Subject: comments on BDCP EIR/EIS and IA
Attachments: BDCPcommentsfinal.pdf

Please find attached comments from Save the California Delta Alliance on the draft Bay Delta Conservation Plan, Draft EIR/EIS, and Draft Implementation Agreement. Also attached are several dozen scientific studies cited in the comments and incorporated into the administrative record. The file sizes are too large to include the reports in one email so following emails will contain the reports.

responsible state and federal resource agencies

From: Save the California Delta Alliance

Comments on the Draft Bay Delta Conservation Plan
Comments on the Draft Environmental Impact Statement / Environmental Impact Report
Comments on the Draft Implementation Agreement

These comments are submitted on behalf of the Save the California Delta Alliance ("STCDA"). STCDA is headquartered in Discovery Bay, California. STCDA represents the interests of individuals who live and work in the Delta, including those with waterfront homes located in Discovery Bay, Delta related businesses, and many who engage in all kinds of water-related recreation in the Delta. STCDA regularly turns out several hundred enthusiastic members at it its town hall style meetings held in Discovery Bay.

These comments address the Draft Bay Delta Conservation Plan, the Draft Environmental Impact Statement / Environmental Impact Report, and the Draft Implementation Agreement.

References cited herein and attached hereto (and hereby made a part of the administrative record for the BDCP and EIR/EIS) are listed in Appendix 1 hereto.

Thank you for the opportunity to submit these comments and for considering our views.

I. The Project Area In The BDCP and The Project Objectives / Purpose In The EIR/EIS Are Defined In Unreasonably Narrow Terms Frustrating Consideration Of A Reasonable Range Of Alternatives.

The EIR/EIS ("EIR") does not consider broad alternatives or compliments to the twin tunnels. For example, although virtually all sides in the California water debate agree that some form of additional storage is a necessary component of any long-term solution, the EIR does not consider any alternatives that include storage options. Likewise, the Public Draft Bay Delta Conservation Plan ("BDCP") does not include any storage components. Nor does the BDCP include actions outside the narrow geographic scope defined in the Plan Area, which is the statutory Delta and several immediately adjacent areas. *See* BDCP § 1.4.1.

A significant justification for the twin tunnels has been the "little sip, big gulp" rationale. Although this seems to have fallen by the wayside in BDCP promotional efforts of late, it still accurately describes the best policy rationale for the tunnels. By relocating the point of diversion and providing large capacity conveyance it would be possible to draw larger quantities of water at times of abundance (big gulp) thereby allowing diversions to be minimized at times of low flow and critical environmental need (little sip). Sounds good. But it doesn't work without storage. Although the tunnels would provide the ability to divert large quantities of water during peak winter flows, there is currently nowhere to store such diversions. The legislature has ordained that it is state policy to "[i]mprove the water conveyance system and expand statewide water storage." Cal. Water Code § 85020(f). It is no accident that storage and conveyance are tightly yoked in legislative policy. Only with the provision of additional storage capacity can the tunnels actually function as a big gulp little sip device. Yet the BDCP does not contain any storage, and the EIR does not analyze a "tunnels plus storage" alternative.

The feasibility and benefits of expanding storage through increased groundwater recharge is beyond dispute. The necessity to provide additional storage and feasibility of doing so is discussed in more detail in section II below.

The project proponents have attempted to insulate the failure to consider storage and other defects in the BDCP and EIR from challenge by narrowly defining the Project Objectives/Purpose in the EIR and geographic scope in the BDCP. *See* EIR ES.2; BDCP § 1.4.1. However, "a lead agency may not give a project's purpose an artificially narrow definition" in order to arrive at its own foreordained result. *In Re Bay–Delta Programmatic Envtl. Impact Report Coordinated Proceedings*, 43 Cal. 4th 1143, 1166 (2008). An "agency cannot define its objectives in unreasonably narrow terms." *City of Carmel-By-The-Sea v. U.S. Dept. of Transp*, 123 F.3d 1142, 1155 (9th Cir.1997). "Instead, agencies must look hard at the factors relevant to the definition of purpose … . Once an agency has considered the relevant factors, it must define goals for its action that fall somewhere within the range of reasonable choices." *Citizens Against Burlington, Inc. v. Busey*, 938 F.2d 190, 196 (9th Cir. 1991).

The Project Objectives provide that a project objective is the "construction and operation of facilities … for the movement of water entering the Delta from the Sacramento Valley watershed to the existing SWP and CVP pumping plants located in the southern Delta." EIR ES-9. This, however, is simply a definition of the twin tunnels. That is an *end result* of the decisional process, not a valid project objective. The project proponents have simply crafted a definition of Project Objectives so narrow that the only result can be to fulfill their own twin tunnel prophecy. However:

> We realize, as we stated before, that the word "reasonable" is not self-defining. Deference, however, does not mean dormancy, and the rule of reason does not give agencies license to fulfill their own prophecies, whatever the parochial impulses that drive them. Environmental impact statements take time and cost money. Yet an agency may not define the objectives of its action in terms so unreasonably narrow that only one alternative from among the environmentally benign ones in the agency's power would accomplish the goals of the agency's action, and the EIS would become a foreordained formality.

Citizens Against Burlington, Inc. v. Busey, 938 F.2d at 196.

The actual purpose of the project is to provide regulatory stability to the operation of the entirety of the state and federal water projects while at the same time lessening and/or mitigating the impact of the operation of the water projects on Delta ecology, and increasing water deliveries with the goal of attaining full contract amounts. These are extraordinarily broad-based policy goals. However, the "Project Objectives" and "Project Purpose" sections in the EIR have been drafted with exceeding precision and care, likely involving many attorney hours in the crafting of these few paragraphs, to limit the range of actions that would fulfill the Project Purpose and Objectives to improving conveyance from the north Delta to the existing export pumps, and providing habitat within the statutory Delta and adjacent areas. *See* EIR ES.2.

The Project Purpose and Project Objectives sections, however, are radically under-inclusive of the actual purposes, as betrayed repeatedly throughout the text of the BDCP: "The overarching goals of the BDCP are to advance the restoration of the ecological functions and productivity in the Delta and restore and protect water supplies provided by the SWP and CVP … ." BDCP 1-5. Successful completion of the BDCP is intended to "afford regulatory stability with respect to the operation of the primary water delivery systems for the State of California." BDCP 1-26. The BDCP "is intended to result in long-term regulatory stability for the state and federal water projects, while furthering the goals of the BDCP to restore and protect ecosystem health, water supply, and water quality." BDCP 1-6. *See also* Draft Implementing Agreement for the Bay Delta Conservation Plan § 2.1.8 ("The overall goal of the BDCP is to restore and protect ecosystem health, water supply, and water quality within a stable regulatory framework.") ("IA").

Surely if the actual goals are to provide regulatory stability for the entire state and federal water projects, protect the drinking water supply and quality for 19,000,000 Californians and millions of acres of irrigated agriculture, and restore the ecosystem health of the largest estuary on the west coast of north America then it is irrational to provide a legal description of those goals in terms so narrow that possible alternatives are limited to exclude almost all components of the state and federal water projects, exclude storage, exclude conservation, and exclude solutions that actually address the problem.

The artificial and impermissible segmenting of Biological Opinions is another attempt to insulate broad effects of the project from challenge by narrowing its legal scope in a way that is inconsistent with its actual scope. BDCP section 1.3.2.2 provides:

> With respect to Reclamation's operation of the CVP, the joint BiOp for the BDCP will cover only those operations that occur after the new water conveyance facilities are operational which is expected to be in 2026. At that time, the joint BDCP BiOp is expected to supersede the existing BiOps (as revised) for the coordinated long-term operation of the SWP and CVP, but only for those operations that occur within the Plan Area. The BiOps on the coordinated long-term operation of the SWP and CVP are expected to continue to provide Section 7 Authorization for operations of the SWP and CVP that occur outside of the BDCP Plan Area.

BDCP 1-9. This segmenting is inconsistent with the fact that "[t]he infrastructure of the state and federal water projects form an integrated system that extends beyond the boundaries of the Delta [and BDCP project area]; as such, the BDCP will affect water operations, species, and habitat both inside and outside the Delta." BDCP 1-3.

For all its discussion of the importance of scale within the fledgling science of restoration ecology, the BDCP does not blush at turning a blind eye to scale when embracing the true dimensions of an issue becomes an impediment to breaking ground on tunnel construction.

II. The BDCP Should Be Revised To Include Storage Through Groundwater Recharge And The EIR Should Analyze A Reasonable Range Of Alternatives That Include Storage Through Groundwater Recharge.

The recently completed Delta Plan, promulgated after years of study and at the charge of the Legislature to set state policy for the Delta, concluded that the key to restoring the health of the Delta and providing a reliable water supply for the state is "Storing Floods to Ride Out Droughts (and Give the Delta a Break)." Delta Plan ES-6. As the Delta Plan is critical to informed decision making for the BDCP and for consideration of a reasonable range of alternatives for the EIR, it is attached in its entirety and made a part of these comments and the administrative record. The Delta Plan further found that groundwater recharge is the best way to achieve additional storage capacity: "using aquifers like bank accounts: to be filled up in wet times, in order that they may be drawn from in dry." Delta Plan ES-7.

A critique of the BDCP by an eminent panel of scientists, commissioned by American Rivers and the Nature Conservancy, Saracino & Mount, LLC, Panel Review of the Draft Bay Delta Plan Prepared for the Nature Conservancy and American Rivers ("Mount Report") also concluded that although one of the objectives of the BDCP is "to increase exports during wet periods and decrease them during dry periods … it does not significantly reduce pressure on the Delta during drier periods." Mount Report 30. The Mount Report suggested that "Expanding potential storage, particularly groundwater storage, would have created considerably more flexibility in exports" allowing more water to be harvested in wet years (big gulp) and conserving environmental flows during periods of scarcity (little sip). Mount Report 22. The Mount Report is attached in its entirety and made a part of these comments and the administrative record.

In Research Brief Issue #102, *Does California Have the Water to Support Population Growth ?* The Public Policy Institute of California Concluded that groundwater storage can provide an additional two million acre feet of "new" water per year. (Attachment ___). Moreover, increasing groundwater storage is the official policy of the state of California. The California Water Plan Update 2005 estimated that through groundwater banking there is "the potential to increase average annual water deliveries by 2 million acre-feet" in conjunction with reoperation of existing surface water reservoirs. California Water Plan Update Chapter 4, page 4-2.

In the report, Groundwater Availability of the Central Valley Aquifer, published by the USGS ("Groundwater Availability"), the authors discuss water banking through groundwater recharge generally and the new groundwater recharge water bank, the Madera Ranch Project, that "would divert floodwaters from the Delta" for storage and future use. Groundwater Availability 108. The Madera Ranch Project involves the banking of CVP water in collaboration between the Madera Irrigation District, A CVP water contractor, and the USBR, a close collaborator on the BDCP. The parties to the BDCP have it well within their means to use additional groundwater banking as a component of the BDCP and it is proven feasible to bank CVP water in groundwater recharge throughout the state.

Groundwater Availability is designed to "be used to identify favorable locations [for groundwater recharge] on a regional scale" and should be of use to BDCP planners in evaluating alternatives that build on the Madera Ranch model. *Id*. Attached are the Madera Ranch federal Record of Decision and Environmental Impact Statement for use in considering additional groundwater banking as an integral component of the BDCP and as part of a reasonable range of alternatives. Also attached are the following scientific reports on groundwater recharge for use in developing alternatives, as listed in Appendix 1.

There is scientific consensus that additional storage through groundwater banking is an essential and feasible element in addressing California's water supply issues and in restoring the health of the Delta. Since these are the two actual goals of the BDCP, there is no reason why groundwater banking should not be a part of the BDCP and failure to consider an alternative that includes groundwater storage is failure to consider a reasonable range of alternatives.

The artificial narrowing of possibilities for infrastructure to exclude groundwater recharge by limiting conveyance to the tunnels and the project area to the Delta by way of an inapt Project Objectives section is no bar to real solutions. Instead, the BDCP proponents "must look hard at the factors relevant to the definition of purpose … . Once an agency has considered the relevant factors, it must define goals for its action that fall somewhere within the range of reasonable choices." *Citizens Against Burlington, Inc. v. Busey*, 938 F.2d 190, 196 (9th Cir. 1991). Here, the range of reasonable choices must include storage, and any reasonable consideration of storage must include groundwater banking.

Investment in infrastructure throughout California to accomplish groundwater recharge is well within the range of reasonable choices available to the BDCP. The water contractor proponents of the BDCP have much of the state's groundwater resources under their collective purview. The water contractors have participated successfully in construction of regional groundwater banking facilities and with USBR in groundwater banking CVP water. As noted in the Delta Plan:

> Statewide water storage capacity, both above and below ground, is currently inadequate, especially south of the Delta, to facilitate export of water at times of surplus when the impacts on the Delta's ecosystem are reduced and the only impediment is lack of available storage capacity (DWR 2009). For example, in 2010, the SWP and CVP pump operations were slowed even though water was available to be pumped at a time when it would not have conflicted with endangered species or other water quality requirements. The SWP and CVP could not convey the surplus water through the Delta at that time because storage capacity south of the Delta was full.

Delta Plan 86.

How much “new” water could be harvested from the existing pumps if lack of storage was addressed through provision of groundwater banking facilities? Construction of the tunnels will cause massive disruption of life in the Delta. The stretch of the Sacramento River and adjacent farmland between Clarksburg and Walnut Grove will be transformed from a peaceful boating and farming landscape into a vast industrial complex supporting tunnel infrastructure. The tens of billions of dollars involved in tunnel construction might be better spent on a series of smaller groundwater recharge projects that would be much less locally disruptive, spare Delta communities from annihilation, and would actually achieve the goals of providing a more reliable water supply to the state, restoring the Bay-Delta ecosystem, and expanding statewide storage capacity as mandated by the legislature.

Or, perhaps, a smaller tunnel project in conjunction with additional storage would be the optimal solution. We will not know until the proponents of the BDCP roll up their sleeves and analyze a reasonable range of storage alternatives—not limited by an artificially narrow project description.

III. The BDCP Should Be Revised To Include Storage / Management With The Sites Reservoir As An Integral Component And The EIR Should Analyze Alternatives Including Sites Reservoir As An Integral Component Of The BDCP.

The proposed Sites Reservoir project, also known as North of Delta Offstream Storage (“NODOS”) is well along in planning and analysis. A preliminary draft environmental impact report and preliminary engineering design were completed in May 2014. Technical difficulties prevented download and inclusion of these documents herewith. They are incorporated by reference and will be provided under separate cover. They are available at http://www.water.ca.gov/storage/northdelta/index.cfm. A technical Memorandum, Sensitivity Analysis of Operation with the BDCP, has not yet been released to the public. The technical memorandum, however, should be currently available to the resource agencies and it is incorporated into the administrative record by reference now even though it is not available to be attached hereto.

NODOS would operate by diverting flows from the Sacramento River at times of high flow through a series of existing irrigation canals to a new surface storage facility. The stored water would then be released back to the river during periods of scarcity. NODOS is well upstream of the Delta, and water released from NODOS could be allocated between in-stream environmental needs and export needs. NODOS could operate in conjunction with any new or existing point of diversion in the Delta, including the tunnels.

NODOS is projected to store up to 1.4 million acre feet. This would add considerable flexibility (which the Mount Report found lacking) to the BDCP for both water supply and environmental needs. The logic of incorporating Sites into the BDCP is obvious. Its technical development has been coterminous with the BDCP. Its function, is to bring to fruition the little sip big gulp approach sorely lacking in the BDCP.

Failure to analyze an alternative that includes Sites makes the range of alternatives analyzed by the BDCP unreasonable. Incorporating Sites would allow the BDCP to become what it must be in order to be successful, a system that can "Store[] Floods to Ride Out Droughts." Delta Plan ES-6.

IV. The BDCP Should Store Floods To Ride Out Droughts.

As currently formulated, the BDCP fails the basic test for providing water supply and environmental solutions because it is a run-of-the-river project. It fails to comply with the coequal goals of the Delta Reform Act, "providing a more reliable water supply for California and protecting, restoring, and enhancing the Delta ecosystem." Cal. Water Code § 85054. Instead, it must continue to rob environmental needs of water at times of scarcity in order to provide water supply. As such, it simply continues the basic problem rather than offering any solution. The problem, in a nutshell, is that there is an overabundance of water that comes all at once, at the wrong time, in the wrong place, and erratically.

Winter storms drop tremendous amounts of water in very short periods and there is currently no way to harvest or store this water. Instead, it is diverted through flood control structures around the Delta and out to sea.

Attached is a DWR fact sheet entitled Sacramento River Flood Control Project Weirs and Flood Relief Structures. It shows historical diversions at the Moulton, Colusa, Tisdale, Fremont, and Sacramento Weirs. These weirs have combined capacity to divert 588,000 cfs. The Sacramento Weir alone, operating at a river stage of 31 feet, diverts over 31,000 cfs. To put this into perspective, that would be 1 MAF approximately every 16 hours, or the equivalent of the high end of total SWP and CVP yearly diversions (6 MAF) in a period of 4 days. From just one of the five weirs.

The BDCP proposes to spend tens of billions of dollars on new water supply infrastructure. Yet no alternative that would harvest and store even a fraction of this abundance is considered.

V. Issuance Of ESA Permits Is Not A Valid Project Objective And Misdescribes The Project.

The stated objective of "[r]espond[ing] to the application for ITPs for the covered species that authorize take," EIR, ES-8, is not a lawfully permissible project objective or purpose. STCDA first pointed out the confusion around what the project actually is in its comments dated November 16, 2011. Our November 16, 2011, comments are attached and incorporated in full here as to project objectives and purpose and all the other issues raised therein. As we pointed out in those comments, the February 13, 2009, Notice of Intent to prepare an Environmental Impact Statement, 74 Fed. Reg. 7257 ("NOI") states that the proposed federal actions are issuance of ESA permits and implementation of one or more components of the BDCP. However that is not correct. The major federal action is the continued operation of the CVP at increased rates of export through implementation of conveyance improvements/alterations.

See Delta Smelt Consol. Cases, 686 F. Supp. 2d 1026, 1042 (E.D. Cal. 2009) (major federal action was not the issuance of biological opinions but rather "planned coordinated operation of the Projects [CVP] that creates the jeopardy found by the BiOp.").
See also U.S. Fish & Wildlife Service, *Habitat Conservation Plans*, *available at http://library.fws.gov/Pubs9/hcp_section10.pdf* (last visited Nov. 14, 2011) (noting that "[t]he purpose of the incidental take permit is to authorize the incidental take of a listed species, not to authorize the activities that result in the take").

The mis-description of the project in the NOI and Project Objectives section of the EIR are part and parcel of the attempt to portray the tunnels as a "conservation measure" and/or integral part of a habitat conservation plan. The tunnels are a piece of water supply infrastructure. They are an operationally indivisible part of the system that *causes* the take. The vast habitat restoration projects are *mitigation* for operation of the tunnels/CVP/SWP.

The BDCP's pervasive attempts to disguise as a habitat conservation plan a project aimed at increasing water exports through construction of large capacity conveyance facilities violates the Endangered Species Act and numerous other state and federal laws, including the federal Information Quality Act. The attempt to disguise and dissemble also means that the BDCP EIR/EIS fails to provide a stable and accurate project description, in violation of CEQA and NEPA. Rather than foster informed public participation, which is at the heart of CEQA and NEPA, the overly-clever scheme to disseminate misinformation about the true nature of the project is a wanton and willful violation of CEQA and NEPA.

A major Project Objective is to "[r]estore and protect the ability of the SWP and CVP to deliver up to full contract amounts" of water as stated in water delivery contracts. EIR ES-8. The SWP and CVP have never been capable of delivering full contract amounts. Environmental consequences of such delivery and the fact that Delta water is vastly oversubscribed have made such exports impossible. Yet, the tunnels, which would make such vastly increased exports possible, are described as a conservation measure. And the project, including the objective of doubling or tripling water exports, is denominated as a habitat conservation plan. Vastly increasing water exports has nothing to do with conserving habitat or arresting the decline of species.

The two key quantitative guardians of maintaining in-stream flow necessary for environmental protection, X-2 and spring outflow, are made subject to manipulation in order to "minimize water supply effects." BDCP 3.4-11. In other words, the BDCP is a plan to shift water from environmental application to export.

To meet the requirements of state and federal law, the project must be accurately portrayed as a water supply project with attendant habitat restoration as mitigation. As currently formulated, the BDCP is not a Habitat Conservation Plan, within the meaning of the federal Endangered Species Act.

VI. The BDCP Fails To Comply With Water Code Section 85321

California Water Code section 85321 provides that:

> The BDCP shall include a transparent, real-time operational decision-making process in which fishery agencies ensure that applicable biological performance measures are achieved in a timely manner with respect to water system operations.

