals. This section presents the general distribution of chemicals in surface and subsurface sediments of the West Basin by location (individual station) and analyte.

The analytical results indicate the presence of 38 chemicals in West Basin surface sediments, including ten high molecular weight PAHs (HPAH), six low molecular weight

0143

R0062752

PAHs (LPAH), eleven priority pollutant trace metals, two butyltin isomers, one PCB Aroclor, five chlorinated pesticides, phenol, and two phthalate esters.

Detailed results of detected chemical analytes are presented in Table 4-16 for all West Basin stations. Tentatively identified compounds (TICs) reported in surface sediment samples are summarized in Table 4-17. A summary of descriptive statistics for detected chemical analytes from surface sediments in West Basin is presented in Table 4-18 for the basin stations and in Table 4-19 for pier stations.

Concentrations of chemicals in surface sediments from underneath the piers were generally higher than those of the basin stations. Chemicals may have accumulated in sediments beneath the piers because these areas are typically regarded as low energy locations and, therefore, considered to be favorable for deposition. These sediments appear to have remained relatively undisturbed after the piers have been constructed, and numerous activities which occur on or near piers (fueling, loading, painting, and ship repair) likely contributed to discharge of chemicals into the sediments beneath the piers as well as into the overall West Basin.

The surface sediments in areas along the seawall of NAVSTA Long Beach, the LBNSY, and the Navy Mole contained concentrations of chemicals generally higher than those of the central areas of the West Basin. Higher levels of chemicals in surface sediments near the seawall may be related to local storm water drains or discharges associated with activities conducted near the seawall and piers.

Subsurface sediment samples collected in the West Basin were analyzed for metals, butyltins, PAHs, PCBs, pesticides, and SVOCs. Subsurface sediment samples were collected at Stations 6, 8, 14, 24, 29, 43 (Pier 15), 46 (Pier 12), and 51 (Pier 2). The analytical results indicated the presence of 24 chemicals in the West Basin subsurface sediments: eight HPAH compounds, ten metals, two butyltin compounds, two PCB compounds, one chlorinated pesticide, and one phthalate compound. Subsurface sediments beneath the piers contained 37 chemical compounds: ten HPAH compounds, five LPAH compounds, eleven metals, two PCB compounds, five chlorinated pesticides, one phthalate ester, trichlorobenzene, and three dichlorobenzenes. Results of the subsurface sediment analyses are summarized in Table 4-20.

The following sections present the results of sediment chemistry analyses. Surface sediment results are compared to ER-L and ER-M values (Long et al. 1995) and reference station values (upper 95% predictive limit).

4.4.1.1 METALS

Surface and subsurface sediment samples were analyzed for the 13 metals that are listed on the U.S. EPA Priority Pollutant List. Antimony and thallium were not detected in any of the West Basin sediment samples. The sediment samples were also analyzed for three butyltin compounds, including tributyltin which was not detected in West Basin sediments

VOL 18
0144
R0062753

Arsenic

Arsenic was detected in all of the surface sediment samples from the West Basin. Concentrations of arsenic ranged from 7.7 to 15 milligrams per kilogram (mg/kg) in sediments from beneath the piers and from 1.6 to 19 mg/kg in sediments from the basin stations. Higher concentrations were detected in samples from beneath Pier 7, from stations near the seawall along the northern portions of the West Basin, and along the north side of the Navy Mole. The lowest concentrations were reported in sediment samples from Stations 5, 6, and 8 in the northwest area of the West Basin, and from Stations 24, 25, 29, 31, and 32 near the opening to the West Basin (Figure 4-10). Many of the arsenic concentrations exceeded the ER-L value; however, none of the concentrations exceeded the ER-M value, and only three concentrations exceeded the reference station value for arsenic.

Arsenic concentrations in the subsurface Sample 1 sediment ranged from 2.2 mg/kg at Station 29 to 9.1 mg/kg at Station 43 (Pier 15). Concentrations were generally higher in subsurface sediments beneath Piers 15, 12, and 2 (Stations 43, 46, and 51, respectively) than the other subsurface West Basin stations (6, 8, 14, 24, and 29). Arsenic levels were higher in Sample 1 than in the other core samples at most stations. At Station 6, arsenic concentrations were highest in Sample 4. Arsenic levels in subsurface sediments beneath the piers were generally higher in Sample 1 and decreased with depth of the core sample. Subsurface sediment samples taken at reference stations showed arsenic concentrations ranging from 2.2 to 13 mg/kg, with higher concentrations in Sample 1.

Beryllium

Beryllium was detected at all sampling stations in West Basin ranging in concentration from 0.27 to 0.88 mg/kg in surface sediments from beneath the piers and from 0.13 to 1.0 mg/kg in sediments from the basin stations. Beryllium was detected at higher concentrations in samples from beneath some piers and from stations near the seawall and the Navy Mole. However, higher concentrations of beryllium were also detected at Stations 20 and 33 (Figure 4-11). No ER-L or ER-M values are available for beryllium. Three of the beryllium concentrations (Stations 22, 44, and 52) exceeded the reference station value for beryllium.

Beryllium was detected in all subsurface sediment samples and ranged in concentration from 0.12 mg/kg in Sample 2 at Stations 6 and 24 to 1 mg/kg in Sample 1 at Station 43 and Sample 2 at Station 51. Beryllium concentrations at most stations decreased with depth of the core sample. However, at Station 6, Sample 3 had a higher concentration of beryllium than the other core samples. Highest beryllium concentrations in subsurface sediments occurred in the top two samples at Stations 43 and 51, at 1.0 mg/kg. Beryllium was detected in subsurface sediment samples taken at reference stations ranging from 0.24 to 0.77 mg/kg, with concentrations varying with depth of core sample.

Cadmium

Cadmium concentrations were detected in surface sediments at all stations in the West Basin, ranging from 0.078 to 1.0 mg/kg at stations in the basin, and from 0.49 to

VOL 18
0145
R0062754

1.5 mg/kg at stations beneath piers. A spatial distribution of cadmium is illustrated on Figure 4-12 for the basin stations. The higher concentrations of cadmium were reported at stations located along the seawall and Navy Mole and beneath piers. Cadmium concentrations at Stations 50 and 51 exceeded the ER-L value, while none of the concentrations exceeded the ER-M or reference station values for cadmium.

Cadmium levels in subsurface sediments ranged from 0.070 to 0.73 mg/kg in the basin stations (6, 8, 14, 24, and 29). In subsurface sediments beneath the piers (Stations 43, 46, and 51), cadmium concentrations ranged from 0.13 to 2.8 mg/kg. Cadmium concentrations at Station 6 were higher in Sample 3 than in the other core samples. Higher cadmium concentrations at Station 43 were found in Sample 2 and at Station 51 in Sample 3. Subsurface sediment samples collected at reference stations showed cadmium levels ranging from 0.11 mg/kg to 1.8 mg/kg.

Chromium

Chromium was detected in surface sediment samples from all the stations in the West Basin. Levels of chromium ranged from 34 to 330 mg/kg in sediments beneath the piers, and from 9.8 to 88 mg/kg in sediments from the basin stations. Higher concentrations of chromium were detected in samples from beneath the piers, from stations near the seawall along the northern portions of the West Basin, and along the north side of the Navy Mole (Figure 4-13). Concentrations of chromium for two samples (Stations 17 and 48) exceeded the ER-L value, while none of the concentrations exceeded the ER-M value. Chromium concentrations at Stations 17, 21, 22, and 48 exceeded the reference station value for chromium.

Chromium concentrations in subsurface sediment samples ranged from 9.6 mg/kg in Sample 2 at Station 8 to 70 mg/kg in Sample 1 at Station 43 (Pier 15). Chromium was detected in all subsurface sediment samples. Samples taken at stations beneath the piers had higher levels of chromium than in samples from the basin stations. Chromium showed a general trend of decreasing concentration with depth of core sample. However, higher levels of chromium were found in Sample 3 than in the other core samples at Stations 6 and 51 (Pier 2). Chromium was found in subsurface sediment samples from reference stations with concentrations ranging from 16 to 65 mg/kg.

Copper

Copper was detected in surface sediments at all stations in West Basin, ranging in concentrations from 120 to 330 mg/kg in sediments from beneath the piers, and from 13 to 530 mg/kg in sediments from the basin stations. Copper was detected at higher concentrations in samples from beneath the piers, from stations near the seawall along the northern portions of the West Basin, and along the north side of the Navy Mole. The highest copper concentration (530 mg/kg) was reported from Station 17 along the seawall near Piers 2 and 3 (Figure 4-14). Almost all of the copper concentrations reported from the West Basin stations exceeded the ER-L value, while only two concentrations (Stations 17 and 48) exceeded the ER-M value. Copper concentrations at Stations 10, 17, 21, 22,

VOL 18
0146
R0062755

and 27 exceeded the reference station value. Pier stations (43, 48, 49, 51, and 52) showed copper concentrations in excess of reference station values.

Copper was detected in all of the subsurface sediment samples from West Basin stations. Concentrations ranged from 7.3 mg/kg in Sample 2 at Station 24 to 50 mg/kg in Sample 3 at Station 6. Copper concentrations in Sample 1 were highest at Station 24 (45 mg/kg). Subsurface sediment copper concentration at Station 6 was highest in Sample 3 and lowest in Samples 2 and 4. Copper concentration in subsurface sediments at Station 43 (Pier 15) ranged from 35 to 260 mg/kg, decreasing with depth of core sample. Copper levels ranged from 1.7 to 64 mg/kg at Station 46 (Pier 12). The copper concentrations at Station 51 (Pier 2) ranged from 84 to 200 mg/kg, with highest concentrations occurring in Samples 3 and 4. Reference stations showed concentrations of copper in the subsurface sediments ranging up to 98 mg/kg.

Lead

Concentrations of lead were detected at all stations in the West Basin ranging from 54 to 94 mg/kg in sediments from beneath the piers, and from 5.2 to 180 mg/kg in sediments from the basin stations. The higher concentrations of lead were detected in samples from beneath the piers, from stations near the seawall along the northern portions of the West Basin, and along the north side of the Navy Mole. The highest lead concentration (180 mg/kg) was reported from Station 17 along the seawall near Piers 2 and 3 (Figure 4-15). Many of the lead levels exceeded the ER-L value, while none exceeded the ER-M value. Stations along the eastern seawall, the Navy Mole, and beneath most piers showed lead concentrations that exceeded the reference station value for lead.

Subsurface sediments at basin stations were also analyzed for lead, which ranged up to 33 mg/kg in Sample 1 at Station 24. Highest lead levels in Sample 1 were detected at Station 24. Lead levels in Sample 2 ranged up to 7.5 mg/kg. Samples 3 and 4 at Station 6 showed higher levels of lead than the other Station 6 core samples. Subsurface sediment lead concentrations detected in samples taken beneath Piers 15, 12, and 2 (Stations 43, 46, and 51, respectively) ranged from 9.2 mg/kg in Sample 5 at Station 46, to 170 mg/kg in Sample 4 at Station 51. Highest concentrations of lead at Stations 43 and 46 were found in Sample 2, while the highest lead levels at Station 51 were found in Sample 4. Lead concentrations in the subsurface sediment samples were found at the reference stations ranging from 6 to 65 mg/kg.

Mercury

Mercury was detected at all stations in the West Basin, except Station 24 located near the center of the West Basin. Concentrations of mercury ranged from 0.27 to 0.88 mg/kg in sediments from beneath the piers, and from 0.11 to 1.8 mg/kg in sediments from the basin stations. Mercury was detected at higher concentrations in samples from beneath the piers, from stations near the seawall along the northern portions of the West Basin, and along the north side of the Navy Mole. The highest mercury concentration (1.8 mg/kg) was reported from Station 17 along the seawall near Piers 2 and 3 (Figure 4-16). Mercury concentrations at Stations 3, 4, 17, 21, 27, 41, and pier station 47 exceeded the ER-M and

VOL 18
0147
R0062756

reference station values. Almost all of the mercury concentrations exceeded the ER-L value for mercury.

Most of the subsurface sediment samples taken in the West Basin showed no detectable levels of mercury. Mercury was not reported in Sample 2 sediments. Mercury concentrations in Sample 1 ranged up to 0.21 mg/kg at Station 24. Subsurface sediments at Station 6 showed detectable mercury only in Samples 1 and 3. Mercury was detected in all the subsurface sediment samples taken beneath the piers. Concentrations of mercury were highest in Sample 2 at Stations 43 (Pier 15), and decreased with depth of core sample. Mercury concentrations at Stations 46 and 51 (Piers 12 and 2, respectively) increased with depth of core sample until Sample 4. Reference stations showed mercury levels in the subsurface sediments ranging up to 0.86 mg/kg.

Nickel

Concentrations of nickel were detected at all stations in the West Basin ranging from 19 to 35 mg/kg in sediments from beneath the piers, and from 7.8 to 41 mg/kg in sediments from the basin stations. Nickel was detected at higher concentrations in samples from beneath the piers, from stations near the seawall along the northern portion of the West Basin, and along the north side of the Navy Mole. The highest concentration of nickel (41 mg/kg) was reported from Station 22 along the seawall near Piers 1 and 2 (Figure 4-17). None of the nickel concentrations in the West Basin exceeded the ER-M or reference station values. Most of the nickel levels in the basin exceeded the ER-L value for nickel.

Nickel concentrations in the subsurface sediment samples taken in the West Basin ranged from 7.6 mg/kg in Sample 2 at Station 8, to 33 mg/kg in Sample 3 at Station 6. Nickel levels were higher in Sample 1 than in Sample 2 for all West Basin stations. However, Sample 3 at Station 6 contained higher nickel levels (33 mg/kg) than the other core samples at that station. The highest level of nickel in Sample 1 was found at Station 24. Concentrations of nickel at Stations 43, 46, and 51 were slightly higher in Sample 2 than in Sample 1, and decreased with depth of core sample. Nickel was detected in subsurface sediments collected at the reference stations in concentrations ranging from 12 to 63 mg/kg.

Selenium

Selenium was detected in only one surface sediment sample from West Basin stations. Selenium concentration of 1.6 mg/kg was reported at Station 21, located along the northern side of the Navy Mole between Piers 15 and 16. There are no ER-L or ER-M values available for selenium. None of the selenium concentrations exceeded the reference station value for selenium.

Selenium was not detected in any of the subsurface sediment samples taken at basin stations (6, 8, 14, 24, and 29). Selenium was only detected in Sample 3 at Station 43 (Pier 15) and Station 51 (Pier 2). Selenium was not detected in any subsurface sediment sample taken at Station 46 (Pier 12). Selenium was detected in Samples 1 and 2 at the reference stations, ranging from 1.5 to 2.8 mg/kg

VOL 18
0148
R0062757

VOL 18

Silver

Concentrations of silver were detected at all stations in the West Basin, except at Station 24 near the center of the West Basin. Silver concentrations ranged from 1.5 to 4.1 mg/kg in sediments from beneath the piers, and from 1.3 to 19 mg/kg in sediments from the basin stations. Concentrations of silver were higher in samples from beneath Pier 3, from stations near the eastern portions of the seawall, and along the eastern end of the Navy Mole. The highest concentration of silver (19 mg/kg) was reported from Station 26 near both Pier 16 and the Navy Mole (Figure 4-18). All of the silver concentrations exceeded the ER-L value and silver concentrations at four stations exceeded the ER-M value (Stations 17, 26, 28, and 50). Seven basin stations and one pier station showed silver concentrations that exceeded the reference station value for silver.

Silver concentrations in subsurface Sample 1 were higher (2.3 mg/kg) at Station 24 than at Stations 6, 8, 14, or 29. Silver levels were higher in Sample 1 than in Sample 2 for the West Basin stations. The highest level of silver in subsurface sediments at Station 6 was found in Sample 3. Silver concentrations in subsurface sediments at Stations 43, 46, and 51 decreased with increasing depth of core sample. Highest silver levels for Stations 43, 46, and 51 were found in Sample 1 for Station 43 (0.60 mg/kg) and Station 46 (0.40 mg/kg). Silver was found in the subsurface sediment samples collected at the reference stations in concentrations ranging from 0.8 to 2.8 mg/kg.

Zinc

Zinc was detected in surface sediments from all stations in the West Basin ranging from 190 to 620 mg/kg in sediments from beneath the piers, and from 33 to 480 mg/kg in sediments from the basin stations. Zinc was detected at higher concentrations in samples beneath the piers, from stations near the seawall along the northern portions of the West Basin, and along the north side of the Navy Mole (Figure 4-19). The highest concentration of zinc (620 mg/kg) was reported from Station 50 beneath Pier 3. Most of the zinc concentrations exceeded the ER-L value, while two exceeded the ER-M value (Stations 17 and 50) and four exceeded the reference station value for zinc (Stations 17, 48, 50, and 52).

Zinc was detected in all subsurface sediment samples taken from basin stations. Zinc concentrations in Sample 1 ranged from 42 mg/kg at Station 8 to 170 mg/kg at Station 24. Zinc levels were generally greater in Sample 1 than in Sample 2. Station 6 showed a greater zinc level in Sample 3 than in the other core samples at the station.

All the subsurface sediment samples taken beneath the piers showed detectable levels of zinc. Concentrations of zinc were highest in Sample 2 at Stations 43 (Pier 15) and 46 (Pier 12), and decreased with depth of core sample. Zinc concentrations at Station 51 (Pier 2) increased with depth of core sample to Sample 4 which had a peak value of 540 mg/kg. Sample 5 had a zinc concentration less than the upper horizons at Station 51. Subsurface sediment samples taken at the reference stations contained zinc concentrations ranging from 36 to 200 mg/kg. Concentrations of zinc in the reference station samples were higher in Sample 1 sediments than in the other core samples.

0149

R0062758

Butyltin

Monobutyltin (3.6 µg/kg at Station 43) and dibutyltin (2.5 µg/kg at Station 47) were each only detected in one surface sediment sample from the West Basin. Tributyltin was not detected in surface sediments of the West Basin. Dibutyltin was detected at 2.5 µg/kg at one of the seven reference stations, while monobutyltin and tributyltin were not detected at reference stations.

Dibutyltin was detected in only two of the subsurface sediment samples from the West Basin, 3.4 µg/kg in Sample 1 at Station 8 and 4.1 µg/kg in Sample 2 at Station 29. Dibutyltin was not detected in any of the subsurface sediment samples taken beneath the piers. Monobutyltin and tributyltin were not detected in any of the subsurface sediment samples. No dibutyltin was detected in subsurface sediment samples from the reference stations. Tributyltin concentrations were detected in the subsurface sediment samples from the reference stations ranging up to 7.1 µg/kg.

SEM/AVS

Surface sediment samples were analyzed for SEM and AVS. Five divalent cationic metals were measured: cadmium, copper, lead, mercury, and zinc. These data are presented herein as molar concentrations (µmol/g) and evaluated as the molar SEM/AVS ratio. AVS concentrations ranged from 0.13 to 18 µmol/g in sediments from basin stations (Figure 4-20), and ranged from 9.7 to 125 µmol/g in sediments from beneath the piers.

Most of the total SEM/AVS ratios (sum of all SEM metals/AVS) were less than 1 for West Basin stations, but many exceeded a ratio of 1. The highest total SEM/AVS ratios for West Basin surface sediments were at Stations 4, 13, and 17 (Figure 4-21). The lowest ratios of total SEM/AVS were for sediments beneath piers.

SEM copper, lead, and zinc were detected at all West Basin sampling stations, while SEM cadmium and mercury were detected at 53 and 62 percent of the West Basin stations, respectively. SEM cadmium levels were detected in most of the sediment samples from beneath piers ranging from 0.0068 to 0.015 µmol/g, with SEM/AVS ratios less than one. In sediments from the basin stations, SEM cadmium levels were detected at 41 percent of the stations ranging from 0.003 to 0.012 µmol/g, with SEM/AVS ratios less than 1. SEM copper concentrations in sediments from beneath piers ranged from 1.4 to 4.7 µmol/g with SEM/AVS ratios of less than 1. Sediments from basin stations showed SEM copper concentrations ranging from 0.22 to 5.2 µmol/g. SEM copper/AVS ratios at Stations 4, 13, 17, and 24 ranged from 1.0 to 11.

Levels of SEM lead ranged from 0.24 to 0.58 µmol/g in sediments from beneath the piers with SEM/AVS ratios of less than 1. The SEM lead levels in sediments from the basin stations ranged from 0.013 to 0.92 µmol/g, with the SEM/AVS ratio exceeding 1 only at Station 4. SEM mercury levels were detected at 73 percent of the stations beneath piers ranging from 0.00023 to 0.0007 µmol/g, and at 59 percent of the sediment samples from basin stations ranging from 0.0001 to 0.0005 µmol/g. All SEM mercury/AVS ratios were less than 1. SEM zinc concentrations in sediments from beneath piers ranged from 2.3 to 6.3 µmol/g with SEM/AVS ratios of less than 1. Sediments from the basin stations

VOL 18
0150
R0062759

showed SEM zinc concentrations ranging from 0.31 to 8.9 µmol/g. SEM zinc/AVS ratios at Stations 2, 4, 5, 7, 13, 17, 24, and 31 ranged from 1.0 to 15.

SEM/AVS ratios for copper, lead, mercury, and zinc exceeded the reference station values only at Station 4. None of the SEM cadmium/AVS ratios exceeded the reference station value.

4.4.1.2 TOTAL SULFIDE

Total sulfide concentrations of surface sediments from the West Basin ranged from 1.1 to 5,400 mg/kg (Table 4-16). Concentrations of total sulfide were greatest at stations beneath piers (except Station 47), ranging from 3,000 to 5,400 mg/kg. Total sulfide at Station 47 (Pier 9) was similar to other basin stations with a concentration of 360 mg/kg. Concentrations of total sulfide in sediments from the basin stations ranged from 1.1 to 400 mg/kg (Figure 4-22). Subsurface sediments were not analyzed for sulfides. All sulfide concentrations from pier stations exceeded the reference value, except Pier 9 (Station 47).

4.4.1.3 POLYNUCLEAR AROMATIC HYDROCARBONS

Surface sediments from the West Basin were analyzed for 16 PAHs, including ten HPAH and six LPAH compounds. Summary results are presented in Table 4-18 and Table 4-19.

Total PAH concentrations ranged up to 3,940 µg/kg in surface sediments from the basin stations, and up to 23,213 µg/kg in surface sediments from beneath the piers. While most of the surface sediment samples from beneath the piers had concentrations of total PAH greater than 1,000 µg/kg, the surface sediment samples from Stations 42 (Pier 16) and 46 (Pier 12) had no detectable levels. The lowest levels of total PAH were found in samples from the center of the West Basin and near its entrance. Stations near the seawall along the northern portions of the West Basin and along the north side of the Navy Mole had concentrations of total PAH greater than those in sediments from the central area of the West Basin (Figure 4-23). Total PAH concentrations in sediment samples from five stations beneath piers exceeded the ER-L value, while none of the total PAH concentrations exceeded the ER-M value. PAH concentrations from stations along the eastern seawall, the Navy Mole, and beneath piers exceeded the reference station value.

Total HPAH concentrations showed a pattern similar to the total PAH concentrations. The higher levels of total HPAH were found in surface sediment samples from beneath the piers, except that none were found in surface sediments beneath the ends of Piers 12 and 16. Total HPAH levels were not detected at most of the stations near the mouth of the West Basin. Concentrations of HPAH ranged up to 17,620 µg/kg beneath the piers, and up to 3,600 µg/kg in sediments from the basin stations. Stations near the seawall along the northern portions of the West Basin and along the north side of the Navy Mole had concentrations of total HPAH greater than the concentrations in sediments from the central area of the West Basin (Figure 4-24). Concentrations of HPAH in sediments were greater than the ER-L value at most of the stations near piers and beneath piers. HPAH levels in sediments from Stations 43 (Pier 15) and 48 (Pier 7) exceeded ER-M values. Sediment samples from beneath the fuel pier (Pier 12, Stations 44, 45, and 46) showed HPAH concentrations similar to or less than the ER-L value. HPAH concentrations from

VOL 18
0151
R0062760

stations along the eastern seawall, the Navy Mole, and beneath piers exceeded the reference station value.

The HPAH compounds, benzo(a)anthracene, benzo(a)pyrene, benzo(b)fluoranthene, benzo(k)fluoranthene, benzo(ghi)perylene, chrysene, fluoranthene, indeno(1,2,3-cd)pyrene, and pyrene were detected at most (45 to 82 percent) of the West Basin stations. Dibenzo(a,h)anthracene was detected at 15 percent of the stations. Highest concentrations of most of these HPAH compounds were found at Stations 43, 48, 49, and 50 (Piers 15, 7, 6, and 3, respectively). Concentrations of the HPAH compounds were also higher at Stations 10, 17, 21, 41, 51, and 52 than at most of the other basin stations (Figure 4-24). While sediment near piers and beneath piers generally showed higher concentrations of HPAH compounds, sediments from beneath Piers 12 and 16 (Stations 44, 45, 46, and 42) showed low or non-detectable levels of HPAH compounds (less than 1,000 to 1,940 µg/kg).

Total LPAH concentrations did not show a pattern similar to the total PAH and total HPAH concentrations (Figure 4-25). The higher levels of total LPAH were found in sediment samples from beneath the piers. Total LPAH levels were not detected at most of the stations in the central area of the West Basin. Concentrations of LPAH ranged up to 5,593 µg/kg beneath the piers, and up to 340 µg/kg in sediments from the basin stations. Total LPAH levels in sediments from Stations 43, 49, 50, and 51 exceeded the ER-L value, while LPAH in sediments from Station 48 exceeded the ER-M value. The LPAH concentrations at Stations 10, 21, 43, 48, 49, 50, and 51 exceeded the reference station value.

Acenaphthylene, anthracene, and phenanthrene were detected in many of the West Basin sediment samples (33 to 50 percent), while acenaphthene, fluorene, and methylnaphthalenes were only detected in a few of the samples (3 to 11 percent).

Results of subsurface sediment core sample analyses showed that PAHs were detected at three of the five basin stations (Stations 6, 8, and 14). No PAHs were detected in subsurface sediment samples from Stations 24 or 29. PAH compounds were detected in almost all subsurface core samples collected at three stations beneath piers.

Eight HPAHs were detected in Sample 1 at Station 6 ranging from 14 to 68 µg/kg. These HPAHs were benzo(a)anthracene, benzo(a)pyrene, benzo(b)fluoranthene, benzo(k)fluoranthene, benzo(ghi)perylene, chrysene, indeno(1,2,3-cd)pyrene, and pyrene. Sample 2 at Station 6 contained three PAHs at concentrations of 12 µg/kg: benzo(a)pyrene, benzo(b)fluoranthene, and benzo(k)fluoranthene. Three PAHs were detected in Sample 1 from Stations 8 and 14 ranging in concentration from 13 to 27 µg/kg.

PAH compounds were analyzed in core samples taken from stations beneath the piers, Stations 43, 46, and 51 (Piers 15, 12, and 2, respectively). PAHs were found in more subsurface sediment samples and at higher concentrations at stations beneath the piers than at other stations in the West Basin. Ten HPAHs and two LPAHs were detected in the subsurface sediments at Station 43, seven HPAHs and one LPAH were detected at Station 46, and ten HPAHs and five LPAHs were detected at Station 51.

VOL 18
0152
R0062761

Concentrations of detected PAHs in subsurface sediments at Station 43 ranged from 73 µg/kg of anthracene for Sample 1 to 1,200 µg/kg of pyrene for Sample 2. The highest concentrations of seven PAHs at Station 43 were found in Sample 2. These seven PAHs were benzo(a)pyrene, benzo(b)fluoranthene, benzo(k)fluoranthene, benzo(ghi)perylene, indeno(1,2,3-cd)pyrene, pyrene, and anthracene. Highest concentrations of four PAH compounds (benzo(a)anthracene, chrysene, fluoranthene, and phenanthrene) were found at Station 43 in Sample 4. Sample 5 at Station 43 showed no detectable PAHs.

PAHs were only detected in Samples 2 and 4 at Station 46. Concentrations of PAHs in Station 46 subsurface sediments ranged from 34 µg/kg of anthracene in Sample 2 to 210 µg/kg of benzo(k)fluoranthene in Sample 4.

Subsurface sediments at Station 51 had higher concentrations of 12 PAHs in Sample 3 than in the other core samples, ranging from 1,400 µg/kg of fluorene to 17,000 µg/kg of methylnaphthalenes. Benzo(b)fluoranthene and fluoranthene had higher concentrations in Sample 4 than in the other cores, 1,500 and 13,000 µg/kg, respectively. Dibenzo(a,h)anthracene was only detected in Sample 5 at a concentration of 110 µg/kg.

