(First received January 1997; accepted in revised form August 1997)

Abstract—Aquatic scientists and managers have no conventional mechanism with which to characterize and compare nutrients and algal biomass in streams within a broader context analogous to trophic state categorization in lakes by chlorophyll (chl) and nutrients. We analyzed published data for a large number of distinct, temperate, stream sites for mean benthic chl \((n = 286)\), maximum benthic chl \((n = 176)\), sestonic chl \((n = 292)\), total nitrogen \((n = 1070)\), and total phosphorus \((n = 1366)\) as a first effort to establish criteria for trophic boundaries. Two classification systems are proposed. In the first system, the boundary between oligotrophic and mesotrophic categories is defined by the lower third of the cumulative distribution of the values. The mesotrophic–eutrophic boundary is defined by the upper third of the distribution. In the second system, individual streams are placed more precisely in a broad geographic context by assessing the proportion of streams that have greater or lesser nutrient and chl values. The proposed relationships for streams were compared to trophic criteria published for lakes. The proposed trophic boundaries for streams generally include a broader range of values in the mesotrophic range than conventional criteria for lakes. The ratio of maximum to mean benthic chl for streams was significantly higher than that found for planktonic chl in lakes, reflecting the greater variance in streams. This high variance in streams suggests that the proposed stream trophic criteria should be viewed only as a general first approach to categorizing stream ecosystems. © 1998 Elsevier Science Ltd. Key words—chlorophyll, eutrophic, mesotrophic, nitrogen, nutrients, oligotrophic, periphyton, phosphorus, rivers, streams

INTRODUCTION

Classification of ecosystems by an index of trophic state is common in the aquatic sciences. Streams occasionally are classified as eutrophic or oligotrophic (e.g., Hornberger et al., 1977; Kelly and Whotton, 1995), but no conventional criteria exist for these terms when applied to lotic systems. Stream enrichment often leads to increases in algal biomass (e.g., Dodds et al., 1997; Lohman et al., 1992, Van Niewenhuyse and Jones, 1996; Welch et al., 1992), and thus, a trophic classification using both nutrients and algal biomass seems useful as it has been for lakes. Autotrophic biomass is important in many streams as a food source for organisms (Lamberti, 1996). Being able to place a stream in a continuum of nutrient concentrations and producer biomass from a variety of temperate streams should aid stream researchers and managers in characterizing ecosystems and facilitate comparative research and management.

Conventional systems exist for classifying lakes into trophic categories using nutrients and algal biomass (e.g., OECD, 1982; Porcella et al., 1980; Ryding and Rast, 1989). Trophic classifications for lakes have a rich history and stem from differences in lake ecosystem function and phytoplankton communities over the range of lake types (Hutchinson, 1967). General functional characteristics exist among lakes within each of the major trophic state categories. Simply put, oligotrophic lakes have low nutrients, low algal biomass, high clarity, and deep photic zones, and may support a cold-water fishery. Eutrophic lakes can have frequent cyanobacterial blooms, high total nutrients, and wide swings in dissolved oxygen (DO) concentrations (potential anoxia) and pH. Mesotrophic lakes have intermediate characteristics. The boundaries placed between these categories by aquatic scientists are similar but not universal (e.g., Forsberg and Ryding, 1980; OECD, 1982; Porcella et al., 1980), in part because

the perceptions of researchers have provided the basis for most schemes and true geographic differences exist among lakes that justify modifying criteria for specific regions (Jones and Knowlton, 1993). Alternatively, Carlson (1977) constructed a Trophic State Index (TSI) on a scale of 0 to 100 based on interrelations among chlorophyll (chl), total phosphorus (TP), and Secchi depth. Each 10 units within this system represent a doubling of TP, a one-third increase in chl, and a half decrease in Secchi depth, thus providing a basis for the scale and a means to identify nutrient-limited conditions (Carlson, 1991).

Stream ecosystems have been described on the basis of carbon sources (Dodds, 1997) and position in the watershed (Vannote et al., 1980), but boundaries separating stream types based on producer biomass and nutrients across watersheds are lacking. Stream nutrients usually have been observed to increase as a function of intensity of land use within the basin (Omernik, 1977; Smart et al., 1985) and with human population density in the watershed (Peierls et al., 1991). Historically, specific zones within streams have been identified in relation to point source inputs of organic pollution and its impact on dissolved O2, nutrient content and stream...

biota (Bartsch and Ingram, 1959). These identifications dealt primarily with longitudinal zones of degradation and recovery but did not allow characterization of the fertility and productivity of individual streams relative to others. A trophic index based on diatoms was proposed for use in the United Kingdom (Kelly and Whitton, 1995), but this index is specific to a limited region, requires sophisticated taxonomic skills that are not generally available, and excludes filamentous green algae which are most commonly associated with nuisance conditions. Photosynthesis/respiration ratios also have been suggested as a method to characterize trophic state in streams (Hornberger et al., 1977), but this characterization requires intensive monitoring of diel variations in dissolved oxygen concentrations and has received little use.