The intent of the legislature was that real-time decision-making would "ensure that applicable biological performance measures are achieved in a timely manner." However, BDCP section 3.4.1.4.5 employs real-time decision-making as a way of maximizing water exports:

> The CM1 real-time operational decision-making process (real-time operations [RTOs]) allows for short-term adjustments in operations within the range of CM1 criteria described above in Section 3.4.1.4.3, *Flow Criteria*, in order to maximize water supply for SWP and CVP relative to the Annual Operating Plan and its quarterly updates subject to providing the necessary protections for covered species.

BDCP 3.4-26. Species are an afterthought in the BDCP's version of real time operations. They were the *only* concern of the legislature in its specification of real time operations. The legislature said *nothing* about using real-time operations to maximize water supply or adjust the Annual Operating plan.

The BDCP further lists the factors to be considered in adjusting real-time operations as "Covered fish species risks; Necessary actions to avoid adverse effects on covered fish species; Allocations in the year of action or in future years; End of water year storage; San Luis Reservoir low point; Delivery schedules for any SWP or CVP contractor; Actions that could be implemented throughout the year to recover any water supplies reduced by actions taken by the RTO team." BDCP 3.4-26–27. This further emphasis on operation of the tunnels as a water supply device simply confirms the obvious that the tunnels are a water supply device; they are not a conservation measure; nor are they properly described as part of a Habitat Conservation Plan.

All real-time operations adjustments are further strictly limited in that they cannot override the bypass flow criteria established in the BDCP. In other words, no matter what, the water contractors are entitled to receive water in the range permitted by the bypass flow criteria. Real time operations cannot reduce exports beyond these levels. *See* BDCP Chapter 3.4.1.4 and IA § 10.2.2.3. That is not what the legislature ordained. Pasting this additional guarantee of water deliveries into real-time operations that were intended to "ensure that applicable biological performance measures are achieved in a timely manner with respect to water system operations" is contrary to the legislative intent and directive.

To be sure, consistent with its penchant for providing result-oriented legal descriptions that endorse its predetermined course of conduct, the BDCP declares that "[t]he RTO's will satisfy Water Code, section 85321." BDCP 34-26. But saying doesn't make it so. Particularly when no analysis or reasoning is provided as to how, given the glaring disparities described above, the BDCP RTOs satisfy section 85321. Moreover, this one-sentence feat of statutory interpretation, along with the other criteria provided in the BDCP to "implement" section 85321, is an illegal underground regulation with respect to DWR and CDFW. *See* section IV of these comments below.

The Draft IA proffers CDFW's finding that the BDCP complies with section 85321. IA § 4.2.2. However, the drafters have misread the Water Code. Section 85320 is within CDFW's purview (although with limited effect and subject to appeal). Section 85321 is not within CDFW's purview at all. The legislature charged a different state agency (the Delta Stewardship Council) with adjudging in the first instance whether the BDCP complies with section 85321.

VII. The BDCP Lacks Effective Adaptive Management Capability.

Despite the lavish attention paid to general concepts of adaptive management and the celebration of adaptive management as essential to any hope of success of the project, adaptive management is effectively hobbled with respect to the variable most crucial to the success of the plan: water exports.

The IA provides that any "change to a Conservation Measure in a manner that would potentially result in the modification of water supplies [must be] consistent with Section 9.3.7" of the IA. "9.3.7" appears to be a typo and should read 10.3.7. Section 10.3.7, in turn, provides that the "limits and constraints" on adjusting water operations through adaptive management "are set out in Chapter 3.4 and Chapter 8." Chapter 3.4, in turn, contains all the flow criteria, including bypass flows, that have been ardently negotiated into the agreement by the water contractors. Thus, adaptive management is no more available to reduce exports below the flow criteria set out in BDCP section 3.4.1.4.3 than is real time management.

Under withering public criticism, state and federal officials finally backed down from previous agreements (in prior drafts of the BDCP) extracted by the water contractors that reductions in guaranteed levels of exports could only be accomplished through a years-long appeal process that ultimately had to be decided by the Secretaries of the Interior and Commerce and Governor of California (virtually assuring that exports would never be reduced). However, in yet another glaring example of regulatory capture, the water contractors appear to have *improved* their position in the latest BDCP draft.

Under regulatory assurances, the IA specifies that "quantity and timing of [water] delivery" may not be altered under the no surprises rule, and additional measures required of the water contractors to address emergent circumstances may not involve "resource restrictions." IA § 14.1.

By providing an exhaustive list of what constitutes changed circumstances in BDCP section 6.4.2, the BDCP insulates the water contractors from reductions in water exports under the no surprises rule for anything that is not listed. Glaringly absent from the list is the simple proposition that the BDCP will simply not work as projected. Much of the BDCP can, most charitably, be described as at the frontier of scientific knowledge.

The BDCP assumes that wetland creation on farmland that has been reclaimed for over a hundred years and has subsided dozens of feet will be wildly successful. This, despite the fact that no wetland creation in similar circumstances has ever been attempted. It assumes that changes in the point of diversion will achieve all hoped for benefits. None of this is proven from experience. All BDCP projections rely on modeling. And as every good scientist knows, all models are wrong but some models are useful. To make the BDCP models useful to species recovery (rather than lethal to it), the list of changed circumstances should be amended to include "any component of the BDCP not performing as projected," and "jeopardy to any species.

Calling the tunnels a conservation measure has lead to a perversion of the Endangered Species Act whereby the largest single stressor to endangered species, water exports, are guaranteed against reduction (even if reduction is needed to assure species recovery) by the no surprises rule. The ESA and HCP here function as a guarantors of economic benefit to the water contractors and not as tools of species recovery. This is not what Congress intended in enacting the ESA and allowing for HCPs.

If it was not the intent of the state and federal resource agencies to guarantee export levels no matter what, the IA and BDCP should be amended to include the following: "Nothing herein, including but not limited to section 3.4.1.4.3 of the BDCP and section 14.1 of the IA, shall limit or constrain any reduction in water exports determined to be appropriate to achieve the biological goals and objectives through the adaptive management process."

VIII. Along With Much Of The BDCP, DWR's Interpretation Of Section 85321 And Promulgation Of Implementing Criteria Are Illegal Underground Regulations.

California Government Code section 11342.600 provides:

> "Regulation" means every rule, regulation, order, or standard of general application or the amendment, supplement, or revision of any rule, regulation, order, or standard adopted by any state agency to implement, interpret, or make specific the law enforced or administered by it, or to govern its procedure.

California Government Code section 11340.5 in turn provides in pertinent part:

> No state agency shall issue, utilize, enforce, or attempt to enforce any guideline, criterion, bulletin, manual, instruction, order, standard of general application, or other rule, which is a regulation as defined in Section 11342.600, unless the guideline, criterion, bulletin, manual, instruction, order, standard of general application, or other rule has been adopted as a regulation and filed with the Secretary of State pursuant to this chapter.

These provisions of the California Administrative Procedure Act ("APA") apply to the BDCP. The BDCP implements, interprets, and makes specific numerous state laws, including the Delta Reform Act. "The provisions of the BDCP were developed to satisfy the requirements of the Sacramento-San Joaquin Delta Reform Act of 2009, California Water Code (Water Code) § 85300 *et seq*." IA 2.1-9.

The criteria promulgated to implement Water Code section 85321, as discussed in section III of these comments above, are regulations within the meaning of the APA. The criteria selected and the statutory interpretation involved therein (for example, that real time operations cannot override pre-established flow criteria) are subject to the APA. "Absent an express exception, the APA applies to *all* generally applicable administrative interpretations of a statute." *Morning Star Co., v. State Bd, of Equalization*, 38 Cal. 4th 324, 335 (2006) (emphasis added). The sole exception, that the agency's interpretation is "the only legally tenable interpretation of a provision of law,' Cal. Gov. Code § 11340.9(f) cannot apply here. The "lone 'legally tenable' reading of the law applies only in situations where the law can reasonably be read only one way." *Morning Star Co.,* 38 Cal. 4th at 337. Only where "the agency's actions or decisions in applying the law are essentially rote, ministerial, or otherwise patently compelled by, or repetitive of, the statute's plain language," does the exception apply. *Morningstar, 38 Cal. 4th at 336*. The interpretation and implementation of section 85321 here involves an exercise of discretion as to how the statute will be applied. The choices made are by no means the only ones possible under the statute.

The BDCP is not limited to a single project but rather is of general application to an entire class of cases and projects: the BDCP's designated "Covered Activities." This is acknowledged by the parties to the BDCP: The BDCP "[s]ets out a comprehensive approach to coordinating and standardizing applicable requirements for Covered Activities and Associated Federal Actions within the Plan Area." IA 3**.** The BDCP "[e]stablishes a more efficient and effective approach to regulatory compliance with State and federal endangered species laws than through project-by-project, species-by-species planning." Draft Implementing Agreement for the Bay Delta Conservation Plan § 2.1.8.

Where implementation or interpretations "apply generally, rather than in a specific case" the rulemaking provisions of the APA apply. *Morning Star Co., v. State Bd, of Equalization*, 38 Cal. 4th 324, 334 (2006).

The Biological Goals and Objectives and performance standards are further examples of regulations. "'Performance standard' means a regulation that describes an objective with the criteria stated for achieving the objective." Cal Gov. Code § 11342.570.

The BDCP is of monumental public interest and importance, essentially governing the operation of the state's water supply infrastructure and managing the Delta's biological resources over the next fifty years. DWR and CDFW may believe that operating the SWP and managing Delta resources are a matters of internally managing their own infrastructure and not therefore subject to the APA. However, matters "of serious consequence involving an important public interest" cannot escape the requirements of the APA on grounds that the agency is simply determining how it will handle its own internal affairs. *City of San Marcos v. Cal. Highway Com.,* 60 Cal. App. 3d 383, 408 (1976).

By way of further example, CDFW has engaged in underground rulemaking by promulgating section 9.5 of the Draft IA, which specifies procedures and standards of future general application for evaluating "Approval, Adoption or Amendment of Future Plans or Projects," which could result in suspension or revocation of state permits; section 11.1.2, which specifies procedures for "Addressing Failure to Maintain Rough Proportionality."

The instances of underground rulemaking in the BDCP are too numerous and extensive to be exhaustively listed here. Wherever the BDCP implements, interprets, or makes specific state law for general future application, that exercise must comply with the APA.

IX. USFWS And NMFS Have Engaged In Disguised Negotiated Rulemaking With The Water Contractors In Violation Of The Administrative Procedure Act And The Negotiated Rulemaking Act.

All rules issued by federal agencies are subject to the requirements of the federal Administrative Procedure Act. A rule is defined as "an agency statement of general or particular applicability and future effect designed to implement, interpret, or prescribe law or policy or describing the organization, procedure, or practice requirements of an agency" in carrying out its functions. 5 U.S.C. § 551(4). All rules promulgated by federal agencies are subject to notice and comment requirements and publication in the Federal Register, not met here. Further requirements are imposed by federal law on "negotiated rulemaking" whereby federal agencies negotiate, as here, the outcome of the rulemaking process with affected entities. *See generally* the Negotiated Rulemaking Act of 1990, the Federal Advisory Committee Act.

The BDCP and Draft IA contain numerous binding pronouncements of the federal agencies of both general and particular applicability and future effect designed to implement and interpret numerous federal statutes, including the Endangered Species Act, the Fish and Wildlife Coordination Act, the Fish and Wildlife Act of 1956, and the Central Valley Improvement Act. These commitments have been arrived at through negotiation with the Water Contractors. As such, both the BDCP and IA are subject to the Administrative Procedure Act, the Negotiated Rulemaking Act, and the Federal Advisory Committee Act.

Indeed, the entire "adaptive management" component of the BDCP was arrived at through disguised negotiated rulemaking and specifies little more than a procedure for future disguised negotiated rulemaking, intended to subvert the requirements of federal law.

Section 10.2.1.3 of the IA acknowledges that specific outflow criteria are integral to the issuance of take permits. However, it further provides that the outflow criteria may be altered by following a process outlined in section 10.2.1.2, without amending the permits. Likewise, section 10.3.6 specifies that a Conservation Measure or a biological objective may be changed through the adaptive management process set out in section 10.3 of the IA without amending the BDCP or any incidental take permit or other regulatory authorization. First, this is unlawful in any event as permit conditions cannot be altered except by amending the permit. Second, specifying a procedure and substantive criteria that are to be used, and the agency is legally committed to using, in order to alter the terms of permits it issues or to alter the terms of the BDCP is an "agency statement of general or particular applicability and future effect" within the meaning of 5 U.S.C. § 551(4).

Moreover, the parties seem blind to the fact, even if the adaptive management process could be used in the way intended by the IA, that each such change would be subject to environmental review pursuant to NEPA and CEQA.

The management of outflow criteria, the amount of freshwater that flows from the Delta into San Francisco Bay and the Pacific Ocean, is of monumental scope and public importance. The federal agencies have bound themselves to future conduct with respect to their responsibilities in this regard. Section 10.2.1.4 further limits the discretion of the federal agencies to act with regard to outflow through the adaptive management process of the BDCP.

X. The BDCP and Draft IA Violate The Delta Reform Act Because They Contain No Provisions Providing For A Statewide Reduction In Reliance On Delta Water Supplies.

The Draft IA acknowledges that the BDCP must comply with the Delta Reform Act of 2009. Draft IA § 4.2.2. However, the BDCP and IA entirely overlook the Delta Reform Act mandate that "[t]he policy of the State of California is to reduce reliance on the Delta in meeting California's future water needs" through regional self-sufficiency. The pervasive preoccupation with finding a path to reduce outflow criteria conflicts with state policy to reduce reliance on the Delta. Rather it is a formula to reduce water committed to environmental needs so more water can be exported from the Delta and reliance on Delta water can be increased.

XI. The BDCP Lacks Required Assurances of Adequate Funding.

The BDCP relies on funding from new state water bonds, yet to be approved by the legislature for placement on the ballot and of uncertain fate with the voters if placed on the ballot. The water bond described in section 8.3.5.1 is, at best, a political football in the state legislature and likely to contain provisions that bar use of any funds for anything related to the BDCP. Several legislators have announced intentions to place such restrictions on the water bond. The statement that "[t]he BDCP is expected to secure a large portion of the funds allocated [by the new water bond] to Delta sustainability as well as smaller portions of funds allocated to conservation and watershed protection" is at best wishful thinking.

The BDCP's reliance on the use of funds from existing water bonds, already approved, is subject to legal challenge as the monies designated by these bonds were not approved by the voters for construction of the BDCP.

As to federal funding, the BDCP acknowledges that "new federal appropriations would be needed to support the BDCP." BDCP § 8.3.6. A wish that Congress will appropriate funds, or the intent to request funds for your pet project, is not an assurance of adequate funding within the meaning of state and federal law.

The IA statement that "there is no federal position as of this time regarding potential funding obligations of the United States," IA § 13.1.2, is accurate. However, the IA's statement that "[t]he parties anticipate reaching agreement on a federal" share of funding seems blissfully ignorant of the fact that "No Money shall be drawn from the Treasury, but in Consequence of Appropriations made by Law." U.S. Const. Art. 1, Sec. 9, cl. 7. Until appropriated by Congress, federal funding is not assured.

XII. Impacts on Discovery Bay Are Not Analyzed In The EIR And The BDCP Lacks Adequate Monitoring For Discovery Bay.

Representatives from Discovery Bay have requested at BDCP public meetings and through other channels that specific analysis of the project's water quality impacts on Discovery Bay be included in the Draft EIR/EIS. They have not been included. Discovery Bay is different than the rest of the Delta. It consists of 16 shallow water bays, ranging in size from less than an acre to several acres. There is little circulation in the bays. The impacts on water quality in nearby open water sloughs and channels do not translate to water quality impacts in the bays, where reduction in high quality fresh water will translate to much greater degradation of water quality. In order to adequately assess the impacts of the project on water quality in Discovery Bay it will be necessary to perform a fine grain RMA or other analysis of the specific impacts on Discovery Bay. The EIR/EIS fails to adequately address water quality impacts in Discovery Bay.

The EIR/EIS also fails to adequately take account of existing and expected baseline conditions for Discovery Bay and other areas of the Delta where invasive aquatic weeds have significantly hampered circulation and degraded water quality. The weeds result in algal blooms and dangerous reductions in dissolved oxygen. Planned operational changes to the cross-Delta gates, which supply high quality water to the central Delta, including Discovery Bay, must be analyzed at a fine grain level with respect to Discovery Bay and taking account of weed infested baseline conditions.

The mitigation and monitoring/adaptive management program lacks monitoring specific to Discovery Bay. Nearby monitoring stations in open water are inadequate to capture conditions in the sheltered bays.

SYSTEM-WIDE CONJUNCTIVE WATER MANAGEMENT

DESIGNING SUCCESSFUL GROUNDWATER BANKING PROGRAMS IN THE CENTRAL VALLEY:

LESSONS FROM EXPERIENCE

THE NATURAL HERITAGE INSTITUTE

Gregory A. Thomas

with case studies by:

David L. Brown, Ph.D., California State University, Chico
Nicholas A. Pinhey, University of Southern California
Jennifer L. Spaletta, Herum Crabtree & Brown LLP

and legal research by

Peter Kiel, Hastings College of the Law

This Report is one of several technical studies prepared by the Natural Heritage Institute as part of a System-Wide Investigation of Conjunctive Water Management Opportunities in the Central Valley of California under a cooperative agreement (99FC200189) with the U.S. Bureau of Reclamation. That project, in turn, is part of a larger program of activities to Enable Water Transactions To Restore Landscapes and Aquatic Habitats In California's Central Valley with support from the David and Lucile Packard Foundation, the Dean Witter Foundation and the William and Flora Hewlett Foundation.

The authors wish to acknowledge the assistance of Sydney B. Coatsworth, at EDAW, Inc., in technical review and editing of the case studies, of NHI's staff members Rebecca Brams, Ellen Chang and Jamie Leighton in editing and designing this document. Our special gratitude goes to Susan Hoffman, the Director, and to Kerry Rae and Richard Whitson of the Division of Planning at the Mid-Pacific Regional Office of the U.S. Bureau of Reclamation, for their unfaltering support of this project.

This report and others from this project are available on-line from NHI's website at www.n-h-i.org or contact the Natural Heritage Institute at the address below.

FIGURES

INTRODUCTION

The Central Valley of California, one of the most transformed landscapes on the planet, reveals its history in the manipulation of its waters. The integrated Central Valley water system encompasses most of California, less the drainages east of the Sierra and west of the coastal ranges. Functionally, it runs from Trinity, Shasta and Plumas Counties in the north to the Mexican border in the south and comprises the largest complex of dams, pumps and canals in the world.

As for over-subscribed water systems throughout the American West, policymakers in the Central Valley of California must now devise ways to expand the benefits of a fixed endowment of water and its storage and delivery infrastructure to meet future needs in every sector. The imperative to find "new" water is driven by Congressional mandates, the CALFED Bay Delta Restoration Program planning process and stakeholder demands. Under the Central Valley Project Improvement Act (CVPIA), the Department of Interior is commanded to "develop and implement" a "least-cost" program to supplement and replace the Central Valley Project (CVP) water dedicated to fish and wildlife restoration through, inter alia, improvements in reservoir operations, water banking and conjunctive use (§§3406(b)(3) and 3408(j)). The CVPIA’s Anadromous Fish Restoration Program (AFRP) will require water for instream flow enhancement. The new Environmental Water Account—perhaps the singular triumph of the CALFED Bay-Delta Restoration Program—will require some 350,000 acre-feet of water per year for restoration of aquatic habitats. CALFED’s commitment to restoration of fishery flows in the San Joaquin River below Friant Dam will also require "new" water if current contract deliveries from the Friant Unit of the CVP are to be maintained. The CVP is unable to make full deliveries under its contracts with agricultural water districts south of the delta in most years. And, municipal water supply agencies are seeking dilution water to improve water quality instead of making large investments in treatment facilities. In response to these needs, a core objective of the CALFED Program is to improve water supply reliability for all sectors. Groundwater banking comprises the largest component of the new storage envisioned.

This paper illuminates the institutional arrangements for actualizing that opportunity. Particularly, we are interested in arrangements to integrate groundwater storage into the existing surface water storage and delivery system of the Central Valley. Such groundwater banking projects would actively recharge the aquifer with imported foreign surface water originating from a source not hydrologically connected to the groundwater banking site.[1] In this important respect, such projects are to be distinguished from the conventional development of native groundwater for purely local use.