Seven HPAHs (benzo[a]pyrene, benzo[b]fluoranthene, benzo[k]fluoranthene, benzo[ghi]perylene, chrysene, dibenzo[a,h]anthracene, indeno[1,2,3-cd]pyrene) were detected in subsurface sediment samples at the reference stations. Concentrations of the HPAHs at the reference stations ranged from 19 to 130 µg/kg, and were only detected in Samples 1 and 2.

4.4.1.4 POLYCHLORINATED BIPHENYLS

Surface sediment samples were analyzed for concentrations of seven PCB compounds. The only PCB compound detected in any of the surface sediment samples was Aroclor 1260, which was detected in most of the sediment samples, including samples from beneath two piers (Piers 6 and 9). However, it was not detected in sediment samples from five stations near the entrance to the West Basin. Concentrations of Aroclor 1260 ranged up to 390 µg/kg in sediments from beneath the piers and up to 880 µg/kg in sediments from the basin stations. Aroclor 1260 was detected at higher concentrations in samples from stations near the seawall along the northern portions of the West Basin (Figure 4-26). Most stations showed levels of Aroclor 1260 that were above the reference station value and the ER-L value. Fourteen stations showed Aroclor 1260 levels that exceeded the ER-M value. PCB compounds were not detected at reference stations.

Three PCBs (Aroclor 1248, Aroclor 1254, and Aroclor 1260) were detected in subsurface sediment samples. Aroclor 1248 was detected only in Sample 3 at Station 51 (Pier 2). Aroclor 1254 was only detected in Sample 1 at Station 24.

Aroclor 1260 was detected only in Sample 1 at Station 6 for the West Basin stations. In subsurface sediments taken beneath the piers, Aroclor 1260 was detected in Samples 1, 2, and 3 at Station 43 (Pier 15), and in Sample 4 at Station 46 (Pier 12) No PCB compounds were detected at the reference stations.

VOL 18
0153
R0062762

4.4.1.5 PESTICIDES

The analysis of West Basin surface sediments for chlorinated pesticides showed that aldrin, lindane, and DDT were present in a few (2 to 7 percent) of the samples, while DDD and DDE were detected in many of the samples (70 and 100 percent, respectively). Aldrin was only detected in sediments from Station 28 (2.3 µg/kg). Lindane (gamma-BHC) was only detected in sediments from Station 1 (0.63 µg/kg), Station 10 (6.8 µg/kg), and Station 26 (2.5 µg/kg). Aldrin and dieldrin were not detected at the reference stations.

DDE was the only DDT-related compound that was detected in sediments from every station in the West Basin. Concentrations of DDD ranged from 13 to 36 µg/kg in sediments from beneath the piers, and from 1.9 to 42 µg/kg in sediments from the basin stations. DDD concentrations at Stations 16, 17, and 48 exceeded the reference station value. Concentrations of DDE ranged up to 110 µg/kg in sediments from beneath the piers, and up to 180 µg/kg in sediments from the basin stations. DDT was only detected in sediments from Station 16 (34 µg/kg) along the north side of the Navy Mole, at a level that exceeded the reference station value. The highest concentrations of total DDT were detected from stations near the seawall along the northern portions of the West Basin, and along the north side of the Navy Mole (Figure 4-27). While none of the DDE or total DDT concentrations exceeded the reference station values, most of the DDE and total DDT reported from the West Basin exceeded the ER-L and ER-M values.

Four chlorinated pesticides were detected in subsurface sediment samples. These pesticides were delta-benzene hexachloride, endosulfan II, DDD, and DDE. Delta-benzene hexachloride was only detected in Sample 5 at Station 46 (7.0 µg/kg). Endosulfan II was only detected in Sample 2 at Station 43 (37 µg/kg). Delta-benzene hexachloride and endosulfan II were not detected in subsurface sediments at the reference stations.

The DDT derivative, DDD, was detected at subsurface sediment samples taken beneath the piers (3.5 to 44 µg/kg), but not detected in samples taken from the basin stations. Another DDT derivative, DDE, was detected in two Sample 1 sediments at West Basin stations (7.1 to 17 µg/kg), and in all of the samples taken beneath the piers (4.2 to 1,100 µg/kg). At the stations beneath the piers, the DDE concentrations were higher in Sample 3 than in the other core samples. The subsurface sediments at the reference stations showed no DDD, and concentrations of DDE ranging up to 30 µg/kg.

4.4.1.6 SEMIVOLATILE COMPOUNDS

Analysis of surface sediment samples for SVOCs detected phenol, bis(2-ethylhexyl)phthalate, and di-n-octylphthalate. Phenol was detected in two sediment samples from the West Basin, but not at reference stations. Bis(2-ethylhexyl)phthalate was detected in one surface sediment sample. Di-n-octylphthalate was found at 17 of the 45 West Basin stations. Highest concentrations of phenol and di-n-octylphthalate were found in sediments collected beneath the piers. Bis(2-ethylhexyl)phthalate and di-n-

VOL 18
0154
R0062763

octylphthalate concentrations at West Basin stations did not exceed the reference station values.

Bis(2-ethylhexyl)phthalate was detected in two core samples at Station 43 (180 and 740 µg/kg) and one core sample at Station 51 (580 µg/kg). Di-n-octylphthalate was only detected in Sample 5 at Station 6 (37 µg/kg). Subsurface sediments at the reference stations showed no bis(2-ethylhexyl)phthalate, and di-n-octylphthalate concentrations ranging up to 84 µg/kg.

Four chlorobenzenes, 1,2,4-trichlorobenzene, 1,2-dichlorobenzene, 1,3-dichlorobenzene, and 1,4-dichlorobenzene, were detected only at Station 51 (Pier 2). Concentrations of all four chlorobenzenes were higher in Sample 3 (8,000 to 60,000 µg/kg) than in the other core samples. None of the chlorobenzene compounds were found in subsurface sediments at reference stations.

4.4.1.7 TENTATIVELY IDENTIFIED COMPOUNDS

TICs from the semivolatile organics analyses were reported for surface sediment samples collected at the West Basin and Reference Stations. Results are summarized in Table 4-17. TICs generally consisted of various PAH isomers commonly generated from the combustion or degradation of fossil fuels. The most prevalent PAH compounds identified in the sample results were benzo(e)pyrene and perylene. The distribution of TICs in the West Basin was similar to distribution of PAHs discussed earlier. Concentrations of TIC analytes were less than the concentrations of PAHs.

4.4.2 Bioaccumulation Data

This section discusses the bioaccumulation data obtained from analyses of tissue samples taken from fish caught in trawl samples, and from laboratory bioaccumulation clam tissue analyses.

4.4.2.1 FISH TISSUE ANALYSES

California halibut and white croaker whole body and fillet samples were analyzed for lipid content, metals, butyltins, PAHs, PCBs, and pesticides. Bile samples collected from California halibut gall bladders were analyzed for parent PAH homologues. Visual observations of each fish retained for analysis are presented in Table 4-21. Overall fish assemblages captured in West Basin and at reference stations are listed in Table 4-22.

Because the two fish species collected are mobile and likely to move about within the West Basin, the analytical results of samples taken from the seven West Basin fish collection transects were "pooled" for data analyses for each of the fish species. Similarly, the analytical results of samples taken from the two reference station fish collection transects were pooled.

California Halibut

The results of tissue chemistry analyses for chemicals which were detected in at least one sample for California halibut fillets and whole body samples are shown in Table 4-23 and

VOL 18
0155
R0062764

Table 4-24, respectively, for both the West Basin and the reference stations. In general, chemical concentrations in whole body samples were higher than in fillet samples and a greater number of analytes were detected. Two analytes, dibutyltin and tributyltin, were detected in West Basin fillets but not in reference station fillets. Both locations showed only one detection of each of these two analytes at a very low level (both at 1.4 µg/kg). Likewise, selenium was only detected in a single West Basin whole body sample (0.9 mg/kg) and not in reference station whole body samples. Selenium was detected in one reference station fillet sample (0.7 mg/kg), and nickel was detected in two reference station whole body samples (mean = 2.5 mg/kg), but neither analyte was found in West Basin fillet samples.

There were no consistent pattern of analyte concentrations between the West Basin and reference station samples (i.e., the West Basin had greater concentrations for some analytes and the reference stations had greater concentrations for other analytes). An ANOVA statistical comparison of the West Basin California halibut whole body samples with reference station whole body samples, and of the West Basin fillet samples with reference station fillet samples, did not detect any statistically significant difference for any analyte.

White Croaker

The results of tissue chemistry analyses for analytes which were detected in at least one white croaker fillet sample and whole body sample are shown in Tables 4-25 and 4-26, respectively, for both the West Basin and the reference stations. There was no consistent pattern of analyte concentrations between the fillet and whole body samples. Several analytes were found in West Basin samples of fillet (endosulfan II, endrin, copper, lead, selenium, and zinc) and whole body (alpha-BHC, endrin, dibutyltin, beryllium, and chromium), but not in corresponding reference station samples. All of the analytes found in the reference station samples were also found in West Basin samples.

An ANOVA statistical comparison of the West Basin whole body samples with reference station whole body samples, and of the West Basin fillet samples with reference station fillet samples, detected a few statistically significant differences. Mercury concentrations in West Basin white croaker fillet statistically exceeded the reference station concentrations. West Basin whole body concentrations exceeded reference station samples for tributyltin, arsenic, and copper. The reference station samples statistically exceeded West Basin samples for fillet tributyltin and whole body zinc concentrations.

4.4.2.2 FISH BILE ANALYSES

The results of gall bladder bile analyses for the twelve California halibut samples collected from the West Basin and the six California halibut samples collected from the reference station trawls are presented in Table 4-27. Bile contains metabolites of chemicals the fish may have been exposed to, and the analytical technique provides chemical-equivalents for these PAH compounds (i.e., two-, three-, four-, and five-ring metabolites, represented by naphthalene, phenanthrene, pyrene, and benzo(a)pyrene). The metabolite concentrations decreased with increasing PAH ring size. The lowest concentrations in the bile samples

VOL 18
0156
R0062765

were measured for benzo(a)pyrene equivalent metabolites, with a range of 1.9 to 58.8 µg/mL.

The PAH metabolite chromatographs were reviewed for major resolved peaks to attempt some identification of individual metabolite compounds. A set of six commonly occurring peaks were identified by retention time for each analysis; however, the results were qualitative. These peaks may be metabolites of the PAH for which the analyses were performed, but could also be other endogenous aromatic compounds responding in the analysis. Analyte identification and additional information on the identity of the compounds producing the major components of the chromatograph is beyond the scope of this RI report.

An analysis of the PAH metabolite ratios showed some sample-to-sample variability, suggesting that some samples came from fish that may have been proportionately more exposed to petrogenic sources of PAH than others. The naphthalene/phenanthrene ratio was fairly constant from sample to sample, suggesting that the sources of PAH may have similar relative compositions of these two PAHs for all 18 samples; they both likely originated in various petroleum products. Similarly, the pyrene/benzo(a)pyrene ratio was quite constant throughout, indicating that the source of the pyrogenic product likely had a fairly similar relative composition of these two PAHs.

An ANOVA performed on the West Basin and reference station results showed no statistically significant difference between the two sample groups for any of the four PAH metabolite levels.

4.4.2.3 CLAM BIOACCUMULATION RESULTS

After exposure to sediment samples collected from the West Basin and reference stations for the purposes of laboratory clam bioaccumulation tests, clam (*Macoma nasuta*) tissue was analyzed for lipids, metals, butyltins, PAHs, PCBs, and pesticides. Chemicals detected in the clam tissue analyses are summarized in Table 4-28.

All of the chemicals detected in West Basin clam bioassay tissue samples were also detected in reference station samples with the exception of pyrene. Thallium and pyrene were not detected in clam bioassay tissue samples for the basin stations, and chromium and thallium were not detected in clams exposed to pier station samples.

Statistical comparisons (ANOVA) were performed for the three groups of clam bioassay results: reference station, basin stations, and pier stations. There were no statistical differences among the three test areas for any analyte. Pyrene, which was not found in the clams exposed to reference station sediment samples, did not demonstrate a statistically significant difference at the reference stations compared to the basin and pier stations.

4.5 BIOLOGICAL CHARACTERISTICS

West Basin surface sediment samples were characterized for biological response estimates of sediment quality using three toxicity bioassays and a benthic infauna study.

VOL 18
0157
R0062766

4.5.1 Sediment Toxicity

This section describes the results of the laboratory toxicity testing and also summarizes the statistical analysis of bioassay test results. An assessment of the distribution of sediment toxicity within the West Basin, and the results of bioassay data evaluation, conducted on a station-by-station basis, are provided below.

4.5.1.1 DISTRIBUTION OF SEDIMENT TOXICITY

Results of the surface sediment bioassay tests are summarized in Table 4-29: percent survival and percent normal development for the echinoderm larva, percent survival and percent reburial for the amphipod, and percent survival and rate of growth for the polychaete.

Basin Stations

Survival and normal development of echinoderm larvae were repressed when exposed to pore water from most of the basin stations, especially pore water from stations located at the western area of and the entrance to the West Basin. Overall, there were no basin stations at which 100 percent normal development occurred, while samples from numerous basin stations exhibited 0 percent normal development (Stations 2, 4, 6, 7, 14, 17, 24, 25, and 31). In addition, normal development of echinoderm larval organisms occurred at a frequency of less than 80 percent when exposed to pore water collected from the following basin stations: 1, 5, 8, 9, 12, 13, 15, 16, 32, 33, and 41. Echinoderm survival ranged from 32 percent (Station 5) to 100 percent.

Amphipod survival ranged from 57 percent (Station 41) to 98.8 percent (Station 11). Amphipod reburial ranged from 77.9 percent (Station 41) to 100 percent (Stations 9, 19, and 24).

Polychaete survival ranged from 84 percent (Stations 21 and 24) to 100 percent. No mortality occurred at approximately one-third of the basin sampling Stations: 1, 2, 4, 12, 14, 19, 23, 25, 27, 28, and 41. Growth rates ranged from 0.066 mg/d (Stations 21 and 28) to 0.134 mg/d (Stations 1 and 24).

Pier Stations

Adverse biological response occurred with both amphipod survival and the echinoderm larvae development when these organisms were exposed to sediments from nearly all stations located underneath piers. Echinoderm survival ranged from 36.3 percent (Station 45, Pier 12) to 91 percent (Station 48, Pier 7). All pier stations resulted in less than 80 percent echinoderm survival except for Stations 43 (Pier 15), 44 (Pier 12), and 48 (Pier 7). All stations from underneath the piers resulted in less than one percent normal development.

Survival for the amphipod bioassay ranged from 16.3 percent (Station 44) to 83 percent (Stations 47 and 52), with survival less than 80 percent occurring from exposure to all pier samples, except for Stations 47 and 52. Amphipod reburial ranged from 24.6 percent (Station 44, Pier 12) to 96.2 percent (Station 43, Pier 15). Reburial was less than 80

VOL 18
018
R0062767

percent for the following Stations: 42 (Pier 16), 44, 45, and 46 (Pier 12), 48 (Pier 7), and 49 (Pier 6).

Polychaete survival ranged from 76 percent (Station 48, Pier 7) to 100 percent (Station 50, Pier 3). Polychaete growth rates were highest when exposed to sediments collected from underneath the piers, most likely due to higher TOC and nutrient levels from those sediments. Growth ranged from 0.083 mg/d (Station 47, Pier 9) to 0.187 mg/d (Station 43, Pier 15).

4.5.1.2 EVALUATION OF SEDIMENT TOXICITY

After omitting data from those reference stations which "failed" the reference sediment performance criterion (Tables 4-9 through 4-11), the RPD was calculated for echinoderm survival and normal development, amphipod survival and reburial, and polychaete survival and growth between West Basin stations and mean reference station data. West Basin bioassay data were also statistically compared to the reference station values to assess whether West Basin toxicity levels were statistically significant relative to reference station toxicity levels. Tables 4-30 through 4-32 provide the results of toxicity determination for West Basin sediments using echinoderm, amphipod, and polychaete bioassays, respectively.

Only West Basin bioassay data that met both criteria were considered a "hit," meaning they were significantly different and mathematically different from reference stations. The distribution of bioassay "hits" findings for the West Basin bioassays are presented on Figures 4-28 through 4-33. Echinoderm larval development "hits" were found at approximately 70 percent of the West Basin stations and were primarily located underneath the piers, in the northwest corner of West Basin, and at the West Basin entrance (Stations 24, 25, 31, 32, and 33). Locations of stations which showed echinoderm development "hits" were also scattered within the basin, along the LBNSY seawall, and along the northern edge of the Navy Mole. Echinoderm survival "hits" were localized at the middle-northern seawall (Stations 13 and 17), Piers 12 (fuel pier) and 16, and the northwest corner of and entrance to West Basin. About 5 times fewer "hits" resulted from the solid phase bioassays than from the pore water bioassays. The amphipod bioassay "hits" were located at stations underneath Piers 16, 12 (fuel pier), and 7, and at Station 41 (survival only), which is next to the fuel pier and close to the seawall. The only polychaete bioassay "hit" (survival) occurred underneath Pier 7 (Station 48).

4.5.2 Benthic Infauna

Benthic infaunal invertebrates, collected at the same locations of and at the same time with the collection of surface sediment samples from the West Basin, were analyzed to identify and describe the community of invertebrate animals living in or on the West Basin surface sediments. The benthic community analysis report, prepared by MEC Analytical Systems, Inc., the laboratory that conducted this analysis, is included as Appendix N. The West Basin samples contained greater than 20,000 organisms representing 352 taxa (species or species group). The results of the benthic infauna analysis are presented herein as indices of the invertebrate community structure, including abundance, number of taxa, and

VOL 18
0159
R0062768

diversity. These indices are summarized in the following sections. The benthic infaunal community indices and major taxonomic groups are presented in Table 4-33; summary statistics are presented in Table 4-34 for the basin and in Table 4-35 for pier stations. Surface sediment spatial distributions of benthic infaunal invertebrates, illustrating abundance and number of species, are shown on Figures 4-34 through 4-41.

The most apparent feature of the benthic infauna data is the difference between the invertebrate communities at the basin stations in comparison to the communities at the pier stations. Despite high sediment sulfide content and an associated low dissolved oxygen level at pier stations, the invertebrate community appeared very diverse with a large number of animals.

4.5.2.1 ABUNDANCE

The abundance values (number of individuals) of organisms found per sample ranged from 14 to 1,856 for the basin, and from 428 to 4,264 for stations beneath piers (Table 4-36). Generally, benthic organisms were more abundant in samples collected from beneath the piers than in samples collected within the basin. The large abundance values for the basin stations were reported for Station 5 and for stations beneath the piers. The largest abundance value of 1,856 for Station 5 appears to have been influenced by the presence of a great many polychaete worms of one species (*Pseudopolydora paucibranchiata*). The lowest abundance values reported for Stations 9, 10, 11, 12, 15, 16, 18, 19, and 20, near the central portions of West Basin, were greater than the reference station values. Mean abundance for the pier stations was 1,360, while the mean abundance for the remainder of the West Basin stations was 157.

4.5.2.2 NUMBER OF TAXA

Individual organisms found in each sample were identified to the lowest or most specific taxonomic level possible. The term "taxa" is used to indicate the taxonomic identifications assigned to organisms, whether the identification is to species, genus, family, or other taxonomic level.

The mean value of the number of taxa was greater for stations beneath the piers (72) than for the remainder of stations in West Basin (31). Number of taxa values were higher for stations near the entrance to the West Basin than at other stations within the West Basin. The number of taxa values were low (less than the reference station value) for stations near the central portions of West Basin: Stations 9, 10, 12, and 15.

4.5.2.3 BIOMASS

Biomass values, the wet weight of all organisms found in the sample, were higher for stations beneath the piers than for the remainder of stations in West Basin. Mean biomass was 83 g for pier stations and 4.0 g for the remaining stations. Low biomass values were reported for stations near the central portions of West Basin (Stations 9, 15, 16, and 20) and for stations along the LBNSY seawall (Stations 1, 10, 27, and 28). High biomass values were reported for Station 22 near the seawall of the LBNSY; Stations 4 and 26

VOL 18
0160
R0062769

along the Navy Mole, Stations 19 and 25 in the central portions of the West Basin, and at Stations 31 and 33 near the entrance to the West Basin.

4.5.2.4 DIVERSITY INDICES

Dominance, Evenness, Margalef Species Richness, and Shannon-Wiener diversity indices were calculated for each of the West Basin benthic infaunal invertebrate samples. Because these indices are calculated from the number of species and the abundance of each species, their values often reflect patterns of forces that are affecting the benthic community. The Margalef's diversity is more sensitive to a greater number of species, while Dominance, Evenness, and Shannon-Wiener are more sensitive to an even distribution of species abundance.

Dominance

Dominance is a diversity index estimating the species distribution in a sample. A larger dominance value often represents a balanced species distribution, while a smaller dominance value often represents a species distribution that is dominated by a few abundant and opportunistic species.

Dominance values for stations within the basin were generally similar for stations beneath the piers and for the reference station values. The highest dominance values were reported from stations near the entrance to West Basin. The lowest dominance value reported was from Station 5, which was possibly influenced by a large number of polychaete worms (*Pseudopolydora paucibranchiata*) which were found in the samples.

Evenness

Evenness is also an index of diversity within a sample. Evenness values for samples from within the basin and from beneath the piers were generally similar to the reference station values. Stations beneath the piers showed lower Evenness values than the other stations within West Basin. Station 5 in the northwest area of West Basin and Station 46 beneath Pier 12 showed the lowest Evenness values (less than the project reference value).

Margalef Species Richness

The Margalef diversity index is more sensitive to a greater number of species in the sample than to an equitable distribution of abundance among the species. Margalef Species Richness values were similar between the reference station values and most of the West Basin stations. However, several stations located at the entrance to West Basin and beneath a few of the piers showed a greater diversity than the reference station value.

Shannon-Wiener

The Shannon-Wiener diversity index, which is biased toward uniform distribution of species abundance, was similar between most of the West Basin stations and the reference station value. Similar to other diversity indices, a greater Shannon-Wiener diversity was reported for stations near the entrance to West Basin and for a few pier stations. Lower

VOL 18
0161
R0062770

Shannon-Wiener diversity was reported for some stations near Pier 12 (Stations 9, 12, 15, 16, and 46) and for Stations 5 and 10 along the LBNSY seawall.

4.5.2.5 SPECIES COMPOSITION

A total of 352 taxa were identified in the sediment samples collected from the West Basin. Sediment quality can often be described in terms of the types of animals found or even, in some cases, the presence of certain species (Pearson and Rosenberg 1978, Gray 1989).

Sample appearance at pier stations was different from the remaining West Basin stations because of the shell hash material that was present in the samples from beneath the piers. The shell hash material provides a more complex environment for benthic organisms, as well as providing a hard substrate material for the organisms to grow on, than the typical soft mud bottom observed in the rest of the West Basin. The difference in bottom or substrate types leads to a difference in benthic community, as noted above for abundance, number of species, and diversity.

Benthic organisms found at pier stations that are typically associated with hard substrates include the mussel *Mytilus galloprovincialis* and slipper shells of the genus *Crepidula*, the crustaceans *Grandidierella japonica* (amphipod) and *Tanais* sp., polychaetes of the genus *Sabellaria* and *Spirorbis*, the tunicate *Ascidia ceratodes*, and various hydroids.

The stations beneath piers showed higher numbers of species, greater abundance, and greater biomass than the non-pier and reference stations for each of the major taxonomic groups, crustaceans, polychaete worms, mollusks, echinoderms, and other phyla. Non-pier station samples contained similar abundance and numbers of species as the reference stations, except for crustacean abundance, molluscan abundance, and molluscan number of species.

Earlier studies of West Basin infaunal communities (Hill and Reish 1975, Reish et al. 1980) have described patterns of community response to stress conditions and species that are indicative of certain benthic conditions. The presence of indicator species contributes to the understanding of benthic conditions; however, all indices of the benthic community must be considered to achieve the best data interpretation.

For example, the greatest abundance of the polychaete worm, *Capitella capitata*, which is an indicator of stressed benthic conditions such as organic enrichment or low oxygen content, was found at pier stations. However, pier stations also represented the greatest number of species, greatest abundance, and greatest diversity indices. Although the presence of *Capitella capitata* can be interpreted to indicate stressed conditions beneath the piers, the level of stress is not sufficient to cause an adverse impact on the overall health of the benthic community as measured by species richness and species diversity. A few *Capitella capitata* were found at three of the non-pier stations (5, 25, and 41).

Basin Stations

Benthic communities found in samples taken from the basin stations were characterized by the predominance of five polychaete worms, *Monticellina tesselata*, *Cossura* sp. A, *Aphelochaeta multifilis* Type 2, *Chaetozone corona*, and *Paraprionospio pinnata* (Table

VOL 18
0162
R0062771

4-36). The predominance of these species suggests a healthy to semi-healthy benthic environment.

Pseudopolydora paucibranchiata, a polychaete worm often indicative of semi-healthy areas (Reish et al. 1980), was only abundant at three basin stations, which were located in the northwest section of the West Basin. The presence of a large number of *P. paucibranchiata* at Station 5 caused this worm to be ranked as the most abundant species found in the West Basin. Two polychaete worms indicating healthy conditions, *Monticellina tesselata* and *Aphelochaeta multifilis* Type 2, were abundant at basin stations, frequently ranking among the three most abundant species identified at any station. The polychaete worm, *Cossura* sp., an indicator of healthy conditions, was one of the most abundant species in the basin samples, except that it was absent or in low abundance at stations along the LBNSY seawall, near the eastern section of the Navy Mole, and at Stations 32 and 33. Two polychaete worms that are indicators of semi-healthy benthic environments, *Chaetozone corona* and *Paraprionospio pinnata*, were abundant at most of the basin stations. One crustacean was abundant at basin stations: *Amphideutopus oculatus*.

Pier Stations

The invertebrate communities found at pier stations were generally represented by species associated with hard substrates, indicator species of semi-healthy conditions, and indicator species of stressed conditions. Because of the hard substrate present beneath the piers (shell hash), the benthic community is very complex compared to areas of soft mud. Therefore, comparisons among the pier stations, basin stations, and reference stations are difficult at best.

Epifaunal organisms associated with hard substrate ranked high at all pier stations, but ranked the highest at Station 42 beneath Pier 16, and Stations 44 and 45 beneath Pier 12. These organisms are often referred to as a "fouling" community because these are the species that will attach to and grow on any item placed in harbor waters. Species of this group that ranked high at pier stations include *Crepidula dorsata* and *C. onyx* (slipper shells), *Cumingia californica* (clam), *Kellia laperousii* (clam), *Cirratulus cirratus* (worm), *Grandidierella japonica* (amphipod), *Mytilus galloprovincialis* (mussel), and *Chone minuta* (worm). These species were almost exclusively found at pier stations and not at basin or reference stations.

Indicator species of semi-healthy benthic conditions (the polychaete worms *Exogone lourei*, *Schistomeringos rudolphi*, *Pseudopolydora paucibranchiata*, and *Mediomastus* sp.) were present at all of the pier stations. *Pseudopolydora paucibranchiata* and *Mediomastus* sp. also ranked high in abundance at reference stations. Indicators of stressed conditions (oligochaete worms, nematode worms, and *Capitella capitata*, a polychaete worm) ranked high in abundance at most of the pier stations, except at Station 42 (Pier 16) and Stations 44 and 45 (Pier 12).

R0062772

4.6 SEDIMENT EVALUATION ZONES

SEZs were developed as groups of West Basin stations for the purpose of describing discrete subareas within the West Basin due to the similar physical and chemical properties of individual sampling stations. For this reason, SEZs were selected as the basic subareal unit for ecological risk assessment purposes, as described in the RAWP (BNI 1995a). In addition, the SEZ approach provided multiple stations for each SEZ, thereby allowing a more robust statistical analysis as compared to single stations. A multivariate statistical process was used to analyze the physical and chemical data at each of the West Basin stations and show groupings of stations with similar characteristics.

Once the sampling stations with similar physical and chemical properties were identified, West Basin SEZs were assessed according to chemical concentrations and biological responses (i.e. toxicity and benthic infauna).