We propose a simple approach for initially characterizing trophic state of streams using the frequency distributions of nutrients and chl to define the three trophic categories. This approach is appropriate given the absence of natural trophic boundaries based on stream ecosystem characteristics. Using the distribution of values across a large number of temperate streams, the lowest third represents the oligotrophic category, the middle third the mesotrophic category, and the top third is proposed to constitute the eutrophic category. These frequency diagrams also allow individual streams or streams within a specific geographic area to be placed in a broader context of stream types (Omernik, 1977). For example, it may be more persuasive to argue that a specific stream is eutrophic if 70% of the streams in this data set have less chl \( a \). We used previously published data for our analyses.

**Sources of Data**

Data on mean and maximum benthic stream chl, and some of the mean water-column total nitrogen (TN), and mean TP were taken from a previously published data set for temperate streams (Dodds et al., 1997). These data were collected for more than 200 streams or sites in North America and New Zealand. The majority of the systems were from temperate habitats. Seasonal means from a single year (for 2 to 3-month periods) generally were used for TN, TP and mean benthic chl. These were not always restricted to summer, because some streams (e.g., those with deciduous tree cover) may have more biomass or production at other times of the year. Seasonal maxima also were taken from this data set. The data set included sites from low order streams up to large rivers, and from nutrient enriched to those with pristine vegetative cover.

Data on planktonic (sestonic) chl and some of the water column TP data were taken from a di/C128erent data set (Van Niewenhuyse and Jones, 1996). These data came from 115 streams for multiple sites and years (almost 300 separate data points) from a variety of watershed types and areas in the temperate zone (primarily North America, with some European streams represented). All TP and chl in this data set were calculated as growing season means.

Additional data on water column TN and TP were taken from a compilation of stream data from the United States Environmental Protection Agency National Eutrophication Survey (Omernik, 1977). These values are represented by means from approximately monthly sampling of 928 streams over a period of a year. The streams sampled in this study were generally small, with watershed use distributed from pristine forests to fully agricultural.
RESULTS AND DISCUSSION

Wide distributions of mean and maximum benthic chl, and water column chl, TN, and TP were observed within the data sets (Figs 1–3). Some of the distributions were not significantly different from a log–normal distribution, but those for maximum chl and TN were. For this reason, the actual data distributions were used to set trophic classification boundaries. The approximate values marking the divisions between the lower and middle thirds, and between the middle and upper thirds of each distribution were used as boundaries between oligotrophic and mesotrophic and between mesotrophic and eutrophic, respectively (Table 1). Sharp, natural boundaries in trophic state and functional relations among the variables have yet to be identified for streams, so these boundaries should be viewed as provisional. The boundaries will likely change somewhat as the database expands, sites from tropical and polar regions are added, macrophytes are considered, and functional relationships among nutrients and algal biomass are developed further in lotic systems. Nevertheless, the suggested boundaries provide general guides to divide the trophic continuum.

Our trophic categories match another trophic characterization proposed on the basis of watershed characteristics for 16 New Zealand streams (Biggs, 1996). The 16 New Zealand streams were divided into unenriched, moderately enriched, and enriched categories based upon the amount of agriculture and geology in each individual watershed. Then the cumulative frequency distributions were plotted for benthic chl. About 90% of the values in the unen-

aData from Dodds et al. (1997).
bData from Van Niewenhuyse and Jones (1996).
cData from Omernik (1977).

A positive relationship occurred between seasonal mean and maximum stream benthic chl (Fig. 4). The ratio of maximum to mean benthic chl for our data set was 4.52 ($n = 178$, std. dev. = 7.61, lower 95% confidence level 3.39). The ratio of maximum to mean chl in lakes has been reported to be 1.7–1.8 by Jones et al. (1979), 2.5 by Chapra and Tarapchak (1976), and 2.6 by OECD (1982). This significantly higher ratio for streams and rivers than for lakes indicates the higher potential variability in chlorophyll in streams. Probably this higher ratio for streams can be explained by the influence of scouring floods (Allan, 1995; Peterson, 1996). Such hydrologic fluctuations between flood and base flow have been demonstrated to greatly influence stream chemical constituents and autotrophic biomass (Lohman et al., 1992; Perkins and Jones, 1994), and these temporal changes complicate stream characterization.