The scenario of greatest interest involves reoperation of the eleven existing terminal reservoirs of the Central Valley tributaries. These reservoirs are owned and operated by the U.S. Bureau of Reclamation, the California Department of Water Resources, the U.S. Army Corps of Engineers and several municipal and agricultural water districts. The storage and release regime of these reservoirs would be modified to allow them to capture a larger fraction of the peak flow events as they move through the system, and carry this water over for use in years of lower than average run-off. This additional storage capacity would be created by moving a substantial portion of the reservoir water into groundwater basins with currently unutilized aquifer storage capacity, such as cones of depression from historic groundwater exploitation. Thus, reservoirs would be reoperated to provide source water to recharge the groundwater banks with water that would otherwise spill for flood control. The sequence could also be reversed in the case of full aquifers, most commonly found in the Sacramento Valley, such that native groundwater is first extracted and exported to create storage space, and then subsequently replenished from an imported surface source. The imported or "new" water would be injected underground or applied to spreading grounds where it could percolate into the aquifer. Later, the banked water would be recovered and reintegrated into the existing (or enhanced) water delivery system to provide supply benefits to non-overlying users during drier years. The recharge and recovery would be conducted by (or under contract with) an overlying landowner, water district or groundwater management authority. The Kern Water Bank and the Arvin Edison/MWD arrangement are examples of this type of conjunctive use project.

Alternatively, the recharge could be accomplished through substitution of surface water supplies for existing groundwater usage, with recovery accomplished by reversing the arrangement. From an aquifer mass balance standpoint, such *in lieu* storage arrangements are indistinguishable from active recharge. In effect, groundwater users agree to forbear pumping groundwater during wetter years and instead use surface water imports to which they would not otherwise have access. The conjunctive use program then purchases groundwater pumped by overlying landowners during drier years, over and above their customary extractions, and exports it from the basin. This differs from groundwater substitution projects, which do not involve the export of groundwater or its replenishment through imported recharge water. In lieu banking may be more appropriate than recharge by percolation in areas with low-permeability soils, such as the east side of the Sacramento Valley. The Semitropic Groundwater Banking Program in the San Joaquin Valley is an example of *in lieu* recharge.

Active recharge and *in lieu* groundwater banking must, as a practical necessity, be developed with the cooperation and consent of overlying landowners, water districts and groundwater management authorities. Indeed, the recharge and recovery operations will generally be conducted by such local interests. These arrangements will require the consent and participation of at least four types of entities: (1) the reservoir owner who would consent to change the current storage and release regime in order to generate source water for groundwater banking; (2) the local groundwater management authority which would participate by, in effect, "renting" aquifer space for temporary storage of the imported recharge water;[2] (3) the operators of the infrastructure needed to move the water from reservoir to groundwater bank to point of end-use; and (4) the end-use beneficiaries who would pay for the new yield and thereby generate a revenue stream to compensate the reservoir owner and the groundwater banker. With the concurrence of these stakeholders, a project is likely to succeed in spite of the institutional complexities described in this paper. Without that concurrence, a project is likely to fail even if these complexities are overcome.

The terms, conditions and assurances to satisfy the second category of participant—the local groundwater management authority and its existing groundwater users—are at once the most elusive and the most critical elements for success. "Local control" of the banking operations is axiomatic but not well defined in practice. Institutional design is an exercise in defining who controls what and how, that is, in detailing the mechanisms for local control. Designing workable mechanisms for local operation of groundwater banks should be markedly easier where the local groundwater users do not have rights to the recovered groundwater because it has been imported into the basin, compared to the case where local groundwater is developed for export.

There is no realistic prospect of "outside" interests imposing a water bank on reluctant local communities. The need for institutional arrangements that can avoid or arbitrate disputes arises not because of the threat that "outsiders" may seek to impose a water bank on unwilling local groundwater communities, but because of the very real possibility of disagreements among the local landowners themselves. Indeed, that has been the etiology of most groundwater banking controversies historically in California, such as the Department of Water Resources' 1994 Emergency Drought Water Bank in Butte County and the Madera Ranch and Azurix projects in Madera County. However, projects will also require consensual contractual arrangements with to two types of "outsiders": a source water rights holder (i.e., a reservoir operator) and one or more end-use beneficiaries. Sufficient financial and/or hydrologic rewards must accrue to each of these parties in order to induce their participation in the banking scheme.

The keystone technical issues in groundwater banking include determining the aquifer baseline conditions, including the extent of unsaturated aquifer space, and recovering the imported water without causing injury to other groundwater users. These issues are fraught with uncertainty. Aquifer geometries are usually rather poorly defined, and subsurface water interacts with surface flows. Water in aquifers is not static, but is in perpetual slow motion along gradients and in response to differential hydrostatic pressures. Artificial recharge alters the hydrostatic pressures within the groundwater basin and may cause some of the native groundwater to become unrecoverable to overlying landowners (by migrating to a salt sink or a surface water body, for example). There is no guarantee that any particular molecule deposited in a groundwater bank in one year will be physically available to extract in a future year. Indeed, it is presumed that some percentage of the banked water cannot be recovered without causing adverse impacts on other users of groundwater in the same basin. That percentage is itself uncertain. However, the potential for injury to other groundwater users may be mitigated or avoided by adjusting the rates, volumes and locations of the extraction wells and the residence time of the banked water. Under the "extract then replenish" scenario, care must be taken not to deplete hydrologically connected streamflows[3] or lower the groundwater table below the level of existing wells.

Water quality, too, is often an issue in groundwater banking. Commingling lower quality recharge water with *in situ* groundwater may constitute a legally cognizable injury to other groundwater users. This could be a problem with recycled municipal wastewater or surface water routed through the Sacramento-San Joaquin Delta, for instance. Even pure recharge water could mobilize salts and agricultural chemicals in groundwater basins that have historically been heavily irrigated. Where feasible, conveying reservoir water directly into groundwater banks, without routing it through the Sacramento-San Joaquin Delta, should avoid water problems since Sierra snowmelt is the cleanest water in the system.

Commonly, impacts that would otherwise constitute legally cognizable injury may be mitigated or avoided through implementation of a "physical solution", which may be incorporated into the project design or imposed by the State Water Resources Control Board or a court.[4] For example, water users could be made whole through delivery of an alternate source of water of equal quality and quantity to that which they are entitled. Additionally, a well owner who has to sink a deeper well could be reimbursed for the increased well construction and pumping costs. Of course, there may also be limitations independent of the no injury rule on the extent to which adverse environmental impacts are allowed. Depending on the nature and severity of the change, adverse impacts on groundwater quality may not be allowable even if the affected well owners accept compensation.

As an early step in designing workable institutional arrangements, this system-wide investigation studied seven historic conjunctive use projects—some successful and some not. Our purpose in studying these cases was to distill the variables in the design and execution of conjunctive use projects that militate in favor of success of a project. The next section of this report explains the scope and methodology of the case analyses. Section Three presents the

Findings and Conclusions that we have distilled from the case studies. Section Four discusses the outstanding legal issues and uncertainties that may warrant attention from the State Water Resources Control Board or the State Legislature to facilitate conjunctive water management in California. In Section Five, the eight cases are presented in detail.

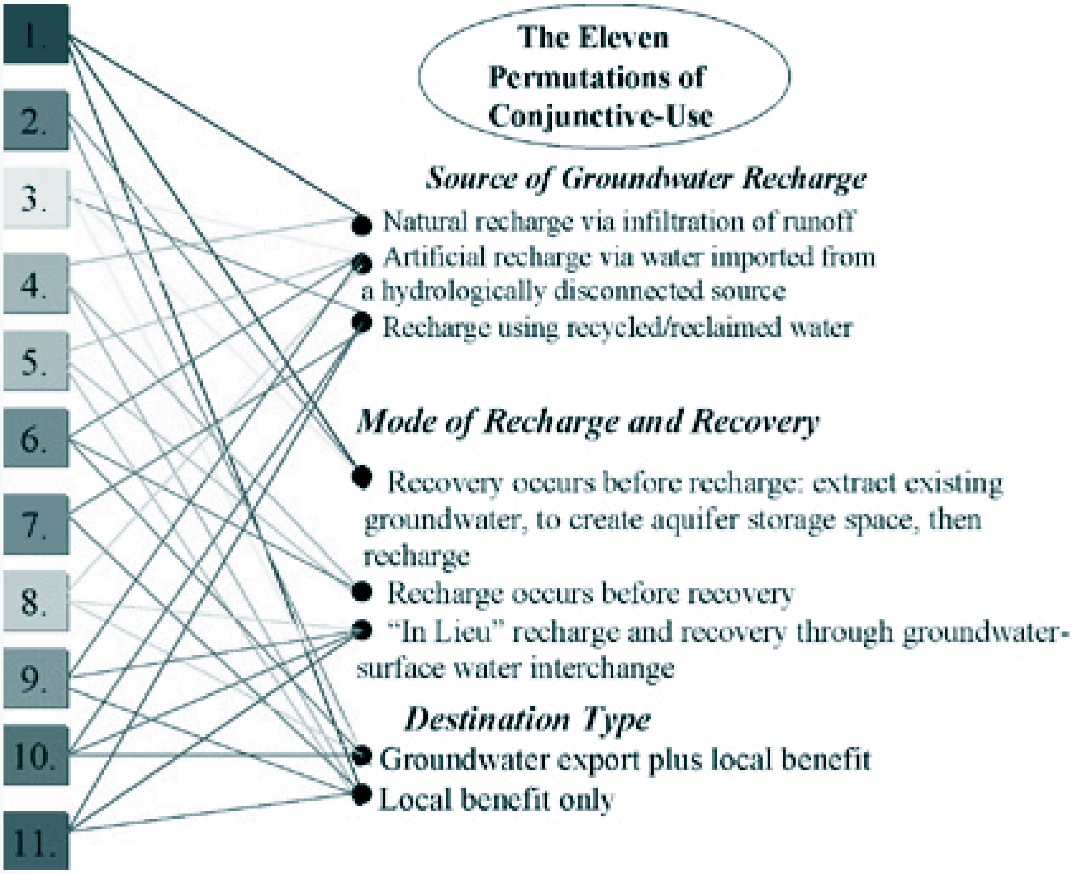
Finally, in Section Six, we sketch hypothetical arrangements based on our research and findings. These arrangements represent the study team's best judgment as to how a program could be set up to satisfy local interests and concerns such that groundwater management authorities would be willing—even eager—to participate in actively recharged groundwater banking projects. The hypothetical arrangements will be the subject of detailed discussions with the local groundwater communities—water users, water districts, groundwater management officials, political leaders and other stakeholders—in a series of "ground-truthing" sessions. In these, we will present the hypothetical arrangements and solicit comments, criticisms and (most important) counterproposals on the essential features and details of institutional arrangements. The end product of this process will be a high-confidence portrait of an ideal local institutional arrangement that should greatly improve the prospects for successful groundwater banking projects throughout the Central Valley waterscape.

SCOPE AND METHODOLOGY

As noted, our purpose in studying the current, high-profile efforts at conjunctive water management in the Central Valley is to emulate the design features that make for successful projects and avoid those that tend to produce failures. For this analysis, we are primarily interested in the institutional factors, but also remain alert to hydrologic, economic or geographic attributes that appear to correlate strongly with success. The term "institutional factors" refers to the mechanisms that:

> - Create and protect the legal rights of the conjunctive water manager to obtain water from the surface reservoir or stream, convey it to the groundwater banking site, recharge the groundwater, extract the stored water and reconvey it to points of end-use;
> - Avoid, minimize, mitigate or compensate for adverse impacts on those holding rights to the waters, reservoirs, conveyance systems, aquifers, and overlying lands involved in conjunctive water projects; and
> - Anticipate and avoid or mitigate potential environmental impacts associated with moving water into and out of groundwater banks.

In tracking these features and variables, the case studies are conscious of the differences in projects with respect to sources of groundwater recharge, modes of banking, and end-use destinations. By combining the alternatives for each of these components, it is possible to describe eleven different types of groundwater storage projects. Depending on their features, these may call for rather different institutional arrangements. The permutations are displayed graphically below:



It is important to note that actively recharged groundwater banks—the species of conjunctive use that is the focus of the system-wide conjunctive water management investigation—involve only three of these possible eleven options. These are the options that provide the largest yield benefits to the broadest range of water stakeholders, are more likely to benefit than harm existing groundwater users, and provide the greatest potential for environmental restoration. As we have previously noted, the system-wide program would utilize artificial recharge from water imported from a hydrologically disconnected source—namely, a terminal reservoir. The destination of most (but not all) of the stored groundwater would be the integrated Central Valley water system, not just the overlying lands. To be sure, some of the water may be left behind to compensate the local groundwater basin for providing temporary storage services, but the objective of the program is to provide system-wide benefits. In regard to the sequence of recharge and recovery, three alternatives would be utilized:

> - Where a pre-existing cone of depression exists, the aquifer would be recharged first and discharged later.
>
> - Where the aquifer is already full, extraction would occur first (to create storage space) and then the "hole" would be replenished with imported recharge water.
>
> - In areas where soils are relatively impermeable to percolation and excess capacity exists to deliver both surface water and to utilize groundwater (or where that condition could easily be created), recharge and recovery could be accomplished through *in lieu* arrangements. In these projects, groundwater would be banked by substituting surface water for groundwater that would otherwise be pumped. It would then be extracted by substituting groundwater pumping for a surface water delivery that would otherwise be provided.

None of the cases analyzed in this document involve the active recharge of a groundwater bank with water generated from reservoir reoperation simply because no such conjunctive use project has yet been implemented in California.[5] Therefore, to learn how to design such a program, we must extrapolate from the lessons distilled from the types of cases that have occurred. In fact, the system-wide proposal has a number of distinct advantages over historic projects from the standpoint of protecting local interests. These are described below.

Favorable Design Features of the System-Wide Approach

The system-wide approach accepts as a design constraints that water must be recharged and recovered in a manner that avoids any injury to legal users of water and in a manner that would provide a net improvement to aquatic environments. Some of the ways these constraints would be observed include:

> - The program would bank water imported from reservoirs rather than exploiting native groundwater for export. This greatly simplifies the requirement of avoiding injury to legal users of groundwater because the water that is extracted and exported is not subject to the correlative rights that attach to native groundwater. The importer enjoys a paramount right to extract the banked water because it would not have been available to the groundwater basin at all but for the act of importation. Indeed, the recharge of the aquifer will benefit all groundwater users in the basin because the water table will be elevated and, therefore, pumping costs will be reduced. The major hydrologic issues associated with avoiding injury go to the rate, timing, location and volume of extractions. To be sure, these issues are somewhat more complicated where some native groundwater must first be extracted to create aquifer storage space and then

replenished with imported water. The hypothetical arrangements set forth at the end of this report propose ways that these types of projects can operate to avoid any significant likelihood of injury to legal users of groundwater.

u The recharge and recovery operations would be controlled by the local groundwater management authority. This might be a local water district, a local groundwater authority established through a county ordinance, a joint powers authority, or an entity created by special act of the legislature. The banking and extraction facilities would either be operated by that local authority or under voluntary contractual arrangements with it, specifying the terms and conditions and the compensation. Local control is therefore taken as axiomatic.

u Water tables would not be allowed to rise to the point where groundwater could invade root zones or surface structures or reduce the natural infiltration capacity of the aquifer. Conversely, water tables would not be allowed to fall below the levels that would occur in the absence of a conjunctive use program. The program would only counteract, not contribute to, subsidence. Phreatophytic habitats would only be enhanced, not degraded, by an elevated water table in the banking region.

u The program would utilize Sierra snowmelt, captured in foothill reservoirs, as the source of recharge water. This is the highest quality water available within the system. Water quality issues would arise only to the extent that this water is commingled with lower quality water, such as delta waters, en route to the recharge facilities.

Thus, actively recharged groundwater banks would avoid many of the problems and issues associated with the development of native groundwater or with groundwater substitution projects. However, the mitigation devices and institutional arrangements illustrated by the cases examined in this paper are instructive in designing all types of conjunctive use projects.

Types of Groundwater Storage Projects Studied

Of the eleven possible permutations of conjunctive use, the cases represent the following groundwater storage typologies:

u Native groundwater export projects utilizing full aquifers and natural recharge. These are a type of groundwater substitution project where existing surface water users are paid to forego those deliveries and pump groundwater instead. This allows their surface water entitlement to be delivered to a user in a different basin. The DWR Drought Water Bank and the DWR Supplemental Water Purchase Program are the only two examples of this type of project of which we are aware, and they are included as case studies. In the future, such projects can be envisioned at the Stony Creek fan, the Butte Basin and the Conaway Ranch area—all sites in the Sacramento Valley.

u Local benefit projects where recharge from imported water sources occurs before recovery. Projects of this type include the Kern Water Bank, SNAGMA, Semitropic's groundwater banking program, Berenda-Mesa's groundwater banking program, and the project of the Mojave Water Agency.

u Groundwater export projects where recharge from imported water sources occurs before recovery. Projects of this type include Madera Ranch, EBMUD-San Joaquin County, Arvin-Edison-MWD, and the Semitropic project.

We did not investigate local benefit projects where recharge is accomplished with recycled or reclaimed water. The water quality issues dominate in these projects. We also did not investigate local benefit projects utilizing full aquifers where storage space has to be created by extracting groundwater first, and then replenished through natural recharge. There are no currently operating projects of this type outside of adjudicated basins (such as the Raymond basin, the San Gabriel basin and the Orange County Water District). However, we may see examples of this type in the future, such as the project that the Glen Colusa Irrigation District is investigating. Finally, we did not study local benefit projects where recharge from native water sources occurs before recovery. The Merced Irrigation District/City of Merced project, the Clovis/Fresno project, and the Bakersfield emergency banking project are all of this type. While these projects are worthwhile, they do not offer a wealth of lessons from the standpoint of transferable institutional design features.

Risk Factors Analyzed

Each of the case studies evaluates how the project has succeeded or failed in dealing with the hydrologic, water quality, financial, legal and political risks associated with groundwater banking. Where pertinent, we specifically looked at how each project dealt with the following factors:

1 HYDROGEOLOGIC RISKS:

A) The risk of losing stored water because it "leaks" out of the aquifer and cannot be recovered without adverse impacts on other groundwater users in that aquifer.

B) The risk of losing stored water because it is not possible to increase the pumping rate at times of extraction without adversely affecting other groundwater pumpers in that aquifer.

C) The risk that raising the groundwater table will reduce natural infiltration and thereby deprive other groundwater users of natural recharge water.

D) The risk that raising the groundwater table will invade the root zone of permanent crops or create phreatophytic vegetation that is subject to regulation as a wetland.

2) WATER QUALITY RISKS:

A) The risk of degrading the receiving aquifer with lower quality recharge water (such as water that is routed through the delta).

B) The risk of leaching soil contaminants into the stored water.

3) FINANCIAL RISKS:

A) The risk that delivery of banked water through exchange arrangements will not be accomplished due to delta pumping restrictions.

B) The risk that energy requirements for pumping will be increased.

4) LEGAL RISKS:

A) The risk that groundwater storage or extraction would cause injury to other legal users of groundwater.

B) The risk that groundwater storage would limit the rights of current or future users of groundwater in the same basin.

C) The risk that the conjunctive use project would take legal action against other groundwater users to protect its rights to extract groundwater.

5) Political risks associated with adverse community reactions in light of real or perceived injuries to local groundwater interests.

For all of these considerations, each case study assesses how successful the project has been, as well as how it could have been designed to deal with these factors more successfully.

Study Plan

The study team progressed through the following sequence of steps:

1) Select the cases:
We screened the historical attempts at groundwater storage and selected a subset of seven cases that are representative of the various possible configurations and variables. The selected cases are regionally significant, illustrate a variety of stakeholder interactions, and are particularly rich in design lessons. The projects illustrate both successful and unsuccessful factors and strategies. All are located within the Sacramento and San Joaquin basins. Projects outside of the Central Valley or in adjudicated groundwater basins were eliminated because they present different and generally easier challenges. Projects were also selected because they provide interesting and lesson-rich contrasts. For example, the Sacramento North Area Groundwater Management Agency/American River Basin Cooperating Agencies Conjunctive Use Program (SNAGMA/ARBCA) and the Kern Water Bank were selected because they both represent successful large-scale programs but have significant differences in the end-uses of water and the types of participating stakeholder groups. Conversely, sometimes successful and unsuccessful cases share similar physical features and socio-economic settings. These cases provide further insight into the variables that can affect the success of conjunctive use programs.

2) Review the literature:
For each selected case, the study team members gathered and reviewed the literature and documents generated by the project and by external commentators, reviewers and critics.

3) Describe the physical features and design characteristics of each project:
The researchers abstracted from this literature the information on the project that is responsive to the issues and questions posed in this report. For easy comparison, the project characteristics are displayed in matrix format in Apendicies A-G.

4) Conduct interviews:
For each project, the researchers interviewed project proponents and opponents, informed community and political leaders, affected water district managers and personnel, and local spokespersons for agriculture and the groundwater users.

5) Write narrative case studies:
The case studies can be found in Section Five of this report.

6) Derive findings and conclusion:
Findings and conclusions are set forth in Section Three of this report.

7) FORMULATE HYPOTHETICAL PROJECT DESIGN RECOMMENDATIONS:

The hypothetical arrangements are outlined in Section Six of this report.

8) TEST THE HYPOTHESES IN FOCUS GROUP SESSIONS:

Focus group sessions will be convened after this report has been circulated for review. They will be conducted in the groundwater basins that have been identified as promising locations for groundwater banking, based on hydrogeologic investigations that are reported in a separate document. The purpose of the focus group sessions is to confirm, adjust and refine the hypothetical design recommendations.