4.6.1 Establishing Sediment Evaluation Zones

Cluster analysis, a multivariate statistical technique, was used to evaluate the physical and chemical data acquired from West Basin surface sediment stations. Physical data included grain size as percent fines and TOC. The chemical data included chemical analytes that were detected in at least 50 percent of the West Basin stations. Twenty-four variables (analytes) were used in the cluster analysis: fines, TOC, total sulfide, ten metals, eight PAHs, two pesticides, and one PCB.

A dissimilarity matrix was calculated from these data using the Bray-Curtis method. The dissimilarity matrix was evaluated by the cluster analysis technique, which calculated theoretical distances between stations and groups of stations. The results of the cluster analysis were displayed on a tree diagram figure (dendrogram) that illustrated the grouping patterns among the stations. Results of the cluster analysis were also displayed in a two-way table that showed the relative concentration of each chemical analyte per station. Relationships among the physical and chemical properties were also evaluated and presented as dendrograms.

The extent of the horizontal area represented by any individual station was determined by a Thiessen polygon method. Generally, this method identifies an area around a station bounded by the sides of a polygon that are drawn at one half the distance to adjacent stations. A detailed description of this procedure is presented in a Status Report prepared by PTI Environmental Services (PTI 1991).

The advantage of using the cluster analysis process to determine SEZs was that the analytical data derived from the sediment samples provided the basis of establishing the SEZs. This process reduced bias that may have been introduced from factors that the project did not measure, such as sedimentation rates, and from analyst interpretations.

The results of the cluster analysis indicated eight SEZs (labeled as SEZs A through H on Figure 4-42). SEZ A consists of six stations near the entrance to the West Basin and SEZ B consists of four stations in the northwest area of the West Basin. SEZ C consists of nine stations representing part of the northwest and central portions of West Basin, and

VOL 18
0164
R0062773

areas near the LBNSY seawall and Navy Mole adjacent to the West Basin entrance. SEZ D consists primarily of the western West Basin area near the marina. SEZ E consists primarily of West Basin areas near piers (Piers 1, 2, 3, and 6), but also includes one area along the mid-length of the Navy Mole adjacent to Pier 12, and the area beneath Pier 9. SEZ F is comprised of two areas near Piers 3 and 6 adjacent to the LBNSY seawall and one area near Pier 15 adjacent to the Navy Mole. SEZ G represents the areas beneath Piers 1, 2, 12, and 16. SEZ H represents the areas beneath Piers 3, 6, 7, and 15. Figure 4-43 presents the West Basin SEZs on a site plan.

Station 24, near the entrance to the West Basin, did not group with any of the other stations and therefore, is not included in any of the SEZs. Station 24 was different from all other stations, showing no detectable chemical concentrations and a coarser grain size than the other stations.

The pattern of SEZ station groupings in the form of two-way result of cluster analysis with physical and chemical patterns are presented on Figure 4-44, where relative concentrations for the analytes are also shown. For example, total sulfide is apparent as an important constituent of pier sediments (Stations 42 through 52).

The pattern of SEZs apparent from the cluster analysis of sediment chemical and physical properties is generally similar to the study areas identified in the Work Plan (JEG 1993a) that were based on suspected sediment depositional patterns. Both patterns describe a transition of sediment condition with distance (east to west) into the West Basin, and a difference between basin area sediments and sediments beneath the piers. The SEZs presented herein were influenced by chemical and physical data patterns that were probably affected by other conditions in addition to sediment depositional rates such as discharge pipe and pier locations. Because the cluster analysis procedure reflects actual measured sediment quality, the SEZs display patterns that result from the combined influences on basin sediment quality. The SEZs show gradients in sediment quality with distance into the West Basin and with proximity to piers and general areas of discharge outfalls into West Basin.

The cluster analysis procedure was repeated, this time including the reference stations (Figures 4-45 and 4-46). The resulting SEZs were identical to the pattern developed excluding reference stations, as described earlier. Reference Stations 40010.1, 40010.2, and 40010.3 grouped together with SEZs C and D. Reference Stations 40018.1, 40018.2, and 40018.3 grouped together with SEZ A. Reference Station 40032.1 grouped together with Station 24.

Mean values of sediment quality parameters were compared among the eight SEZs and the reference stations using ANOVA procedures. The data were tested for homogeneity of variances (homoscedasticity) using Levene's test prior to the ANOVAs. If the data failed Levene's test, the data were logarithmically transformed ($\log_{10}$ [x+1]) and tested for homogeneity of variances again. If the transformed data failed Levene's test, then the data were rank-transformed and tested by ANOVA (equivalent to the non-parametric Kruskal-Wallis test). Significant differences among the means for α=0.05 were tested using Tukey's HSD method, a multiple comparison test.

VOL 18
0165
R0062774

4.6.2 Sediment Physical Characteristics

A summary of the surface sediment physical characteristics is presented for SEZs A through H in Table 4-37. Surface sediment physical parameters, grain size, and TOC were evaluated among the SEZs by ANOVA tests.

SEZ F had the greatest percentage of fine grained sediment (87 percent) and was significantly different from SEZs A, B, and D, which showed the lowest amount of fine grained material (45 to 59 percent). Results of the ANOVA showed that sediment percent fines for the reference stations were not different from the percentage of fines at any of the SEZs.

Clay size particle content was greatest beneath the piers at SEZs G and H and lowest at SEZ B. Silt size particle content did not show a pattern similar to clay size particle content. SEZs G and H showed a lower silt size particle content than most other SEZs. Sand size particle content was highest at SEZs A and B and lowest at SEZs G and H. The percentage of sediment particles in the gravel size or larger was greatest at SEZs G and H, probably due to the shell hash material in the sediment samples. Median and mean grain size values show that SEZs A and B contained the coarsest size sediments, while SEZ F contained the finest size sediments.

TOC was significantly higher at SEZs F, G, and H than at the other SEZs. TOC for the reference stations was similar to the TOC levels at most SEZs, except that TOC was higher at the reference stations than at SEZs A and B.

4.6.3 Sediment Chemical Data

Descriptive statistics of detected chemical analytes are shown in Table 4-38 for each of the SEZs. A summary of mean analyte concentrations for West Basin SEZs is shown in Table 4-39. Mean values of analytes were compared among the SEZs and the reference stations by ANOVA with a Tukey multiple comparison test. Mean analyte concentrations exceeding the mean reference concentrations are shown in Table 4-40 by SEZ. Sediment ER-L values were compared to the 95% UCL for each chemical analyte by SEZ. Mean analyte concentrations exceeding mean reference concentrations and the ER-L values are shown in Table 4-41 by SEZ.

None of the pesticides (aldrin, lindane, DDD, DDE, DDT) or SVOCs (phenol, bis[2-ethylhexyl]phthalate, di-n-octylphthalate) were significantly greater at the SEZs than at the reference stations.

Metals concentrations were generally greater at SEZs representing sediments beneath and adjacent to the piers. Cadmium, nickel, selenium, and silver concentrations were not significantly different at any of the SEZs than the concentrations at the reference stations. Concentrations of arsenic, beryllium, copper, lead, mercury, and zinc were higher at SEZ F than for the reference stations, and exceeded ER-L values. Chromium, copper, lead, zinc, and monobutyltin levels were higher at SEZ H than for the reference stations, and also exceeded ER-L values.

VOL 18
0166
R0062775

Results of the ANOVA showed that almost all of the PAH compounds at SEZ H, which represents the area beneath Piers 3, 6, 7, and 15, were at significantly greater concentrations than for the reference stations. Most of the PAH compounds at SEZ H also exceeded the ER-L values.

SEZs E, F, and G had concentrations of several PAH compounds that were significantly higher than the reference stations as well as exceeding the ER-L values. SEZ D had concentrations of several PAH compounds that were significantly higher than the reference stations, but only total HPAHs exceeded the ER-L as well. None of the PAH concentrations at SEZs B and C exceeded those at the reference stations, and none were greater than the ER-L values. None of the PAH concentrations detected at SEZ A were greater than those at the reference stations.

PCB concentrations (as Aroclor 1260) in West Basin sediment samples, except at SEZs A and G, were significantly greater than the reference stations and exceeded the ER-L value. Aroclor 1260 was found at sampling stations within all SEZs, except for SEZ G, the area beneath Piers 1, 2, 12, and 16. The highest level of Aroclor 1260 among the SEZs was at SEZ F.

4.6.4 Sediment Toxicity

The mean response for each bioassay is presented in Table 4-42 for the SEZs and reference stations. The distribution of biological response among SEZs did not appear to follow any specific pattern (i.e., no single SEZ consistently had the lowest or the highest adverse biological response across the three bioassays). However, percent survival (echinoderm, amphipod, and polychaete), echinoderm normal development, and amphipod reburial were generally lower at the pier SEZs (SEZs G and H). In addition to the pier SEZs, SEZ B and Station 24 exhibited lower echinoderm survival and normal development as compared to the other SEZs. Polychaete growth was generally higher at SEZs B, G, and H, and at Station 24.

Mean echinoderm survival ranged from 53 percent (SEZ B) to 88 percent (SEZ E). Echinoderm survival averaged less than 80 percent at over one-half of the SEZs: SEZs A, B, D, G, and Station 24. Normal echinoderm development averaged less than 70 percent at each of the SEZs, ranging from 0 percent (SEZs G, H, and Station 24) to 68 percent (SEZ E).

Amphipod survival ranged from 45 percent (SEZ G) to 92 percent (Station 24). Survival was less than 80 percent at both of the pier SEZs (SEZs G and H). Mean amphipod reburial ranged from 63 percent (SEZ G) to 100 percent (Station 24).

Polychaete survival ranged from 84 percent (Station 24) to 97 percent (SEZ D). Survival was greater than 80 percent at each SEZ. Growth was highest at pier SEZs (0.160 and 0.139 mg/d at SEZs H and G, respectively) and lowest at SEZ F (0.0780 mg/d).

Evaluation of the bioassay results by SEZ was conducted as presented in Section 3, which is similar to the station-by-station evaluation. The RPDs between the mean biological response at each SEZ and mean reference data were first calculated for the three

VOL 18
0167
R0062776

bioassays. Tables 4-43 through 4-45 provide the RPDs between SEZ and reference stations by test organism and endpoint. SEZ data were also statistically compared to reference station data by ANOVA followed by Tukey's multiple range test. Appendix S contains the results of the bioassay statistical analyses.

Overall results of the bioassay data evaluation by SEZ are shown in Tables 4-43 through 4-45, showing the decision matrices used to identify bioassay "hits". The distribution of bioassay "hits" by SEZ within West Basin is presented on Figure 4-47. The only SEZ bioassay "hits" were SEZs B, G, and H for echinoderm development. Station 24 is not considered a "hit" even though development and survival data are both statistically significantly different and greater than 20 percent different from reference station data. DO levels fell to below 60 percent saturation during the bioassay test; the low DO most likely contributed to the reduced survival and normal development of test organisms.

Although SEZs B and G normal development data were not statistically significantly different from the reference station data as determined by ANOVA, every station within the two SEZs resulted in "hits" when individually compared to the reference station data. SEZs B and G were thus considered "hits" for echinoderm development despite the lack of statistical significance on a SEZ level. The wide range of responses reported from the echinoderm development test probably accounted for this condition.

Although several of the SEZs showed RPDs exceeding 20 percent for echinoderm survival and amphipod survival and reburial, those SEZs were not considered as "hits" because there was no statistically significant difference between SEZ mean response and reference mean response. The primary reason that the statistical tests did not detect significant differences between such SEZs and reference station data is attributed to the large variance that exists in the echinoderm survival and amphipod data sets. Statistically significant differences were detected via ANOVA between polychaete growth data at the pier SEZs (G and H) and reference stations. These results were not considered "hits", however, since biological response was actually more favorable (higher growth rate) at the pier SEZs than at reference stations.

4.6.5 Benthic Infauna

The benthic infauna community at each SEZ was evaluated by community indices and species composition (Table 4-46). None of the SEZs showed a significant adverse effect compared to the reference stations. SEZs A through F were dominated by species indicating healthy or semi-healthy conditions, and indicator species of stressed conditions were absent.

SEZ G, the area beneath Piers 1, 2, 12, and 16, showed a significantly enhanced number of taxa, abundance, and Margalef diversity compared to the reference stations. SEZ G showed the highest number of taxa, abundance, biomass, and Margalef diversity, while SEZs F and C showed the lowest values of these indices.

Three indicators of semi-healthy sediment conditions, *Exogone lourei*, *Schistomeringos rudolphi*, *Mediomastus* sp., ranked among the most abundant species at SEZ G.

VOL 18
0168
R0062777

Oligochaetes and *Capitella capitata*, indicators of stressed conditions, ranked high at Pier 1 of SEZ G. The other species that ranked high at SEZ G were fouling species growing on the shell hash material.

Oligochaetes, *Capitella capitata*, *Schistomeringos rudolphi*, and *Pseudopolydora paucibranchiata*, ranked high in abundance at SEZ H, a combination of both stressed and semi-healthy indicator species.

4.6.6 Bioaccumulation Data

The laboratory clam bioaccumulation tests have limited applicability to the SEZ analyses because only 25 percent of the stations (5 reference, 5 basin, and 4 pier stations) were selected for this test prior to development of SEZs. After the completion of the laboratory analyses and the development of SEZs, it was observed that, even though the stations to be tested for bioaccumulation had been selected by random assignment, a few of the basin stations used in the test grouped in several SEZs: Station 24, which was not assigned a SEZ; Station 29 in SEZ A; Stations 6, 8, and 14 in SEZ B; pier Stations 46 and 51 in SEZ G; and pier Stations 43 and 49 in SEZ H. Because of the small sample sizes, statistical tests were performed on the clam bioaccumulation stations grouped by reference, basin, and pier, and not by SEZ.

An examination of the data indicated that the SEZ A and B clams showed chemical concentrations essentially less than or equal to the reference station data. The pier samples from SEZs G and H showed a few chemical concentrations higher than the reference station data, but the differences were not statistically significant when the pier samples were all considered together. Clams from three of the four pier samples contained pyrene, which was not found at the reference stations but was measured in the pier sediment samples.

4.7 SELECTION OF CHEMICALS OF POTENTIAL CONCERN

COPCs were selected separately for human health and ecological risk assessments since each assessment has different focus and potential receptors. Therefore, in order to facilitate separate listing and discussions, COPCs for human health and ecological risk assessments were designated herein as chemicals of potential health concern (COPHCs) and chemicals of potential ecological concern (COPECs), respectively, and which are discussed in the following sections.

4.7.1 Chemicals of Potential Health Concern

COPHCs for West Basin were determined on the basis of fish chemistry data. The measured concentrations of analytes in West Basin and reference station fish samples were subjected to ANOVA to determine if there was a statistically significant difference between the concentrations of chemicals in fish from the two areas. No statistically significant difference ($p \leq 0.05$) was found between the concentrations of any of the chemicals identified in California halibut samples from the West Basin and the reference stations. In white croaker samples, mercury concentrations were statistically significantly

VOL 18
0169
R0062778

higher in the fillets of West Basin white croaker than in those from the reference stations. In the whole body samples, white croaker from the West Basin had statistically significantly higher concentrations of arsenic, copper, and tributyltin than whole body samples from the reference stations. Details of the statistical analysis were presented earlier in Section 4.

Upon completing the statistical analyses and evaluation of the data, only three compounds found in whole body white croaker samples were at significantly greater concentrations at the West Basin than at the reference; only one compound found in white croaker fillet samples was at a significantly greater concentration at the West Basin than at the reference; and none of the analytes for halibut fillet and whole body were at significantly greater concentrations at the West Basin that at the reference. To develop conservative estimates of risk related to analyte concentrations in fish tissue, any compound detected in a fish sample type was considered a COPHC for that fish sample type. For example, any compound detected in white croaker fillet samples from West Basin were considered COPHCs for white croaker fillet. The compounds detected in fish and designated as COPHCs are presented in Table 4-47.

4.7.2 Chemicals of Potential Ecological Concern

COPECs were selected individually for West Basin surface sediments and fish, and were evaluated using the hazard quotient and the preponderance-of-evidence approaches to ecological risk assessment, respectively. The following sections describe how West Basin COPECs were derived.

4.7.2.1 FISH COPECS

West Basin fish COPECs were determined on the basis of whole body white croaker chemistry. California halibut chemistry was not included in fish COPEC determinations because concentrations of chemicals measured in West Basin California halibut were not statistically significantly higher than reference station values. Chemicals detected in West Basin whole body samples of white croaker were designated fish COPECs if the concentrations of such chemicals statistically significantly exceeded the concentrations found in whole body white croaker collected from the reference stations (details of fish tissue chemistry results and statistical analyses are found in Section 4.4.2.1). Chemicals found in West Basin whole body samples of white croaker and not in reference samples were also designated as fish COPECs. The fish COPECs, listed in Table 4-48, were used in hazard quotient calculations related to assessing potential risk to an aquatic predator, as described in Section 6.

4.7.2.2 SEDIMENT COPECS

Sediment COPECs were considered separately for each SEZ. Any chemical, having a SEZ mean concentration that statistically exceeded the reference mean concentration, was designated a sediment COPEC for that SEZ. Analytes that were found at West Basin stations and not at reference stations were also designated as sediment COPECs. The sediment COPECs are listed by SEZ in Table 4-49.

VOL 18
0170
R0062779

West Basin sediment samples contained measurable concentrations of most metals for which they were analyzed. Antimony and thallium were not detected in any of the West Basin sediment samples. None of the mean concentrations of cadmium, nickel, selenium, or silver exceeded the reference station mean values. Arsenic, beryllium, chromium, copper, lead, mercury, and zinc were found in at least one SEZ at concentrations that exceeded the reference station values. Therefore, these seven metals were designated as sediment COPECs. The seven sediment COPEC metals were found at higher concentrations in SEZs F and H.

While tributyltin, dibutyltin, and monobutyltin were analyzed for in West Basin sediment samples, only dibutyltin and monobutyltin were found at detectable levels. Dibutyltin concentrations did not exceed the reference station values. Monobutyltin was designated a sediment COPEC because it was detected at SEZ H and not at the reference stations.

All of the PAH compounds for which the West Basin sediment samples were analyzed, exceeded reference station levels. Summary estimates of PAH concentrations, such as total PAH, total HPAH, total LPAH, total benzofluoranthenes, also exceeded the reference station values. All of the measured PAH compounds and the PAH summary estimates were designated as COPECs. The presence of PAH compounds at levels exceeding the reference station values generally occurred at stations beneath the piers (SEZs G and H) and at stations adjacent to piers (SEZs E and F).

Aroclor 1260, the only PCB compound detected in West Basin surface sediment samples, was found at levels that exceeded the reference station value. Aroclor 1260 was designated a sediment COPEC for all of the SEZs, except for SEZ G.

Aldrin, lindane, DDD, DDE, and DDT were detected in West Basin surface sediment samples. Aldrin, lindane, and DDT were designated as sediment COPEC compounds because they were found in West Basin sediments but not at the reference stations. Concentrations of DDD, DDE, and total DDTs in West Basin samples did not exceed the reference station values.

Phenol, bis(2-ethylhexyl)phthalate, and di-n-octylphthalate were found at measurable concentrations in surface sediment samples from the West Basin. Only phenol, which was present at concentrations that exceeded the reference station values, was designated as a sediment COPEC. Bis(2-ethylhexyl)phthalate and di-n-octylphthalate concentrations did not exceed the reference station concentrations.

4.8 IDENTIFICATION OF AREAS OF POTENTIAL ECOLOGICAL CONCERN

Areas of potential ecological concern (AOPECs) were designated according to the guidelines described in the RAWP (BNI 1995a). The RAWP guidelines specify an evaluation matrix, shown in Table 4-50, to be used in defining SEZs potentially requiring remediation or additional characterization, including the "triggering" of a water column study. Table 4-50 shows all of the potential combinations of data results presented in four categories (sediment chemistry, bioassay, benthic community analysis, and

VOL 18
0171
R0062780

bioaccumulation), along with the assigned SEZ status. The evaluation matrix was designed as a tool to interpret AOPECs based on a range of chemical or biological data.

SEZs were evaluated for chemicals exceeding reference station values; toxicity effects to polychaetes, amphipods, and echinoderm larvae greater than the reference; benthic infauna significantly different than the reference; and bioaccumulation of chemicals in clam tissue. These results were used to compile an evaluation matrix specific to West Basin (Table 4-51). This evaluation matrix provides a summary of the results of SEZ characterization discussed earlier. The evaluation matrix input for each of the SEZs shown in Table 4-51 are discussed below.

Station 24, which was dissimilar to all other West Basin stations in sediment physical and chemical properties and was not a member of any of the SEZs, was not considered an AOPEC. Eight metals and DDE were detected at Station 24, but none of these chemicals exceeded the reference station values. No PAH compounds were detected at Station 24. Also, there were no apparent toxicity effects or adversely affected benthic infauna.

SEZ A, comprising primarily stations near the entrance to the West Basin, was not considered an AOPEC. Although most of the metals, a few of the PAHs, Aroclor 1260, DDTs, and phenol were detected in SEZ A sediment samples, only Aroclor 1260 and phenol concentrations exceeded the reference station value. No toxicity effects, adverse benthic infauna effects, or clam tissue bioaccumulation were noted at SEZ A.

SEZ B, comprising primarily stations in the northwest area of the West Basin, was considered an AOPEC. Most of the metals and PAH compounds were detected in SEZ B, as well as Aroclor 1260, pesticides, and SVOCs. Three PAH compounds and Aroclor 1260 exceeded the reference station values. No toxicity effects were noted for the polychaete and amphipod tests; however, SEZ B sediment samples showed a toxicity response for the echinoderm larvae that was greater than the reference data. There was no significant bioaccumulation of chemicals in the clam tissue tests. Because of the sediment chemistry concentrations and echinoderm toxicity, SEZ B was considered an AOPEC.

SEZs C and D, comprising stations in the central portions of the West Basin, were not considered as AOPECs. Sediment samples from both SEZs C and D contained detectable levels of metals, PAHs, Aroclor 1260, pesticides, and SVOCs. At SEZ C, two PAH compounds, Aroclor 1260, and DDT exceeded the reference station values. At SEZ D, three PAH compounds and Aroclor 1260 exceeded the reference station values. No toxicity effects or adverse benthic infauna effects were reported at either SEZ C or SEZ D. None of the sediment samples from these SEZs were tested for clam bioaccumulation.

SEZs E and F, comprising stations adjacent to the West Basin piers, were not considered as AOPECs. Sediment samples from SEZ E contained PAH compounds, Aroclor 1260, and phenol that exceeded the reference station values. Six metals, PAHs, Aroclor 1260, and lindane were detected at concentrations exceeding reference station values at SEZ F. There were no significant toxicity effects or benthic community effects noted at either SEZ E or SEZ F. None of the sediment samples were analyzed for clam tissue bioaccumulation.

VOL 18 0172

R0062781

SEZ G, comprising several piers, was considered an AOPEC because of chemical concentrations, echinoderm toxicity, and clam tissue bioaccumulation. Ten PAH compounds were detected at SEZ G at concentrations exceeding the reference station values. Echinoderm larvae showed an adverse toxic response when exposed to SEZ G sediment samples. Clam tissue bioaccumulation tests showed concentrations of pyrene exceeding bioaccumulation levels at the reference stations.

SEZ H, also comprising several piers, was considered an AOPEC because of chemical concentrations, toxicity levels, and clam tissue bioaccumulation. Four metals, monobutyltin, sixteen PAH compounds, and Aroclor 1260 were detected in sediment samples from SEZ H at concentrations exceeding the reference station values.

SECTION 5

ASSESSMENT OF HUMAN HEALTH RISK ASSOCIATED WITH CONSUMPTION OF WEST BASIN FISH

0174

VOL 18 0175

Section 5

ASSESSMENT OF HUMAN HEALTH RISK ASSOCIATED WITH CONSUMPTION OF WEST BASIN FISH

This section presents an assessment of human health risk associated with ingestion of chemicals measured in fish tissue collected from the West Basin, and provides descriptions of the methodologies used, as well as the findings of, the risk assessment. The objective of this task was to assess whether risk to human health posed by ingestion of West Basin fish exceeded the risk to human health posed by ingestion of fish collected from reference stations.

Comparison of the concentrations of chemicals measured in the sediments to the concentrations of chemicals measured in fish tissue was beyond the scope of this RI and not an objective of this human health risk assessment, as the migration and feeding history of the fish collected for this RI, as well as the sources of chemicals measured in fish tissue, cannot be ascertained with any degree of reliability. Some fish may have spent their entire lives within, and fed throughout, the West Basin; others may have moved in and out of the West Basin before being captured for this RI.

A variety of fish appear to live or forage in the West Basin. The Navy has conducted a series of creel census surveys of individuals fishing at the Navy Mole area within the West Basin (BNI 1994b). The surveys have revealed that the species most often caught by anglers in that area are barred sand bass (*Paralabrax nebulifer*), rubberlip perch (*Paralabrax toxotes*), kelp bass (*Paralabrax clathratus*), opaleye (*Girella nigricans*), California halibut (*Paralichthys californicus*), and white croaker (*Genyonemus lineatus*).

The California halibut and white croaker were identified in the RAWP (BNI 1995a) as being appropriate candidates for the purposes of both human health and ecological risk assessments. Both species of fish were caught by trawl in the West Basin and at the reference stations, and used to represent fish typically caught in and outside of the West Basin and consumed by recreational and subsistence anglers. The number of fish caught and the methods used to identify and quantify the concentrations of chemicals in their tissues were described in Section 4.

5.1 OVERVIEW OF THE HUMAN HEALTH RISK ASSESSMENT PROCESS

The standard four-step process recommended by the U.S. EPA (1989b) for conducting human health risk assessments was used. This section briefly describes each step. The sections that follow present a more detailed description of the process.

The first step was to identify the chemicals that would be evaluated in the risk assessment. To perform this step, samples of fish were collected and analyzed for chemicals of interest. The resulting analytical data were carefully scrutinized to identify and list the chemicals that were actually in the samples when collected. The list was then modified by removing chemicals determined to be non-site related contaminants introduced either in the field or the laboratory. The final list of chemicals, COPHCs, were then used in the risk assessment calculations.

R0062784

The second step in the human health risk assessment was to evaluate dose-response. This step entailed evaluating the relationship between exposure and biological effects to humans using published toxicological information.

The third step of the risk assessment process was to assess exposure. This step consisted of identifying the pathways by which receptors could be exposed to the COPHCs and estimating the exposure levels.

The fourth step was to generate the risk characterization. This final task consisted of using the exposure-biological effect information to generate a numerical answer which expressed the degree of risk to human health associated with the estimated exposure level.

5.2 CHEMICALS OF POTENTIAL HEALTH CONCERN

Data collection and evaluation techniques, including selection of chemical stressors, data validation, quantitation limits, data qualifiers and usability, and screening criteria, are discussed in Sections 3 and 4 of this RI Report. Tables 4-23 through 4-26 in Section 4 list chemicals detected in fish tissue collected from West Basin. The list of COPHCs for each fish tissue sample type included any analyte detected in samples of that fish tissue type (Table 4-47). For example, any compound detected in California halibut whole body samples from West Basin was considered a COPHC for the evaluation of California halibut whole body from West Basin.

5.3 TOXICOLOGICAL EVALUATION

Eight of the 15 COPHCs are metals and seven are manufactured organic compounds. Arsenic and hexavalent chromium are known human carcinogens. Beryllium, nickel, DDD, DDE, and α-BHC have been shown to cause cancer in laboratory animals only, and they are considered to be potential human carcinogens. Information on the acute toxicity, chronic systemic toxicity, and carcinogenicity (where applicable) of these COPHCs is summarized in Tables 5-1 and 5-2.

Dose-effect information needed to quantify the risk presented by each of these COPHCs consisted of oral cancer slope factors (CSF) for carcinogens and oral reference doses (RfD). CSFs and RfDs (hereinafter collectively called toxicity criteria) used in this RI are listed in Table 5-3 for each of the COPHCs. A CSF is an estimate of the upper-bound probability that an individual will develop cancer as a result of exposure to a unit dose of a carcinogen. An RfD is an estimate of a daily exposure level that is unlikely to cause deleterious effects in a human population, including sensitive subpopulations, over a lifetime.