The papers that analyze nutrient chlorophyll relationships in streams more thoroughly (Dodds et al., 1997; Van Niewenhuyse and Jones, 1996) have demonstrated relationships between TN or TP and chl for streams that are weaker than they are in lakes. This is probably because high turbidity (non-algal TN and TP) may be more common in streams than in lakes. Also, our cumulative frequency distributions for TN and TP contained a large number of points for which no chl data were available. Therefore, it may not be advisable to attempt to tightly link distributions of TN or TP concentrations to the benthic chl distributions presented here.

We evaluated our trophic criteria for streams against those published for lakes because trophic state characterization for lakes is more established through actual use. We compared the areal phytoplankton chl content in lakes to benthic chl in enriched and moderately enriched watersheds fell below 20 and 100 mg m$^{-2}$ chl respectively. These categories compare favorably to our proposed upper boundaries of 20 and 70 mg m$^{-2}$ chl for oligotrophic and mesotrophic systems respectively.

The cumulative frequency diagrams (Figs 1–3) depict the broad variation inherent in stream chl and nutrient chemistry when many streams are considered. The diagrams also provide a relative scale to locate individual streams of interest along a larger continuum of nutrients and chl. For example, a stream may be considered to be moderately enriched if TN is 1000 µg/l because about 50% of the streams in our data set have less N (Fig. 3B). Comparisons of this type may also help identify functional processes in streams. If a stream has TP levels in the top 10% of our distribution and either benthic or sestonic chl in the bottom 10%, some factor other than nutrients likely is controlling accrual of biomass. Specific functions to determine the expected relationships between TN:TP and benthic chl (Dodds et al., 1997) and TP and sestonic chl (Van Niewenhuyse and Jones, 1996) are available, if more detailed analysis is required.

Previous studies have suggested that benthic chl above 50–200 mg m$^{-2}$ may represent a cut point for nuisance conditions (Table 2). These values of chl have been determined subjectively and there may be a regional basis for the four-fold range. However, most of these objectionable levels fall above the proposed lower boundary for eutrophic streams (Table 1). About 85% of the streams analyzed in our database had mean benthic chl below 100 mg m$^{-2}$, and 50% had maximum values below this level. Therefore, a general suggestion that a mean of 150 mg m$^{-2}$ represents nuisance levels agrees with values suggested by other authors (Table 2).

streams and volumetric planktonic chl concentrations in lakes and streams. A popular fixed boundary system for trophic classification (OECD, 1982), using chl, TN, TP, and Secchi depth, was employed for this comparison (Table 3). Assuming that chl is distributed evenly down to two times the Secchi depth (roughly the compensation point for photosynthesis), we also calculated areal chlorophyll values for lakes. These data suggest that the OECD (1982) mesotrophic range for areal chl in lakes is slightly narrower than the range for streams. This could be because chl (on an areal basis) is distributed differently in lakes than in streams or the methods used to define trophic state in lakes led to drawing boundaries at different levels. The reader should keep in mind how the OECD (1982) system was constructed. Data were provided for a large number of lakes by a number of investigators. Each investigator signified if their lakes were oligotrophic, mesotrophic, or eutrophic. The boundaries for each trophic classification were then derived for all lakes proposed for each of the three categories.

We used our cumulative frequency method to define boundaries for lakes in a similar fashion as that used for streams. When Smith (1982) data for approximately 309 lakes and Jones and Knowlton (1993) data for 94 reservoirs were used, the trophic boundaries for chl, TN, and TP of lakes were similar to those proposed for streams in this paper. In fact, TP boundaries for lakes and streams from cumulative frequency distributions were virtually identical. Thus, our trophic classifications for streams may vary from the OECD values for lakes largely because of methodology. That is, a statistical approach to classification of lake trophic state

yielded categories for lakes more similar to those proposed here for streams, whereas the more subjective methods used by others for lakes yielded trophic classifications less similar to ours. The distributions presented here can be refined as more data become available, particularly for benthic and suspended chl. Tropical streams and rivers may vary from their temperate counterparts analyzed here. Eutrophic streams may be more abundant in particular geographic regions. For example, areas with considerable agricultural activity typically have streams with high nutrient content (Omernik, 1977). Detailed analysis in specific regions may lead to categorization of streams that has more geographic relevance (e.g. Biggs, 1995; Biggs, 1996). It is also certain that the distributions we report are influenced by anthropogenic nutrient sources and do not represent pristine, background conditions. The past can not be re-visited and there are virtually no large, completely pristine temperate rivers left to construct a data base from, so the next best approach is to provide a baseline using data collected over the past few decades. We suggest that frequency distributions can be used to assist stream scientists and managers in determining the trophic states of their individual streams relative to others.