FINDINGS AND CONCLUSIONS

Measures of Success

As we have noted previously, conjunctive use projects must provide sufficient local benefits to prompt the local groundwater management entity or individual landowners to enter the deal. Thus, the success of the project depends upon financial or water supply rewards at the local level. The program must also insulate the local groundwater users and managers from perceptible risks. These risk factors are of three types: (1) hydrologic (the risk that either the quantity or quality of groundwater currently available for local use will be diminished); (2) financial (the risk that the energy costs of lifting groundwater will be increased); and (3) legal (the risk that existing rights and entitlements will be clouded or will have to be defended). Perceived risks must be taken at face value in the groundwater arena. Thus, risk management is more important than risk assessment in the design of conjunctive management institutions.

The design features summarized below provide a template for successful projects in settings throughout the Central Valley. Successful programs:

> - Are financially rewarding for the water district, management authority or local landowners that operate the bank.[6]
> - Are financially and/or hydrologically rewarding for local groundwater users.
> - Pose no unacceptable hydrologic or legal risk to local groundwater users, the banking district or the local groundwater management authority.
> - Involve local communities and stakeholders throughout the process of developing and implementing the groundwater banking plan.

Factors in Successful Programs

Projects that the case studies reveal to be successful under the above criteria include the Semitropic, Arvin-Edison, Kern Water Bank and SNAGMA projects. There are many common features to these projects that account for their success. We have organized analysis of these features under topical headings below.

CHARACTER OF BANKED WATER

In all successful cases, the banked water is imported from a hydrologically disconnected source. Thus, the banked water would not otherwise be available to the groundwater basin. None of the successful projects involved the development of native groundwater either alone or as part of a groundwater substitution scheme. In the case of the Semitropic groundwater bank, the source water is state or federal project water belonging to Metropolitan Water District (MWD) and Santa Clara Valley Water District (SCVWD) or supplies imported by Vidler Water Company or Alameda County Water District. In the case of Arvin-Edison, the source water is MWD's State Water Project (SWP) entitlement or flood releases from Friant Dam. By contrast, DWR's unsuccessful 1994 Emergency Drought Water Bank in the Sacramento Valley failed in part because it did involve the substitution of native groundwater for State Water Project deliveries.

Also, in the majority of successful cases, the recharge water is of better quality than the *in situ* groundwater at the banking site.

SITE THE BANK WITHIN THE BOUNDARIES OF A LOCAL WATER MANAGEMENT AGENCY

One of the factors most determinative of the success of a groundwater bank is locating it within a water district, joint powers authority or other local groundwater management authority that genuinely represents the interests of affected landowners.

AVOIDING HYDROLOGIC RISKS

Successful programs such as Semitropic and Arvin-Edison used a number of devices to ensure that neighboring groundwater users will not be adversely affected during the recovery operations. These fall into three categories: (1) limits on operations to avoid adverse impacts on other groundwater users; (2) arrangements to compensate for impacts or absorb the costs of measures to avoid impacts; and (3) information systems sufficient to avoid adverse impacts. Examples of measures to minimize hydrologic risks are detailed below.

> **Volumetric limits:** In these successful projects, the volume of extractions is limited to a fixed percentage of the water percolated into the groundwater bank to account for presumed losses due to evaporation from spreading basins and migration out of the aquifer. The percentage, fixed at 90% in the Semitropic and Arvin-Edison examples, is subject to adjustment based on monitoring data.
>
> **Water table limits:** For example, under its "fifteen-foot/three-year" rule, Semitropic will not make groundwater withdrawals that cause the average groundwater level in an area to decline by over fifteen feet compared to what would have occurred without the project over a three-year period.
>
> **Limits on the placement of extraction wells:** The extraction wells are located so as to avoid significant impacts on the pump lifts of neighboring groundwater users.[7] The groundwater bank should also be located to avoid interaction with surface stream systems (unless a purpose of the bank is to increase base flows).
>
> **Limits on the timing of pumping:** It may be advisable to restrict operation of recovery wells to the off-season or to off-days for irrigation pumping. Recovery can also be restricted until a specified period after recharge to allow sufficient time for the water to percolate into the aquifer.
>
> **Curtail pumping:** If its pumping interferes with neighboring wells, the project may be required to either stop pumping or compensate for the interference.
>
> **Compensation:** The project can guarantee neighboring groundwater users that it will compensate them for any costs occasioned by increased power requirements for pumping compared to the historic baseline, with an easy and fast claims processing procedure.
>
> **Provide alternative water supplies:** An alternative to monetary compensation is a guarantee of a substitute water supply to impacted overlying users. For instance, a groundwater bank could agree to supply neighbors with water out of the bank in exchange for their forbearance from pumping, perhaps including the right to use the neighbors' wells as extraction facilities.
>
> **Assume responsibility for deepening wells** to avoid impacts or restrict recovery wells to those shallower than the neighbors'.
>
> **Develop good baseline information:** Designing a project that can avoid hydrologic impacts may depend crucially on improving the understanding of pre-project groundwater conditions including the drawdown tolerances (pumping thresholds) of existing wells.

MONITORING PROGRAM

The successful conjunctive use projects have established monitoring programs run by a committee that includes potentially affected landowners. The monitoring committee has the right to hire its own expert consultants to assist in data collection and analysis. In the case of the Kern Water Bank, the committee oversees a comprehensive monitoring program to determine groundwater levels and water quality under project and non-project conditions and has the power to modify operations if they are found to be inconsistent with local groundwater management plans.[8] In the case of Semitropic, the monitoring program has the right to curtail extractions if certain benchmarks are hit in the monitoring results.

AVOIDANCE OF LEGAL RISKS: DISPUTE RESOLUTION PROCEDURES

One technique that emerges from the case studies is entrusting dispute resolution to the monitoring committee, which includes local groundwater users. Another option, exemplified by the Semitropic bank, is to submit factual disputes to binding arbitration before a registered civil engineer with a background in groundwater hydrology.

LOCAL BENEFITS

As stated previously, sufficient local benefits are an integral part of successful conjunctive use projects. These can be in the form of cash payments or a share of the banked water. However, the case studies show that first priority to the banked water does not have to be allocated to the banking district, provided that the benefits to that district and its members are otherwise sufficient to induce its voluntary participation. In fact, successful case studies show a myriad of arrangements that are the product of negotiated agreements among the parties.

In the Kern Water Bank, local water supply agencies are accorded a "right of first refusal" on extractions from the bank and a first call on its recharge capacity. By contrast, in the Semitropic example, the agreements do not reserve to Semitropic a first right to extract water or to use the extraction facilities or other facilities of the program. Instead, the first right to extract is given to the Banking Partners. In the Arvin-Edison program, the district has the first right to use extraction facilities to meet its own needs while MWD has a priority over others who enter the banking arrangement later.

FINANCIAL ARRANGEMENTS

The contractual arrangements must assure the water district or groundwater management authority that all foreseeable costs of operating the program (conveyance, recharge, extraction, reintegration) will be defrayed by the beneficiaries or some other party. Thus, Semitropic Water District, for instance, receives payments when water is stored and when water is extracted, including its energy costs and its operation and maintenance costs. Semitropic's banking partners have made the project essentially cost and risk free for Semitropic, while giving the district numerous facilities and other benefits. From a financial perspective, the program has been very successful. Revenue generated from Semitropic's banking program has in part allowed the district to reduce water charges to its landowners from almost $60 per acre-foot in 1995 to less than $50 per acre-foot in 1998.

The Arvin-Edison program illustrates another device for managing financial risks. The agreement insulates the district from the risk that it will be unable to deliver the stored water to the intended beneficiary due to constraints beyond its control, such as pumping constraints in the delta which may prevent it from exchanging banked water for project deliveries. In the Arvin-Edison example, the district is entitled to buy back the banked water at its marginal cost of alternative supplies in the event that delivery cannot be accomplished. As in its arrangement with Semitropic, the Metropolitan Water District of Southern California (MWD) was willing to make the project essentially cost and risk free for Arvin-Edison while providing the district with substantial benefits.

Local Control

In all successful cases analyzed, the overlying water district is in charge of the recharge and recovery operations. For agricultural water district bankers, this construct seems to work because landowners who rely on groundwater are represented in the governance of the water district. This provides a measure of local control that lends comfort and confidence to the groundwater users. It is notable also that, in most cases, the active outreach of the district's president and/or general manager was a key to overcoming the landowners' initial apprehension regarding a banking program. For instance, in the examples of the Kern Water Bank, Semitropic, and SNAGMA, local officials understood and supported the program and did a good job of explaining it to the members of the district and surrounding landowners.

Institutional Cohesion

Cohesiveness among water agencies and a common planning framework are helpful in creating successful groundwater banking projects. In the SNAGMA case, the General Plan for the region provided that common framework. In addition, the water agencies within the Sacramento area have multiple forums for communication and cooperation. In the Kern Water Bank example as well, the water agencies work together in the Kern County Water Agency, which serves as an umbrella organization and represents local interests at the state level. It is notable that Paramount Farms' involvement in the Kern Water Bank negotiation process was beneficial, as private sector organizations often have more flexibility than do public agencies.

Local Support and Public Involvement

The consistent and meaningful involvement of the range of local stakeholders is a common element of successful programs. While it is to be expected that landowners will have some concerns, the more supportive and cooperative they become, the greater the likelihood that the project will succeed. Efforts to involve landowners and other stakeholders in project development, implementation and monitoring help to garner their support. Leadership by local officials also plays an important role.

Involvement of local stakeholders in the process of building consensus and forming collaborative organizations is an important element of the SNAGMA project. This case demonstrates that, while the process may not be simple or quick, interest-based negotiation is an effective method to address these complex issues. Taking the time to train and educate the participating stakeholders, as well as using professional facilitation, increases the likelihood of success. In the Kern Water Bank example, the monitoring committee offers a structure and a forum for the involvement of overlying users adjacent to the project and an opportunity for their concerns to be addressed.

Ease in garnering local support is often due to a region's history with water banking projects and water management efforts in general. For example, internal opposition to Arvin-Edison's conjunctive use program has been non-existent. While some opposition has come from outside the district, the landowners inside the district were already familiar with conjunctive use and have seen it operate successfully in their district for almost fifty years. Notably, Arvin-Edison is a district that was originally formed to conduct conjunctive use operations for the benefit of its own landowners. Thus, the concept of conjunctive use and/or groundwater banking was never new or foreign to landowners in the district. In the example of the Kern Water Bank, water banking projects are common in the area and tend to be accepted as necessary to preserve and enhance the local economy. Also, the Bank has done an effective job of creating habitat and enhancing the natural environment, thus winning over environmental stakeholders.

ENVIRONMENTAL DOCUMENTATION

The Semitropic case proved to be fairly easy to implement environmentally, and the Arvin-Edison project only had to comply with CEQA, not NEPA, and was implemented with an Initial Study and Negative Declaration instead of an EIR or EIS. These more streamlined processes for environmental documentation probably increased the likelihood of success for these projects.

Factors in Unsuccessful Programs

By the criteria set forth at the beginning of this chapter, the 1994 DWR Drought Water Bank in Butte County, the Madera Ranch case, and the initial EBMUD-San Joaquin County negotiations must be regarded as unsuccessful efforts, at least so far. We can learn important design lessons from these cases as well. The most salient findings are summarized below.

CHARACTER OF BANKED WATER

According to the case studies, projects that rely on passive recharge (natural infiltration), such as the 1994 Emergency Drought Water Bank, are perilous. These groundwater substitution programs are particularly likely to be unacceptable when the water exporter does not have the power to curtail pumping in the event of injury to others, as in the Butte County example. However, this does not mean that projects that feature active recharge with imported water are always successful, as the San Joaquin County example shows. In those cases, the failure results from factors other than the source of the banked water. Banking water of inferior quality compared to the native groundwater, as was the case in the Madera Ranch project, is problematic and more likely to suffer local opposition.

TECHNICAL ANALYSES

Thorough technical analysis and comprehensive environmental impact reporting are important parts of a successful groundwater banking program and also crucial components in winning public support. In addition, the perception that implementation steps are being taken before technical studies are completed can undermine public confidence in the project before it even starts.

Technical analyses were a major point of contention in the Madera Ranch groundwater banking project. The technical analyses performed by the U.S. Bureau of Reclamation were preliminary in nature and designed to assist the USBR in making decisions regarding the feasibility of the project. However, project opponents considered the studies to be superficial and flawed. They believed that the feasibility of the proposed project was not demonstrated sufficiently for policymakers to commit public funds to the project and characterized the USBR's decision to proceed as "getting the cart before the horse." Particularly, they were concerned that the banked water would interact with surface streams and migrate from the site, creating root zone flooding problems for neighboring orchards and other sensitive crops,[9] and that extractions from the bank would come at the expense of neighboring wells due to the failure to account for the lost water. Although the quality of the technical analyses was not necessarily the primary problem with the State Drought Water Bank project, the programmatic environmental impact report (PEIR) prepared by DWR in 1993 was not convincing to local stakeholders. A common view in Butte County is that the PEIR was not very useful. It offered only general predictions of the nature and magnitude of potential impacts of the program. As is typical of programmatic reviews, site- or project-specific impacts were not addressed. Mitigation measures for groundwater overdraft or impacts on surface water flows were neither identified nor adopted.

In contrast, the EBMUD project is considered to be technically strong, illustrating that technical merit, while important, is not the only factor necessary to garner local support or ensure project success.

TIME CONSTRAINTS

While not always controllable, compressed timeframes for project development can impair a project. When the development is rushed, it is less likely that local stakeholders will be involved adequately to "buy into" the project, which is especially important in regions without a strong history of support for conjunctive management. Shortened timeframes also can lead to inadequate technical analysis. For instance, had the Madera Ranch project continued into a second phase of investigation, the technical analysis would have addressed several outstanding issues in more detail. It appears that the landowner-imposed deadline for USBR action to commit to the project, or acquire the project site, lent impetus to move ahead without the benefit of more definitive technical studies or significant local involvement. Some feel that the property owner's deadline for USBR action forced a premature commitment by USBR that would have been avoided given a longer timeline.

PLANNING AND RESPONSE TO DROUGHT

Drought conditions can provide the impetus for local agencies to engage in groundwater banking. In the case of the Kern Water Bank, the formation of the Future Water Supply Committee, an important first step that led to the establishment of the Bank, was spurred on by the prolonged drought from 1987 to 1992, which resulted in significant impacts to water users in Kern County. However, projects primarily created as emergency responses to drought conditions rather than deliberately designed water resource projects can encounter significant problems if they are extended. For example, the State Drought Water Bank in Butte County functioned well from 1991 to 1992, when it was created in response to drought conditions. However, in 1994 it foundered, at least partly due to the increased pumping associated with the extraction phase of groundwater banking. In Butte County, many wells were too shallow to operate in the drawdown conditions caused by the drought and the combined pumping of the water bank on top of the agricultural extractions. These wells went dry, causing financial impacts on local users and fostering local opposition to the project.

A lesson from this experience is that counties and their local groundwater management entities would do well to set up "stand by" drought water banking arrangements well in advance of the next period of extended drought. Prior to a drought or other emergency, these authorities could design a program with a specified range of extraction rates, tied to various hydrologic conditions, that would avoid well interference. With adequate lead time, the technical analyses needed to set these rate could proceed deliberately with ample public review. After the required EIR and related analyses have undergone adequate review, the local agency could approve the terms for the operation of the groundwater bank in advance of the need to actually implement the program. Then, when a drought condition or other circumstance arises that requires a relatively quick response, the "stand by" plan will have received all necessary approvals and permits. Two key ingredients for the success of such an anticipatory plan would be adequate hydrogeologic understanding of the aquifer and an appropriate monitoring system already in place. This approach would require significant initial investment from the water sellers. However, given the value of a reliable supplemental source of groundwater in times of statewide need, some form of funding to subsidize establishment of such a system would seem an investment worth evaluating.

MONITORING PROGRAMS

Monitoring programs are important to winning local support. Accurate and extensive monitoring programs can ease landowners' concerns over the potential that the groundwater bank will extract native groundwater in addition to the banked water (more "take" than "put") and thus diminish their supply. Monitoring programs can also lead to improved understanding of basin stratigraphy and recharge mechanisms and may therefore help prevent groundwater bank operation problems such as those that occurred in the 1994 State Drought Water Bank. One area of strong consensus within Butte County and DWR is that the monitoring network in Butte County should be expanded prior to future conjunctive use projects. They believe that additional dedicated monitoring wells are needed in locations currently being identified through hydrogeologic investigations. A related need is to improve public access to the monitoring data. One proposal is to make continuously recorded water levels and pumping rates available in real-time over the Internet.

INSTITUTIONAL ARRANGEMENTS AND LOCAL CONTROL

The cases teach that local interests view groundwater projects more favorably when they are locally controlled. And, it is common for local groundwater users to worry that a proposed groundwater export project could present a means for outside interests to gain access to native groundwater and, potentially, surface water entitlements. This fear seems to persist irrespective of the actual or proposed terms of the contract, probably as a result of the “water grab” from the Owens Valley in the 1920s. There is also fear that reliance on aquifer storage by a municipal water agency might eventually be codified by the legislature. These are fears that may not be well founded, but they are genuine. In general, local interests must be assured that the potential third party impacts are mitigated before a project can move forward.

In both the EBMUD and Madera Ranch projects, fear of losing local control over groundwater supplies presented a considerable obstacle to the successful implementation of the project. In the EBMUD example, while the pilot project was technically sound, fear of an outside entity gaining control of San Joaquin County groundwater supplies enmeshed the project in political controversy. Overlying landowners were concerned that the project represented a means for a municipal water supply agency to "stick a straw" into the local aquifer and to become reliant on the water supplied by the banking operation, eventually leading to the loss of their water rights. Even with the protections provided by the amended County ordinance in place, local interests still feared the encroachment of outside agencies into the Eastern San Joaquin Groundwater Basin.

The EBMUD example is not unique in that the issues of local control of groundwater and the protection of overlying landowner rights are a common theme in the San Joaquin Valley as well as other areas. In the Madera Ranch project as well, issues of local control were a major factor in local opposition to the project.

There are several potential antidotes to the fear that local control will be lost. As on this writing, some nineteen counties have passed groundwater export ordinances that generally prohibit exports in the absence of a permit of limited duration, issued by a local groundwater management authority. Water Code Section 1016, added in 1999 to address the specific concern that groundwater transfers can exceed contractual term limits, now removes any legal basis for that concern. However, contractual limitations on the duration of a water supply may be more appealing than statutory limitations because a breach of contract would give rise to a right to compensation for damages. Concerns over local control can also be addressed through contracts that cede control over project operations to local authorities. In the Madera Ranch case, for example, an agreement could have been negotiated with the county to establish a stakeholder monitoring committee and set up enforceable operational rules for the project. This, coupled with an agreement to provide a quantity of banked water to alleviate conditions of overdraft, might have decreased concerns over loss of local control. Notably, such measures were successful in garnering local support in the Kern Water Bank.

Local Support and Public Involvement

As one commentator noted: "a public interaction program, or the lack thereof, is often the sole or major reason for the failure to implement a water program."[10] Establishing and maintaining early, continuous, and two-way communications between the public, stakeholders and the water agency, preferably starting on "day one" of the project, is an essential element for a successful program and for building consensus. [11, 12] Local opposition was the factor that had perhaps the most significant impact on all three of the unsuccessful projects. These projects show that local support is crucial to the success of groundwater banking projects and that substantial opposition at the local level can "sink" a project even when its technical merits are strong. In the 1994 State Drought Water Bank example, there is a general consensus within Butte County that the DWR Bank "managers" were not well connected with the local communities that the project impacted. Based on earlier success in 1991 and 1992, the 1994 bank clearly did not anticipate the problems that arose, nor did it effectively address the complaints of third parties who were, or perceived they were, adversely affected. While the local DWR office in Red Bluff dealt with citizen complaints about increasing impacts of pumping on third parties, the bank managers were not in regular communication with the staff of that office. The 1994 experience demonstrated to DWR staff the need for public education and involvement in the process of developing and implementing groundwater banking projects. Following the problems experienced in the summer of 1994, a few workshops and public meetings were conducted by local DWR staff in Butte County.

In the example of Madera Ranch, local opposition is cited as the major factor in the USBR's decision to abandon the project. [13, 14] The USBR undertook what it saw as a logical response to the landowner's proposal by performing a preliminary analysis of potential "fatal flaws." However, local stakeholders felt that USBR should have consulted with them about the project at the conceptual stage and utilized local knowledge of geography, aquifer response, and historic water levels during the preliminary investigation. Local concerns that the project was "top-down" and driven by political rather than technical considerations were reinforced when the project was prematurely championed in several political arenas before technical studies were completed. In the EBMUD project, local opposition was very strong and centered around the fear of an outside entity gaining control of groundwater in San Joaquin County.