The toxicity criteria for all of the COPHCs were obtained from the Integrated Risk Information Service (IRIS), which is a database sponsored by U.S. EPA; the U.S. EPA Health Effects Assessment Summary Tables (HEAST) [U.S. EPA 1994a]; or the February 1995 preliminary remediation goals (PRG) published by U.S. EPA Region IX (U.S. EPA 1995), in the order listed. The U.S. EPA Region IX PRGs was used primarily to obtain toxicity criteria developed by the U.S. EPA's Environmental Criteria and Assessment

VOL 18
0176
R0062785

Office (ECAO) in Cincinnati, OH. In accordance with SWDIV policy, cancer risk estimates based on CSFs developed by the Cal-EPA were used for hexavalent chromium. The Cal-EPA CSF value for hexavalent chromium was obtained from the November 1994 table of CSFs published by the Office of Environmental Health Hazard Assessment (Cal-EPA 1994).

Although the tissues were analyzed for the mercury ion rather than for methyl mercury, mercury was assigned the RfD for methyl mercury because inorganic mercury is readily transformed by bacteria to methyl mercury in aquatic systems (Bisogni and Lawrence 1975; Wood 1974), making methyl mercury rather than inorganic mercury to be the form most likely present in the tissues of fish.

Dibutyltin was not evaluated because of the absence of an RfD. It is probably less toxic than tributyltin (SWRCB 1988), which was evaluated and was present in the fish tissues at higher concentrations than dibutyltin.

Lead was evaluated and addressed separately due to the premise that the risk it presents is estimated in a manner different from that used to estimate the risk of other chemicals. Both the U.S. EPA and Cal/EPA recommend using a pharmacokinetic model to determine if exposure to lead in the medium of concern will, when added to normal sources of lead, cause the concentration of lead in blood to rise above 10 micrograms per deciliter (µg/dl), which is currently regarded as a level above which neurological and other effects of lead could occur.

Cal/EPA's Leadspread Program, which is based on a pharmacokinetic model, is being used in other projects within CLEAN II to assess the potential risk presented by lead in soil and water. Although it accounts for lead in food, the Leadspread program is not designed for use in estimating the risk presented by lead in food, except for produce grown in contaminated soil. A rough estimate of blood lead levels resulting from ingestion of lead-contaminated fish was obtained using parts of the program. The procedure is described in subsequent sections.

5.4 EXPOSURE SETTING

Two types of fish consumers were evaluated in conceptualizing the exposure setting: the consumer who fishes for recreational purposes (recreational consumer); and the consumer who fishes out of necessity (subsistence consumer).

The types of information needed to estimate the potential risk associated with human consumption of contaminated fish consist of: (1) concentrations of the COPHCs in the fish samples; (2) fish consumption rate; (3) the ratio of test fish (fish collected for this RI) consumed to the total amount of fish consumed; and, (4) the length of time (days, months, or years) during which consumption of test fish might occur. COPHC concentrations in fish samples were acquired from the findings of this RI. Fish consumption rates, exposure frequencies, and exposure durations were obtained from the U.S. EPA (1991b) supplement to the Risk Assessment Guidance Manual for Superfund (U.S. EPA 1989b). The fraction of test fish in the total fish diet of the consumer was estimated.

VOL 18
0177
R0062786

Both types of consumers were assumed to fish the West Basin for a period of 30 years and have families whose members also eat fish. Thirty years is the 90th percentile for residency time at one address for the U. S. population (U.S. EPA 1989a). Assuming that family members also consume fish allows for the possibility that at least one family member consumes fish from birth to the age of 30 years. Cancer risk estimates were based on that member of the family. Noncancer risk estimates were based on exposure of a family member from birth to the age of six years and an adult family member exposed for 30 years. Although neither type of consumer or family member probably eats fish every day, for calculation purposes chemical dose was based on a fish consumption frequency of 350 days/year. The remaining 15 to 16 days of the year were assumed to have been spent away from the Long Beach area. This period is the average vacation time for the U.S. working population.

Certain people may consume all soft parts of fish (i.e., cook fish whole without first removing skin and entrails). To allow for that possibility, the risks associated with consuming whole body fish as well as fillets alone were estimated for both the recreational and subsistence consumer.

The recreational consumer was assumed to fish the West Basin occasionally, so that only one-third of the fish eaten by the consumer or family members came from the West Basin. The rest of the fish consumed was assumed to be purchased from fish markets or caught elsewhere. The average daily consumption of fish by adult members of the family was assumed to be 0.054 kg, which is based on a study by Pao and co-workers (1982), who used data from the Nationwide Food Consumption Survey conducted in 1977 and 1978 by the U. S. Department of Agriculture (USDA 1983). The consumption rate (0.054 kg/day) is recommended by the U.S. EPA (1991b) as an appropriate rate for recreational fish consumers, although in the Exposure Factors Handbook (U.S. EPA 1989a), the U.S. EPA states that the rate for recreational fish consumers may be higher.

For the child member of the recreational consumer's family, the fish consumption rate was assumed to be 15/70th of the adult consumption rate, which is the ratio of the standard body weights of 15 kilograms and 70 kilograms assigned by the U.S. EPA to the 0- to 6-year age group and adults, respectively. It is the procedure used by the U.S. EPA (1994b) to estimate acceptable concentrations of chemicals in fish for different human age groups and based on the assumption that food intake is directly proportional to body weight.

All of the fish eaten by the subsistence consumer was assumed to come from the West Basin. The average daily consumption rate of fish by adult members of the family was assumed to be 0.132 kg/day, which is the rate recommended by the U.S. EPA (1991b) as appropriate for subsistence anglers. According to the U.S. EPA (1991b), this rate is the 95th percentile for daily fish consumption based on the above-mentioned study by Pao and co-workers. The consumption rate for the child was calculated in the same manner as described for the recreational consumer.

VOL 18
0178
R0062787

The consumption frequency of 350 days per year appears high; however, as mentioned earlier, it was used for computational purposes only because the fish consumption rate is expressed on a per-day basis. If a meal consists of 227g (8 ounces) of fish, a consumption rate of 0.054 kg/day for 350 days/year amounts to 1.7 fish meals per week. For the subsistence consumer, the consumption rate of 0.132 kg/day for 350 days/year amounts to approximately four 8-ounce fish meals per week. Thus, the consumption rate and frequency become reasonable when expressed on a per meal basis. Table 5-4 summarizes the exposure conditions used in the risk assessment.

5.5 EXPOSURE ESTIMATION

Human exposure to COPHCs in fish samples was assumed to occur only by ingestion. Other routes of exposure, such as dermal contact while cleaning the fish, were believed to be insignificant relative to ingestion, and therefore not evaluated. The equation used to calculate dose by ingestion was as follows:

$$\text{Dose} = (C_f \times IR_f \times EF \times F \times ED)/(BW \times AT)$$

where:

Dose	=	ingested dose (mg/kg-day)
C_f	=	concentration of chemical in fish (mg/kg)
IR_f	=	fish ingestion rate (kg/day)
EF	=	exposure frequency (day/year)
F	=	ratio of fish ingested from West Basin to total fish ingested (unitless)
ED	=	exposure duration (year)
BW	=	human body weight (kg)
AT	=	averaging time (25,550 days for cancer risk, ED x 365 day/yr for noncancer risk)

The values assigned to all of the equation parameters are shown in Table 5-4 except for chemical concentration in fish (C_f). For each chemical, C_f was assigned a value equal to the 95% UCL of the mean concentration. In the calculation of the 95% UCL, chemical concentrations reported as being below the SQL were assigned a value equal to 0.5 SQL.

5.6 RISK CHARACTERIZATION

Risk characterization was the final step in the risk assessment process. It consisted of two parts: (1) quantification of risk, described in this section; and, (2) analysis of uncertainties in the risk estimates, described in subsequent sections.

Cancer and noncancer risk estimates were generated for the COPHCs on the basis of four basic exposure settings, as listed below:

- consumption of fillets by recreational consumers,

VOL 18
0179
R0062788

- consumption of whole body fish by recreational consumers,
- consumption of fillets by subsistence consumers, and
- consumption of whole body fish by subsistence consumers.

Application of these four basic settings to West Basin and reference station California halibut and white croaker, consumed by children and adults, produced a total of 32 exposure settings and thus a total of 32 sets of cancer and noncancer risk estimates. Although there was no statistically significant difference between the concentrations of chemicals found in California halibut samples from the West Basin and reference stations, health risk associated with human consumption of California halibut from both areas was estimated for the purposes of this RI. The same set of 15 COPHCs was used with both fish species.

5.6.1 Quantification of Cancer Risk

For each exposure setting, the cancer risk presented by each of the carcinogenic COPHCs was estimated in the following manner:

$$\text{Cancer Risk} = \text{Dose} \times \text{CSF}$$

The estimated cancer risks for carcinogenic COPHCs were then summed to obtain an estimate of total cancer risk. Cancer risk estimates represent the probability that a person will develop cancer of any kind in a lifetime because of exposure to the carcinogens under evaluation. The probability of developing cancer as a result of exposure to a single carcinogen increases with dose. That probability will also increase if exposure to other carcinogens occurs.

For regulatory purposes, cancer caused by chemical carcinogens is treated as a nonthreshold effect. Therefore, there is theoretically no safe exposure level for carcinogenic effects. Zero risk cannot be achieved because of limitations in chemical analytical methods and the presence of natural carcinogenic chemicals in the environment. Cancer risk estimates generated by a risk assessment must therefore be evaluated in terms of acceptable risk. The U.S. EPA has developed risk-based guidelines for establishing acceptable remediation goals for chemicals. For carcinogens, the NCP states that upper-bound lifetime cancer risk less than 1×10^{-6} is unconditionally acceptable and that upper-bound lifetime cancer risk between 1×10^{-6} and 1×10^{-4} is generally acceptable. These guidelines suggest that cancer risk above 1×10^{-4} is unacceptable.

5.6.2 Quantification of Noncancer Risk

The numerical estimate of the noncancer risk presented by a chemical is called a hazard quotient (HQ) and was calculated in the following manner for each COPHC:

$$\text{HQ} = \text{Dose/RfD}$$

For each exposure setting, HQs of the COPHCs were summed to obtain a preliminary estimate of the total noncancer risk presented by the COPHCs involved. The sum of any

VOL 18
0180
R0062789

set of HQs is called a hazard index (HI). A HQ or HI larger than 1.0 means that the estimated dose exceeds the reference dose, which is a dose above which toxic effects could occur.

5.6.3 Quantification of Lead Risk

The lead dose resulting from the ingestion West Basin fish was calculated for children and adult subsistence and recreational anglers using fish consumption rates shown in Table 5-4 and lead concentrations of 2.6 and 0.55 mg/kg, respectively, for white croaker fillets and California halibut whole body samples. No measurable concentrations of lead were found in the whole bodies of white croakers or fillets of halibut.

The median blood lead level was calculated using the following equation, which appears in the Leadspread program: blood lead = dietary constant * dose. The dietary constants from the Leadspread program are 0.04 and 0.16 for adults and children, respectively.

5.7 RESULTS

The total cancer and noncancer risk estimates for the 32 exposure settings produced as the result of risk quantification are listed in Table 5-5. Under the exposure conditions used to estimate risk, cancer risk was always higher in the adult than in the child, and noncancer risk was identical in both the adult and child. Cancer risk was higher in the adult because the adult was assumed to consume fish for a longer duration than the child, and therefore receive a higher chemical dose. The risk estimates are discussed below in terms of risk to the adult only.

5.7.1 Cancer Risk

The upper-bound cancer risks presented by all of the carcinogenic COPHCs identified for this RI, via consumption of the whole body and fillets of white croaker from the reference stations by recreational anglers, were approximately the same (2.2×10^{-4} for whole body versus 3.7×10^{-4} for fillets). The upper-bound cancer risk associated with consumption of white croaker from the West Basin was similar to the risk associated with consumption of reference station white croaker. With the fillet samples, the risk was 2.5×10^{-4} for West Basin white croaker and 3.7×10^{-4} for reference station white croaker. With whole body samples, the risk was 3.0×10^{-4} for West Basin white croaker and 2.2×10^{-4} for reference station white croaker.

The upper-bound cancer risk was about one magnitude higher for the subsistence angler than for recreational anglers because of the higher fish consumption rate assumed for the subsistence angler. However, as observed with the recreational angler, the risk presented by the carcinogens in white croaker from the West Basin stations (2.2×10^{-3} for whole body and 1.9×10^{-3} for fillets) was within the risk range presented by carcinogens in fish from the reference stations (1.6×10^{-3} for whole body and 2.7×10^{-3} for fillets).

The upper-bound cancer risk was above 1×10^{-4} for the subsistence angler consuming whole body California halibut collected from both West Basin and reference stations. The

VOL 18
0181
R0062790

carcinogenic risk to the subsistence angler extended into the 10^{-3} range for reference station California halibut fillets.

COPHCs that consistently contributed most to West Basin and reference station cancer risk were arsenic, DDD, and DDE. Arsenic was by far the most significant contributor. It accounted for 86 to 94 percent of the total cancer risk. Appendix T identifies the chemicals in California halibut and white croaker fillet and whole body samples presenting the highest cancer risk to the recreational and subsistence angler.

According to a published review of the toxicological properties of arsenic by the Agency for Toxic Substances and Disease Registry (ATSDR 1993), inorganic arsenic is rapidly converted to arsenobeteine and arsenocholine in fish; both forms of arsenic exhibit low systemic toxicity, and neither are carcinogenic. Table 5-6 shows the total upper-bound cancer risk presented by carcinogenic COPHCs identified for this RI in West Basin California halibut and white croaker and adjusted total upper-bound risk after subtraction of the risk estimates for arsenic.

The results of the assessment of cancer risk suggest that there appears to be no appreciable difference in the cancer risks associated with consumption of white croaker and California halibut from the West Basin and the reference stations, even though the concentrations of some of the carcinogenic COPHCs were statistically significantly higher in white croaker from the West Basin than those from the reference stations. The results indicate, however, that the upper-bound cancer risk associated with consumption of California halibut and white croaker, regardless of the source, is within the range considered to be unacceptable in accordance with criteria presented in the NCP.

5.7.2 Noncancer Risk

The sum of the HQs (i.e., HIs) for the COPHCs in the fillets and whole bodies of white croaker from the reference stations and the West Basin ranged from 1.1 to 1.5 for recreational anglers. Considering the uncertainties in the reference doses and the quantification of the COPHCs, there appears to be no appreciable difference in the noncancer risk associated with consumption of white croaker from the reference stations and the West Basin. The HQs for the COPHCs in the fillets of white croaker were 11 for the subsistence consumer for the West Basin and 10 for the reference station subsistence consumer. This finding indicates that for subsistence consumers, the noncancer risk associated with consumption of the fillets of white croaker from the West Basin was the same as that associated with the consumption of fillets of white croaker from the reference stations. There appears to be a higher degree of risk associated with subsistence consumers consuming whole body of white croaker from the West Basin than from the reference stations. The HI for the West Basin whole body white croaker was 11 compared to the HI for the reference stations of 8.4.

The HIs for the COPHCs in the California halibut fillet and whole body samples were higher for reference stations than for West Basin, whether the consumer was recreational

VOL 18
0182
R0062791

or subsistence consumer. The HIs for reference California halibut ranged from 0.74 to 6.7, whereas HIs ranged from 0.52 to 4.3 for West Basin California halibut.

A HQ or a HI greater than 1.0 indicates that the estimated dose is higher than the RfD, which is an estimate of the highest nontoxic dose. A HI greater than 1.0 therefore suggests that the concentration of at least one of the COPHCs in the fish is high enough to produce toxic effects alone or in combination with other COPHCs. The HIs for all combinations of consumer, fish species, body part consumed, and source of the fish were greater than 1.0 except for consumption of California halibut from the reference stations and the West Basin by recreational anglers.

Where the HI exceeded 1.0, the COPHC with the highest HQ was arsenic. Arsenic HI accounted for at least 90 percent of the total HI. Appendix T identifies the chemicals in California halibut and white croaker fillet and whole body samples presenting the highest noncancer risk to the recreational and subsistence angler.

The results of the assessment of noncancer risk indicate that, with one exception, there appears to be no appreciable difference between the noncancer risk presented by the COPHCs identified for this RI in California halibut and white croaker from the West Basin and the reference stations. The risk associated with the consumption of whole body white croaker from the West Basin by subsistence anglers (HI = 11) might be higher than the consumption of whole body white croaker from the reference stations (HI = 8.4), but the difference may not be significant given the uncertainties in the risk estimation process.

5.7.3 Lead Risk

Estimated dose ranged from 0.13 µg/kg-day for the California halibut whole body and child recreational angler to 4.7 µg/kg-day for the white croaker fillet and adult subsistence angler. Calculated median blood lead levels ranged from 0.0054 to 0.745 µg/dl for California halibut whole body with the adult recreational angler and for the white croaker fillet with the child subsistence angler, respectively. Median blood lead levels for white croaker and California halibut with adult and child, subsistence and recreational anglers were within that range.

These results showed that the concentration of lead in the fillets of white croaker and whole body of California halibut from the West Basin were high enough to cause the concentration of lead in the blood of subsistence and recreational consumers of the fish to be as high as about 0.745 µg/dl (child subsistence angler), which is considerably lower than the threshold of 10 µg/dl. These predicted levels result from consuming fish only. Lead from other sources such as air, drinking water, soil, and food other than fish will increase the concentration of lead in the blood.

The Leadspread Program was used to estimate the contribution to blood lead from the lead in ambient air, drinking water, and diet (excluding fish). Default concentrations recommended by Cal/EPA (1992) were assigned to drinking water (15 µg/L) and diet (9.5 µg/kg), and the highest reported quarterly average lead concentration in ambient air (0.08 µg/m^3) measured at the California Air Resources Board's North Long Beach air

VOL 18
0183
R0062792

VOL 18 0184

monitoring station in 1989 and 1990 (CARB, 1989, 1990) was assigned to ambient air. The predicted additional median blood lead level was 1.8 and 3.1 µg/dl for the child and adult, respectively, and the 99th percentile levels were 4.1 and 7.0 µg/dl, respectively. Adding the 99th percentile values to the predicted blood lead levels based on fish consumption alone did not cause predicted blood lead levels to rise above 10 µg/dl.

The contribution of lead in soil to blood lead levels could not be estimated because of the absence of information on the concentration of lead in soil in the residential areas of Long Beach or wherever the anglers might live.

In summary, the concentration of lead in the fillets of the white croaker and the whole body of California halibut from the West Basin do not appear to be high enough to cause lead toxicity in children or adults consuming West Basin fish, even when contributions from other sources of lead are considered.

5.8 DISCUSSION

The primary purpose of assessing risks associated with human consumption of fish was to estimate whether consumption of California halibut and white croaker from the West Basin poses a greater threat to human health than consumption of California halibut and white croaker caught at the reference stations. The scope of this RI did not include determining whether there exists a link between chemicals found in the sediment samples and the chemicals found in fish samples collected for this RI. The results of the risk assessment indicated that the cancer and noncancer risks associated with consumption of West Basin fish did not appear to be appreciably different from the risks associated with consumption of fish from the reference stations.

These results, on the other hand, also indicate that the concentrations of chemicals identified in some of the California halibut and white croaker samples may be high enough to adversely affect individuals who catch and consume these two species of fish. California halibut and white croaker from the reference stations were treated in the risk assessment as representatives of fish not impacted by the activities of the LBNC. The Cal-EPA OEHHA has recommended fish consumption limits for the LA/LB Harbor (where LBNC is located) based on chemical contamination, specifically DDT and its congeners (DDD and DDE) (Cal-EPA 1991). When arsenic is removed as a carcinogen in the human health risk assessment conducted for this RI, DDD and DDE become the primary cancer risk drivers.

Although the conversion of inorganic arsenic to organic arsenic eliminates this metal as a primary risk driver for carcinogenic effects, it remains the primary risk driver for noncarcinogenic effects. The concentrations of arsenic in the California halibut and white croaker samples are not unusually high. The highest concentrations of arsenic were found in the whole body samples: 0.7 mg/kg in California halibut and 1.8 mg/kg in white croaker. By comparison, fish and shellfish from U.S. supermarkets have been found to contain between 4 and 5 mg/kg of arsenic (ATSDR 1993).

R0062793

5.9 UNCERTAINTIES OF THE RISK ASSESSMENT

The human health risk calculations were based on " estimates " of chemical dose rate and toxicity. This section discusses uncertainties associated with the estimates and the potential effect of the uncertainties on the risk estimates.

5.9.1 Chemical Dose Rate

The chemical concentrations in West Basin fish were based on analysis of 15 fish of each species. The chemical concentrations used to calculate dose were the 95% UCL of the mean concentrations. The concentrations of several of the COPHCs in many of the samples were reported as being below their detection limits. In accordance with U.S. EPA guidelines, the concentrations of chemicals in the samples in which chemicals were reported as undetected were assigned a value equal to one-half the detection limit. When most or all of the samples contained a measurable concentration of a chemical, there was very little difference between the mean and 95% UCL, suggesting that 15 samples were sufficient for estimating the true mean when the concentrations were measurable.

Use of one-half the detection limit in the calculation of the mean increases the uncertainty in the mean. This uncertainty increases as the number of undetected concentrations increases. Use of one-half the detection limit may overestimate or underestimate the mean concentration and, therefore, the level of risk, depending on whether the actual concentration is closer to the detection limit or to zero.

The fish consumption rates were based on an analysis by Pao and coworkers (1982) data from a nationwide food consumption survey in which people were asked to record the amount of specific kinds of food they ate over a period of three days. According to Pao, the average fish consumption rate is 0.054 kg/day and the 95 percentile rate is 0.132 kg/day. U.S. EPA (1991b) recommends using the average rate for recreational anglers and the 95th percentile rate for subsistence anglers. These rates are probably inaccurate for several reasons. First, people may eat fish only on certain days of the week (e.g., Friday). If the survey days did not include the days during which fish was eaten, the consumption rate would be underestimated. Second, the survey was limited to purchased food. Therefore, the fish consumption rates do not necessarily apply to anglers whose fish consumption rate is related to fishing success. Third, in a study of fish consumption rates by recreational anglers in the Los Angeles area, Puffer (1981) estimated a median fish consumption rate of 0.037 kg/day and a 90th percentile rate of 0.225 kg/day. Puffer's results indicate that 0.225 kg/day is a better estimate of upper-bound fish consumption rate than 0.054 kg/day and that use of 0.054 kg/day underestimates risk.

A study by Pierce and coworkers (1981) showed that the fish consumption rate among anglers increases with angling frequency. Anglers who fish daily consume more fish per day than those who fish weekly, monthly, or annually. For those who fish daily, the rate was 0.381 kg/day. That rate may be more appropriate for a subsistence angler.

The fish consumption frequency of 350 days per year and the exposure duration of 30 years probably overestimate the dose calculations.

VOL 18
0185
R0062794

In summary, the chemical concentrations used to estimate dose may overestimate upper-bound risk and the fish consumption rates used to estimate the dose rates for adults may underestimate risk.

5.9.2 Toxicity Estimates

There are several hypotheses regarding cancer development. Mathematical models based on the difference hypotheses have been developed to estimate the cancer potency of chemical carcinogens. The potency estimates produced by these models can differ by several orders of magnitude. Therefore, there is some degree of uncertainty in the accuracy of the models in estimating potency. For most carcinogens, EPA has used the linear multistage model. That model tends to produce potency estimates of intermediate value relative to the other models.

The RfDs used in the human health risk assessment presented in this section are estimates of the " daily exposure level for the human population, including sensitive subpopulations, that is likely to be without an appreciable risk of deleterious effects during a lifetime. " (U.S. EPA 1989a). RfDs are derived either from a no-observed-adverse-effect-level (NOAEL), or a lowest-observed-adverse-effect-level (LOAEL). Each RfD has a built-in uncertainty factor that takes into account for as many as four uncertainties:

- using an LOAEL instead of an NOAEL;
- using an NOAEL from a subchronic study rather than from chronic study;
- using an LOAEL or NOAEL from animal studies rather than from human studies; and
- variation in sensitivity of people in the general population to the chemical.

Each uncertainty has been assigned a value of 10. Therefore, if all four of the uncertainties were to apply to a given chemical, its RfD would have an uncertainty factor of 10,000 built into its value. While use of a factor of 10 for each type of uncertainty may increase the certainty in the predictive value of the RfD, 10 is an arbitrary number that is itself uncertain.

FOCUSED ECOLOGICAL RISK ASSESSMENT

0187

VOL 18

Section 6

FOCUSED ECOLOGICAL RISK ASSESSMENT

This section contains the results of the ERA prepared using data presented and discussed in previous sections of this RI Report. The methodologies and the hazard quotient calculations used in the ERA are also presented herein. The focus of the ERA was the sediments of West Basin. In addition, potential ecological risk posed by ingestion of chemicals measured in West Basin fish tissue (whole body) to an aquatic predator (harbor seal) was estimated.

The ERA follows standard regulatory agency guidance and the RAWP (BNI 1995a). This ERA consisted of developing a conceptual site model, performing an exposure assessment utilizing site-specific ecological data, assessing the ecological effects of the exposure assessment, and characterizing the ecological risk at West Basin, including a discussion of uncertainties in the risk assessment. The risk characterization relied on a quantitative approach of calculating hazard quotients for one higher trophic level receptor (harbor seal) and on a preponderance-of-evidence approach for final assessment of West Basin sediments.

The preponderance-of-evidence approach considered data collected from the West Basin, including surface sediment physical and chemical measurements, sediment and pore water toxicity tests, and fish tissue chemistry. The preponderance-of-evidence approach also considered the findings of the clam bioaccumulation studies and benthic infauna studies. The hazard quotient approach used fish whole body chemistry to estimate harbor seal chemical exposure (dose). This exposure was then compared against chronic toxicity benchmark values, and hazard quotients were produced. AOPECs (SEZs B, G, and H), which were initially identified in Section 4.8, were evaluated in this ERA for the purpose of assessing whether the ERA findings warranted any of these AOPECs to be classified as areas of ecological concern (AOECs).

6.1 PROBLEM FORMULATION

The purpose of this ERA was to assess whether chemicals found in West Basin surface sediments were associated with adverse effects to components of the marine ecosystem. The ERA is largely confined to effects from surface sediments and does not address the water column, suspended sediments, or other media as they were not within the scope of work of this RI. Surficial sediments were considered to be the biological habitat of principal concern. These sediments may have been recipients of chemicals discharged into West Basin in the past and, as such, may currently constitute a potential secondary source of chemicals to West Basin.

This subsection identifies the ecosystems potentially at risk, develops the RACSM, and selects assessment and measurement endpoints.

6.1.1 Ecosystems of Concern

The LA/LB Harbor contains a variety of marine habitats and marine life (Dailey et al. 1993). These habitats may be subdivided into hard substrate, soft bottom, water column, and specially designated habitats. Hard substrate habitat typically includes riprap (e.g., boulders, concrete rubble), walls, and wood and cement pilings. These different habitats

0188

R0062797

support diverse types of biota, which are dominated by invertebrates. Barnacles, mussels, echinoderms, and seaweed dominate hard substrate habitat in LA/LB Harbor, while polychaetes, amphipods, and other burrowing infaunal invertebrates dominate soft bottom substrates. The water column generally is inhabited by fish and various plankton species. A variety of bird species inhabit the West Basin area.

The marine ecosystem in the West Basin is largely nonnatural in that man-made structures, such as the Navy Mole, piers, and even the San Pedro Bay breakwater, have altered the natural environment of this general area for over 50 years. Before human intervention, the natural shoreline, where the LBNSY is presently situated, was a sandy beach. The margins of the West Basin are currently protected from wave action by concrete or wood walls that are lined with large angular rocks. Water depth is 45 feet or greater over most of the West Basin, with maximum depths of about 80 feet near the entrance. Water depth in the West Basin is maintained by occasional dredging to allow use by large ships. There are a small number of intertidal and shallow water habitats associated with the pier pilings and steep rocky faces located along the periphery of the West Basin.

Two distinct bottom habitats occur in the West Basin: the basin area and areas beneath the piers. The bottom substrate in the basin area is generally considered to be soft silty clay comprised mostly of fine grained sediments, with grain sizes ranging to coarse sand near the opening of the basin; there is no rock bottom substrate. The habitats beneath the piers are of three types: soft sediment, shells and debris protruding from the sediment, and columnar pilings extending from the sediments to above the water surface.

6.1.2 Risk Assessment Conceptual Site Model

The RACSM focuses on pathways and receptors discussed in both the CLEAN I RI/FS Work Plan (JEG 1993a) and the RAWP (BNI 1995a) for the NAVSTA Long Beach, with particular reference to potential aquatic pathways and receptors associated with the West Basin. Potential contaminant migration and subsequent exposure pathways associated with ecological receptors are shown schematically on Figure 6-1. Primary sources of discharges into West Basin, as identified in Section 2, may have been associated with numerous shore- and ship-based activities such as lead caulking, painting, welding, sand blasting, vehicle and equipment washing, process tank drainage, and boiler, water softener, cooling system, and pipe flushing operations. Storm and sanitary sewer discharge, flushing of dry-docks, accidental leaks or spills, and bilge discharge represent past primary release mechanisms of chemicals into the West Basin waters.

6.1.2.1 RECEIVING MEDIA

Following release or discharge into West Basin, chemicals may dissolve in West Basin waters, sorb to suspended particulates in the water column, or settle into bottom sediments. Thus, the three exposure media for primary and secondary receptors identified for the purposes of developing this RACSM are surface waters, suspended particulate matter, and undisturbed bottom sediments. Of these three media, chemicals remaining

VOL 18
0189
R0062798

within West Basin are most likely to reside in bottom sediments (see Appendix U of this RI Report for information on chemical fate within West Basin).

Surface Water

Hydrophilic chemicals may become dissolved following discharge to surface waters, may desorb from bottom sediments, or may desorb from suspended sediments into the water column. Chemicals residing in the water column are difficult to measure because surface water represents a highly dynamic system due to oceanographic processes such as currents, flushing, and tidal flux.

Based on information gathered on discharge identification (Section 2.2), current major land- and ship-based Navy discharges to West Basin are controlled. Thus, no discernible point sources are presumed to exist that could lend themselves to quantification of chemical discharge. However, uncontrolled outside sources may exist and cause trace concentrations of chemicals to enter West Basin waters, which would be difficult to measure.

Suspended Sediments

Resuspension of bottom sediments could occur as a result of mechanical actions such as dredging, propeller disturbances, ship movements, and, to an extent, tides or other oceanographic factors. For the purposes of this RI, no distinction was made between dissolved chemicals and those that are sorbed to particulates suspended in the water column.

Although it is likely that sediment resuspension will occur in West Basin, it was deemed that resuspended sediments represent a minor exposure medium when compared to bottom sediments for the following reasons: 1) suspended sediment particulates are generally settleable solids; and 2) even when sediment particles become suspended in the water column, they are difficult to quantify or trace to a specific land or ship use activity (BNI 1995a). Thus, any chemicals possibly adsorbed to disturbed sediments will ultimately reside on the West Basin floor or may be transported out of the West Basin altogether.

Undisturbed Bottom Sediments

Exposure of aquatic biota, especially demersal and benthic-dwelling organisms, may occur as a result of sediment ingestion, e.g., during burrowing, ingesting invertebrates as prey, direct contact, or uptake via the gills. Because they may represent both a sink (reservoir) and potential source of chemical toxicants, the bottom sediments are most representative of the possible exposure pathways for chemicals in the surface waters resulting from discharges or releases to West Basin. Chemicals discharged into West Basin would be expected to adsorb to suspended sediment particles or bottom sediments to some extent. Therefore, undisturbed surficial sediments were emphasized as the medium of principal concern in this ERA.

VOL 18
0190
R0062799

6.1.2.2 EXPOSURE ROUTES AND RECEPTORS

Sediments in West Basin were considered to be the potentially affected media for this RI. Principal exposure routes to chemicals associated with bottom sediments (the predominant exposure medium), dissolved in surface water, or sorbed on suspended sediment particles include ingestion, dermal absorption, and respiration. Primary receptors of the chemicals include marine invertebrates and fish, both benthic and pelagic. Secondary receptors, defined as predators potentially exposed to chemicals via ingestion of prey species, include predatory wildlife (JEG 1993a), such as carnivorous fish, and marine birds and mammals, consuming fish caught from West Basin. These pathways and potential associated receptors are illustrated in Figure 6-1.

Analyses of sediment and food ingestion pathways provide information about indications of significant contamination. Dermal contact with the water column, respiration of chemicals in the water and sediment, and ingestion of chemicals in the water column were not addressed in this ERA as these tasks were not within the scope of this RI. Dermal contact with sediments by benthic infauna and demersal fish was considered an exposure pathway; this exposure route was indirectly evaluated via benthic community analysis and the harbor seal hazard index calculation based on ingestion of demersal fish.

Based on the ingestion exposure routes, the following general classes of ecological receptors might be potentially exposed to chemicals in West Basin sediments:

- fauna living in contact with the sediments,
- fauna living near the sediments (i.e., organisms beneath piers living on exposed shells),
- fauna eating the sediments, and
- fauna foraging on organisms living in contact with the sediments.

No fish or invertebrates in the West Basin are known to be species of special concern by federal or California state regulatory agencies. However, numerous marine organisms inhabit the West Basin that are similar to those found in LA/LB Harbor (LA/LB Harbor Departments and U.S. ACOE 1990). The following discussion summarizes major taxa of marine wildlife found in the LA/LB Harbor.

Invertebrates

Soft bottom habitats typically support organisms that burrow into sediment (infauna), such as worms, and those that inhabit the surface of the harbor floor (epifauna), such as sea stars and sea urchins. Diverse benthic species typical of other southern California bays and harbors exist in LA/LB Harbor. Annelid worms dominate soft bottom habitats with other abundant phyla, including mollusks, arthropods, and echinoderms. Annual seasonal changes in community composition of infaunal organisms are expected due to physical and climatic changes.

R0062800

VOL 18

0191

VOL 18

Plankton

Among the organisms that typically inhabit the water column are plankton, which can be characterized as small floating or weakly swimming animals (zooplankton) or plants (phytoplankton) and larval forms of many fish species (ichthyoplankton). Water column habitat is defined as the area of water from the surface to the harbor bottom. The outer LA/LB Harbor exhibits seasonal phytoplankton patterns with diatoms dominating in the spring and dinoflagellates in the fall. The most dominant phytoplankton species found in LB Harbor include *Chaetoceros* sp., *Asterionella japonica*, and *Skeletonema costatum*, while red tides are mainly attributed to seasonal blooms of *Gonyaulax polyhedra*. Dominant zooplankton organisms include copepods and cladocerans (LA/LB Harbor Departments and U.S. ACOE 1990).

Fish

LB Harbor contains a large and diverse population of fish. Both pelagic and demersal fish are well-represented by this population. The distribution and abundance of fish varies by season and location within the harbor. Population peaks generally occur in the spring and early summer, while populations tend to decrease in the late summer and fall. The dominant fish in terms of both abundance and biomass is the white croaker (*Genyonemus lineatus*) (JEG 1993a). Fish species captured in the West Basin using trawls for this RI are listed in Table 4-22.

The productivity of LB Harbor ichthyofauna is estimated at being 1.7 to 1.9 g/m^2 dry weight per water surface area per year. Other southern California in-shore and estuarine habitats yield one-fifth to one-half the productivity of LB Harbor. LB Harbor is a nursery for all species of fish that reside there as adults (MEC 1988), as all fish collected as adults have also been collected as larvae.

Birds

The LA/LB Harbor habitat is used by both marine and land birds, especially migratory and wintering water birds. The greatest abundance of birds occurs between September and March. MBC documented 85 species of birds (67 water- and 18 land-associated) during a 1983 to 1984 LB Harbor biological survey (MBC 1984). The most abundant bird species were Hermann's gull, California brown pelican, western gull, surf scoter, Brandt's and double-crested cormorants, ring-billed gull, black-bellied plover, and western grebe. This high diversity is presumed to be due to the variety of habitat and food resources within LB Harbor.

A few of the bird species known to reside in or that frequent the LA/LB Harbor are threatened or endangered:

- The California least tern (*Sterna antillarum browni*) is a state and federal endangered species. It migrates from Mexico to coastal southern and Central California in the spring (early April) to breed, and migrates south again in August. The least tern's migration is linked to onshore movement of the northern

0192

R0062801

anchovy, topsmelt, and jacksmelt. It nests in coastal areas adjacent to shallow marine and estuarine habitats. Two breeding colonies of California least terns have been reported on Terminal Island about one mile west of the West Basin, and they are known to forage in LB Harbor (LA/LB Harbor Departments and U.S. ACOE 1990).

- The California brown pelican (*Pelecanus occidentalis californicus*) is a state and federal endangered species. It forages along the California coast year round. The highest densities of the pelican occur in the LA/LB Harbor from early July through early November (LA/LB Harbor Departments and U.S. ACOE 1990). It is known to forage in the West Basin.
- The American peregrine falcon (*Falco peregrinus*) is a state and federal threatened species. LB Harbor is part of its habitat range, but it is rarely sighted (LA/LB Harbor Departments and U.S. ACOE 1990) and not known to forage in the West Basin (peregrine falcons feed almost exclusively on other birds).
- The Western snowy plover (*Charadrius alexandrinus nivosus*) is a federal threatened species. It resides on coastal sandy beaches and shores of salt ponds and alkaline lakes. It feeds at the water's edge or among scattered debris on sandy beaches, but sightings of this bird near LB Harbor are sporadic and infrequent (LA/LB Harbor Departments and U.S. ACOE 1990), and no suitable habitat for the species exist in the West Basin.

Mammals

The only marine mammals known to use the West Basin, and this only on an occasional basis, are the harbor seal (*Phoca vitulina*) and the California sea lion (*Zalophus californianus*). The Guadalupe fur seal (*Arctocephalus townsendi*) is a state and federally threatened marine mammal which occurs occasionally offshore in southern California, but has never been known to use the West Basin. Whales, including all listed species, are also not known to use the West Basin (JEG 1993a).

6.1.3 Ecological Endpoints

Ecological endpoints are receptors and their characteristics that may be adversely affected by environmental stressors. Ecological risk assessment guidance specifies two types of endpoints: assessment and measurement (U.S. EPA 1992c). Assessment endpoints are qualitative or quantitative expressions of environmental values to be protected from site-related stressors. The identification of assessment endpoints at any site is dependent upon several factors, including the species that are considered to be of concern and the stressors that are present within the assessment area. Assessment endpoints link the ERA to the risk management process. Measurement endpoints are characteristics of species or ecosystems that can be evaluated through ecological monitoring or other sampling activities and can be quantitatively or qualitatively related to the assessment endpoints. The measurement endpoints are generally determined for indicator species likely to inhabit

VOL 18
01993
R0062802

the areas of investigation. The following sections describe the selection of the assessment endpoints and identification of the measurement endpoints for the West Basin.

6.1.3.1 ASSESSMENT ENDPOINTS

Criteria used for the selection of assessment endpoints for West Basin included: 1) regulatory and social significance; 2) ecological relevance; 3) amenability to measurement or prediction; and 4) susceptibility to contaminants (U.S. EPA 1992c). Social significance indicates that the assessment endpoint has value to the public or to regulatory agencies (e.g., population abundance of game animals, viability of endangered species). Ecological relevance refers to the role of the assessment endpoint in the ecosystem or community. Measurability indicates that some measurement exists to allow evaluation of the endpoint. Susceptibility to contaminants indicates the potential for the assessment endpoint to be exposed to and adversely affected by chemicals.

Numerous characteristics of species, communities, and ecosystems in the West Basin could be considered as potential assessment endpoints. For example, species of regulatory or social significance may occur in the AOPECs. These species could be susceptible to COPECs through ingestion of contaminated media or food items, and the COPECs could affect their growth, survival, or reproduction. In terms of ecological relevance, functional groups such as invertebrates could also be considered, since these are important prey organisms for higher trophic levels. These receptors would also be highly susceptible to COPECs in sediments due to their burrowing habits. The criterion of measurability is also an important consideration, since toxicological data for aquatic invertebrates and fish are limited, and assessment endpoints must be carefully selected to allow evaluation.

Taking these considerations into account, several categories of assessment endpoint species were selected as representative of the aquatic ecosystem in West Basin (Table 6-1). Benthic infauna, analyzed as a community because of the large numbers of species and the complexity of the invertebrate ecosystem, and a primary consumer fish species (white croaker) were chosen to signify potential West Basin primary receptors of chemicals. One secondary consumer fish species (California halibut) and a marine mammal (harbor seal) were chosen to represent potential West Basin secondary receptors of chemicals.

No threatened or endangered species, except birds, regularly use the West Basin. Birds were not deemed a receptor for the purposes of this ERA under the premise that no direct link existed between the bird's foraging activity and the surface sediment chemical concentrations. The bird species identified as potentially residing in or frequenting West Basin feed primarily at the surface of the water column, and thus are not likely to prey on demersal fish, which are designated as primary receptors for the purpose of this ERA.

A systematic method was used to identify fish assessment endpoint species. First, fish species likely to be found in West Basin were divided into major taxonomic groups. The relative abundance of each species likely to occur at the site and thus be caught by predators was evaluated. Only species known to be abundant or common in West Basin

VOL 18 0194
R0062803

were considered for selection as assessment endpoint species. Second, each taxonomic group was divided into functional groups by combining species with similar potential for exposure to sediment COPECs (e.g., bottom feeders, pelagic species). This was accomplished by defining the trophic level, the feeding habitat, and the nonfeeding habitat of each fish species expected to occur in West Basin. The trophic levels were generally defined as herbivore, carnivore, omnivore, and detritivore. The feeding habitat and nonfeeding habitat types included bottom sediment or water column. Each of the feeding and nonfeeding habitats may be further subdivided to represent different niches within each habitat.

In order to limit the number of functional groups for consideration, only those groups presented in Table 6-1 were selected for further analyses. These groups represent three aquatic assessment endpoint species groups: invertebrates, fish, and mammalian carnivore. For purposes of this ERA, each of the species in a functional group was considered representative of others in the same group with regard to potential exposure to COPECs and toxicological effects.

Assessment endpoints for the West Basin ERA include the health and viability of the benthic invertebrate community, the fish community, and the mammalian carnivores. These assessment endpoints will be evaluated through the measurement endpoints described below.

6.1.3.2 MEASUREMENT ENDPOINTS

Specific measurement endpoints were based on the ecological assessment endpoints discussed above, with the emphasis placed consistently on measurement of indicators relating to sediment quality. Selection criteria for measurement endpoints (indicators) were also based on U.S. EPA's Framework documents (U.S. EPA 1992c, 1992d), and included: 1) relevance to assessment endpoints; 2) ability to measure response within the context of natural (e.g., biological) variability; 3) early warning ability; 4) stress-specificity, ease, or economy of measurement; 5) level of documentation; and 6) predictability.

Measurement endpoints used to assess the health of the benthic invertebrates included community analysis, bioassays, and chemical measurements. Benthic invertebrates were identified and counted, providing for an assessment of the balanced and healthy nature of the community composition. The bioassays provided a direct measurement of acute and chronic toxicity from surface sediment and surface sediment pore water using survival, development, and reburial as acute endpoints and growth as a chronic endpoint. Surface sediment chemical concentrations provided a direct measurement of chemical loadings in the sediment. Direct measurements of the potential for bioaccumulation from sediment were made using clam tissue chemical concentrations.

The fish community was assessed with fish tissue chemical concentrations as measurement endpoints. Fillets and whole-body homogenates of white croaker and California halibut

VOL 18
0195
R0062804

were analyzed for chemical residue. California halibut bile was also analyzed for residues for PAH compounds.

Mammalian carnivores, representing higher order predators, were assessed with an HQ calculation based on dose and toxicity benchmark.

6.2 EXPOSURE ASSESSMENT

The exposure assessment consisted of four components: 1) identifying and evaluating potential sources of chemicals discharged into West Basin waters; 2) defining nature and extent of chemical distribution and COPECs; 3) evaluating sediment fate and transport; and 4) developing exposure scenarios for bioaccumulation and food chain transfer. This section focuses on the development of an exposure profile for an indicator predator species (harbor seal). The source identification and nature and extent of chemical distribution within West Basin were discussed in Section 2 and Section 4 of this RI Report, respectively. COPECs identified in sediments at each SEZ are listed in Table 4-49 and discussed in Section 4. COPECs identified in fish tissue that were used in the harbor seal hazard quotient calculations were also discussed in Section 4.

6.2.1 Fate and Transport of West Basin COPECs

This section contains the conclusions of the West Basin COPEC fate and transport analysis contained in Appendix U. The qualitative analysis utilizes physical and chemical parameters commonly used to evaluate transport and fate processes. The parameters include volatilization coefficients (Henry's Law Constant, vapor pressure), octanol-water partition coefficients, sediment-water partition coefficients, water solubility, and half-lives in surface water.

The predominant fate of PAHs, PCBs, organochlorine pesticides, organotins, and metals released to a marine environment such as West Basin involves adsorption to both suspended particulate and bed sediments. Additionally, PAHs, PCBs (especially the heavier chlorinated compounds [5 or more chlorine atoms]), and organochlorine pesticides will degrade via photolysis, and metal ions will form complexes with both organic and inorganic ligands. All four groups of chemicals will bioaccumulate in aquatic organisms.

Chemical-sorbed particles within the water column will eventually deposit into bed sediments, which is the ultimate fate of West Basin COPECs. Once within the bed sediments, the organic compounds (including organotins) will, over time, biodegrade. Metals will either remain bound to the bed sediments or remobilize into the marine ecosystem through microbial processes. As sorbed to sediment particles, West Basin COPECs may be resuspended in the water column and transported via currents to other areas of West Basin.

6.2.2 Quantification of Exposure

The exposure route for benthic invertebrates was deemed to be dermal contact with sediments, and ingestion of sediment and smaller sediment dwelling organisms, assuming the greatest amount of exposure to sediment occurs at a depth of not greater than 10 cm below the surface of the sediments. The wildlife exposure routes included: ingestion of sediment dwelling invertebrates and incidental ingestion of sediment by white croaker; ingestion of sediment dwelling invertebrates and incidental ingestion of sediment, as well as ingestion of smaller fish by California halibut; and ingestion of white croaker by the harbor seal. These ingestion routes were based upon known foraging behavior of each receptor. The exposure scenarios for ecological receptors identified within West Basin are presented in Table 6-2.

The exposure medium used in the HQ calculation portion of the ecological investigation was white croaker, which were captured in the West Basin by trawl nets. Whole body and fillet tissue analyses were performed for each sample, but only whole body results were used because it was assumed that harbor seals consume the entire fish. The fish COPEC list consisted of only those chemicals (a total of seven) statistically significantly greater in concentration in the West Basin than in the reference stations and those chemicals occurring in West Basin samples and not in reference station samples. Quantitative risk calculations were not made for the harbor seal feeding on fish from the reference area on the basis of the premise that the risk to the harbor seal would be lower when exposed to chemicals in whole body white croaker ingested from the reference stations than from the West Basin. This premise is supported by the findings that concentrations of the fish COPECs are statistically significantly lower in reference station fish than in West Basin fish. California halibut were not used in this analysis because the concentrations of chemicals measured in California halibut tissue from the West Basin were not statistically different than reference station values for any fish COPEC.

Consistent with U.S. EPA guidance for risk assessment (U.S. EPA 1989b), the 95% UCL of the arithmetic mean concentration was used as an estimate of the average concentration in the fish tissue for the purposes of estimating exposure and risk. The exposure of the harbor seal to a fish COPEC from ingestion was calculated based on the following assumptions:

- harbor seals consume only white croaker,
- harbor seal body weight is 84.6 kg (U.S. EPA 1993c), and
- harbor seal consumption rate of white croaker is 5.9 kg/day (consumption of 0.07 kg of fish per kg of harbor seal body weight per day [U.S. EPA 1993c]).

6.3 CHARACTERIZATION OF ECOLOGICAL EFFECTS

This section characterizes ecological effects in two ways: 1) it derives toxicological benchmark values for each fish COPEC in support of the harbor seal hazard quotient calculations; and 2) it evaluates potential surface sediment toxicity by using West Basin-

VOL 18
01971
R0062806

specific surface sediment bioassay and benthic infaunal data, and assesses bioaccumulation potential of sediment COPECs by using fish and clam tissue chemistry data, in support of the preponderance-of-evidence approach. Section 6.3 concludes with a discussion of the sediment COPECs as they relate to West Basin-specific biological findings.

6.3.1 Hazard Quotient Approach

The toxicological evaluation involved characterizing the inherent toxicity of the fish COPECs and establishing toxicity benchmarks (TBs) for each fish COPEC for the harbor seal. The TB is a concentration or dose representative of the expected "no observed adverse effect level" (NOAEL) for any given receptor and fish COPEC. TBs were selected from published dose response studies, which typically involve the use of standard laboratory or domestic test species of animals. Extrapolation of these benchmarks to wild populations is uncertain; thus, a conservative approach was taken to avoid underestimating potential toxicity. These uncertainties and their relevance to the ERA are discussed further in this section.

Each COPEC being evaluated in the risk assessment for the harbor seal, the TB selected for evaluation was termed a Toxicity Reference Value (TRV). Potential impacts to the harbor seal at estimated exposure doses were evaluated using published toxicological data for mammalian species (Opresko et al. 1995). From these data, a test species NOAEL was selected as a TB for each fish COPEC. Toxicity data reported as dietary concentration (mg/kg in food) were converted to a dose (i.e., mg/kg-body weight as an average daily intake) using data and weight adjustments (Opresko et al. 1995) presented in the source study or from information on average ingestion rates and body weights of test animals (see Table 6-3). TBs were drawn from studies that considered reproductive and developmental effects, or other critical effects indicative of overt impacts to individual organisms that may affect population size. Studies incorporating chronic exposure durations, multiple exposure levels, and statistical evaluation of test results were preferred.

Within any group of animal species, the major source of variation in sensitivity to toxic effects of contaminants is varying body size (Opresko et al. 1995). In general, smaller organisms are more tolerant of toxins as a result of their higher rate of metabolism and greater detoxification capability. To account for this source of variation in sensitivity, the TBs were adjusted to estimate species-specific wildlife TRVs using the approach described by Opresko et al. (1995). Dose equivalency for organisms of varying body sizes was adjusted for differences in body size between test species and endpoint species by dividing the body weight of the test species by the body weight of the endpoint species, taking the one-third power of the result, and multiplying by the known toxicity benchmark (NOAEL) of the test species. The resulting TRVs were used to calculate an HQ for each COPEC.

The TRVs for the harbor seal are listed in Table 6-3. The TRVs are presented as dose estimates, in units of mg/kg-body weight/day, to allow direct comparison with the

VOL 18
0198
R0062807

exposure estimates. From examination of the values shown in Table 6-3, it can be seen that TRVs vary greatly among fish COPECs.

Dibutyltin was not evaluated because of the absence of a TRV. It is probably less toxic than tributyltin (SWRCB 1988), which was reported to be present in the fish tissues at higher concentrations than dibutyltin.

6.3.2 Preponderance-of-Evidence Approach

Sediment bioassay, benthic community analysis, and bioaccumulation data were used to evaluate chemical concentrations of surface sediments in the preponderance-of-evidence approach discussed herein. This approach involved development of an evaluation matrix that summarized results from all project data sets (Table 4-51). The evaluation matrix was used to score and rank SEZs, with the intent of classifying them as either an AOPEC or a nonAOPEC. This section discusses the results of statistical comparisons used to identify patterns and trends between bioassay, benthic infaunal, and clam tissue chemistry data with surface sediment chemistry data.

6.3.2.1 BIOASSAY

The results of solid phase and pore water bioassay tests for each SEZ were compared statistically with reference values (Section 4). If the bioassay results were judged to implicate a sediment COPEC in the observed effect, the SEZ was considered to pose a potential hazard to the intact ecosystem in that SEZ. Correlation analysis, principal components analysis, or multiple regression were used to investigate patterns between the bioassay and sediment chemistry data. If the toxicity results can be associated with physical or chemical data patterns, a distributional or toxilogical pattern may exist.

Results of the toxicity bioassays for West Basin showed the echinoderm larvae as most sensitive (30 of 50 stations exhibiting a response) and the polychaetes as least sensitive (1 of 52 stations exhibiting a response). The amphipod sensitivity was intermediate to the echinoderm and polychaete (6 of 52 stations exhibiting a response). Toxicity test results were often contradictory in that patterns between toxicity and sediment chemistry and physical properties could not be established. Results of the echinoderm survival and development tests were especially paradoxical.

The environment beneath the piers appears to be different than in the basin and at reference stations. Sulfide levels were several times higher in the anaerobic environment beneath the piers and most TOC levels at most of the pier stations were elevated (Section 4). The beneath-pier pore water used in bioassay tests had greater ammonia and sulfide concentrations than any other samples (Appendix M), though there were no clear patterns of these concentrations with bioassay test results. The only clear trend discernible from the data was that pore water conditions beneath the piers appeared to be detrimental to echinoderm development. Conversely, polychaetes exhibited greater growth, for samples collected from beneath the piers, than for reference stations, which indicates that beneath-

R0062808

VOL 18
0199

pier conditions may not be as toxic as an examination of chemistry or echinoderm bioassay results might suggest.

Correlation Analysis

To investigate patterns between toxicity and sediment chemistry and physical properties, correlation analyses were performed measuring the intensity of association between sediment chemistry and physical traits, and bioassay results. All detected chemicals were used in the analysis, regardless of sediment COPEC status of the analyte. Minimum threshold for the correlations was set at r = 0.40; data were evaluated as both untransformed and log-transformed, and separated by pier samples and samples from the remainder of West Basin for different permutations (Section 4).

There was no clear trend to the results of these analyses (Table 6-4). A few significant correlations were found, but these appear to be nonsensical (i.e., a positive relationship between echinoderm survival and acenaphthene concentration [r = 1.0]). This type of correlation derives from the low frequency of detection of acenaphthene and has no biological meaning. Results of correlation analyses must be interpreted with respect to the frequency of detection of each analyte. Also, correlations among the various bioassay tests showed a significant positive correlation, such as between echinoderm survival and echinoderm development (r = 0.65) and amphipod survival and amphipod reburial (r = 0.94). These expected correlations are due to the dependence of one endpoint on the performance of the other endpoint for any bioassay test species. Other significant correlations between the bioassay tests were negative (e.g., amphipod survival and polychaete growth [r = -0.62) and amphipod reburial and polychaete growth [r = -0.51]), which indicates that the tests themselves were possibly responding to different stressors. The acute echinoderm tests, run for a duration of 48 hours in this study, appeared to reveal little about ecological effects of the West Basin sediments.

The relationship between pier station sediments and adverse biological response is strong (i.e., 100 percent of the pier stations had at least one bioassay "hit" compared to 58 percent of the basin stations). The pier stations were characterized by sulfide levels approximately 40 times greater than the basin stations. These high sulfide levels infer anaerobic conditions. This distinguishing feature correlated well with other characteristics of the pier sediments, such as concentrations of some PAHs and gravel size particles (shell hash). Sulfide correlated weakly with most concentrations of metals and other PAHs, clay size particles, and TOC. Because of these complex correlations, it is difficult to identify the most important variable associated with any bioassay response. Sulfide levels correlated well with poor amphipod performance, but also correlated well with enhanced polychaete performance.

Multivariate Analysis

PCA was used to describe chemical and physical variables that displayed similar variance patterns (Appendix S). The results of the PCA suggest five primary factors: 1) several

VOL 18
02000
R0062809

HPAH compounds, 2) Aroclor 1260, copper, lead, and mercury; 3) cadmium, DDE, and TOC; 4) beryllium, nickel, and fines; and 5) sulfides.

Predictably, the PCA recognized the HPAH compounds as a similar unit. However, TOC and fines were recognized as separate factors despite a good correlation between them ($r = 0.70$). Sulfide also, predictably, comprised its own factor. Elements in each PCA factor corresponded to the condition for that factor at each individual sediment sampling station (e.g., the PCA algorithm accounts for the sediment chemical concentrations and variance for PCA factor number two [Aroclor 1260, copper, lead, and mercury] and calculates a single value for each sampling station which accounts for those chemicals). This value was used in regression analysis to determine the significance of those chemicals, at the concentrations detected at each station in relation to all other stations, on West Basin biological systems.

Stepwise multiple regression was used to evaluate the predictive relationship between the bioassay results and the PCA factors (Appendix S). As might be expected, the multiple regression equation for echinoderm normal development included all of the five primary PCA factors, except the HPAH factor. This appears to agree with the bioassay results that did not exhibit a clear distributional pattern, and may have been sensitive to several stress variables.

Sulfide was either the most important factor or second most important factor of the multiple regression equation for all bioassay endpoints. Amphipod survival and reburial, which showed a strong negative correlation with sulfide, also had the sulfide factor as the most important variable of the multiple regression equation.