Making the process open and transparent by keeping all information "on the table" to the extent possible (outside of privileged negotiations) is also important for gaining public trust. One complaint of the local opponents of the Madera Ranch groundwater banking project was that this did not occur in that case.

OUTSTANDING ISSUES

The case studies illuminate many of the institutional design factors that produce successful results. However, several design issues remain due to uncertainties in the state of the law governing groundwater rights in California. These uncertainties translate into risks to the operation of conjunctive use projects that could be ameliorated by legislative clarifications. The legislative recommendations at the end of this section are specifically intended to facilitate actively recharged groundwater banking projects as described earlier in this document, but would be beneficial to conjunctive use projects in general.

Among the needlessly problematic legal uncertainties is the demarcation of regulatory authority over the recharge and extraction of water banked in aquifers. At present, several types of entities with different procedural and regulatory requirements may assert jurisdiction and vie for control. In cases where the legislature has unambiguously vested management authority over specific groundwater resources in a special district, the competing jurisdictional claims are probably quieted.[15] However, this circumstance is rare. Typically, the jurisdictional boundaries are unsettled and unsettling.

Unless the banked surface water is held under a pre-1914 appropriative right, the project likely must obtain a "change order" from the State Water Resources Control Board (State Board), authorizing the transfer from a surface source to the groundwater bank.[16] To obtain such an order, the proponent of a conjunctive management project bears the burden of establishing, before commencing the project, that the recharge and withdrawal of water will not adversely affect other legal users of water.[17] Commonly, impacts that would otherwise constitute legally cognizable injury may be mitigated or avoided through implementation of a "physical solution," which may be incorporated into the project design or imposed by the State Water Resources Control Board or a court.[18] Such change orders generally must comply with the California Environmental Quality Act, which requires that changes in groundwater tables and their effects be disclosed, assessed and mitigated. Yet, the project may also have to comply with regulatory requirements imposed by a local groundwater management authority or a permitting authority created by county ordinance. The local bodies may assert jurisdiction at both the importation and storage stage and at the extraction stage and generally impose their own version of a "no injury" rule. The potential for conflicting or overlapping standards, procedures and requirements is obvious.

Uncertainty as to the division of regulatory jurisdiction is compounded by a degree of uncertainty as to proprietary rights among: (1) the importer of the recharge water; (2) the overlying landowner(s); and (3) the overlying water district. Additionally, the application of area of origin protections to the re-export of imported recharge water has not been decided.[19] Lastly, whatever the rights and remedies, enforcement problems haunt groundwater banking to the same extent as other groundwater entitlements.

In the discussion below, we approach the legal issues from two vantage points: (1) who has proprietary rights and (2) who has regulatory authority over the exercise of those rights.

Proprietary Rights to Imported Water

With respect to proprietary rights, it is important to clarify that, in the case of actively recharged groundwater banks, we are not concerned with native or *in situ* groundwater, to which the overlying landowners presumptively enjoy correlative possessory rights. In the case of imported water,[20] the case law seems clear that the recharged water belongs to the importer, less whatever losses may occur.[21] A water right holder who imports the water with the purpose of later extracting it has the paramount right to extract that water for use either on the overlying lands or on remote locations,[22] subject of course to the requirement of avoiding injury to legal users of the native groundwater with which the imported groundwater may commingle. Injury could arise, for instance, where extraction wells are located proximate to those of pre-existing groundwater users and where the rate of extraction creates a cone of depression that increases the neighbor's pumping power requirements compared to pre-existing conditions. Calculating the amount of water to which the importer is entitled to withdraw, however, is challenging. Equally difficult is enforcing one's rights to imported water against unauthorized withdrawals by other users of the aquifer.

Another complication arises around who has the paramount claim to augmented groundwater recharge as a consequence of reoperation of upstream reservoirs. Stated another way, the question is: when the operations of a reservoir are changed to release additional amounts of water to the stream channel, some of which percolates into the downstream aquifer system, is this recharge water to be considered "imported" water that would not have been available but for the act of reoperating the reservoir? In that event, it would seem to belong to the reservoir operator. Or is this water natural recharge that would have been available to the overlying groundwater users but for the pre-existing operations of that reservoir, and therefore belongs to those groundwater users?[23]

In the main, however, the critical uncertainties are not over who owns the imported water, but over how that ownership right can be enforced where there are numerous overlying groundwater rights holders whose respective rights to pump from the aquifer have not been determined.

Property Interests in Aquifer Storage Space

As a practical necessity, groundwater banking must be developed with the cooperation and consent of overlying landowners, water districts or groundwater management authorities. As we have noted previously, there is no realistic prospect of some outside entity imposing a groundwater bank on unwilling local interests. However, where there is local opposition to a locally initiated project, the issue arises as to who owns and controls the dewatered storage space in an aquifer and who has the right to utilize that space or to exclude others from doing so.[24] It is likely that the courts would regard the storage space in an aquifer as a shared asset that all overlying landowners have a correlative right to use but that such rights holders may neither exclude other overlying landowners from using the aquifer storage space nor exact a "rental fee" for such use.[25]

Rather than characterizing the issue as one of trespass on a property interest, it may be more workable to regard it as just another application of the "no injury" rule. Thus, the correlative rights holders might well be legally entitled to prevent a water banking project from reducing the natural infiltration capacity of the aquifer. These results seem likely because the California Supreme Court has already held that public agencies can store water in aquifers.[26] The Court, analogizing groundwater banking to a surface water reservoir, deems this an economical and efficient method of "natural storage," only subject to the limitation that storage and withdrawal does not harm other legal users by, for instance, interfering with natural recharge. In the case of such interference, imported water is deemed to "spill first" after the aquifer becomes fully recharged.[27]

Under this view, the real issue is not "who owns the storage space" but how does one calculate the amount of water that the importer is entitled to withdraw. The basic theory behind the importer's exclusive right is that the water would not be there at all but for the act of importation. But where the importation supplants natural recharge or increases leakage from the aquifer, the basic theory does not justify giving the importer any right at all, let alone an exclusive right. However, it would obviously be helpful for the legislature to make clear that groundwater users do not have an ownership interest in unoccupied aquifer storage space beneath their property.

Tort-based decisional rules may serve well to protect landowners from physical injuries or water supply impacts associated with groundwater banking, but the courts may need to revert to property based rules to apportion unsaturated aquifer storage space among overlying landowners competing to bank imported surface water. In the usual case, these overliers will be seeking to operate recharge and recovery facilities under contract with a non-overlying end-user such as a municipality. Several potential allocation formulas could be applied: (1) correlative rights to storage under which, like the right to exploit native groundwater, each overlying landowner has an equal right to access and utilize the aquifer storage space subject to mutual avoidance of harm and subject to the paramount right of other overliers to the natural recharge of that aquifer; (2) equitable apportionment of aquifer storage considering populations served by the banked water, investments in effecting it, etc.; (3) "first in time is first in right", analogizing to the appropriative rights doctrine to encourage and reward initiative to create groundwater banks. There are no known precedents to suggest how, ultimately, these aquifer apportionment issues will be resolved.

Restricting Groundwater Users to Historic Usage

Whether pre-existing groundwater users can be restricted to historic levels of usage to assure that they are not taking imported water that has been banked in the same aquifer is a contentious issue.[28] The general rule is that, subject to the avoidance of mutual harm, groundwater users are entitled to as much groundwater as they can beneficially use as long as the "safe yield" of the aquifer is not exceeded. This is true irrespective of their historic usage. If their historic use is less than their correlative share of the safe yield or the amount available for appropriation under their priority of right, restricting these users to their historic usage arguably diminishes their legal entitlement.

However, the problem may be more apparent than real. Groundwater banking programs are most likely to be established in two circumstances: (1) where there is a pronounced pre-existing cone of depression that can be filled (i.e. the San Joaquin Valley) or (2) where aquifers are already full such that groundwater will have to be extracted first in order to create storage space (i.e. the Sacramento Valley). In the first instance, the aquifer is already in overdraft. Current users are not entitled to increase their pumping because that would necessarily injure other rights holders.[29] In the second case, increased pumping by historic users is unlikely to adversely affect other users, including the groundwater banking project, because the aquifer has plenty of water in it.

The problem is also less likely to arise in areas of groundwater use that are incorporated within a water district, even those that do not regulate groundwater. Where a water district operates a groundwater bank within its service area, such as the Semitropic Water Storage District, Kern Water Bank or Arvin-Edison Water Storage District projects, it does so with the consent and support of those members who rely on groundwater.[30]

In the intermediate case—where the basin is close to balance and the groundwater bank is in an unincorporated area—the appropriate principle would seem to be that existing uses can be allowed to increase only to the level that would represent safe yield, absent the groundwater bank, but no further. The problem in applying that principle is the difficulty in establishing the safe yield level short of adjudicating the basin. Even in the relatively rare circumstances where these conditions prevail, groundwater banking may be practical without adjudication if the bank can tolerate some increase in groundwater pumping or can purchase forbearance from pumping increases from existing groundwater users.

Who Has Regulatory Authority Over Groundwater Banks?

State Water Resources Control Board

The issue here is whether the State Water Resources Control Board enjoys continuing jurisdiction over imported surface water stored in groundwater basins, and if so, the extent of its regulatory authority.[31] The State Board clearly has jurisdiction over the source water if it is subject to an appropriative permit, i.e., if the appropriation occurred after 1914. If the State Board receives a petition to change the place and manner of use of that water so that it can be banked in an aquifer and then extracted for ultimate use on non-overlying lands, does the State Board retain jurisdiction over each link in this chain, including the process of recharge and recovery? Or does the imported water lose its character as surface water when it becomes commingled with the native groundwater, thereby precluding further regulatory supervision by the State Board?

Though no state board opinions are directly on point, continuing limited State Board jurisdiction over surface water placed into underground storage can be inferred from various permits issued over the last fifty years. Initial research shows that, in a limited number of cases, the State Board has issued permits and change orders to store surface water underground. These permits and change orders specify both the place of underground storage as well as the beneficial use to which the water will ultimately be put when it is subsequently diverted out of storage.[32] And, once the Board approves underground storage of surface water, several State Board decisions and water rights orders[33] make clear that the State Board retains jurisdiction to ensure that the water is ultimately used beneficially and reasonably.[34] The State Board's jurisdiction stems from its permitting authority over the original diversion from a natural watercourse, and its control extends to not only the diversion but also to the subsequent use.[35] The State Board decisions seem to treat surface water placed into groundwater storage as if it were still surface water, subject to the reasonableness and public trust limitations which the Board places on all permitted water rights.

While the State Board does have jurisdiction, the important issue is how that authority interfaces with the powers asserted by local groundwater management entities. That issue is treated on the next page.

Local Groundwater Agencies

Assembly Bill 3030[36] permits existing water agencies to create groundwater management districts. However, the authority that AB 3030 confers on districts is limited to determining safe yield, imposing modest restrictions on withdrawals, replenishing supplies, and imposing fees and assessments on extractions. The districts are not authorized to make binding determinations on matters related to water rights. Nor are AB 3030 districts authorized to prevent the exportation of groundwater. The authority to limit or suspend extractions may only be exercised if the district determines that replenishment programs or alternative water supplies are infeasible or inadequate.[37]

There are ten specially enacted groundwater management districts[38] and several other local agencies with groundwater management authority.[39] The powers of these districts and agencies are varied, and a few require a permit for withdrawal or export of groundwater.

CITY AND COUNTY REGULATION

Cities and counties possess the power to regulate groundwater[40] except to the extent that such ordinances conflict with specific state legislation.[41] There has been a great increase in the number of counties passing groundwater management ordinances, especially in the last few years.[42] The ordinances vary greatly in terms of purpose (e.g., monitoring, replenishment, export restriction) and type of restriction (e.g., permit compliance, impact analysis, fees). Most of the ordinances require a permit to export groundwater outside of the county or to extract groundwater *in lieu* of surface water use. Few of them distinguish between native groundwater and imported water.[43] Some do explicitly recognize the value of conjunctive management and provide an exception to the permit requirement where it is demonstrated that the activity will result in net annual recharge.[44]

The Potential for Conflict Between State and Local Jurisdictions

As noted above, the State Water Resources Control Board asserts jurisdiction over permitted surface water that is temporarily stored underground, essentially treating it like surface storage. Counties also assert jurisdiction over water that is temporarily banked in their local aquifers, generally through ordinances creating groundwater planning and permitting authorities. Demarcating the division of regulatory labor between these levels of government in advance would help demystify groundwater banking and reduce the regulatory risk factors.

Jurisdiction could be shared sequentially or concurrently. In a groundwater banking operation, the water moves through a series of discrete steps: from a surface water source, through a conveyance channel (which may be a natural channel), to a recharge facility, to an aquifer, through a recovery well, through a conveyance facility (which, again, may be a natural channel), and finally to a point of ultimate beneficial use. Through each link in this chain, the banking operation has the potential to affect other water rights or cause injury to other legal uses of water, including instream beneficial uses. If the source water is subject to permit, clearly the State Board has jurisdiction over its appropriation and use. Is there then some point in the "life history" of that water at which the State Board loses its jurisdiction, or does the it retain jurisdiction to the point of ultimate consumptive use or outflow from the system? Some water lawyers believe that, when the imported water is commingled with native groundwater, State Board jurisdiction ceases. However, we have not been able to find any precedent or other legal support for this view. Moreover, it is not apparent why surface water stored underground should be treated any differently than water stored in a surface reservoir for purposes of the State's administration of water rights.

There is, however, a compelling practical limit to the State Board's ability to regulate groundwater recharge and recovery operations. While it may well be that the State Board could act to protect native groundwater users from the effects of a groundwater banking operation, it could not apparently act to protect the banker from the other groundwater users. This is because it does not have jurisdiction over the latter. This asymmetry may render its nominal authority in the aquifer ineffectual in a practical sense.[45]

If, not withstanding this asymmetry, jurisdiction is to be shared concurrently, then it would seem that the State Board pre-empts or supplants local regulation of the stored groundwater only to the extent of actual conflict. This raises the question whether the local authorities are able to go beyond the State Board's extent of jurisdiction or only beyond its scope of jurisdiction. In other words, may the local jurisdiction prescribe measures that are more protective of the other "legal uses of water" or is it restricted to protecting against types of injury not covered by State Board regulation, such as impacts to structures or crops from rising water tables? Under the latter approach, county regulation that substantially affects the definition or exercise of water rights, especially post-1914 appropriative rights, is likely to be preempted. For instance, the State Board's determination as to the volume or rate of banked water that can be extracted without adverse consequence to users of native groundwater would preclude contrary determinations by the local jurisdiction.

Area of Origin Statutes

The application of area of origin protections to the re-export of imported recharge water has not been decided but likely does not pose an impediment to groundwater banking.[46] California Water Code Section 1220[47] prohibits the export of groundwater from the "combined Sacramento and Delta-Central Sierra basin" unless the pumping is in compliance with a groundwater management plan approved by the county board of supervisors and subsequently approved by popular vote. The statute does not distinguish native groundwater from imported, foreign water, notwithstanding that imported water transferred into groundwater storage under a permit issued by the State Board can readily be distinguished from native groundwater. Since the statute's apparent intent is to apply area of origin protections to groundwater, the courts will probably limit its application to exports of native groundwater, not imported recharge water.

Recovering Water Banked Through "In Lieu" Arrangements

Under an *in lieu* arrangement, the groundwater banking authority would enter into arrangements with overlying landowners who already use groundwater for all or a portion of their supply and also have access to surface water deliveries. During periods when the banker desires to recharge groundwater, the overlying landowners would forego pumping and accept a substitute surface delivery instead. The aquifer recharges passively from natural infiltration and percolation of the applied surface water. When the program desires to extract groundwater, the landowner would curtail its surface water use and substitute groundwater pumping. The mass balance in the groundwater basin is the same whether the water is actively recharged or delivered *in lieu* of groundwater pumping. In both cases, during years of storage, more water is contained within the basin than would have been stored absent the program. Ideally, arrangements should also be made with other groundwater users not participating in the *in lieu* recharge, such as appropriators, to minimize the risk that non-participants will take "banked" water and to provide relief in the event the banking operation injures a non-participant's water rights.[48]

In lieu banking projects differ from active recharge projects in that the groundwater that they extract is not water that the project has physically put into the aquifer. Instead, *in lieu* projects require groundwater rights holders in some years to forego pumping water that they are otherwise legally entitled to extract and to offset that forbearance by drawing more heavily on the aquifer in other years. Notwithstanding this operational difference, California Water Code sections 1005.2 and 1005.4 treat *in lieu* projects as equivalent to actively recharged projects with respect to the right to extract the groundwater that becomes available as a result of the program.[49] As is the case with active recharge, there are problems of enforcement and accounting. In years of forbearance, the other pumpers might extract the water that the program intended to store. In years of extraction, the contracting landowner's rates of withdrawal may harm correlative pumpers.

Of course, the problem associated with *in lieu* recharge may be avoided where groundwater basins have been adjudicated and the particular extraction rights have been quantified. This is the situation with a number of groundwater basins in Southern California. The great drawback of adjudication is the time and cost associated with the process. In non-adjudicated basins where rights have not been quantified, contractual arrangements among all or most basin users may provide sufficient reliability to assure that a banking entity can recover the banked water.

Recommended Resolution of Issues

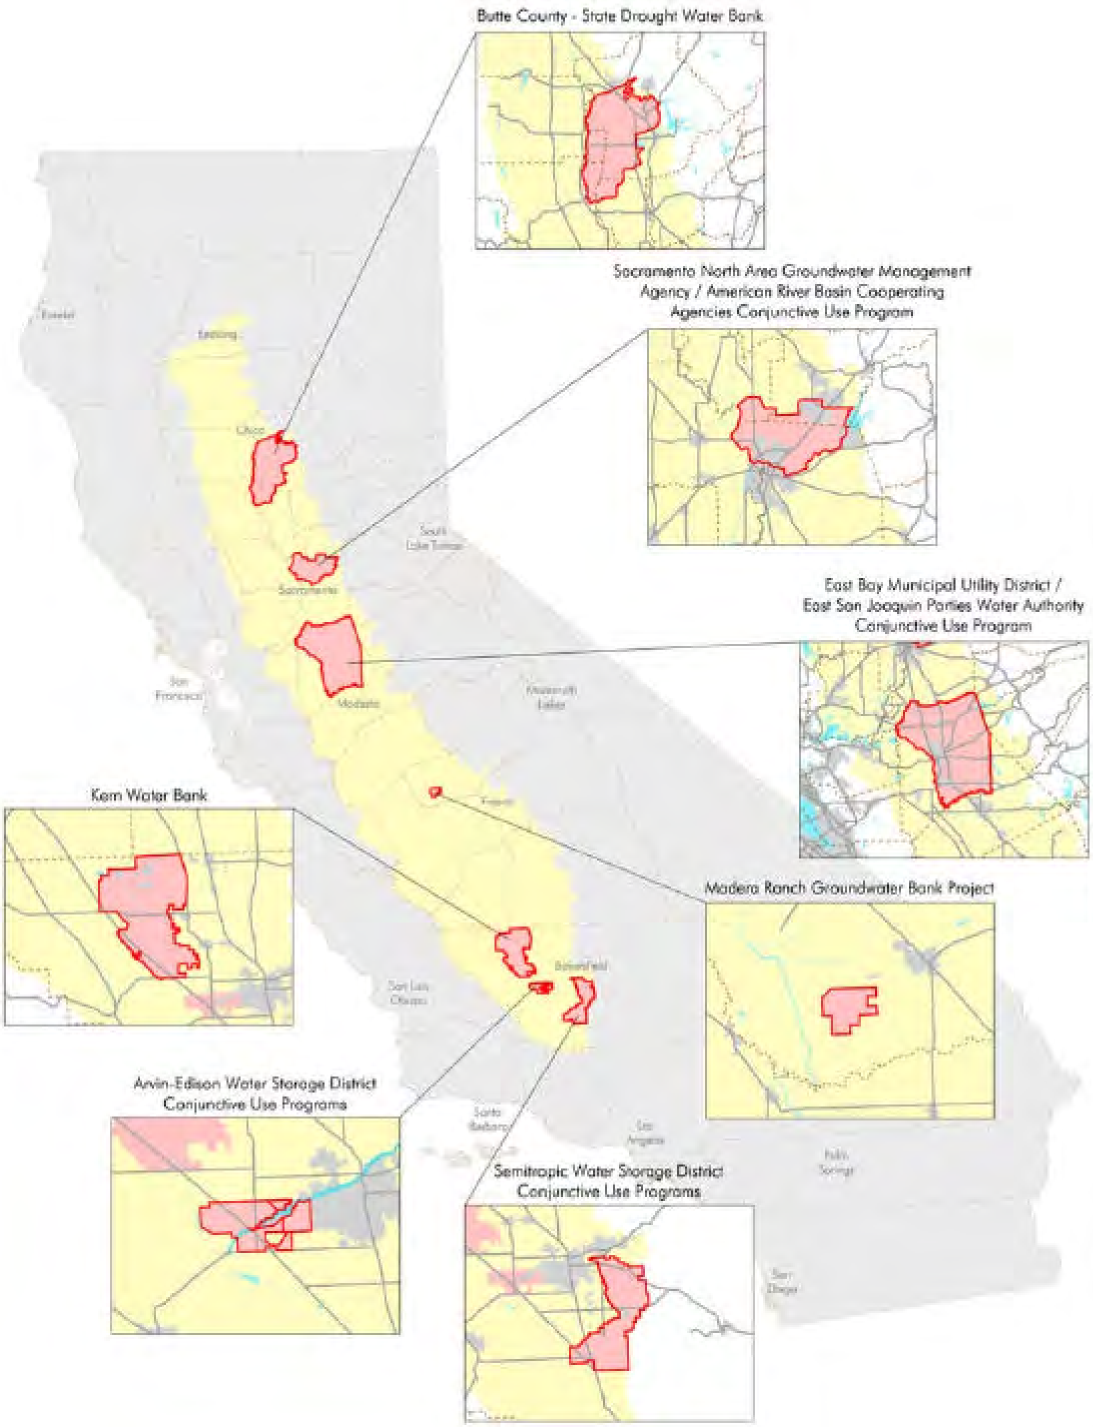
Improved hydrogeologic baseline information, including information on the depths of existing wells, would greatly assist in devising successful conjunctive use projects and in ameliorating local concerns. DWR’s update of its groundwater report, Bulletin 118, now mandated by the legislature, is not detailed enough to serve as the vehicle. Use of Proposition 204 and Proposition 13 funds should be investigated for this purpose. If this is not an eligible use of funds, the Legislature should consider substantial additional appropriations for this specific purpose.