The PCA and multiple regression analyses appeared to show results that displayed similar patterns regarding bioassay performance and sediment chemical and physical traits. Bioassay performance was clearly related to pier station sediment chemistry, as represented primarily by sulfide, but also PAHs. Distinguishing any individual stress variable that was controlling the response of any bioassay endpoint was not readily possible with these data.

Effects Range Analysis

Table 6-5 presents the mean and 95% UCL chemical concentrations at different SEZs in relation to toxicity test results. Also shown are the highest individual chemical concentrations for the basin stations which did not show a toxicity test "hit" for any of the six bioassays, and for pier stations which only showed a toxicity test "hit" for the pore water echinoderm development bioassay. The ER-L and ER-M levels are also shown for each chemical for comparison purposes. Six chemicals (dibutyltin, monobutyltin, acenaphthene, fluorene, methylnaphthalenes, and phenol) were either not detected in the basin stations or detected at too few stations to produce a no "hit" result.

Mean chemical concentrations from only three SEZs (F, G, and H) were found to exceed the no "hit" chemical concentration (Table 6-5). For SEZ F, the only chemical concentrations which exceeded the no "hit" value were copper, lead, mercury, zinc,

R0062810

VOL 18 0201

benzo(b)fluoranthene, Aroclor 1260, and di-n-octylphthalate. However, mean bioassay results showed that there was no adverse toxicity response at SEZ F.

In SEZ G, the only chemical concentrations which exceeded the no "hit" value were di-n-octylphthalate and total sulfide. These data indicate that either di-n-octylphthalate or total sulfide may be related to the toxicity response observed in the echinoderm development test for SEZ G.

SEZ H had 17 chemicals with concentrations which exceeded the no "hit" value. A review of the maximum concentrations associated with toxicity responses indicates that the echinoderm development toxicity response may be related to one or more of these 17 chemical compounds.

The mean concentrations of benzo(a)anthracene, dibenzo(a,h)anthracene, acenaphthylene, and Aroclor 1260 at SEZ B, the only sediment COPECs at this AOPEC, were less than the highest concentrations of these compounds associated with no toxicity responses. It appears unlikely that the existing concentrations of benzo(a)anthracene, dibenzo(a,h)anthracene, acenaphthylene, and Aroclor 1260 at SEZ B are related to the toxicity response observed in the echinoderm normal development test.

6.3.2.2 BENTHIC COMMUNITY

The results of the benthic infaunal community analysis for each SEZ were compared with the results of reference stations and results of other applicable investigations from the literature. If the infaunal results were statistically significantly different than the reference stations in a manner that adversely effected the ecosystem, the SEZ was considered to contain adverse benthic impacts.

There is a high degree of variability between the piers and basin stations in the results of the benthic community analysis. Among the West Basin stations, the pier stations had the greatest species diversity, number of individuals, and biomass. Even the three separate samples (Stations 44, 45, and 46) collected at intervals beneath a single pier (Pier 12) were only about 50 percent similar in species composition.

Infaunal communities are generally considered good indicators of habitat quality because they respond to chemical inputs as well as to cessation of inputs to their environment on relatively short time scales (Canfield et al. 1994, Chapman et al. 1991, Ferraro et al. 1991). Community interactions (e.g., predation and competition) result in variability over time and from place to place, but, in general, the condition of *in situ* organisms can be the primary determination in evaluating suspected toxicological effects on an ecosystem.

The benthic community at the basin stations appeared healthy and diverse. Many species were observed that are considered indicators of nonpolluted conditions. Station 9 (SEZ C) had the lowest values for some infaunal measures, but this station also had acceptable results for all of the bioassay tests, and it did not have any chemical occurrence or concentration that might result in a degraded community. This variability can be

VOL 18
0202
R0062811

attributed to variations typically encountered during the sampling of any media such as sediments at West Basin and at reference stations.

The beneath-pier benthic invertebrate community appeared to be more complex because three primary types of organisms occurred: 1) those attached to pier pilings, 2) those living at the sediment surface on protruding objects such as shells, and 3) those living in contact with surface sediments. The organisms attached to pilings typically modify the surface sediment chemistry when they detach and sink to the bottom and decay. These organisms were not directly studied for this risk assessment and will not be discussed further, except that they are probably the source of much of the shell hash material observed in the sediments beneath piers.

Studies have shown a measurable response by infaunal organisms along gradients of chemicals (Ferraro et al. 1991, Lenihan 1992). There appeared to be a gradient of chemical concentrations from beneath-pier surface sediment stations to stations between piers (SEZs E and F) for many sediment COPECs. There was no gradient of benthic infauna response from beneath-pier stations to stations between piers as demonstrated by the benthic infauna cluster analysis, in which the pier stations formed their own unique grouping while the between-pier stations grouped with the basin and reference stations (see Appendix N). The benthic infaunal community beneath the piers appeared to be responding to pier-related conditions that likely had a greater effect than simply sediment chemical concentration. This is not to say that conditions under all piers are identical, however.

The pier stations with the fewest sediment COPECs and lowest chemical concentrations were Stations 42 (Pier 16, the pier nearest the entrance to the West Basin) and 47 (Pier 9, a more recently constructed pier in the northwest area of the West Basin). Station 42, with 106 taxa, had the highest number of benthic infauna taxa in the West Basin, and Station 47 had the third highest with 91 taxa. Tidal flushing and lower chemical concentrations appear to slightly improve benthic infauna species diversity beneath these two piers.

The benthic communities in the West Basin do not appear to be at risk from chemical concentrations found in the surface sediments. Typically, harbor environments are highly artificial and are not representative of pristine conditions, but since abatement and control of chemical releases into LA/LB Harbor and the West Basin, the existing benthic community has reached a level of 'semihealthy' composition (Reish et al. 1980). There is no indication that the benthic community in the West Basin is at risk from existing chemical concentrations in surface sediments of the basin; a functional infaunal community exists even at stations with the highest sediment chemical concentrations.

The benthic community beneath the piers appears to be quite different than in the basin and at the reference stations, possibly as a result of exposure to a chemical or combination of chemicals in sediments. However, it is certain that the physical differences between the benthic habitat of the basin and the area beneath the piers has caused much of the differences between the benthic communities. The laboratory analyses performed as part

VOL 18
0203
R0062812

of this RI (toxicity, bioaccumulation, and benthic infaunal community assessment), however, have indicated that the benthic community is healthy and not at risk from possible chemical effects. These results correspond well with the findings of Reish et al. (1980), who demonstrated significant improvements in the benthic infauna of the LA/LB Harbor and West Basin since 1962. Thus, the benthic community of West Basin appears to have improved over time as discharge of chemicals into basin waters has been eliminated or is being controlled.

The fuel pier (Pier 12), for which construction began in 1984 following dredging of the immediate area, shows a benthic invertebrate community that is similar to the other pier stations. This suggests that invertebrate recruitment has been active in the area beneath the fuel pier. Approximately 10 years after sediment dredging, the benthic community beneath the fuel pier appears to be similar to the benthic community beneath other piers where dredging has not occurred for at least several decades.

The sediments beneath the piers do not appear to be a threat to other areas of the West Basin or LA/LB Harbor as long as they remain undisturbed; there were no plans known at the time of writing this RI Report to disturb the sediments beneath the piers. There was no discernible relationship between infaunal species observed at between-pier and beneath-pier stations to indicate that the beneath-pier conditions, including chemical concentrations, were having an effect on any other nearby station (i.e., the sediments beneath the piers are not acting as a source of chemicals). Also, the hard substrate epifaunal taxa living just above the beneath-pier sediments were thriving, so there appears to be no transport of any detrimental chemicals at the sediment-water interface.

There are no known ARARs or defined cleanup levels for sediments in LA/LB Harbor and this RI was unable to establish any specific sediment quality guidelines. Treatment of sediments beneath the piers, including removal or capping, is unlikely to result in any different benthic infaunal community than the one now present because of the unique conditions found beneath these piers.

Correlation Analysis

Correlation of all chemical and physical analytes with seven benthic infaunal measurement indices (dominance, evenness, Margalef diversity, number of taxa, Shannon-Wiener diversity, total biomass, and total abundance) produced both positive and negative correlations (Table 6-4). Even if the number of actual chemical detections is taken into account and individual stations are separated according to pier and general harbor area stations, the correlation results were not very informative.

The correlation analysis shown in Table 6-4 suggests some strong correlations between the benthic infaunal indices and some chemical compounds. However, these apparent correlations are artifacts of the analysis because of very few data values. Chemical compounds such as LPAHs, lindane, phenol, and bis(2-ethylhexyl)phthalate were detected infrequently in the West Basin and show an artificial correlation with the benthic infaunal indices.

VOL 18
0204
R0062813

A strong correlation was noted between the gravel fraction of the sediments and five of the seven infaunal indices. This correlation is probably due to the response of the benthic community to the presence of shell hash in the surface sediment underneath piers, which was reported by the analytical laboratory as gravel fraction sediments. Other correlations were present between the infaunal indices and parameters that appeared to be strongly associated with the sediments beneath the piers, such as some HPAH compounds (e.g., pyrene) and total sulfide.

Multivariate Analysis

PCA analysis and stepwise multiple regression were used to evaluate the relationship between benthic infauna community indices and groups of chemical and physical parameters displaying similar variance patterns. This procedure was similar to the one used with the bioassay results and groups of chemical and physical parameters.

The results of the PCA (Appendix S) show five primary groups of variables, or factors: 1) several HPAH compounds; 2) Aroclor 1260, copper, lead, and mercury; 3) cadmium, DDE, and TOC; 4) beryllium, nickel, and fines; and 5) total sulfide. PCA assigns scores for each of these factors by station, which were used as variables for the stepwise multiple regression.

Similar to the PCA/stepwise multiple regression results for toxicity, total sulfide was shown as a primary factor in the multiple regression equation for the benthic infaunal indices. Total sulfide was the primary variable for abundance, number of taxa, biomass, and Margalef's diversity. Because these benthic infaunal indices generally increased at pier stations, it is not possible to discern whether the relationship between the indices and total sulfide is genuine or if the relationship is due to the physical presence of the pier.

Although the PCA analysis identified several unique factors or groups of variables, the stepwise multiple regression only showed total sulfide as a strong contributor to patterns of benthic infaunal indices. The PCA/multiple regression analysis, therefore, shows a similar finding as the correlation analysis.

6.3.2.3 BIOACCUMULATION INVESTIGATIONS

In addition to toxicity tests and the benthic infauna community assessment, several other ecological studies were performed to assess bioaccumulation potential. These studies involved analyses of fish tissue, fish bile, and clams, as discussed below.

Fish Tissue

In general, the fish population in the West Basin appears robust. Several different types of fish were captured during project trawls and the fish appeared in similarly good condition in the West Basin and in the reference stations (Tables 4-21 and 4-22). Specific tissue chemical analyses are reported below.

California Halibut. The California halibut tissue chemical concentrations were not statistically significantly different between fish in the West Basin and at the reference

VOL 18
0205
R0062814

stations. There were no statistically significant differences between the two locations for any chemical analyte in either fillet or whole body samples. The West Basin samples contained three analytes that were not found in corresponding reference fish (tributyltin and dibutyltin for fillets, and selenium for whole body), but the concentrations were very low and each analyte occurred in only a single sample. Chemical concentrations found in California halibut from several other locations within southern California are provided in Appendix E. The ranges found in California halibut from the West Basin, from the reference stations, and from other California harbors are similar.

California halibut are occasional residents in the West Basin. Appendix V contains a synopsis of the life history and biology of California halibut. Concentrations of analytes measured in California halibut from the West Basin indicate no ecological concern at the population or community level.

White Croaker. The statistical results indicate significant differences for some analytes in white croaker between the West Basin and reference station values. Appendix V contains a synopsis of the life history and biology of white croaker. White croaker are most likely year-round residents of the West Basin, and it was by far the most common fish caught during trawls for this study (almost 600 white croaker were caught in 27 trawl attempts in the West Basin). Considering individual analytes, white croaker often have higher concentrations than associated with California halibut, but the trend is not comprehensive, as demonstrated in both West Basin and reference station values (Section 4).

Arsenic and mercury in fillets, and mercury in whole body West Basin samples were within or below the range of values commonly measured in southern California harbors, as shown in Appendix E. Concentrations of copper and zinc (both fillet and whole body), lead (fillet only), and arsenic and chromium (whole body only) in West Basin samples were above the commonly measured ranges. This trend in metals concentrations as compared to other southern California harbors was also true for white croaker from the reference stations. The coefficient of variation for the various analytes commonly exceeded 75 percent, and there was no clear pattern to determine the locations where the fish were swimming or feeding and thus obtaining elevated chemical levels.

The analytes which were statistically greater in West Basin fillets or whole body than the reference station values were endosulfan II, dibutyltin, tributyltin, arsenic, copper, and mercury. Furthermore, based on the number of fish captured (Table 4-21) and their external physical appearances (Table 4-22), there was no evidence of the elevated levels of chemicals having any detrimental effects on the white croaker population in the West Basin.

Fish Bile

Little historical data are available for levels of PAH metabolites in finfish bile. Typical total PAH metabolite levels in the bile of fish from urban areas (e.g., Puget Sound) have generally been reported to be significantly above 100 microgram per gram (µg/g), whereas for fish from nonurban regions, the levels are typically less than 100 µg/g when determined

VOL 18
0206
R0062815

based on naphthalene (Krahn et al. 1986b, 1986c, 1987). Hellou and Payne (1987) found that residence time of naphthyl glucuronide-type metabolites within trout which had been injected with No. 2 fuel oil was approximately 6 days, and that residence time decreased as water temperature increased. Dixit and Anderson (1977) reported that total naphthalenes have been shown to bioaccumulate in gall bladder bile by a factor of 1,000 or more in fish exposed to water-soluble fractions of fuel oil for a few days. In 1986, Krahn et al. (1986c) reported total PAH metabolite levels averaging 200 µg/g (based on naphthalene) and 210 µg/g (based on phenanthrene) in the bile of white sturgeon caught 57 miles downstream of an oil spill in the Columbia River, five days after the spill. Fish caught in a relatively nonurban location 13 miles upstream had total PAH metabolite levels in the bile ranging from 17 to 32 µg/g when determined based on naphthalene, and 9.6 to 9.7 µg/g when determined based on phenanthrene. Krahn et al. (1987) reported total PAH metabolite levels ranging from 1.3 to 21 µg/g in English sole collected from Puget Sound when determined based on benzo(a)pyrene. However, significantly higher concentrations would likely have been determined if these analyses had been performed at the naphthalene or phenanthrene wavelength pairs. In 1986, Krahn et al. (1986c) reported on the analysis of a set of fish bile samples that had been analyzed at each of the benzo(a)pyrene, naphthalene, or phenanthrene wavelength pairs; the concentrations determined based on naphthalene and phenanthrene were approximately 10 times greater than the concentrations determined based on benzo(a)pyrene.

When comparing the data generated in this RI Report to data reported by Krahn et al., the measured levels of PAH metabolites in the bile of several of the fish appear to be similar to levels from an urban/industrial or contaminated region, while other samples had levels that were closer to what could be expected for regions remote from industrialized areas. The relationship between the naphthalene, phenanthrene, and benzo(a)pyrene metabolite levels were comparable to what have been reported by Krahn et al. in studies where two or three parameters were determined. However, it must be pointed out that PAH metabolite levels may vary significantly from one species of fish to another, even if they are from the same environment, and different species of fish were evaluated as part of this RI than the Krahn studies. Additionally, different analytical detectors, and slightly different detector conditions, were used which can yield data differences. Furthermore, the sample-specific metabolite composition affects the apparent total metabolite concentration because of the significant analytical detector response differences for different metabolites. Total PAH metabolite data should therefore not be considered absolute, but only a component of a data set in an environmental assessment.

ANOVA results indicated no statistically significant difference between the bile content of West Basin and reference station California halibut for naphthalene, phenanthrene, pyrene or benzo(a)pyrene. Although correlations between concentrations of aromatic hydrocarbons in sediments and biological response in fish have been reported (Malins et al. 1987), it was impractical to conduct a correlation of sediment PAH chemistry and California halibut bile PAH concentrations for this RI. The sediment chemistry analyses for portions of West Basin, particularly beneath the piers, have shown elevated PAH

R0062816

VOL 18 02071

levels. However, the California halibut, the fish species captured for bile analyses as part of this RI, is a wide-ranging tertiary carnivore (Dailey et al. 1993), and there does not appear to be a direct link between chemical concentrations in these fish to chemical concentrations in sediments beneath the piers. Also, it was impossible to relate bile chemical concentrations with California halibut fillet tissue chemistry (nine fish had chemical analyses performed for both bile and fillet) because the fillet tissue chemistry concentrations were all less than reporting limit for naphthalene, phenanthrene, pyrene, and benzo(a)pyrene.

It is not practical, from existing data, to relate bile chemistry results from this study to existing or possible future health risks to the California halibut population using LA/LB Harbor. The California halibut typically use the West Basin only seasonally, and the amount of time an individual fish might spend within the West Basin is not known. Judging from the condition and number of California halibut captured during this RI, the fish do not appear to have been detrimentally impacted by their use of the West Basin.

Clam

The bioaccumulation tests were intended to provide information about the availability of chemicals in surface sediments to benthic organisms, and possibly for use to calculate bioaccumulation factors for estimating chemical uptake by benthic organisms. Bivalve mollusks do not rapidly metabolize PAHs and can be considered as acceptable indicators of chemicals in the marine environment. Gossett (1983) reported that mussel tissue PAH concentration was ten-times the concentration in nearby sediments.

Five basin stations which were selected for the laboratory bioaccumulation tests (Stations 6, 8, 14, 24, 29) all showed relatively low concentrations of chemicals in the sediment samples.

Correlations of surface sediment chemistry with the associated clam tissue analyses for detected chemicals showed no remarkable relationships. The correlation coefficients for compounds detected in clam tissue (r values) were: 0.14 for DDE, -0.40 for arsenic, 0.00 for chromium, 0.48 for copper, 0.31 for mercury, 0.26 for zinc, 0.10 for pyrene, and -0.07 for tributyltin. Thallium was not detected in sediments and therefore was not included in the correlation analysis. Clam tissue chemical concentrations appeared not to be dependent upon sediment chemical concentrations found in the West Basin sediments. The one exception may be pyrene which was only found in clams exposed to sediments from beneath piers, the concentrations of which ranged up to 30 µg/kg (Station 49). The sediments beneath the piers had the greatest concentrations of pyrene: 870 µg/kg for Station 51, 2,800 µg/kg for Station 43, and 2,000 µg/kg for Station 49. However, there was no correlation between these sediment concentrations and the clam tissue concentrations. Also, several other PAH compounds were found at elevated levels in the sediments from beneath the piers, yet none were discovered at detectable levels in the clam tissues. Clam tissue concentrations of chemicals have been shown to vary greatly throughout the year regardless of the surrounding sediment concentration (NOAA 1991b)

VOL 18
02008
R0062817

Pyrene concentrations in clam tissue (20 µg/kg at Stations 43 and 51, and 30 µg/kg at Station 49) at the end of the 28-day test were not exceptionally high compared to findings in other harbors. NOAA (1991b) compiled data for bivalves from several studies and reported average values: 1.25 mg/kg for arsenic, 0.08 mg/kg for chromium, 0.63 mg/kg for copper, 0.02 mg/kg for mercury, and 8.91 mg/kg for zinc in Los Angeles Harbor; 1.54 µg/kg for tributyltin at San Pedro Fishing Pier; and 65.0, 84.4, and 34.0 µg/kg for pyrene in the entire United States (reported as HPAH), West Coast, and the Bight, respectively.

The fact that the clam tissue data did not correlate with associated sediment chemical concentrations may indicate that the chemical concentrations and forms found in the West Basin sediments are not particularly bioavailable.

6.3.3 Discussion of Sediment COPECs

An evaluation of the toxicological effects, concentration, and extent of distribution was made for each sediment COPEC found in each SEZ. If a sediment COPEC was found to have an adverse effect on the ecosystem, that particular SEZ was considered to contain adverse concentrations of chemicals.

The following section contains a discussion of sediment COPECs as they relate to specific findings from the biological studies discussed in Section 6.3.2.

6.3.3.1 METALS

Seven metals were identified as sediment COPECs: arsenic, beryllium, chromium, copper, lead, mercury, and zinc in SEZ F; and chromium, copper, lead, and zinc in SEZ H. Pier stations in SEZ H and between-pier stations in SEZ F are located in close proximity to each other. Arsenic and beryllium at SEZ F were found at concentrations below the maximum concentration associated with a toxicity response, and these two metals probably do not occur at detrimental levels in the West Basin sediments.

Bioassay results were quite variable in SEZ F, with Stations 10 and 21 showing healthy results and only Station 17 with significantly lower results. SEZ H stations also performed variably under the bioassays and there was no clear trend. Bioassay and benthic infauna community results were as variable for stations with low metals concentrations as stations with high metals concentrations, and there were no statistically significant correlations of metal concentrations (total or extractable) with any bioassay or benthic infauna result which could explain the findings. The benthic infaunal community beneath the piers performed very well when considering number of taxa, number of individuals, and biomass.

Sediment metal concentrations have been considered in light of the SEM/AVS ratio (Allen 1993, Allen et al. 1993). In the case of SEZ F and SEZ H, the average sediment sulfide levels were drastically different, 157 mg/kg and 4,050 mg/kg, respectively. The low SEM/AVS ratio could account for the apparent noneffect of metals under the piers, but it is less useful in understanding the results from SEZ F.

VOL 18
02099
R0062818

There was a relatively high accumulation of clay size particles in sediments between the piers, such as SEZ F. Negatively charged exchange sites on the surface of clay particles have been shown to adsorb cationic metals (Woodward et al. 1984). Once bound, the metals may remain biologically unavailable, especially under high pH values (up to 8.7 [LA/LB Harbor Departments & U.S. ACOE 1990]) and oxidizing conditions found at the sediment-water column interface. Metals deeper than the surface sediment layer encounter reducing conditions which cause them to precipitate, also making them biologically unavailable.

The bioaccumulation study illustrates the complexity of the situation in that correlations of sediment metal concentrations and clam tissue metal concentrations yielded only two statistically significant results. Copper was positively correlated ($r = 0.48$) and arsenic was negatively correlated ($r = -0.40$), indicating the poor relationship between sediment concentration and biological availability for these sediments.

Based on this discussion, metal concentrations in the West Basin do not appear to have a detrimental ecological effect as evidenced by the biological and chemical data results.

6.3.3.2 SULFIDE

Sulfide was a sediment COPEC only in sediment samples from beneath the piers. This appears to be a natural phenomenon resulting from reducing conditions in the sediments beneath the piers, since these sediments are likely to be poorly oxygenated. Sulfide is typically derived from organic matter which could have at least three major sources beneath the piers:

- A portion of the sediments beneath the piers has been left intact from effects of natural impacts. The West Basin area was historically at the mouth of the Los Angeles River and the entire Long Beach coastal area was a mosaic of estuaries and salt marshes. The natural sediments in this area would have contained large amounts of decaying organic debris which would serve as a source of sulfur.
- Every piling of each pier has a substantial epifaunal community. These animals are the source of the large amount of shell hash encountered beneath each pier. As the animals die, they sink to the bottom, and their decaying remains contribute sulfur to the sediments.
- The benthic invertebrate community beneath each pier is substantial in terms of taxa, number of individuals, and biomass. The natural death and decay of these organisms contributes sulfur to the sediments.

The benthic organisms living in the sediments beneath many of the piers are opportunistic deposit-feeding taxa which have a high tolerance for elevated chemical concentrations, and it is difficult to distinguish if their occurrence is related to sulfide concentrations or other chemicals (e.g., PAHs) which were also found at elevated concentrations beneath the piers.

VOL 18
02/10
R0062819

VOL 18

02-11

6.3.3.3 BUTYLTINS

Monobutyltin was defined as a sediment COPEC at SEZ H because of a single occurrence at Station 43 (beneath Pier 15, 3.6 µg/kg). Dibutyltin was detected once in the West Basin and once at the reference stations, without a statistically significant difference. There is no known explanation for the occurrence of monobutyltin at Station 43.

The bioassay results at Station 43 were among the healthiest when considering all of the piers. The benthic infauna at Station 43 contained 38 taxa and 3.2 grams of biomass. Considered overall, surface sediments at Station 43 had many detected chemicals with some of the highest concentrations of all West Basin stations. It is impossible to assess the impact of a single constituent such as monobutyltin; however, it does not appear that the *in situ* community at Station 43 has been detrimentally impacted by monobutyltin.

6.3.3.4 PAHs

The most numerous sediment COPECs and the ones which in general most greatly exceeded the reference station levels were the PAHs. PAHs were found at elevated levels at the between-pier SEZs E and F and at the pier SEZs G and H. SEZs F and H showed the greatest number of individual PAH chemicals and highest concentrations. At SEZ H, sixteen PAH compounds were identified as sediment COPECs: benzo(a)anthracene, benzo(a)pyrene, benzo(b)fluoranthene, benzo(ghi)perylene, benzo(k)fluoranthene, chrysene, dibenzo(a,h)anthracene, fluoranthene, indeno(1,2,3-cd)pyrene, pyrene, acenaphthene, acenaphthylene, anthracene, fluorene, methylnaphthylenes, and phenanthrene.

The results of PCA/multiple regression analysis and correlation analysis suggest that the concentrations of PAH compounds may be related to the patterns of toxicity response. These analyses also indicate that the distributions of PAH compounds are similar. HPAH compounds show similar distribution patterns and were recognized in the PCA analysis as a single factor.

PAH concentrations constitute an important factor in the chemical characteristics of the sediments beneath and adjacent to the piers (SEZs E, F, G, and H). None of the mean concentrations of PAH compounds at SEZs E or G exceeded the maximum concentration associated with no toxicity response. At SEZ F, the only mean PAH concentration to exceed the maximum value associated with no toxicity was benzo(b)fluoranthene. None of the PAH concentrations at SEZs E, F, or G exceeded the ER-M value. Because the PAH concentrations were less than ER-M values and less than maximum concentrations associated with no toxicity, it is possible that the adverse toxicity response noted at SEZ G is not related to concentrations of PAH compounds.

6.3.3.5 PCBs

Aroclor 1260 was the most ubiquitous sediment COPEC in the West Basin. PCBs were reportedly disposed of at unknown locations in the West Basin many years ago, but there is no clear pattern to Aroclor 1260 distribution that might implicate suspected disposal

R0062820

points. PCBs were not found in sediments beneath the piers at SEZ G and at relatively low levels in sediments under piers in SEZ H. PCBs have been shown to be naturally degraded by bacteria (Boyle et al. 1993, Higson 1992), even under anaerobic conditions such as what is likely occurring beneath the West Basin piers; however, no general explanation could be developed for the lack of PCB in sediments collected from beneath the piers.

There was no correlation between Aroclor 1260 concentration and any measured bioassay or infaunal effect. For example, two stations with high Aroclor 1260 levels (Station 17 with the highest Aroclor 1260 level [880 µg/kg] and Station 10 with an Aroclor 1260 level of 540 µg/kg) showed similar responses for bioassay results except for echinoderm survival and development which exhibited the following responses: Station 17 had 46 percent survival and 0 percent normal development, and Station 10 had 100 percent survival and 90 percent normal development. Moreover, both stations had a healthy infauna community. Based on this evaluation, Aroclor 1260 levels do not appear to cause any detrimental ecological effects to the overall West Basin ecosystem.

6.3.3.6 PESTICIDES

DDT and its derivatives are commonly found throughout southern California coastal waters (Dailey et al. 1993) including at all reference stations utilized for this RI. DDT was a sediment COPEC only in SEZ C as a result of a high concentration at a single station (Station 16). Station 16 had concentrations of DDD of 42 µg/kg, DDE of 60 µg/kg, and DDT of 34 µg/kg. This was the only station which had a detected concentration of DDT. Station 16 is very close to the shore and the existing sediment concentrations of DDT and its derivatives may be the result of a single disposal episode.

Bioassay results and benthic infauna results indicated no adverse ecological effects from the DDT and DDT derivative concentrations at Station 16. Also, there was no significant correlation found between DDT and any biological response.

Likewise, lindane (γ-BHC) was a sediment COPEC at SEZs C, D, and F because of concentrations ranging up to 6.8 µg/kg, which occurred at Station 10. As discussed above for Aroclor 1260, Station 10 performed well with respect to all bioassays and apparently has a healthy benthic infaunal community. No toxicity response was associated with lindane concentrations of 6.8 µg/kg.

Aldrin was detected once in the West Basin, and was shown as a sediment COPEC for SEZ C. No toxicity was associated with this occurrence of aldrin.

Based on this evaluation, pesticides do not appear to cause unfavorable ecological effects in the West Basin.

6.3.3.7 PHENOL

Except for PAHs, the only SVOC that was a sediment COPEC was phenol, which was found at Station 47 (SEZ E beneath Pier 9, 210 µg/kg) It was also detected at one other

VOL 18
0212
R0062821

location, Station 31 (SEZ A, 94 µg/kg), at a level below the PSDDA screening level. The reported occurrence of phenol at Station 47 is unaccountable since this location is not near any known outfall; phenol may have been discharged from the pier directly into West Basin waters.

The bioassay test results at Station 47 were depressed, as was typical for all pier stations; however, the benthic infauna was remarkable at Station 47, boasting 96 taxa and over 92 grams of biomass. There does not appear to be an adverse ecological effect from phenol concentrations in the West Basin.

6.4 RISK CHARACTERIZATION

In this section, the ecological hazard that may exist as a result of exposure to the COPECs (both for fish and for sediments) at the West Basin are identified and discussed. The ecological significance of the identified risks is discussed in terms of the spatial, temporal, and biological scale of potential adverse effects on the West Basin ecosystem. Measurement endpoints and assessment endpoints are linked to provide a framework for interpretation of the ecological risks.

The methods of ecological risk characterization used were two-fold: the hazard quotient (HQ) approach and the preponderance-of-evidence approach. The HQ approach used bioaccumulation (fish tissue) data to evaluate potential adverse effects of fish ingestion by harbor seals. Section 6.4.1 compares this exposure against chronic toxicity benchmark values (derived in Section 6.3.1) and calculates HQ values. The preponderance-of-evidence method involved developing an evaluation matrix for all chemical and biological data (Table 4-50), and used statistical correlations (multivariate techniques) in an attempt to identify patterns and trends (Section 6.3.2). This method utilized what has become known as the sediment quality triad approach to ERA (Alden 1992, Green et al. 1993), and directly supported the designation of SEZs B, G, and H as AOPECs. Considering the findings of Section 6.3.2, Section 6.4.2 evaluates whether SEZs B, G, and H warrant classification as AOECs.

6.4.1 Hazard Quotient Calculation

To identify risks to the harbor seal, estimated exposure doses and TRVs (Section 6.3.1) were used to calculate an HQ for each of the fish COPECs identified in whole body tissue of white croaker. The HQ was calculated from total exposure to white croaker, divided by the TRV for that receptor. If the HQ was greater than 1, a potential hazard of adverse effects resulting from exposure was presumed for a given fish COPEC. If an adverse effect arising from total exposure was identified, the hazards of exposure to individual fish COPECs were examined to partition and evaluate the potential sources of risk.

The HQ values calculated for the harbor seal are shown in Table 6-6. The sum of each individual HQ is also shown as a Hazard Index (HI), which equaled 11. The arsenic HQ accounted for 100 percent of the total HI. The sum of the HQs for the remaining fish COPECs, excluding arsenic, equaled 0.29.

VOL 18
0213
R0062822

A potential risk of adverse effects for arsenic was identified for the harbor seal on the basis of the calculated HQ. Although the estimated risk attributed to arsenic was above the threshold for the harbor seal, West Basin white croaker arsenic concentrations were similar to arsenic concentrations measured in fish collected throughout the southern California Bight (Appendix E). In addition, since the potential risks were quantified for effects on individual organisms using conservative assumptions to account for uncertainty, significant ecological effects at the population and community levels are not expected.

Arsenic exceeded an HQ value of 1 for the harbor seal. The arsenic concentration in whole body white croaker from the West Basin was about 40 percent greater than in whole body white croaker collected at the reference stations. Only one small area of the West Basin, SEZ F, has surface sediment arsenic concentrations which exceeded the reference station surface sediment concentrations. It is impossible to determine where in the LA/LB Harbor the white croaker, which were collected in the West Basin, have obtained elevated arsenic levels, but it is unlikely that the sediments in one small area, SEZ F, are the only source of arsenic. Arsenic concentrations in the West Basin sediments ranged from 6.8 to 19 mg/kg while arsenic in reference sediments ranged from 2.8 to 14 mg/kg.

6.4.2 Preponderance-of-Evidence Approach - Discussion of AOPECs

Three AOPECs were identified in Section 4.8: SEZs B, G, and H. These three SEZs were identified as AOPECs because of sediment chemistry concentrations exceeding reference station values, and adverse toxicity response in the echinoderm bioassay. In addition, SEZs G and H showed bioaccumulation of pyrene in tissue of laboratory clams.

6.4.2.1 SEZ B

SEZ B had four sediment COPECs: three PAHs and Aroclor 1260. All of these compounds were listed as sediment COPECs because none were detected in the reference station sediments. All the PAH concentrations were less than the maximum value associated with toxicity responses. Benzo(a)anthracene and acenaphthylene concentrations were also less than the ER-L value; no sediment quality guidelines are available for dibenzo(a,h)anthracene. Aroclor 1260 concentrations exceeded the ER-L value (for total PCBs), but were less than the maximum value associated with no toxicity response. The low concentrations of PAHs and Aroclor 1260 at SEZ B do not appear to be related to the toxicity response observed in the echinoderm bioassay. The benthic infauna represented at SEZ B appear healthy and normal.

SEZ B is not considered an AOEC because the sediment chemistry appears to be below levels that would cause adverse biological responses and the benthic infauna appear not to be adversely effected. The cause of the toxicity response in the echinoderm development test is not known.

VOL 18
0214
R0062823

VOL 18

6.4.2.2 SEZ G

SEZ G, comprised of Stations 42, 44, 45, 46, 51, and 52 (sediments beneath Piers 1, 2, 12, and 16), had eleven sediment COPECs: ten PAHs and total sulfide. Adverse echinoderm toxicity response was noted at all of the stations in SEZ G. However, Stations 42 and 46 showed no detectable concentrations of any chemical analytes. HPAH and LPAH detection limits were higher at Stations 42 and 46 than at the other basin stations, but the HPAH detection limits were less than the maximum concentration associated with no toxicity response. These data suggest that the adverse echinoderm toxicity response at Stations 42 and 46 were not related to chemical concentrations because none were detected, and most detection limits were less than the ER-L value and the maximum concentration associated with no toxicity. The echinoderm toxicity does not appear to be related to a stressor other than those chemicals listed as sediment COPECs for SEZ G. No other bioassay tests showed toxicity "hits" for SEZ G.

Pyrene concentrations were noted in clam tissue at SEZ G, and not at the reference stations. However, pyrene was not a sediment COPEC for SEZ G and the pyrene concentrations were within the range reported from other southern California studies. The clam tissue data is insufficient to adequately describe the bioaccumulation pattern for pyrene in the SEZ sediments.

SEZ G is not considered an AOEC because the concentrations of chemical analytes appear to be below levels that are associated with adverse biological response, and the echinoderm toxicity results are probably due to an environmental stress other than those measured in this RI. The benthic invertebrates at SEZ G were abundant and diverse, and predominantly represented by the invertebrate community found living on the shell hash material.

6.4.2.3 SEZ H

SEZ H, comprised of Stations 43, 48, 49, and 50 (sediments beneath Piers 3, 6, 7, and 15), had 23 sediment COPECs: five metals, sixteen PAHs, Aroclor 1260, and total sulfide. However, these chemical concentrations do not appear to adversely affect the sediment quality, as assessed by toxicity bioassays and benthic infauna studies. The echinoderm toxicity response found at SEZ H should be expected due to environmental stresses related to conditions beneath the piers but not measured during this RI (see SEZ G discussion of echinoderm toxicity above). Clam bioaccumulation tests suggest that pyrene has accumulated in the tissues of these animals, but there is insufficient data to determine if this represents an adverse effect. The pyrene concentrations found in clam tissue were similar to levels reported by other southern California studies, and appear to be at tolerable levels within clam tissue. The benthic invertebrates at SEZ H are a combination of those invertebrates living in or on the sediments and those invertebrates living on the shell hash material. Although some of the invertebrates living in the sediments may indicate stressed environmental conditions unlike those found at other

R0062824

West Basin stations, the invertebrate community living just above the sediment on the shell hash is quite abundant and diverse, apparently well adapted to life beneath the piers.

SEZ H is not considered an AOEC because: 1) the observed toxicity response is probably related to a stress variable associated with the presence of the piers but not measured by this project; 2) the clam bioaccumulation results do not indicate an adverse effect due to sediment chemistry; and 3) the benthic infaunal community does not indicate an adverse condition.

On the basis of the results of AOPEC evaluations, described above, the evaluation matrix containing preliminary status of SEZs (Section 4) was finalized as shown in Table 6-7. This evaluation matrix reveals that SEZs B, G, and H are not considered West Basin AOECs.

6.5 UNCERTAINTIES OF THE RISK ASSESSMENT

In this section, the principal uncertainties of the ecological risk assessment are evaluated and interpreted.

There are uncertainties inherent in the selection of COPECs which include potential limitations introduced by the number and type of chemicals targeted to be analyzed, and the lack of ecological risk-based screening criteria for many of the chemicals and media of concern. It must be assumed that the sample collection and analyte list, under the scrutiny of the technical oversight agencies, followed standard practices of sample collection and laboratory analyses and the data set was reliable. The lack of screening criteria is an inherent limitation of ERAs. Instead, chemicals found in West Basin fish and sediments were screened against reference station values and those found to be at concentrations statistically significantly exceeding reference station values, and those chemicals occurring in West Basin samples and not in reference station samples, were evaluated in the ecological risk assessment.

The reference stations encompass the range of physical variability found in the basin stations; therefore, the screening of West Basin analytes by reference station concentrations was deemed adequate. There was no commensurate reference for the pier stations, and it is possible that the identified COPECs for the pier stations are an overestimate of the specific chemicals which might be having biological effects in sediments beneath the piers.

The California halibut bile analyses statistically demonstrated that the West Basin and reference station fish were similar. Some of the West Basin fish had elevated levels of PAH compounds in bile, but it is impossible to determine if these PAH compounds are derived from the West Basin. Also, the possible pathway for these PAH compounds from sediment or water to the fish bile is unknown. It is not possible to determine whether the fish have obtained the chemicals found in whole body and fillets in the West Basin, because fish are mobile and the amount of time they spend or forage in the West Basin is unknown.

VOL 18
0216
R0062825

The potential risks of arsenic to the harbor seal are subject to uncertainty as a result of the simplifying assumptions used to estimate exposure. Principal uncertainties of the extrapolation methods used to derive TBs include the use of uncertainty factors for converting LOAEL values to NOAEL values, body size scaling from taxonomically unrelated species, and toxicity of the forms of chemicals used in toxicity tests versus the forms of COPECs in whole body white croaker occurring in the West Basin. Uncertainty and scaling factors associated with each of these extrapolations are provided in Opresko et al. (1995).

The harbor seal was assumed to ingest 100 percent of its dietary intake as white croaker from the West Basin which is very conservative and highly unlikely. Also, the dose of COPEC the harbor seal receives from white croaker was conservatively estimated.

Uncertainty associated with the preponderance-of-evidence approach is that the sampling for this RI occurred as a one-time event and, even though present conditions are judged acceptable, it is not practical to determine the trend of ecosystem health from a single measurement. Fortunately, the major sources of contamination to the West Basin sediments have been stopped or greatly reduced for some time, contributing to improved ecological conditions and suggesting that ecological conditions will continue to improve in the future. Also, other studies (Reish 1959, 1971, 1978, Reish et al. 1980), which were not as extensive as this RI, have shown a general improvement in the condition of the marine environment in the LB Harbor, including West Basin sediments, over the past 30 years. It is therefore presumed that this RI represents an adequate representation of existing conditions in West Basin sediments and that ecological conditions in these sediments will likely continue to improve in the future, all things being equal.

The design of the evaluation matrix was very conservative regarding designation of a "hit" in any category. The conservative design introduces an uncertainty about the described risk: the actual risk may be less than indicated.

Uncertainties of the risk assessments presented in this section are not expected to diminish the significance of data acquired in this RI or the conclusions supported by these data. Investigations of marine sediments typically have to deal with similar uncertainties. Such uncertainties can conceivably be reduced by significantly increasing the scope and cost of the investigation, but the results may not reduce the uncertainties appreciably.

The evaluations described in this report are based on currently available information that contain inherent uncertainties and could vary if further data concerning the site or its conditions or other information become available. In conducting sampling, site conditions were evaluated from a limited number of data points, following accepted industry statistical practices in selecting the number and types of samples and tests to be performed. However, due to the size of the West Basin, the types and lengths of naval operations performed there, and the complexity of the sediments, there is the potential that conditions away from the sampling points may differ.

SECTION 7

CONCLUSIONS AND RECOMMENDATIONS

0218

VOL 18 0219

Section 7
CONCLUSIONS AND RECOMMENDATIONS

This section summarizes the findings of this RI, including the human health and ecological risk assessments.

7.1 HUMAN HEALTH RISK ASSESSMENT

Human health risk assessment was performed to evaluate the potential hazard of human consumption of California halibut and white croaker caught in the West Basin by recreational and subsistence anglers. Previous to this RI, the California Department of Fish and Game had issued a fish advisory for the LA/LB Harbor, including the West Basin, to alert anglers to limit their consumption of fish caught in this area because of chemical contamination, specifically PCBs and DDT and its congeners (DDD and DDE).

The results of the risk assessment suggest that chemicals in California halibut and white croaker tissues from the West Basin, particularly arsenic and DDT congeners, may occur at concentrations that could adversely affect individuals who consume these fish. However, cancer and noncancer risks associated with consumption of California halibut or white croaker from the West Basin do not appear to be appreciably different from the cancer and noncancer risks associated with consumption of California halibut or white croaker from the reference stations. In addition, no statistical significance existed between DDT congener concentrations in West Basin fish and reference fish as a result of the ecological risk assessment (see Section 7.2). Although arsenic concentrations in West Basin white croaker whole body samples were statistically significantly higher than reference whole body samples, West Basin arsenic concentrations were within or below the range of values commonly measured in fish collected from southern California harbors.

7.2 ECOLOGICAL RISK ASSESSMENT

Chemical analyses of surface sediments detected several analytes in excess of project screening criteria; these analytes were designated as sediment COPECs. Results of toxicity tests and a benthic infauna community assessment performed for this RI were evaluated in light of the sediment COPECs present at each station and SEZ. Toxicity test results did not show patterns related to chemical distribution. Project-derived sediment COPEC-noneffect-levels indicated that only a few samples with the highest chemical concentrations might possibly be of ecological concern. The locations of these samples were beneath or immediately adjacent to piers.

The results of toxicity tests indicated that sediments from beneath the piers exhibited toxic characteristics for echinoderm development -- the most sensitive test used in this RI. Examination of the data suggests that this pattern is related to a physical or chemical stressor (analyte) not measured during this RI and not related to contaminant releases by the LBNC. Echinoderm toxicity response occurring at basin stations did not show a noticeable pattern. Toxicity responses for echinoderms were reported at some basin stations with measurable chemical analytes and at other basin stations without measurable chemical analytes.

R0062828

The infaunal community, the chief ecosystem of concern, for basin areas appears to be robust in terms of number of taxa, ecological function of different taxa (i.e., 'healthy', 'semihealthy' species), number of individuals, and total biomass. The infauna appears to have improved significantly since abatement of chemical discharges to the West Basin over the last 30 years, and there does not appear to be an ecological risk from surface sediment chemical concentrations. The invertebrate community beneath the piers exceeds basin and reference stations in number of taxa, number of total individuals, and total biomass and is also a mixture of healthy and semihealthy species.

The ERA for West Basin stations suggests that conditions beneath several piers appear to have modified the infaunal community in that they are quite different in species composition, number of individuals, and biomass than the basin stations. The beneath-pier infaunal community does not appear to be at risk from detected surface sediment chemical concentrations and seems to contain a wide variety of taxa taking advantage of a diversity of micro-habitats. Sediments beneath piers, if left intact, appear to present no risk to other pelagic or benthic communities in the West Basin. However, concentrations of some of the analytes in surficial sediments from beneath some of the piers were determined to be higher than in sediments from reference stations. Significant changes to these sediments, such as removal of the piers, construction of additions to existing piers, construction of new piers, dredging beneath piers, or other activities that would disturb the sediments beneath the piers could result in an ecological risk.

In addition to the sediment chemistry analysis, toxicity tests, and benthic community analysis, the ERA also considered clam bioaccumulation test results, chemical analyses of fish tissues, the condition of captured fish, including physical examinations and types of fish, and a toxicological evaluation of the possible effects of ingestion of West Basin fish with known chemical concentrations on an aquatic predator, the harbor seal.

White croaker collected in the West Basin showed elevated tissue concentrations for arsenic and according to a very conservative estimate, if consumed in large quantities by harbor seals, may present a risk to the harbor seal. The source of arsenic in white croaker is undetermined and does not appear to relate to West Basin surface sediment concentrations. White croaker arsenic values were generally similar to results of other studies in the LA/LB area. No other chemical analytes were noted at significantly greater concentrations for the West Basin than for the reference for clam or other fish samples.

No AOECs were identified because no areas of the West Basin, as presently managed, appear to present an undue risk to the selected ecological endpoints on the basis of the results of this RI. Further characterization of West Basin sediments is, therefore, not indicated.

No assessment was made of specific sediment transport processes into the West Basin. Future uses of the LA/LB Harbor outside of the West Basin could result in transport of sediment-sorbed chemicals into the West Basin which may cause an increase in human health risk or ecological risk.

VOL 18
0220
R0062829

7.3 RECOMMENDATIONS

Based on discussions related to, and the results of the human health risk assessment and the ecological risk assessment provided in this RI Report, no chemicals or areas of concern were identified for the West Basin which require remedial action or further characterization, such as water column investigations. Therefore, no further action is recommended for the West Basin.

Sediment chemical concentrations beneath some of the piers were determined to be higher than project reference. Significant changes to these sediments, such as removal of the piers or the sediments, construction of additions to existing piers, construction of new piers, or other activities which disturb sediments beneath the piers could result in an ecological risk.

No assessment was made of specific sediment transport processes into the West Basin. Future uses of the LA/LB Harbor outside of the West Basin could result in transport of sediment-sorbed chemicals into the West Basin that may cause an increase in human health risk or ecological risk."

GLOSSARY OF TERMS

02399

VOL 18

GLOSSARY OF TERMS

ABUNDANCE	The number of individuals in a population of a species in a given unit of area.
ACUTE TOXICITY	Death or physiological disorder in an organism resulting from a single dose of, or exposure to, a compound or compound mixture. All acute exposures occur over a small portion of an organism's life span or life cycle; see CHRONIC TOXICITY and SUBCHRONIC TOXICITY. Most acute toxicity testing is conducted over a short exposure period, *e.g.*, 72 or 96 hours.
ADSORPTION	Physical adhesion of molecules, colloids, or other chemical substances to solid particulate surfaces without chemical reaction. Adsorption is an important factor affecting environmental movement and fate of chemicals; see DESORPTION and SORPTION.
ADVECTION	Removal or transport of suspended materials via currents or other oceanographic processes.
ADVERSE EFFECT	A condition caused by a specific action that results in harm to an organism or its habitat.
APPARENT EFFECTS THRESHOLD	A chemical concentration in sediment above which an adverse toxic effect would always be expected.
AQUATIC LIFE	Organisms inhabiting water for all or part of their life cycle.
AQUEOUS PHASE	Referring to the dissolved phase in water rather than the solid phase.
ASSESSMENT ENDPOINT	The ecological resource which requires evaluation and, ultimately, protection. For example, the viability of a population is a commonly used assessment endpoint requiring evaluation. Also see MEASUREMENT ENDPOINT.
BENTHIC/BENTHOS	Refers to the ocean or harbor bottom, including the sediments and biota inhabiting the bottom.
BENTHIC COMMUNITY ANALYSIS	Numerical evaluation of infaunal invertebrate communities inhabiting a site/location; data are used to evaluate the potential effects of contaminated sediments on native biota.
BIOACCUMULATION	The process whereby exposure of an organism to chemical residues results in concentrated levels of that chemical in specific receptor tissue. Exposure may occur through dermal, respiratory, and ingestion routes; see BIOCONCENTRATION.

02400

R0062849

VOL 18

Glossary of Terms (continued)

BIOASSAY	A test using organisms to determine the toxicity of a compound or chemical mixture; primary function is to provide case-specific information regarding the toxicity of such compound or chemical mixture.
BIOCONCENTRATION	The process whereby exposure of an organism to chemical residues results in concentrated levels of that chemical relative to the surrounding aquatic environment. Exposure normally occurs through passive accumulation from the water column; see BIOACCUMULATION.
BIOCONCENTRATION FACTOR (BCF)	The ratio of concentration of a chemical within the tissue of an organism to that of the surrounding aquatic medium.
BIODEGRADATION	Decomposition of a chemical contaminant which is catalyzed or aided by the action of microorganisms, *e.g.*, bacteria.
BIODEPLETION	A reduction or depletion of a chemical substance from an organism specifically or food chain in general; see BIOMAGNIFICATION
BIOLOGICAL IMPACT	Any impact to a population of organisms; the impact may be measured using species abundance, species diversity, or other measurement indices.
BIOMAGNIFICATION	The process by which a chemical compound concentrates with increasing trophic level as it moves through the food chain; see BIOACCUMULATION and BIOCONCENTRATION.
BIOMARKERS	Test organisms used as indicators of environmental conditions.
BIOMASS	Refers to the amount of biotic matter within a specific area. For example, when sampling benthos, one of the indices used to evaluate benthic communities is the total amount of biomass present within a fixed volume.
BIOTA/BIOTIC	Relating to living organisms, including plants and animals, i.e., as opposed to inanimate or nonliving matter.
CHRONIC TOXICITY	An adverse biological response, such as mortality or an effect on growth or reproductive success, resulting from repeated or long term exposures to a compound, usually at low concentrations; see ACUTE TOXICITY and SUBCHRONIC TOXICITY.
CONCENTRATION	An amount of a chemical compound in a specified amount of medium, *e.g.*, water, sediment. Measured in standard units such as milligrams per liter (mg/L), microgram per kilogram (µg/kg), or other appropriate units.

0241

R0062850

VOL 18

Glossary of Terms (continued)

CONTAMINATION	Refers to the presence of specific chemical compounds, typically those included on U.S. EPA's Priority Pollutant list, present in special media of concern. Does not refer to or imply the occurrence of a toxic effect or adverse impact associated with the chemical or group of chemicals.
DEGRADATION	Transformation of a chemical compound by physicochemical or biochemical processes into its basic components.
DEMERSAL	Fish which dwell at or near the sea bottom.
DESORPTION	Dissociation of a chemical from a surface to which it had previously adhered; also see ADSORPTION and SORPTION.
DETRITIVORE	Organisms, such as insect larvae, worms, and crustaceans, that digest and recycle dead and dying material on water beds.
DOSE	An amount of substance administered per unit of animal body weight. Measured in milligrams of substance per kilogram of animal body weight (mg/kg), or other appropriate units. Useful for calculating risk in a receptor organism.
EC_{50}	MEDIAN EFFECTIVE CONCENTRATION; concentration eliciting a sublethal response in 50 percent of the organisms tested; see LC_{50}.
ECOLOGICAL COMMUNITY	Any assemblage of populations living in a specific habitat.
ECOLOGICAL HAZARD	Actual or potential adverse effects of chemical substances on aquatic biota (plants or animals).
ECOLOGICAL RISK ASSESSMENT	An evaluation of the actual or potential long-term or short-term effects of chemical compounds on aquatic receptors.
ED_{50}	MEDIAN EFFECTIVE DOSE; dose eliciting a non-lethal response in 50 percent of the organisms tested; see LD_{50}.
ENDPOINT	A toxicological response or measured effect.
ENVIRONMENTAL FATE	The result of natural processes acting upon a substance, including transport (*e.g.*, sedimentation), physical transformation (*e.g.*, volatilization, precipitation), chemical transformation (*e.g.*, photolysis) and biological transformations (*e.g.*, oxidation and reduction).
EQUILIBRIUM PARTITIONING	Refers to a theoretically based process whereby chemical agents reach equilibrium between the sediment solid phase and its interstitial water; the theory holds that total organic carbon (TOC) is one of the key driving factors for governing this distribution, especially for organic chemicals.

0242

R0062851

Glossary of Terms (continued)

EPIBENTHIC	Organisms inhabiting the sediment surface; i.e., living on top of the sediment. Also see INFAUNAL ORGANISMS.
EXPOSURE ASSESSMENT	Also EXPOSURE ANALYSIS; an evaluation of potential likelihood that humans, non-target wildlife, or biological habitats will be exposed to potentially harmful effects of a chemical.
EXPOSURE PATHWAY	The route by which exposure to a toxicant occurs. A complete exposure pathway consists of contaminant source(s), transport media (*e.g.*, surface water or sediments), the contact point between the transport medium and the receptor (*e.g.*, water supply system), and the receptor route or mechanism of entry (*e.g.*, ingestion of water, biota, or inhaled dust). If an exposure pathway is incomplete, it does not warrant further consideration in the risk assessment.
EXPOSURE SCENARIO	Overall description of the potential contact of an organism or population with a chemical substance under specified conditions, *i.e.*, routes of contact, life history of the organism, *etc.*
HABITAT	An environment that provides the requirements (*i.e.*, food, water, and shelter) essential to development and sustained existence of a species.
HALF-LIFE ($t_{1/2}$)	The time necessary for the concentration of a chemical to decrease by 50 percent. Provides a measure of the persistence of a chemical in a given medium. The greater the half-life, the more persistent a chemical is likely to be.
HAZARD	A potential adverse effect associated with exposure to a chemical substance.
HAZARD QUOTIENT	Risk expressed as a ratio of dose (exposure) to toxicity for a specific exposure duration. HQ values are used to address both acute and chronic risk.
HENRY'S LAW CONSTANT	Provides a measure of the extent of chemical partitioning between air and water at equilibrium. The higher the constant, the more likely a chemical is to volatilize than to remain in solution.
HOMOLOGUE	Specific chemical compound within a larger group of chemical compounds (e.g., benzo(a)pyrene is a homologue within the PAH class of organic chemicals).
HOMOSCEDASTICITY	Homogeneity of variances in a set of samples (data).
HUMAN HEALTH RISK ASSESSMENT	Appraisal of the actual or potential short-term or long-term effects of chemical compounds on humans, such as fishermen or residents.

VOL 18
0243
R0062852

VOL 18

Glossary of Terms (continued)

HYDROLYSIS	The decomposition of chemical compounds resulting from a reaction with water.
ICHTHYOFAUNA	The fish life of a region.
INDICATOR SPECIES	A species thought to be biologically representative of the reproductive success of other key species within a particular population or biological community.
INDIGENOUS SPECIES	Biota which are native to a specific habitat.
INFAUNAL INVERTEBRATES/ ORGANISMS	Organisms living within the sediments (usually within 10 cm of the surface) rather than on top of the sediments. Also see EPIBENTHIC ORGANISMS.
INTERTIDAL ZONE	Sediments lying between the high- and low-tidal marks.
K_d	SEDIMENT-WATER DISTRIBUTION COEFFICIENT; the ratio of concentrations of a specific chemical substance sorbed to sediment versus the concentration dissolved in water. The higher the K_d value, the more likely the chemical will adsorb to sediment than dissolve in water.
K_{oc}	The ratio of concentrations of a specific chemical substance sorbed to the organic carbon fraction of sediment versus the concentration dissolved in water. The higher the K_{oc} value, the more likely the chemical will adsorb to organic carbon in sediment rather than dissolve in water.
K_{ow}	OCTANOL/WATER PARTITION COEFFICIENT; a ratio that provides a measure of the extent of chemical partitioning between water and octanol at equilibrium. Octanol is used as a surrogate for lipids, *e.g.*, fatty tissue or other organic substrate.
LC_{50}	MEDIAN LETHAL CONCENTRATION; a calculated concentration of a substance expected to kill 50 percent of laboratory test organisms.
LD_{50}	MEDIAN LETHAL DOSE; a calculated dose of a substance expected to kill 50 percent of laboratory test organisms.
LOCALIZED SPECIES	Species which does not seasonally migrate.
LOEC	LOWEST OBSERVED EFFECT CONCENTRATION; the lowest exposure level, or concentration at which an observable toxic effect occurs.
LOEL	LOWEST OBSERVED EFFECT LEVEL; the lowest exposure level (dose) at which an observable toxic effect occurs.