The State Board should convene a process involving its staff and outside experts to develop principles and guidelines for such key terms as "injury," "safe yield," "baseline conditions," "basin," "imported water," etc.

The following clarifications in California groundwater law would markedly facilitate groundwater banking while increasing the protection for other groundwater users. The legislature should consider codifying these clarifications:

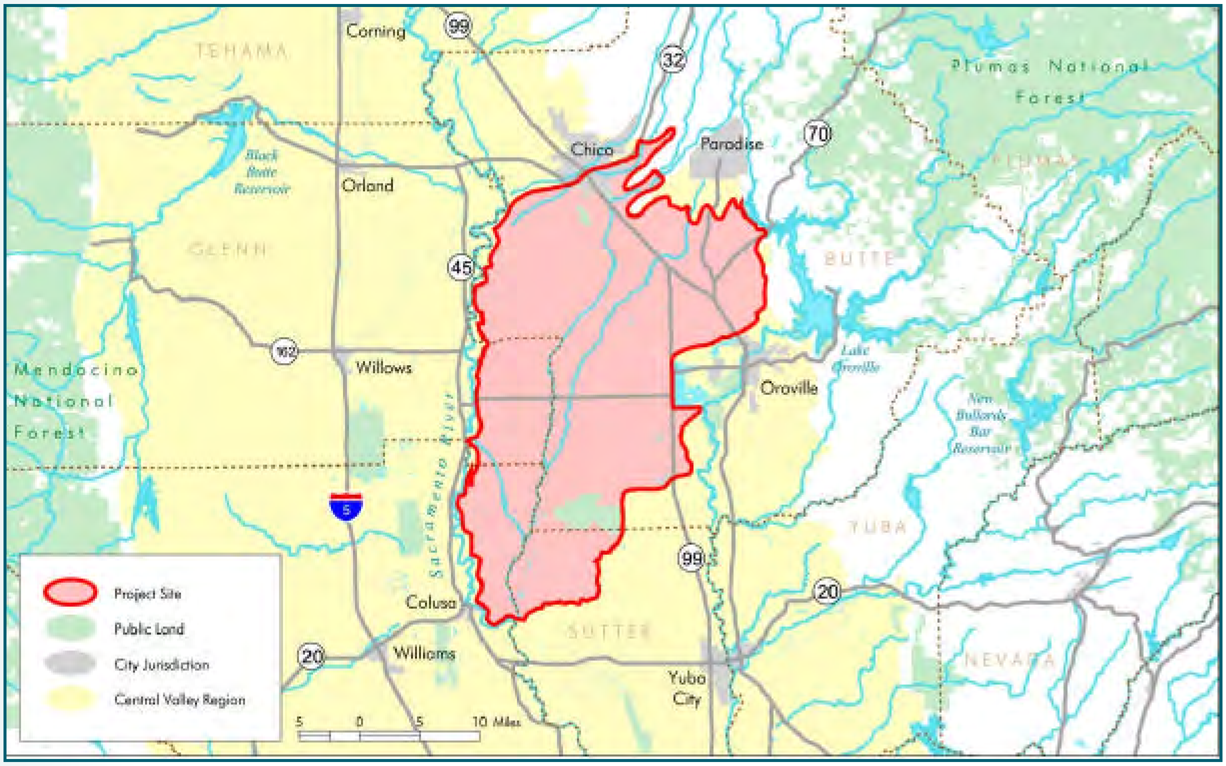
- Overlying landowners have correlative rights to the groundwater but do not have a right to exclude other overliers from utilizing the unsaturated aquifer storage space, although such overlying landowners are entitled to compensation for any injury to crops, lands or structures resulting from the recharge of the aquifer by others.
- Unless it initiates an action to adjudicate the entire groundwater basin, a banker of imported water may not enjoin historic levels of use of groundwater on overlying lands. However, the banker retains the right to protect banked water from net increases in extractions by the pre-existing groundwater users, beyond that historic baseline, in aquifers that are in an overdrafted condition. The groundwater banker would have to first proceed against groundwater appropriators, if any.
- A legal user of water may not enjoin a groundwater banking project that offers to provide a "physical solution" to such legal user, whether or not that offer is accepted, provided that the appropriate regulatory authority or court finds that the physical solution would have constituted adequate mitigation.
- The State Water Resources Control Board retains jurisdiction over surface water (subject to post-1914 appropriative rights) that is stored in groundwater basins and pre-empts conflicting requirements imposed by county ordinance that significantly affect or redefine water rights or legally cognizable injury.
- County ordinances and local groundwater management authorities may not restrict recovery and re-export of "foreign" water imported into the groundwater basins, except to the extent necessary to prevent injury to other legal users of the groundwater basin, as that principle is understood under existing law.

The Case Studies



Map above shows the locations of the seven conjunctive use projects studied in this report

BUTTE COUNTY — STATE DROUGHT WATER BANK



Introduction

On February 1, 1991, after four years of drought in California, and facing a fifth year of below-average precipitation, Governor Wilson initiated the State Drought Water Bank (SDWB) to meet anticipated critical water needs. This case study reviews the 1991, 1992, and 1994 State Drought Water Bank programs in the Butte Basin, in which local water districts were paid to relinquish deliveries out of Oroville Reservoir and substitute groundwater instead. The relinquished surface water was then available for delivery to drought victims south of Sutter County (primarily State Water Project [SWP] contractors south of the delta and in the San Francisco Bay Area). Therefore, within the Butte Basin, the SDWB operated as a groundwater substitution project. While the 1991 and 1992 SDWB programs are generally considered successes, the 1994 SDWB generated considerable controversy within Butte County. Coupled with an additional year of intense drought, elevated SDWB pumping was perceived as having adversely affected local wells. Details of specific program years are discussed below.

Physical Characteristics

PHYSICAL AND ENVIRONMENTAL SETTING

The geopolitical area of study is Butte County, located in the northeastern Sacramento Valley. Butte Basin, the primary groundwater basin, lies within western Butte County, the southern portion of Tehama County, the northern portions of Sutter and Colusa Counties, and the eastern portion of Glenn County. The Butte Basin has traditionally been defined as bounded on the west by the Sacramento River, on the east by the foothills of the Sierra Nevada, to the north by Pine and Singer Creeks, and to the south by the Sutter Buttes and the Yuba River.[50] Land use in the region is predominantly agricultural, and large volumes of surface and groundwater are dedicated to producing rice, walnuts, almonds, prunes, wheat, and row crops. Urban water demand is approximately 10% of the total water use.[51] A list of the major water delivery systems, both agricultural and municipal, is presented in Table 5.1 below.

Table 1

WATER SERVICE DISTRICTS AND AREAS IN BUTTE COUNTY/BUTTE BASIN

Note: Districts shown in italics participated in sales to the 1994 SDWB.

AGRICULTURAL WATER SERVICE DISTRICT	CITY / MUNICIPAL WATER SERVICE AREAS
M&T Ranch Inc.	Chico
Durham Municipal Water Company	Durham
Parrott Investment Company (Llano Seco)	Oroville
Western Canal Water District	Biggs
Richvale Irrigation District	Gridley
Reclamation District 1004	Live Oak
Biggs-West Gridley Water District	Yuba City
Butte Water District	Marysville
Sutter-Extension Water District	
Thermalito Irrigation District	
Oroville-Wyandotte Irrigation District	
Browns Valley Irrigation District	
Rameriz Water District	
Cordua Irrigation District	
Hallwood Irrigation Company	

HYDROLOGY

The climate of the region is Mediterranean with cool, wet winters and hot, dry summers and little to no rainfall. Unpublished precipitation records suggest that, in three out of ten years, the Butte Basin area experiences precipitation that is significantly less than the long-term average rainfall. Precipitation shows strong orographic patterns with the foothills receiving over twice the precipitation of the Sacramento Valley floor (greater than 50 inches versus approximately 25 inches, respectively).

Surface water runoff entering the Butte Basin is dominated by the spring snowmelt period. High magnitude rainfall in the late fall and early winter, or during infrequent rain-on-snow events, can also generate peak flows in regional creeks and rivers.[52] At present, the Butte Basin aquifer system is described as being full or nearly full during years of normal or above normal precipitation (i.e., the average annual recharge appears to be sufficient to replenish local groundwater use). Drought conditions, especially over multiple years, cause water levels to decline until normal or above-normal precipitation years resume. Overdraft within the basin does not appear to be occurring based on long-term groundwater well hydrographs maintained by the Department of Water Resources (DWR). There is a perception among individuals interviewed for this study that overdraft may be occurring in the Chico area due to increasing urban demand. The DWR staff with the Groundwater Section at the Northern District Office in Red Bluff has recently re-evaluated Chico area groundwater level data. They found an average water level decline of approximately 12 feet for the period

1978–2000, accounting for periods of drought and subsequent recovery. Water levels appear to have stabilized since the end of the 1994 drought. Rather than evidence of overdraft, these data have been interpreted as evidence that the groundwater system has responded to increased pumping stresses with declining water levels but appears to be reaching a new equilibrium.

Project History

The State Drought Water Bank was initiated in early 1991 after four years of drought. Water was made available to the 1991 Bank by curtailing surface water deliveries to water districts in Butte County so that this water could be delivered to SWP contracting districts south of the delta. In 1991 and 1992, irrigation districts within the Butte Basin had their surface water allocations reduced by 375,000 acre-feet each year to meet emergency statewide needs, as permitted by delivery contracts. Butte County farmers were paid for water they made available by improving irrigation efficiency, reusing tailwater, fallowing agricultural fields, or substituting groundwater for relinquished surface water. During the 1991 program period, approximately 10,000 acre-feet of groundwater was pumped directly for export. Groundwater substitution pumping in 1991 totaled 62,000 acre-feet, with approximately 33,000 acre-feet produced by the Western Canal Water District and approximately 29,000 acre-feet produced by the four districts of the Joint Water Districts Board. Pumping rates, timing and locations were such that parties relying on groundwater for domestic, agricultural or municipal uses noticed no significant adverse impacts. Most of the public in Butte County apparently was unaware that the SDWB program was underway.

The Butte County/Basin districts that increased groundwater pumping during the 1991 State Drought Water Bank included: Western Canal Water District, the Joint Water Districts Board (Richvale Irrigation District, Biggs-West Gridley Water District, Butte Water District, and Sutter Extension Water District) Ramirez Water District, Cordua Irrigation District, Hallwood Irrigation Company, and Browns Valley Irrigation District. Participants in the 1994 State Drought Water Bank were Richvale Irrigation District, Western Canal Water District, Browns Valley Irrigation District, Cordua Irrigation District, and Ramirez Water District.

Below-average precipitation continued during 1992, prompting DWR to establish a second SDWB program. The 1992 Bank generally followed the model of the 1991 Bank, except that fallowing was discontinued (as was also the case in 1994) because it was perceived to have undesirable economic and social impacts. Drought conditions in 1992 were less severe, and thus the SDWB transactions were the smallest of the three years of SDWB operation. The consensus within Butte County appears to be that the 1991 and 1992 SDWB programs were successful statewide responses to real emergencies.

After an average precipitation year in 1993, severe drought conditions returned in 1994, leading to the most recent and controversial SDWB program. Based on the apparent success of the 1991 and 1992 SDWB programs, five local water districts (Western Canal, Richvale, Browns Valley, Ramirez, and Cordua) elected to participate in water sales to the 1994 SDWB. Three of the districts (Browns Valley, Ramirez, and Cordua) are quite small and third party groundwater users did not experience adverse impacts from SDWB pumping by these districts. The other two Butte Basin water sellers (Western Canal Water District and Richvale Irrigation District) increased their groundwater substitution pumping to approximately 100,000 acre-feet in 1994 to help meet statewide needs.

Western Canal Water District and Richvale Irrigation District entered into contracts with

DWR on behalf of individual district members intending to act as willing sellers to the Bank. These contracts prescribed the volume of groundwater that could be substituted for relinquished surface water deliveries. For example, the Western Canal Water District contract set pricing of substituted groundwater at $50 per acre-foot up to a maximum of 90,000 acre-feet. Water was sold to DWR, which in turn entered into water sales contracts with willing buyers. The contracts between the districts and DWR specified that SDWB activities would not invalidate any existing water rights. CEQA responsibilities were assigned to DWR but were addressed through a Programmatic Environmental Impact Report (PEIR) as described below. Liability for damages arising from pumping was retained by DWR. The sellers, not DWR, retained control of the timing and rate of pumping itself. This proved to be problematic during the 1994 SDWB because, although DWR retained liability for pumping and water level related impacts, the Department could not readily suspend pumping if problems arose.

Several factors contributed to the problems encountered in 1994. First, very low precipitation during the spring forced farmers to initiate irrigation earlier than normal to flood rice fields and support orchard demands, thus significantly increasing groundwater pumping. Second, spring surface runoff reduced recharge to the local aquifer system, which had already been depleted by the previous multi-year drought.

The magnitude and location of pumping by Western Canal and Richvale near the eastern boundary of the Butte Basin, combined with higher than average pumping by others, reduced groundwater levels to the point that, by July 1994, some nearby domestic and agricultural wells were adversely affected. During the summer of 1994, water levels in wells not participating in the SDWB declined such that several domestic wells failed to produce water. Some wells reportedly sustained pump damage, while others had to be deepened. A complicating factor is that many agricultural groundwater users primarily pump on weekends, when electrical rates are the lowest. This tended to temporally concentrate pumping stresses and may have contributed to depressed water levels in some areas.

In July 1994, third party complaints prompted a temporary cessation in pumping by the SDWB at selected wells. It is important to stress, however, that the problems that occurred in 1994 likely resulted from the combination of drought history, SDWB pumping, and agricultural pumping practices. Groundwater level monitoring data did not conclusively point to SDWB pumping as a unique source of the problems, and thus pumping was resumed in some wells. However, the majority of the SDWB wells adjacent to the Cherokee Strip were turned off until the second week in August. Individuals who experienced pumping-related problems began to coalesce in ad hoc groups and later in organized forums such as the Valley Water Protection Association.

Subsequent to the 1994 SDWB program, the State of California began development of a Supplemental Water Purchase Program. The intent of the program was to develop a more systematic approach to future groundwater management in relation to droughts and water transfers. Initial groundwater substitution production targets were approximately 400,000 acre-feet. A draft EIR was issued by DWR in 1996, but opposition by local interests in the Sacramento Valley was sufficient to cause DWR to reduce the groundwater substitution goals to 200,000 acre-feet. The CEQA process has never been completed, and the original Supplemental Water Purchase Program is viewed as having been superseded by the CALFED process. Opposition continues to statewide or regional groundwater pumping targets developed in the absence of local planning.

SDWB PARTICIPANTS

The 1991 SDWB, like subsequent programs in 1992 and 1994, relied on willing surface water users to forego portions of their entitlements so that the project could deliver that water to buyers south of the delta and in the San Francisco Bay Area whose normal supplies were constrained by the drought. DWR operated the SDWB, including identifying willing buyers and sellers and serving as the "broker" for the water transfers. DWR entered into contracts for both the purchase of water from the selling water districts and for the resale of that water to the buyers. The selling water districts obtained the water through contracts with willing sellers (district members) and then managed the pumping regime.

DWR identified potential sellers to the 1991 Bank through the State Water Contractors. In 1994, the SDWB was well established and likely sellers were already known. Buyers for the 1994 SDWB were primarily agricultural users (93% of sales). In Butte County, local water users sold but did not buy water from the Bank. Individual users within the water districts elected to pump groundwater as a substitute for surface water that was transferred through the Feather River or other surface water conveyances.

BENEFICIARIES

From a financial perspective, the individuals who sold water to the Banks and those who purchased water from it were the primary beneficiaries. Sellers who benefited may be presumed, in most instances, to have used proceeds from water sales to invest in their farm operations or buy goods and services in the local communities. However, the benefits to the local water users in Butte County were uneven. Some water districts were better equipped with production wells than others, and, thus, the ability of districts to participate in the program was highly variable. Likewise, within districts that did participate, some individuals had the wells and/or financial resources to increase pumping capacity, while others did not. Groundwater users not participating in the SDWB programs received no benefits from the program.

As a result of the SDWB programs, buyers in urban areas were able to minimize impacts on landscaping and reduce the need for emergency water conservation measures. Agricultural buyers were able to protect orchards and other permanent crops and minimize potential layoffs of farm employees. Environmental benefits also accrued from the increased instream flows to maintain fisheries and to protect water quality in the Delta. One environmental benefit that is not widely recognized within Butte County was a significant contribution of SDWB proceeds to fund a $9 million siphon project on Butte Creek aimed at improving local salmon populations. In addition, the County received 2% of the gross proceeds from groundwater sales to help fund development of a Butte Basin Groundwater Model.

STAKEHOLDER PARTICIPATION

Throughout all three SDWB programs, DWR viewed the water sellers and the districts that represented them as the stakeholders of concern. These water sellers organized the Butte Basin Water Users Association (BBWUA) in 1992. This group became the point of contact with DWR technical staff and Butte County staff who had little direct involvement in the Bank activities beyond monitoring the SDWB process itself.

PUBLIC PARTICIPATION

While the public was not excluded from the SDWB process, little evidence exists of efforts to actively involve local communities or third parties who rely on groundwater but were not involved in groundwater substitution pumping. During 1991 and 1992, such public participation was viewed as unnecessary, but the 1994 experience demonstrated a need for the public to be educated and involved. Following the problems experienced in the summer of 1994, local DWR staff from the Red Bluff office conducted a few workshops and public meetings in Butte County.

Environmental Review

The 1991 and 1992 banks were one-year emergency programs, and as such were exempted from CEQA compliance. Environmental reviews were conducted when preparing the individual water sale contracts, but no formal CEQA documents were prepared for the overall SDWB program prior to 1993.

A programmatic environmental impact report (PEIR) was prepared by DWR in 1993 to address potential impacts of the SDWB. However, a common view in Butte County is that the PEIR was not very useful. It offered only general predictions of the nature and magnitude of potential impacts of the program. As is typical of programmatic reviews, site or project-specific impacts were not addressed. Mitigation measures for groundwater overdraft or impacts on surface water flows were neither identified nor adopted. With the data collected since 1993 and better predictive methodology, it seems likely that creating new EIRs for conjunctive use projects would be more useful than attempting to update the 1993 document.

Technical Studies

To date, the only comprehensive technical study of groundwater use in the county has been through the development of a groundwater management computer model for the Butte Basin. In 1992, the BBWUA retained a private consultant, Hydrologic Consultants, Inc., to develop the model in order to aid future water management. Hydrologic data from a variety of agency and water district sources was compiled for use in the simulations. Grid-scales employed in the model are on the scale of miles, and thus the model cannot simulate third-party impacts at individual well locations. Rather, the model is intended to aid in basin-scale analyses and planning. The Red Bluff office of DWR conducts studies of countywide land and water use every five years. Additionally, there have been a variety of geologic, hydrologic, and soils investigations conducted by various agencies and universities.

Monitoring Program

Since the inception of the SDWB programs, DWR, Butte County, and the Western Canal Water District have monitored groundwater conditions systematically. Approximately eighty to ninety wells have been monitored for groundwater levels on a quarterly basis. However, only about ten of the wells are solely for monitoring and not also used for production. Some additional monitoring wells have been added through investigations at the M&T Ranch towards the northern end of the Butte Basin. There is a strong consensus within Butte County and DWR that more monitoring is needed to prevent recurrence of the problems experienced in 1994. All believe that additional dedicated monitoring wells are needed in locations currently being identified through hydrogeologic investigations. A related need is to improve public access to the monitoring data. One proposal is to make continuously recorded water levels and pumping rates available in real-time over the Internet.

Financial Characteristics

Costs of the SDWB Program

The costs of operating the SDWB programs were recovered through the difference between the buying and selling prices. In 1991, water was purchased at $125 per acre-foot and was sold at $175 per acre-foot. Approximately 37 percent of the water purchased in 1991 was surplus to the demand that year and was carried over to the following year.[53] During the 1992 and 1994 Banks, water was purchased for $50 per acre-foot and sold for $72.50 per acre-foot. Reductions in the price offered by DWR to sellers and adjustments in the timing of commitments to sell and buy allowed the 1992 and 1994 banks to be more efficient so that they accumulated less surplus water.

Issues and Risks

HYDROGEOLOGIC RISKS

One of the significant challenges to future conjunctive use projects in Butte County and elsewhere in the Sacramento Valley stems from the fact that a significant number of wells are relatively shallow. DWR estimates that there are approximately 5500 domestic wells with 50% reaching depths less than 135 feet.[54] It is unlikely that these wells can function reliably with large drawdowns during drought conditions. Thus, it may be difficult to conduct groundwater substitution projects without substantial investments in deepening a large number of wells. Given the ad hoc nature of the SDWB programs compared with other strategic conjunctive use projects, there have been no systematic analyses of pumping thresholds required to prevent or avoid third-party impacts similar to the ones experienced in 1994. Pumping volumes were specified in contracts as a range, but the upper and lower limits were not based on detailed knowledge of local groundwater systems or the potential for third party impacts.

ENVIRONMENTAL RISKS

Currently, a wide variety of efforts are underway to protect and restore riparian ecosystems. One of the recent concerns raised about future groundwater substitution projects is the potential for adverse impacts on riparian vegetation and certain oak species that are reliant on adequate deep soil moisture associated with ambient water table levels. Very little is known about the potential impacts of lowering regional groundwater levels on sensitive vegetation communities. If managed groundwater level fluctuations occurring in future conjunctive use projects were shown to be adversely affecting local riparian systems, it is likely that some form of administrative or legal intervention could occur.

LEGAL RISKS

Based on its success in 1991 and 1992, the 1994 Bank clearly did not anticipate the problems that arose, nor did it effectively address the complaints of third parties who were, or perceived that they were, adversely affected by its operations. Third parties interviewed for this case study cite a period following the end of the 1994 SDWB program when neither DWR nor participants in the SDWB pumping would acknowledge that impacts occurred. This seems to have been due to the fact that the possibility of damage occurring to third parties was not seriously considered during development of the SDWB. Affected third-parties contracted with a consulting firm to identify SDWB pumping impacts. Following that study, dialogue between DWR staff and the consultant failed to resolve different interpretations as to whether SDWB pumping caused adverse impacts to third party wells. At that point, a group of affected third parties retained a law firm to explore the prospects of successful litigation for SDWB-related damages. Estimates of legal fees reached approximately $500,000, which was beyond the financial resources of the parties involved. However, given the increase in community involvement since the last SDWB, several organizations and individuals have threatened litigation if the problems of 1994 recur.

Subsequently, DWR established a process to evaluate claims of damages resulting from Bank-related pumping. DWR, and in many instances the water district where SDWB pumping occurred, reviewed claims and groundwater data for evidence of third-party impacts.

Where claims were substantiated, DWR offered monetary settlements, most of which covered the increased power costs for pumping from greater depths. These compensation efforts were generally viewed as insufficient to compensate third parties, and the entire claims process remains a source of dissatisfaction and distrust among some of the interviewees. The countywide consensus is that every effort should be made to avoid a repeat of the 1994 conflicts.

Other Third Party Impacts and Community Relations

Following the 1994 SDWB, Butte County placed a short-term moratorium on new wells in mid-1994. Opposition from the water districts coupled with potential impacts on agriculture and new residential development caused the moratorium to be lifted by late 1994. Seeking another solution, the County developed and circulated a concept paper that explored local controls on groundwater management. Local water districts reportedly opposed the language—if not the concept—and this effort was also discontinued.

A group of individuals that experienced third party impacts formed in 1996 to seek local legislation via a ballot initiative (Measure F) to protect groundwater resources and users. Several weeks later, local water users and participants in the SDWB programs placed an alternative groundwater management initiative (Measure G) on the ballot. It was apparently difficult for many voters to distinguish differences between the competing measures. Supported by significantly greater campaign funding, Measure G was approved by the voters in November 1996. Prior to Measure G, there was no program to manage water issues at the County level. The most significant elements of Measure G, codified as Chapter 33 of the County Codes, include establishment of a permit process for approving water sales in future SDWB or related programs; a County Water Commission with support from a Technical Advisory Committee; and administrative staff to follow water issues. The Commission and staff are in place, but no individual or district has applied for a water sale permit to date. Details of the application process are still being refined.

Local stakeholders hold divergent views regarding progress in implementing Chapter 33 {Measure G}. One person contacted in this study commented, "this Measure was born in crisis and remains in crisis." Some perceive implementation as a slow but steady process. In July 1999, the County formed a Department of Water and Resource Conservation. The Water Commission and the new Department are working to implement Chapter 33, mainly through the development of small workgroups representing various interests. More recently, Butte County has entered into a Memorandum of Understanding with DWR to examine local options under the Integrated Storage Investigation (ISI) program. The ISI program is designed to support locally initiated and controlled conjunctive use programs that will contribute to statewide water supplies under both drought and non-drought conditions. A local ISI stakeholders group has been formed with representatives from all sectors of the community actively participating in local water issues.

In general, the current process is viewed as a significant improvement over the situation prior to 1996. Policy questions are being debated in a more open manner and with substantial public participation. Virtually all of the individuals contacted who are involved in water sales feel the Water Commission adequately represents the County’s interests. In contrast, individuals who rely solely on groundwater sources see the need for greater representation of third parties on the Commission.

Several potential problems in the water permitting process have been identified. For example, the time frame to complete a permit under optimal conditions (no legal challenges) is estimated to be about nine months. This may conflict with the time period between a drought declaration on February 15 and the onset of peak water demands in the spring (approximately 4 months). However, if the permit processing time is reduced, the time available for citizens concerned about potential third-party impacts to comment would also be reduced. Observers agree that the Measure G permit process cannot be accurately evaluated until the first permit application creates a test case.

Conclusions

Comparing the activities of the SDWB programs in 1991, 1992 and 1994 to other conjunctive use programs in California is very difficult in that the three programs were primarily emergency responses rather than deliberately designed water resource projects. When problems arose in 1994, the SDWB program was unable to respond in an effective manner. Accordingly, the current implementation of Chapter 33 (Measure G) may be viewed as the first process in Butte County for designing conjunctive use projects.

The problems experienced during the 1994 SDWB program exposed several core issues that must be addressed in future groundwater management and conjunctive use projects. These issues may be grouped into two general areas: (1) monitoring of basin surface and subsurface hydrology and (2) planning and decision-making processes.

Efforts to evaluate 1994 pumping impacts were seriously impeded by insufficient knowledge of local groundwater systems and an inadequate network or monitoring wells. There is a consensus among interviewees that the monitoring network in Butte County should be expanded prior to future conjunctive use projects. Despite the existence of substantial groundwater level data in the Butte Basin, there is general agreement that a detailed understanding of the structure of the aquifer system is still lacking. The local U.S. Geological Survey Hydrologic Atlas[55] describes the Sacramento Valley as a single undifferentiated groundwater basin unit. Current investigations by the Northern District of DWR suggest that a much more complex pattern of distinct aquifers and recharge areas may exist. The type and spatial distribution of recharge mechanisms needs to be thoroughly investigated as future conjunctive use planning proceeds. Improved understanding of Butte Basin stratigraphy and recharge mechanisms may significantly contribute to preventing a recurrence of the problems encountered in the 1994 SDWB.

Changes in the planning and decision-making processes seem to be of equal or greater importance. As previously noted, the planning that occurred in the SDWB programs was essentially an emergency response. Subsequent attempts to develop groundwater management and water transfer programs[56,57] have been unsuccessful due to intense local opposition in the Sacramento Valley in general and Butte County in particular. Local acceptance and control appears to be critical to any stable conjunctive use planning program.

From the interviews, it seems that third parties (non-SDWB pumpers) carried and still seem to carry the burden of proving that pumping impacts occurred in 1994. Unfortunately, given the passage of time and the limitations on knowledge of the aquifer system described above, the magnitude and spatial distribution of SDWB impacts on third-party groundwater levels may never be known definitively. One possible resolution of this issue is to shift the responsibility for identifying pumping-related impacts from third parties to future conjunctive use projects themselves. Prospects for such a change in Butte County appear promising.

Significant efforts have been made to create a more open framework for future conjunctive use planning and decision-making in the region. Virtually all interest groups in Butte County recognize that the state government is likely to impose measures on the County in response to future emergencies if a local planning framework does not evolve soon. While there is general interest in finding an acceptable approach, much work remains to be done to fully implement Chapter 33. To create an optimal project planning and review process, local and state interests will need to commit adequate funding and other forms of support this implementation work. Some specific changes that have been recommended for the current planning and decision making processes are listed below. The first water sale permit application under Chapter 33 will be a vital test of the durability of the willingness of local stakeholders to work together.

The County should consider adopting a template for evaluating future conjunctive use projects and/or water sales. This might allow an individual or water district to obtain pre-approval of a proposed groundwater pumping rate prior to actually implementing a drought banking scheme. After any required environmental review and related analyses, the County could then approve the proposal which would be implemented when and if the need were to arise. Approval might require that the proponent present an adequate characterization of the aquifer system and have appropriate monitoring program already in place. This approach would require significant initial investment from the water sellers. Given the value of a reliable supplemental source of water in times of statewide need, some form of funding to subsidize establishment of such a system would seem an investment worth evaluating.

Summary of recommendations proposed by interviewees to improve planning for future conjunctive use projects

LEGAL ASSURANCES

- Liability for damages resulting from conjunctive use projects should be clearly defined.
- A trust fund or escrow account should be established to ensure timely compensation in the event of third party impacts on groundwater pumpers not involved in the water sale.

HYDROLOGIC ASSURANCES

- Specific thresholds of impacts that would trigger a cessation of pumping need to be set in more definitive terms than those specified in Measure G.
- Water sale permits should require that drawdowns created by groundwater substitution pumping be confined to within the project or water district boundaries.
- An emergency pumping shutoff procedure is a critical need and must be established.
- Initial conjunctive use projects should emphasize locations where delineation of sub-basins or specific aquifer zones that are sufficiently characterized to determine acceptable drawdown limits.

IMPROVEMENTS IN THE PLANNING PROCESS

- Mitigation measures necessitated by conjunctive use projects or related water transfers should be reviewed in the planning process.

- The County should review the composition of the Water Commission to improve its representation of diverse interest groups.
- The basin management objectives approach being pursued in Glenn County should be employed in Butte County.

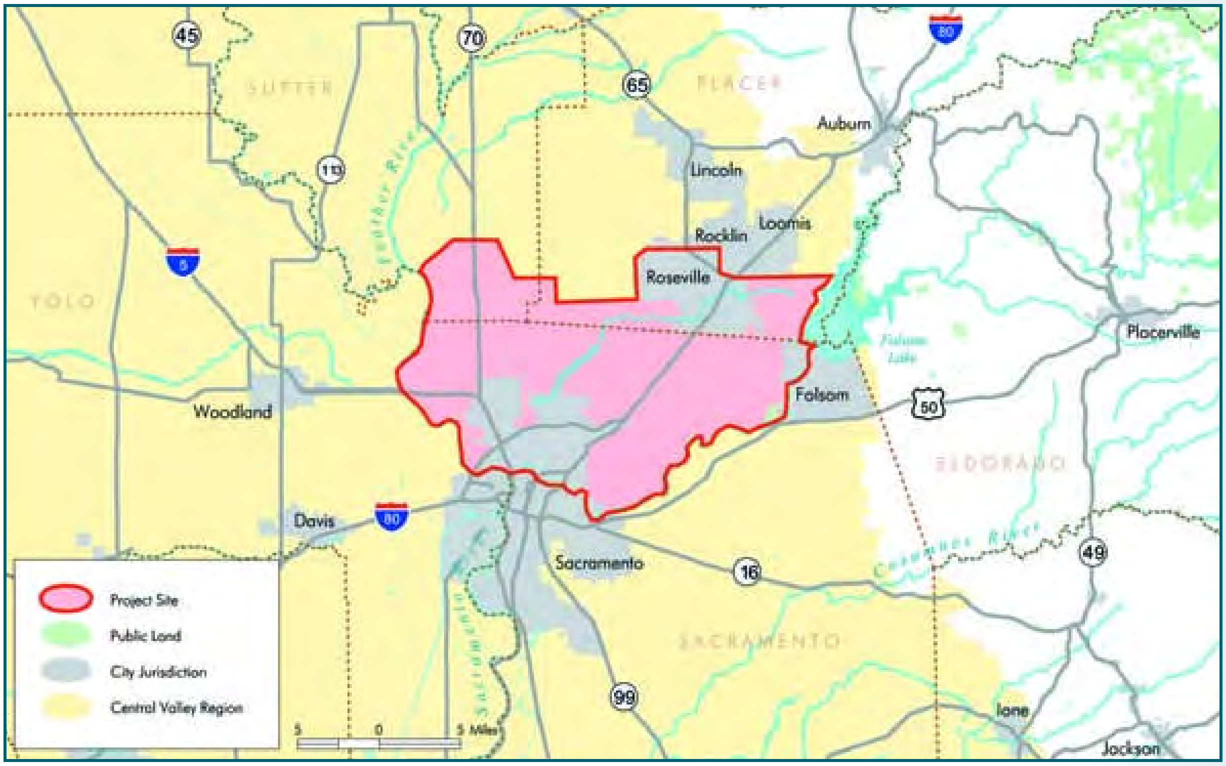
IMPROVEMENTS IN THE PERMITTING PROCESS

- The time frame for water sale permits must be streamlined, but adequate time for EIR review must also be provided.
- Water sales approved by the Water Commission should require five "aye" votes out of the nine members rather than a majority of a quorum present.
- The overall permit process needs to be made more understandable to the public.

IMPROVEMENTS IN THE MONITORING PROCESS

- Monitoring data must be made available to all interested public and private parties in an expedited manner.
- Cumulative effects of multiple water sale permits must be evaluated and monitored.

SACRAMENTO NORTH AREA GROUNDWATER MANAGEMENT AGENCY
AMERICAN RIVER BASIN COOPERATING AGENCIES
CONJUNCTIVE USE PROGRAM



Introduction

This case study reviews the conjunctive use program proposed by the Sacramento North Area Groundwater Management Authority (SNAGMA) and the American River Basin Cooperating Agencies (ARBCA). The Sacramento North Area Conjunctive Use Program illustrates how interest-based negotiations can lead to consensus on regional water issues and formulation of regional water plans. While a full-scale conjunctive use project for the north area of Sacramento has not yet been implemented, a regional conjunctive use program is currently being planned in collaboration with a broad range of stakeholders. SNAGMA and ARBCA, as well as other collaborators, have expended significant time and effort in order to build consensus for a regional water plan. Their efforts have been based largely on the Sacramento Water Forum process and the resultant Water Forum Agreement.

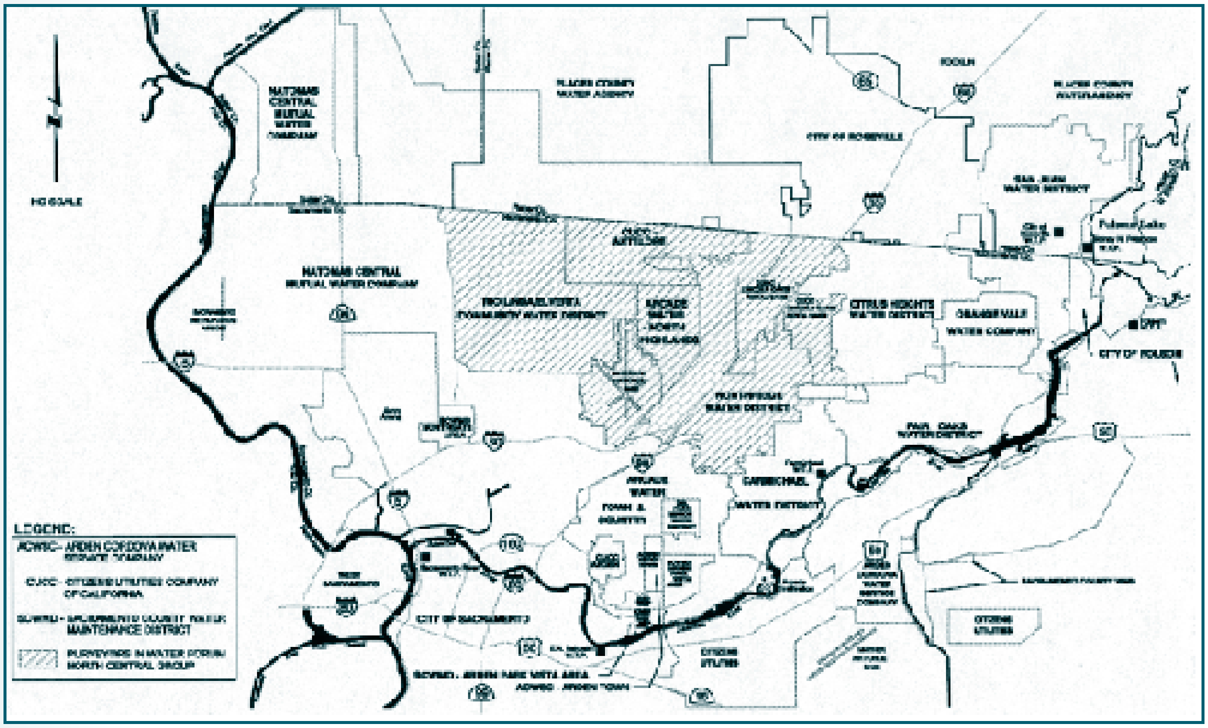
Physical Characteristics

SETTING

The proposed Sacramento North Area Conjunctive Use Program falls inside the northern portion of the Sacramento Groundwater Basin, which is located within the southern portion of the Sacramento River Hydrologic Region. Northern Sacramento County and southern Placer County overlie the potential project area, which is bounded on the north by the Placer County Water Agency, on the south by the American River, on the west by the Sacramento River, and on the east by the Sierra Foothills, (see figure 1 on the following page). While much of the overlying area is urbanized, significant agricultural activities still exist in western areas of Sacramento and Placer counties. The political jurisdictions and water purveyors within the proposed project boundaries include the following:[58]

- Arcade Water District
- Carmichael Water District
- Citizens Water Resources
- Citrus Heights Water District
- City of Folsom
- City of Roseville
- City of Sacramento
- County of Sacramento
- Del Paso Manor Water District
- Fair Oaks Water District
- Natomas Mutual Water Company
- Northridge Water District
- Orange Vale Water Company
- Placer County Water Agency
- Rio Linda/Elverta Community Water District
- Southern California Water Company
- San Juan Water District

AMERICAN RIVER BASIN COOPERATING AGENCIES / REGIONAL WATER MASTER PLAN
Figure 1



HYDROLOGY

Current water demand in the proposed project area is approximately 320,000 acre-feet per year. Approximately sixty percent of water demand is met with surface water, while forty percent is met with groundwater. Water usage can be characterized as approximately eighty percent municipal and industrial, fifteen percent agricultural, and five percent "self-supplied" via groundwater.[59] Groundwater pumping in the area, mostly for municipal and industrial uses, averages 125,000–130,000 acre-feet per year. Overdraft is estimated to have created 1 .5 million acre-feet of available storage (i.e., de-watered aquifer capacity), with a cone of depression centered in the vicinity of McClellan Air Force Base.[60,61,62] Approximately 400,000 to 600,000 acre-feet of the de-watered aquifer space is assumed to be useable for recharge.

Primary sources of surface water in the area include Folsom Lake, the American River, and Sacramento River. Nearly 900,000 acre-feet of surface water is available to agencies in the proposed project area pursuant to pre-1914 water rights, other appropriative water rights, Central Valley Project (CVP) contract entitlements, and settlement agreements.[63] The Sacramento metropolitan area is the largest urban area within the Sacramento River Hydrologic Region and is the largest urban user of surface water. The largest city within the Sacramento metropolitan area, the City of Sacramento, meets the water needs of its 400,000 residents with a mix of eighty percent surface water and twenty percent groundwater (approximately 100,000 acre-feet per year surface water and 22,000 acre-feet per year groundwater).