0244

R0062853

Glossary of Terms (continued)

LYOPHILIZATION	A laboratory freeze-drying technique.
MEASUREMENT ENDPOINT	Specific measurable data taken to evaluate whether assessment endpoints (e.g., the viability of a specific population) have been potentially affected by the presence of chemical contaminants; also see ASSESSMENT ENDPOINT.
MINERALOGY	The chemical constitution of sediment particles occurring in the aquatic environment.
NEGATIVE CONTROL	Bioassay in which test organisms are exposed to clean sediments. Used to obtain a measure of biological response associated with exposure to clean sediment.
NOEC	NO OBSERVED EFFECT CONCENTRATION; the highest concentration level tested at which no observable difference between the test and control population occurs.
NOEL	NO OBSERVED EFFECT LEVEL; the highest dose tested at which no observable difference between the test and control population occurs.
NON-POINT SOURCE	Discharge that originates from a number of undefined sources, including storm water runoff, precipitation, or accidental spills or releases.
NUMBER OF SPECIES	The number of species in a specific area. Often compared to an equivalent area at a reference location.
NUMERICAL SEDIMENT QUALITY GUIDELINES/CRITERIA	Chemical analyte-specific toxicity-based values, normally expressed as a chemical concentration, used to establish concentrations in sediment which are expected to be protective of aquatic organisms.
OMNIVORE	Organisms that eat both plants and animals.
PARTITION COEFFICIENT	A chemical-specific property describing the ratio in one substrate or phase compared to another, *e.g.*, the amount of a chemical sorbed to sediment compared to the amount dissolved in water.
PELAGIC	Organisms inhabiting the water column rather than the benthic environment.
PERSISTENCE	The ability of a chemical compound to remain intact following its release into the environment.
PHOTOLYSIS	Also PHOTODEGRADATION; the decomposition or dissociation of a molecule resulting from ultraviolet light absorption.
POINT SOURCE	Discharge that originates from a well-defined location, typically a wastewater discharge, subject to regulation under the Clean Water Act.

VOL 18
0245
R0062854

VOL 18

Glossary of Terms (continued)

POLLUTION	Refers to the presence of specific chemical compounds present in specific media of concern. Differs from the term "contamination" in that it does imply the occurrence of a toxic effect associated with the presence of the chemical or group of chemicals.
POPULATION	A group of organisms belonging to the same species which inhabits a specific area or habitat.
PORE WATER	The water residing in the interstices or pores between sediment particles.
POSITIVE CONTROL	Bioassay in which a known quantity of toxicant (reference toxicant) is spiked into the test matrix; used to measure the sensitivity of test organisms.
PREDATOR	An animal that hunts, kills and consumes another (prey) organism.
PREPONDERANCE OF EVIDENCE	Using all available site-specific chemical and biological data to evaluate the potential for ecological effects associated with the presence of specific chemical compounds.
PREY	An organism which is hunted, killed, and consumed by another (predatory) organism.
RECEPTOR ORGANISM	Organisms potentially exposed to a chemical compound of potential concern via any of a number of potential pathways.
RESECTION	Removal of specific organs or tissues from organisms (e.g., fish) captured for the purpose of sampling.
RISK	A potential adverse effect associated with exposure to a chemical substance.
SEDIMENT QUALITY OBJECTIVE	A site-specific term used to define cleanup goals for specific chemical compounds of potential concern.
SEDIMENTOLOGY	The dynamics associated with erosion, deposition, transport/advection, or other behavior of sediment particles in an aqueous environment.
SEDIMENTATION	The deposition of sediment particles in an aqueous environment resulting from a number of oceanographic processes.
SEICHE	An oscillation of the surface of a lake or landlocked sea that varies in period from a few minutes to several hours. The regular resonating waves pass from one edge of the body of water to the other and back.
SOLID PHASE BIOASSAYS	Bioassays conducted on the bulk phase of sediment (i.e., not from the interstitial water or other phase).

0246

R0062855

Glossary of Terms (continued)

SOLUBILITY	The amount or ratio of a solute (a dissolved substance) that will saturate a fixed volume of solvent under static conditions. Solubility is important to understanding a chemical's mobility in water. More soluble substances are potentially more bioavailable but also will be distributed more efficiently through the water column (less concentrated).
SONICATION	An ultrasound-based laboratory technique used to separate or extract specific chemical analytes.
SORPTION	A generalized term referring to both adsorption and desorption.
SUBCHRONIC TOXICITY	Adverse biologic response of an organism, such as mortality or an effect on reproductive success, resulting from relatively short term exposure to a test sample or compound.
SUBLETHAL RESPONSE	Toxicological response which is less severe that mortality, such as growth inhibition or reproductive impairment.
SUBTIDAL ZONE	Sediments lying below the lowest tide level.
SYNERGISTIC EFFECT	The result of a combined action of two or more chemical substances to achieve an effect (either positive or negative) which is greater than that of which the individual chemical is capable.
THREATENED/ENDANGERED (T&E) SPECIES	A species in danger of extinction throughout all of its native range.
TOXICANT	A chemical substance capable of inducing a toxic effect.
TOXICITY	The ability or capacity of a chemical substance to induce an adverse effect.
TOXICOLOGICAL BENCHMARK	A guideline value derived as a measure of sensitivity to acute or chronic exposure for the purpose of protecting aquatic life; may be derived for the protection of individual species or species groups.
TOXICOLOGICAL EVALUATION	An assessment of the potential adverse effects of specific compounds of potential concern.
UNCERTAINTY	Inherent error resulting from any activity relating to sampling or analysis of data.
UNCERTAINTY ANALYSIS	Estimation or evaluation of the contributions or magnitudes of errors resulting from analysis of environmental or other data.
UNCERTAINTY FACTOR	A factor which quantifies the numerical relative uncertainty in deriving toxicological benchmarks, especially when compound-specific data are based on non-project specific toxicological testing. Such uncertainty can arise from overall data quality, interspecies variability, endpoint

Glossary of Terms (continued)

	sensitivity, endpoint extrapolation, and many other sources.
VAPOR PRESSURE	The pressure exerted by a chemical in its solid or liquid phase to convert to its gas (vapor) phase in equilibrium at a given temperature.
VOLATILIZATION	Conversion of a solute from solid or liquid phase to vapor phase; e.g., converting liquid water into steam.

Table 3-1
Data Quality Objectives

Objectives	Activities	Data Uses	Data Quality/ Analytical Level
Characterize the toxicity of surface sediments within West Basin.	Collection of surface sediment samples from randomly chosen locations within West Basin; chemical analysis for SVOCs[a], pesticides, PCBs[b], organotins, metals, and general physical/chemical parameters; performed bioassay/bioaccumulation testing; and BCA[c].	Ecological Risk Assessment	Validated laboratory analysis (Level III) for sediment chemical testing. Special analytical methods (Level V) for organotins, bioassay/ bioaccumulation testing, and BCA.
Characterize contaminant levels in deeper sediments within West Basin.	Collection of sediment core samples from a subset of the surface sediment sampling locations; and analysis for SVOCs, pesticides, PCBs, organotins, metals, and other physical/chemical parameters.	Remedial Alternatives Evaluation	Validated laboratory analysis (Level III). Special analytical methods (Level V) for organotins.
Characterize contaminant levels in fish captured within West Basin.	Collection of demersal fish from transects located within West Basin; chemical analysis of whole body and fillet tissue for PAHs[d], pesticides, PCBs, organotins, and metals; and chemical analysis of bile for PAH parent compounds and metabolites.	Human Health and Ecological Risk Assessment	Special analytical methods (Level V) for tissue and bile chemical testing.

Notes:

[a] SVOC - semivolatile organic compound
[b] PCB - polychlorinated biphenyl
[c] BCA - benthic community analysis
[d] PAH - polynuclear aromatic hydrocarbon

Table 3-3
Target Fish Species for Collection, Listed by Data Use and Relative Priority

Common Name	Advantages	Disadvantages
	Human Health Only	
Barred sand bass *Paralabrax nebulifer*	Abundant Predatory benthic and pelagic feeder Nonmigratory local species Frequently caught Well documented in similar studies High lipid content	Low catch frequency by trawl
Rubberlip surfperch *Rhacochilus toxotes*	Abundant in harbors, bays and around piers Nonmigratory local species Frequently caught	Pelagic feeder Not well studied
Kelp bass *Paralabrax clathratus*	Abundant Frequently caught Nonmigratory local species Well studied l Recommend for contaminant studies High lipid con	Predatory pelagic feeder Seldom caught/observed away from kelp beds
Opaleye *Girella nigricans*	Abundant in water depths of about 20 feet Frequently caught	Omnivorous pelagic feeder, especially feeds on seaweeds and the animals that live on them
Queenfish *Seriphus politus*	Caught locally Nonmigratory local species	Water column feeder Not well studied
Barred surfperch *Amphistichus argenteus*	Occasionally caught in Long Beach Harbor Recommended by EPA for contaminant studies Predatory benthic feeder Nonmigratory local species	Most abundant in breaking surf along sandy beaches
	Ecological Only	
Hornyhead turbot *Pleuronichthys verticalis*	Abundant Predatory benthic feeder Nonmigratory local species Life history well understood Probably common prey species	Not frequently caught by fishermen
Spotted turbot *Pleuronichtys ritteri*	Predatory benthic feeder Nonmigratory local species Probably common prey species	Not frequently caught by fishermen

VOL 18 0332

Table 3-3 (continued)

Common Name	Advantages	Disadvantages
	Ecological Only	
Diamond turbot *Hypsopsetta guttulata*	Predatory benthic feeder Nonmigratory local species Probably common prey species	Not frequently caught by fishermen
Speckle-finned sanddab *Citharichthys stigmaeus*	More abundant than turbot Predatory bottom-feeder Prey to large fish, diving birds, and marine mammals	Not frequently caught by fishermen
Blue rockfish *Sebastes mystinus*	Recommended by EPA for contaminant studies Abundant in shallow water in and around rocky areas Benthic and pelagic feeder	Low catch frequency in Long Beach Harbor, but occasionally caught
	Human Health and Ecological	
California halibut *Paralichthys californicus*	Abundant on sandy bottoms in water shallower than 60 feet Benthic dweller Used by State of California for major contaminant study Frequently caught Prey to sharks, rays, and marine mammals Desirable game fish	Pelagic feeder May migrate as adults
Fantail sole *Xystreurys liolepis*	Occasionally caught locally Benthic feeder Common prey species	Not well studied Locally migratory
Dover sole *Microstomus pacificus*	May occur as far south as Baja California Benthic feeder Recommended by EPA for contaminant studies	Resides in water depths up to 3,000 feet Not frequently caught in Long Beach Harbor Locally migratory
White croaker *Genyonemus lineatus*	Abundant in shallow bays Omnivorous benthic feeder Nonmigratory local species Frequently caught Well documented in similar studies Abundant reference data Fish consumption advisory has been issued locally

Table 3-6
West Basin and Reference Station Samples Analyzed by Sample Type and Location

Sample Type	West Basin	Reference	Total	Chemical and Physical Analyses/ Biological Endpoints
Sediment				
Surface	47[a]	9[b]	56	SVOCs[c], pesticides, PCB[d] Aroclors, moisture content, priority pollutant metals, butyltins, AVS/SEM[e], total sulfides, particle size, TOC[f]
Surface	0	11[g]	11	Particle size, TOC
Subsurface	27[h] (8 cores)	7 (2 cores)	34 (10 cores)	SVOCs, pesticides, PCB Aroclors, moisture content, priority pollutant metals, butyltins, particle size, TOC
Tissue and Bile				
Clam Bioaccumulation	9	5	14	PAHs[i], pesticides, PCB Aroclors, lipid content, priority pollutant metals, butyltins
Fish Whole Body	30	15	45	PAHs, pesticides, PCB Aroclors, lipid content, priority pollutant metals, butyltins
Fish Fillet	12	6	18	PAHs, pesticides, PCB Aroclors, lipid content, priority pollutant metals, butyltins
Fish Bile	12	6	18	PAH parent compounds and metabolites, normalized to specific PAH equivalents
Biological				
Bioassay	45	15[g]	60	Sediment solid phase: amphipod mortality and polychaete growth/mortality
				Interstitial (pore) water (aqueous phase): echinoderm normal development/mortality
Benthic Community Analysis	45	15[g]	60	Specific indices relating to benthic community structure

Notes:

[a] Includes additional two field replicates at Station 1
[b] Includes additional two field replicates at Reference Station 40010.1
[c] SVOC – semivolatile organic compound
[d] PCB – polychlorinated biphenyls
[e] AVS/SEM – acid volatile sulfides/simultaneously extracted metals
[f] TOC – total organic carbon
[g] Includes additional two field replicates each at Reference Stations 40010.1, 40010.2, 40010.3, and 40018.3
[h] Includes one duplicate sample at Station 43
[i] PAH – polynuclear aromatic hydrocarbon

VOL 18

Table 3-7
Target Analyte Rationale

Target Analyte Class	Rationale
	Surface Sediment
Semivolatile Organic Compounds	Characterize possible constituents of disposed waste.
Pesticides/PCB* Aroclors	Characterize possible constituents of disposed waste.
Priority Pollutant Metals	Characterize possible constituents of disposed waste.
Butyltins	Characterize possible constituents of disposed waste.
Acid Volatile Sulfide	Aid in interpretation of potential for sediment toxicity and sources of contamination; provide index of divalent metal bioavailability.
Simultaneously Extracted Metals	Aid in interpretation of potential for sediment toxicity and sources of contamination; provide index of divalent metal bioavailability.
Total Sulfide	Aid in interpretation of potential for sediment toxicity and sources of contamination.
Total Organic Carbon (TOC)	Aid in interpretation of potential for sediment toxicity and sources of contamination; measure hydrophobic organic compound bioavailability.
Grain Size	Aid in interpretation of potential for sediment toxicity (contaminant bioavailability) and sources of contamination.
Percent Moisture	Aid in interpretation of potential for sediment toxicity and sources of contamination.
Echinoderm Survival and Normal Development	Characterize potential ecological risk of test sediments (acute exposure); directly measure test sediment contaminant bioavailability.
Amphipod Survival and Behavior	Characterize potential ecological risk of test sediments (subchronic exposure); measure test sediment contaminant bioavailability.
Polychaete Survival and Growth	Characterize potential ecological risk of test sediments (chronic exposure); measure test sediment contaminant bioavailability.
Benthic Community Indices	Directly measure and evaluate potential effects of sediment contaminants to native biological communities.

VOL 18

Table 3-7 (continued)

Target Analyte Class	Rationale
	Subsurface Sediment
PAHs[b]	Characterize possible constituents of disposed waste.
Pesticides/PCB Aroclors	Characterize possible constituents of disposed waste.
Priority Pollutant Metals	Characterize possible constituents of disposed waste.
Butyltins	Characterize possible constituents of disposed waste.
TOC, grain size, and percent moisture	Aid in interpretation of potential for sediment toxicity and sources of contamination.
	Fish and Clam Tissue
PAHs	Characterize possible constituents of disposed waste; indirectly measure test sediment contaminant bioavailability and potential for bioaccumulation.
Pesticides/PCB Aroclors	Characterize possible constituents of disposed waste; indirectly measure test sediment contaminant bioavailability and potential for bioaccumulation.
Priority Pollutant Metals	Characterize possible constituents of disposed waste; indirectly measure test sediment contaminant bioavailability and potential for bioaccumulation.
Butyltins	Characterize possible constituents of disposed waste; indirectly measure test sediment contaminant bioavailability and potential for bioaccumulation.
Lipid Content	Normalize contaminant concentrations for comparisons between samples.
	Fish Bile
PAH parent compounds/metabolites	Indirectly measure the potential effects of test sediment to exposed fish.

Notes:
[a] PCB - polychlorinated biphenyl
[b] PAH - polynuclear aromatic hydrocarbon

Surface Sediment Visual Observations

Station ID	Texture	Color	Odor	Cohesiveness	Presence and Nature of Obvious Strata	Disturbed Sediment	Other Remarks
West Basin							
1	No Obs[a]	No Obs	Weak hydrogen sulfide	No Obs	Dense, dry clay under upper 2 cm[b] organic layer	No	None
2	No Obs	Blackish	None	No Obs	Gooey silt; slight clay	No	Little observed infauna
3	No Obs	Blackish	None	No Obs	Gooey silt	No	Little observable life
4	No Obs	Blackish/brown	Slight	No Obs	Clayey silt	No	Ghost shrimp holes; some polychaetes
5	No Obs	No Obs	None	No Obs	Overlying organic layer (2 cm) over dense and relatively dry clay; some sand	No	Relatively healthy infauna; polychaetes and shrimp
6	Very soft	Dark brown top 2 cm; dark black bottom 8 cm	None	No Obs	Silt (ooze)	No	None
7	Fine	No Obs	None	No Obs	Silt with some clay and fine sand	No	Shell hash; some animals
8	Hard	Dark brown top 2 cm; black bottom 8 cm	None	No Obs	Top 2 cm: silt/clay; bottom 8 cm: harder, packed clay	No	Visible biota
9	No Obs	Light brown	None	No Obs	Light silt with some clay	No	Polychaetes
10	No Obs	Brown organic layer top 2 cm; black bottom 8 cm	None	No Obs	Dense, dry clay	No	Polychaetes inhabiting clay but no evidence of shrimp or bivalves
11	No Obs	Dark brown	None	No Obs	Clayey silt	No	Some polychaetes
12	No Obs	Black with 0.5 cm brown overlayer	Strong	High	Clayey silt with minor vertical stratification	No	Few infaunal organisms apparent; oil-like; mucky
13	No Obs	Light to dark brown	None	High	Clayey silt	No	Shrimp burrows; few differences in grain size
14	No Obs	Dark brown	None	No Obs	Silt/clay	No	No obvious infauna
15	No Obs	Very dark brown	Some petroleum hydrocarbon	High	Some vertical stratification; silty clay	No	Very little infauna

Table 4-2 (continued)

Station ID	Texture	Color	Odor	Cohesiveness	Presence and Nature of Obvious Strata	Disturbed Sediment	Other Remarks
16	Very fine	Brown to black	None	Very high	Clay/silt with slight vertical stratification	No	Few infauna
17	No Obs	Brown on top; black on bottom	Slight	High	High clay content with some sand	No	None
18	No Obs	Light brown	Moderate	High	Silty clay; little strata	No	Healthy looking surface community
19	No Obs	No Obs	None	High	Silty clay	No	None
20	No Obs	No Obs	None	High	Silty	No	Healthy with considerable epifauna
21	Slightly coarse	Light brown	None	High	Silty clay with some sand	No	None
22	Firm yet soft	Brown top layers; black bottom 5 cm	None	High	Silty mud	No	Crabs and ghost shrimp
23	No Obs	Light brown	None	High	Clayey silt; no strata	No	Relatively few animals present
24	Coarse	Grey	None	No Obs	Sandy	No	Lots of shell hash
25	No Obs	No Obs	Minimal	High	Silty sand upper 5 cm, then silty clay	No	None
26	No Obs	Dark	None	High	Clay	No Obs	Kelp crabs and clams at surface
27	Soft	Green	None	Moderate to high	None	No	None
28	Soft	Green	None	Moderate	None	No	None
29	No Obs	Dark brown	None	No Obs	Silt/clay; no real stratification	No	Visible infauna
30	No Obs	Brown	None	High	60 - 80 percent silt	No	Healthy; mostly silt with some clay
31	Soft	Green/grey	None	Low	Silt/sand upper 5 cm; silt/clay bottom 5 cm	No	None
32	No Obs	No Obs	None	No Obs	40 - 50 percent sand	No	Rock crabs in surface mud

VOL 18

Table 6-1
Assessment Endpoint Species

Assessment Endpoint Species	Ecological Relevance	Regulatory or Social Significance	Susceptibility to COPECs	Measurability/Predictability
Benthic Invertebrates Communitywide assessment	Primary consumers/ decomposers and base of food chain for other wildlife. Dominant taxa of infauna.	Often considered key indicator species of pollution by regulatory agencies.	Vulnerable to exposure through ingestion and direct dermal exposure. Benthic invertebrates are in direct contact with sediments and can be sensitive indicators of toxic chemical contaminations.	Levels of COPECs in sediments were measured and toxicity and bioaccumulation tests of invertebrates in West Basin sediments and pore water were performed. An analysis was performed of the types of infauna taxa present, their biomass, and numbers.
Fish: California halibut White croaker	Important food chain elements. Occur in wide range of habitats, including beneath piers. California halibut is a major predatory fish. White croaker is the most common fish in West Basin.	Fish are important as a community because of significance as a food item for other species, including humans.	Susceptible to direct exposure due to consumption of contaminated food. Consumption of small vertebrates and invertebrates as primary food in study area are representative of worst-case exposure for large predatory fish (halibut). Consumption of small vertebrates as primary food item and year-round presence in West Basin are representative of worst-case exposure for small fish (croaker).	Levels of COPECs in fish tissue, including whole body, fillets, and bile (halibut only), were measured and can be related to published toxicity benchmarks or related to existing data from other sites. Number of fish caught during sampling indicates prominence in West Basin.
Mammalian carnivore: Harbor seal	Top mammalian predator in West Basin aquatic food chain. Common marine carnivore.	Of recreational and aesthetic importance.	Could be exposed through consumption of contaminated food items. Consumption of small vertebrates as primary food item and possible year-round presence in study area are representative of worst-case exposure for aquatic mammalian carnivores.	Levels of COPECs in fish tissue were measured and can be related to published toxicity benchmarks for prey items. Can predict dietary intake of COPECs from concentrations in fish tissue.

Note: COPEC - Chemical of Potential Ecological Concern

Table 6-3
Toxicity Reference Values and Their Derivation for the Harbor Seal

Fish COPEC	Test Species	Body Weight of Test Species (kg)	NOAEL[1] of Test Species (mg/kg-day)	Reference	Toxicity Reference Value[2] for Harbor Seal (mg/kg-day)
Arsenic (arsenite)	Mouse	0.030	0.126	Opresko et al. 1995	0.00892
Beryllium (sulfate)	Rat	0.35	0.660	Opresko et al. 1995	0.106
Chromium VI ($K_2Cr_2O_4$)	Rat	0.35	3.28	Opresko et al. 1995	0.527
Copper (sulfate)	Mink	1.0	11.7	Opresko et al. 1995	2.67
Dibutyltin	NA[3]				
Tributyltin (oxide)	Mouse	0.030	23.4	IRIS 1994	1.66
α-BHC[4]	Rat	0.35	8.00	IRIS 1994	1.28
Endrin	Mouse	0.030	0.0920	Opresko et al. 1995	0.00651

Note:

[1] NOAEL - No observed adverse effects level.

[2] Toxicity reference value = NOAEL * (body weight of test species / body weight of harbor seal)$^{1/3}$

[3] NA - not available

[4] BHC - Hexachlorocyclohexane. NOAEL unavailable; risk based on NOAEL for lindane (gamma-BHC).

Notes:

[a] A toxicity test 'hit' is a test result which was different than project reference in an adverse manner (see Section 4.4).
[b] Pier value did not exceed open water highest 'no hit' concentration value.
[c] HPAH - High molecular weight polynuclear aromatic hydrocarbon.
[d] LPAH - Low molecular weight polynuclear aromatic hydrocarbon.
[e] PCBs - Polychlorinated biphenyls.
[f] SVOCs - Semi-volatile organic compounds.
Blank space indicates samples were analyzed for compound, but not detected.
Also shown for comparison are Mean Zone, Zone 95% upper confidence level and, when available, effects range-low (ER-L) and effects range-median (ER-M) values (Long et al., 1995).
* Puget Sound Dredge Disposal Analyses (PSDDA) screening level values (U.S. ACOE 1988).

Table P-2
Variable Code Descriptions for Analytical Results Electronic Database
Long Beach Naval Complex - West Basin (Site 7)

Station ID	Description
R1	Fish sampling transect located at reference station 40010
R2	Fish sampling transect located at reference station 40018
T	Fish sampling transects located located within West Basin

Sample Type	Description
DUP	Duplicate Sample
FDB	Field Blank
REG	Regular Sample
REP1	First Field Replicate
REP2	Second Field Replicate
REP3	Third Field Replicate
RSB	Rinsate Blank

Result and Detection Units	Description
MG/KG	milligram per kilogram
MG/L	milligram per liter
UG/KG	microgram per kilogram
UM	micrometer

Laboratory Qualifier	Description
NSF	Insufficient Sample Quantity
U	Not detected above the reported sample quantitation limit (concentration reported is the Practical Quantitation Limit [PQL])

Review Qualifier	Description
J	Reported value is estimated
R	Sample results are rejected; presence or absence of analyte cannot be verified
U	Not detected above the reported sample quantitation limit (concentration reported is the PQL)
UJ	Reported value is estimated as not detected above the reported sample quantitation limit (concentration reported is the PQL)

Qualification Code	Description
1	Holding Times
5A	Calibration (Initial)
5B	Calibration (Continuing)
7	Laboratory Blanks
8	Matrix Spike
9	Duplicate of Matrix Spike
10	Laboraty Control Standard
11	Detection Limit
13	Surrogates
15	Furnace Quality Control
19	Internal Standards

Table P-2 (continued)

Result Type and Matrix	Description
CLAM	Clam
FAU	Fauna
FB1	Fish Bile
FF1	California Halibut Filet
FF2	White Croaker Filet
FW1	California Halibut Whole Body
FW2	White Croaker Whole Body
LIQ	Liquid
SED	Sediment
SED-D	Dry Weight Sediment
SED-W	Wet Weight Sediment

Method	Description
EPA 160.3	Moisture Content
EPA 608	Organochlorine Pesticides/Polychlorinated Biphenyls by Gas Chromatography
EPA 6010	Inductively-Coupled Plasma Emission Spectrometry - Priority Pollutant Metal Scan
EPA 7041	Graphite Furnace Atomic Absorption Spectrometry - Antimony
EPA 7060	Graphite Furnace Atomic Absorption Spectrometry - Arsenic
EPA 7131	Graphite Furnace Atomic Absorption Spectrometry - Cadmium
EPA 7191	Graphite Furnace Atomic Absorption Spectrometry - Chromium
EPA 7421	Graphite Furnace Atomic Absorption Spectrometry - Lead
EPA 7470	Cold-Vapor Atomic Absorption Spectrometry - Mercury
EPA 7740	Graphite Furnace Atomic Absorption Spectrometry - Selenium
EPA 7760	Flame Atomic Absorption Spectrometry - Silver
EPA 7761	Graphite Furnace Atomic Absorption Spectrometry - Silver
EPA 7841	Graphite Furnace Atomic Absorption Spectrometry - Thallium
EPA 8080	Organochlorine Pesticides/Polychlorinated Biphenyls by Gas Chromatography
EPA 8270	Semi-Volatile Organic Compounds by Gas Chromatography/Mass Spectrometry: Capillary Column Technique
EPA 9030	Total Sulfide
EPA 9071	Lipid Content
EPA DRAFT	Acid Volatile Sulfide / Simultaneously Extracted Metals
GC-FPD	Gas Chromatography/Flame Photometric Detection (Organotins)
GC/MS	Gas Chromatography/Mass Spectrometry, Selective Ion Mode for Polynuclear Aromatic Hydrocarbons
KRAHN 1986 MOD	Polynuclear Aromatic Hydrocarbons Parent Compounds
MENZEL&VACCARO	Total Organic Carbon
PLUMB 1981	Grain Size

Collection	Description
BOXCORE	Box Corer
TRAWL	Otter Trawl
VBCORE	Vibra-Corer

Station Type	Description
MFAUNA	Marine Fauna
SEDIMENT	Sediment

Usage	Description
VU	Verified, Unvalidated
VV	Verified, Validated

Notes:

[a] The last two digits of the Sample ID's are not included for the purposes of this decoder.
The Sample ID numbering system is as follows:

1. The first three digits of the Sample ID correspond to the CTO number.
2. The fourth through seventh digits of the Sample ID corresponds to a sequentially assigned blind number for that sample.
3. The last two digits of the Sample ID (not shown in this table) correspond to the container number.

[b] Sample followed by a number refers to subsurface sediment cores (1 = shallowest, 5 = deepest).

[c] T - West Basin transect

[d] R - Reference transect

[e] H - Unspecified West Basin (harbor) transect