Available aquifer storage space, the potential for making use of excess surface water flows, and the combination of public agencies and investor-owned water purveyors that use both surface and groundwater create the necessary pre-conditions for a regional conjunctive use program in the Sacramento area.

Project History

Over its eight year history, the Sacramento Water Forum has evolved from a city-county effort into a program with buy-in from a broad range of regional stakeholders. Using a process of interest-based negotiations, the Water Forum has had several successes including the development of: SNAGMA, a regional water master plan, a water action plan agreement, an EIR, a joint-powers authority for the management of groundwater, a cooperative organization for the implementation of conjunctive use projects and the analysis of potential conjunctive use projects.

The following brief history of the Sacramento North Area Conjunctive Use Program outlines several of the most important processes that have led the Program to where it is today.

THE SACRAMENTO WATER FORUM

The Sacramento City-County Office of Metropolitan Water Planning (CCOMWP) was formed in October 1991 for the purpose of conducting regional water planning for the Sacramento area. The mission of the CCOMWP was to develop a regional water plan to address development and environmental needs in Sacramento through the year 2030. Initially, the CCOMWP conducted water demand analyses and groundwater modeling. Efforts expanded to include input from twenty-two Sacramento area water purveyors and the community at large. A stakeholder-driven process to develop a water action plan was initiated when the CCOMWP convened meetings with a variety of stakeholders including water purveyors, representatives of the business community and representatives from development, environmental, and agricultural interest groups.[64]

Out of this stakeholder-driven process, the Sacramento Water Forum (Water Forum) was formed in 1993. The Water Forum is an ongoing water planning effort that has been cited as an outstanding example of how a collaborative process can be used to develop a regional water plan and cooperative projects. Its mission is to develop and implement a plan to meet two coequal objectives: (1) to provide a safe and reliable water supply for the region's economic health and planned development through the year 2030 and (2) to preserve the fishery, wildlife, recreational, and aesthetic values of the lower American River.[65] After six years of research and negotiation among the stakeholder groups, the members of the Water Forum signed an agreement and action plan to meet the coequal objectives. The agreement and action plan seek to avoid future water shortages, environmental degradation, groundwater contamination, threats to groundwater reliability, and limits to economic prosperity.

For the purposes of this study, the key element of the Water Forum Agreement is the one dealing with groundwater management. This element provides the basis for the formulation of the Sacramento North Area Groundwater Management Authority (SNAGMA, adopted in August 1998), the American River Basin Cooperating Agencies (ARBCA), and the Sacramento North Area Conjunctive Use Program.

SNAGMA

The Sacramento groundwater basin consists of three sub-basins—the North Area, South Area, and Galt Area—each with its own unique conditions and problems.[66] The Water Forum Groundwater Management Element recommends an annual sustainable yield for each sub-basin. In the case of the North Area, the recommended sustainable yield is 131,000 acre-feet per year, a figure based on the volume extracted in 1990.[67]

The North Area is bounded by the American River on the south, the Sacramento County line on the north, the Sacramento River on the west, and the City of Folsom on the east. The Water Forum Groundwater Management Element recommended that the North Area move ahead with groundwater management under a Joint Powers Authority (JPA) form of governance structure. This decision was based on the following four factors:[68]

- The North Area is closer to build-out than the other two areas;
- Delivery systems for surface water are already being expanded and utilized to a greater extent in the North Area;
- Organized purveyors serve almost all of the North Area, including agriculture. Thus, the institutional infrastructure necessary to implement groundwater management is further developed in the North Area; and
- The Sacramento Metropolitan Water Authority, which includes eight of the twelve water purveyors in the North Area, wishes to implement a groundwater management plan as soon as possible and has already taken action to do so.

Pursuant to the Water Forum recommendation, a Joint Powers Agreement that uses the existing authority of the Cities of Citrus Heights, Folsom, Sacramento, and County of Sacramento established the Sacramento North Area Groundwater Management Authority (SNAGMA).[69] SNAGMA boundaries are coincident with those of the North Area Basin. The JPA requires the participation, through its Governing Board, of representatives of the County of Sacramento, the cities, private and public water purveyors, investor-held utilities, and groundwater rights holders in the North Area. Additionally, the SNAGMA Governing Board includes representatives of agriculture and commercial/industrial self-supplied (groundwater) users within the JPA boundaries.[70] The membership of the SNAGMA Governing Board consists of representatives from the boards or councils of the following North Area agencies, water purveyors, and stakeholders:

- Arcade Water District
- Carmichael Water District
- Citrus Heights Water District

- Del Paso Manor Water District
- Fair Oaks Water District
- Northridge Water District
- Rio Linda/Elverta Community Water District
- San Juan Water District
- City of Folsom
- City of Sacramento
- Sacramento County Water Maintenance District
- Southern California Water Company
- Citizens Water Resources
- Natomas Mutual Water Company
- Orange Vale Water Company
- Agricultural representative
- Self-supplied representative

SNAGMA is responsible for a wide variety of groundwater management functions in the North Area, including: collection and monitoring of groundwater data; maintenance of the recommended sustainable yield; and development and administration of a conjunctive use program. Additionally, SNAGMA is authorized to do the following:[71] (See next page).

Buy and sell water on other than a retail basis;

Exchange water, distribute water for ceasing, or reducing, groundwater extractions;

Spread, sink, and inject water into the North Area Basin;

Store, transport, recapture, recycle, purify, treat, or otherwise manage and control water for the beneficial use of persons and property within the authority;

Implement any conjunctive use program the Authority deems necessary to maintain sustainable yields in the North Area;

Study and plan ways to implement any or all of the foregoing powers;

Store water in underground basins or reservoirs within or outside of the Authority;

Exercise the right of eminent domain to take property necessary to supply the Authority with replenishment water;

Levy taxes, fees, or charges to accomplish the purposes of the Authority;

Require permitting of groundwater extraction facilities within the boundaries of the authority and meters for groundwater extraction facilities;

Carry out technical investigations to further the purposes of the Authority;

Set rates at which water acquired by the Authority can be sold for replenishment purposes;

Participate in *in lieu* contracts; and

Apply for and accept state, federal, or local licenses, permits, grants, loans, or aid.

Cited as one of the first authorities of its kind in California, SNAGMA provides an example of how collaborative negotiation processes can supply a structure for local control of groundwater resources. As seen from the list of SNAGMA's responsibilities and the number of participants, the Authority is a consolidation of local interests that have delegated their powers to it for the purposes of collectively managing groundwater resources.

ARBCA and the Regional Water Master Plan

While SNAGMA's role is primarily one of groundwater management, American River Basin Cooperating Agencies (ARBCA) was formed for the broader purpose of creating a regional partnership for water resources planning and conjunctive use project implementation.[72] ARBCA is funding the development of a Regional Water Master Plan (Regional Plan), estimating the cost of infrastructure needed for implementing a regional conjunctive use program, and developing operating agreements and institutional arrangements for conjunctive use, water banking and exchange.[73] The objectives of the Regional Plan are to enhance water supply reliability, provide high quality water and protect economic interests, while allowing each water purveyor to make its own business and policy decisions.[74]

ARBCA consists of water purveyors from Sacramento County, the City of Roseville, and Placer County Water Agency.[75] The total membership of Cooperating Agencies consists of the following:[76]

- Arcade Water District
- Carmichael Water District
- Citizens Water Resources
- Citrus Heights Water District
- City of Folsom
- City of Roseville
- County of Sacramento
- Del Paso Manor Water District
- Fair Oaks Water District
- Northridge Water District
- Placer County Water District
- Rio Linda/Elverta Community Water District
- San Juan Water District
- Southern California Water Company

In addition to the Cooperating Agencies, there are six Collaborating Agencies participating in the ARBCA regional water master planning and conjunctive use effort. These are:

- California Department of Water Resources (DWR)
- Natomas Mutual Water Company
- Orange Vale Water Company
- Sacramento Metropolitan Water Authority
- SNAGMA
- U.S. Army Corps of Engineers
- U.S. Bureau of Reclamation

In particular, the Bureau of Reclamation and DWR have provided assistance in the form of grant funding and in-kind services. ARBCA and SNAGMA have formed a partnership for the purposes of developing and coordinating the Regional Plan and implementing a conjunctive use program. The goals and objectives of ARBCA and SNAGMA are fully compatible and the significant membership overlap simplifies facilitation of the partnership. SNAGMA's role in the partnership is to establish the contractual arrangements needed to implement the conjunctive use program per the Regional Plan, exercise its authority to manage the groundwater basin, and provide the legal and political certainty for entering into long-term water banking and water exchange agreements.[77]

The ARBCA Cooperating Agencies are bound together by a series of Memorandums of Understanding (MOUs) that commit each agency to fund their share of the Regional Plan.[78] ARBCA has also established an organizational structure to oversee the development of the plan. An executive committee, consisting of technical experts and policy makers representing each member agency, provides direction and guidance. A coordinating committee, composed of a subset of the executive committee, oversees consultant team activities and develops meeting agendas. Finally, an implementation options committee evaluates institutional and policy issues that could impact the implementation of the Regional Plan. The San Juan Water District acts as the financial agent of ARBCA, as directed by the executive committee.

The development of the Regional Plan is proceeding in the following three phases:[79]

> Phase I — develop common goals and objectives for the implementation of conjunctive use, establish the current setting (supplies, demands, existing facilities), identify potential conjunctive use opportunities, and prepare a Phase II scope of work for evaluating water management and conjunctive use opportunities. Phase I was completed in June 1999.
>
> Phase II — configure the opportunities identified in Phase I into a Regional Plan institutional framework with specific projects identified and studied. Phase II includes the development of Integrated Groundwater and Surfacewater Model and economic and financial models and a communications strategy. Phase II is anticipated to be complete by April 2001.
>
> Phase III — develop draft agreements, conduct an environmental review of the Regional Plan and implement the conjunctive use program.

Groundwater Banking Opportunities

The ARBCA/SNAGMA partnership is exploring ways to establish a North Area Conjunctive Use Program to satisfy the Groundwater Element of the Water Forum Agreement. The partnership is developing a groundwater banking and exchange program that will take advantage of the regional cone of depression in the Sacramento area and integrate the operation of Folsom Lake with the recharge of the groundwater basin. Several options that have been proposed are described below.

The concept holds that, during a banking cycle, or "put" operation, surface water diversions from the American and/or Sacramento Rivers would be stored in the groundwater aquifer underlying the North Area and southern Placer County. The banking could occur either as *in lieu* recharge or direct recharge via spreading or injection. During the exchange cycle, or "take" operations, the banked groundwater would be extracted for local use *in lieu* of surface water diversions. Thus, surface water could be left in reservoirs for temperature control for fisheries, recreational uses or for releases to satisfy a variety of other purposes.[80]

To test the potential of the concept and the strength of institutional arrangements, the ARBCA/SNAGMA partnership conducted a pilot program to use conjunctive water management for water supplies to the Sacramento Area Flood Control Agency (SAFCA) on an on-call basis. Implemented with the participation of ARBCA/SNAGMA, SAFCA, and the U.S. Bureau of Reclamation (USBR), the program allows SAFCA to divert and bank water in the basin during wet months. Exchange water is available for SAFCA to satisfy its refill obligation associated with flood pool reservation in Folsom Lake.

Under the pilot program, banking is accomplished by diversion of raw water from Folsom Reservoir and treatment at San Juan Water District Water Treatment Plant. Treated water is wheeled through the Cooperative Transmission Pipeline and the Northridge Water District Transmission Pipeline for banking via *in lieu* groundwater recharge. In the exchange cycle, Citrus Heights Water District extracts groundwater in an amount equal to the banked water, foregoing a portion of the treated water normally supplied to the city by San Juan Water District. This frees an equal amount of water that San Juan Water District can then make available to SAFCA. San Juan Water District then foregoes portions of its diversions from Folsom Reservoir to make water available to SAFCA.[81]

The ARBCA/SNAGMA pilot program has been successfully implemented, and the partnership is now pursuing an expanded banking and exchange program with the CALFED Environmental Water Account (EWA). The pilot program serves as a good test of the institutional capabilities to bank and exchange water and is indicative of the willingness of the regional partners to move forward with the full-scale Sacramento North Area Conjunctive Use Program.

Institutional Arrangements

PROJECT TIME FRAME

The proposed Sacramento North Area Conjunctive Use Program is on a four to five year schedule, based on the Regional Water Master Plan timeline (1998 to beyond 2000). However, as stated previously, the Program actually has it roots in the 1991 CCOMWP formation, progressed through six years of Water Forum negotiations, and is now in the ARBCA/SNAGMA regional planning phase. Thus, the timeframe for development of the Sacramento North Area Conjunctive Use Program could be viewed as extending over ten years or more.

PARTICIPANTS

See list of Cooperating and Collaborating Agencies involved in the ARBCA Regional Water Master Plan formulation above.

BENEFICIARIES

Project beneficiaries include the participating agencies listed above as well as the environmental and business interests represented by SNAGMA. Essentially, a variety of stakeholders across the entire region benefits from the conjunctive use program.

PROJECT OPPOSITION

At the Water Forum stage, there was some opposition by regional environmental interests because of recommendations for increased diversions. These issues were resolved through the interest-based negotiation process.[82] San Joaquin County interests were somewhat opposed because they were not included in the Water Forum process, which was specific to the American River Basin. There is now overall stakeholder support for the ARBCA/SNAGMA stage, most likely due to the collaborative structure of the initial Water Forum.

STAKEHOLDER PARTICIPATION

A CEQA document was prepared for the Water Forum action plan. The EIR was certified with no public comment in December 1999. This success was largely attributed to the focused outreach program and the consensus-based negotiations that resulted in development of the action plan in advance of EIR preparation.

ENVIRONMENTAL REVIEW

The environmental documentation for the Regional Plan and Sacramento North Area Conjunctive Use Program will start sometime in 2001, after the completion of Phase II of the Regional Plan.

TECHNICAL STUDIES

Phase I technical studies for the Regional Plan were completed by Montgomery Watson, in association with CH2M Hill and Bookman-Edmonson. A "Blue Ribbon" panel of experts was assembled to review the approach taken by the project consultant team and to comment on the technical studies. The approach and studies were well received by the panel.[83]

MONITORING PROGRAM

Once it has been fully implemented, the monitoring program will be administered by SNAGMA.

Financial Characteristics

Costs for the Groundwater Management Element of the Water Forum Agreement were not tracked separately from the other six elements of the agreement. Overall costs for the eight year Water Forum effort totaled nearly $13 million.[84] The Water Forum Successor Effort has an initial annual budget of $720,000 per year. Until 1998, CCOMWP bore Water Forum costs. Since then, the participants have shared the cost of the work: the City of Sacramento funds approximately thirty-five percent, the County funds approximately fifty percent, and other cities and districts fund fifteen percent of the effort.

The cost of the Regional Plan Phase I Study was $267,000. The Phase II Study will cost approximately $1,000,000.[85,86] Participants share these costs, and the finances are managed by San Juan Water District. In addition, SNAGMA has funded about $350,000 of studies in support of the conjunctive use program. Costs of the conjunctive use program will be identified in the Regional Plan Phase II Study.

Issues and Risks

Many of the issues, risks (e,g., hydrologic, economic, legal), operational details, and environmental impacts of the program will be determined in the Regional Plan Phase II Study and supporting CEQA documentation, which will be completed in 2001. Funding for project planning and implementation will be provided by the participating agencies. Water rate increases were estimated at four percent per agency in the Water Forum, but this estimate will be refined based on the Phase II Regional Plan work.

SNAGMA will manage the groundwater resources and administer program rules in the North Area. The risk to crops is expected to be minimal as most of the project area is urbanized.

Because the ARBCA/SNAGMA conjunctive use project is an outgrowth of the Water Forum process, political risks and risks of substantial opposition are expected to be minimal. All stakeholders, including potential project opponents, were identified at the outset and included in the process of interest-based negotiations. The principal role of the Water Forum Successor Effort is to review implementation of the conjunctive use program. As noted above, the Water Forum is cited as an example of an outstanding stakeholder effort to develop a cooperative water action plan, and political opposition is unlikely.

Conclusions

The Water Forum, and the subsequent formation of SNAGMA and ARBCA for the purposes of groundwater management and conjunctive use, is an example of the effectiveness of interest-based negotiation in addressing water resources issues in California. This case demonstrates that the process is not simple or quick. Rather, it shows that, in order to be successful, the process of building consensus and forming collaborative organizations requires planning, organization, education, negotiation, and implementation, as well as ongoing follow-up. Some of the factors that most likely contributed to the success of the Water Forum and subsequent efforts include:

GENERAL PLAN — having a clear General Plan for the region that demonstrates the need for securing water resources over the next thirty years provides a focus for generating discussion and planning.

FORUMS — SMWA provides a forum for communication and interaction among local water purveyors and was instrumental in carrying out the American River Water Resources Investigation and helping to initiate the formation of SNAGMA. Also, the Sacramento Area Water Works Association (SAWWA), founded in 1958, is a volunteer organization representing thirty-five Sacramento area water purveyors. SAWWA promotes communication, cooperation, and the integration of resources among its members.[87]

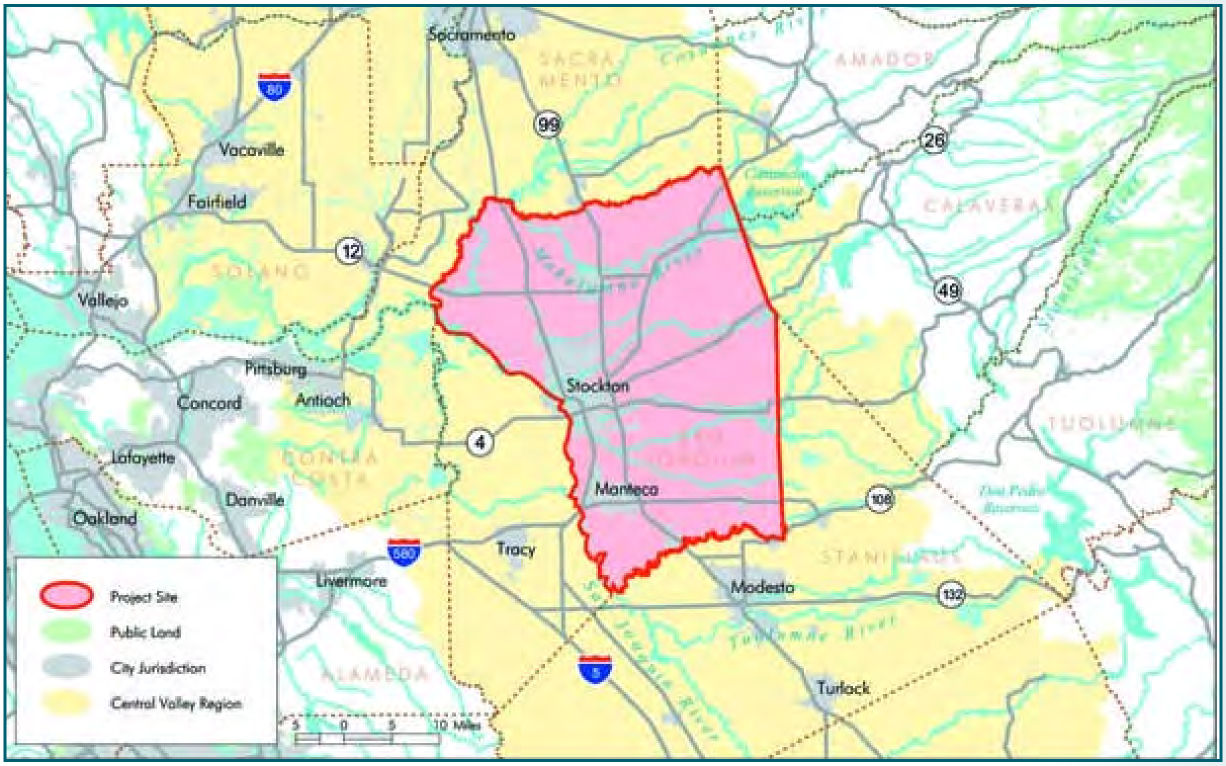
LEADERSHIP — having good leadership within the local water interests that recognized the need to reach out and include stakeholders in the Water Forum process is essential for success.

FACILITATION — recognizing the need for and retaining professional facilitation and mediation is a key element for success. Likewise, using interest-based negotiation and taking the time to train and educate the participating stakeholders is also crucial.

UNIFORM LAND USE — for the most part, the North Area has been extensively urbanized, and the remainder will most likely be urbanized over the next thirty years. Uniform land use contributes to the focus of the participants.

The Sacramento North Area Conjunctive Use Program is a good demonstration of how interest-based negotiations can lead to consensus on regional water issues and the formation of water plans. The Water Forum process led to an effective means of collective action for managing groundwater resources at the local level. As stated in the Water Forum Groundwater Management Element, this collective action is intended to avoid the "train wreck" that can occur when all overlying users exercise their right to pump groundwater beyond the sustainable yield of the basin. The Water Forum, and now SNAGMA and ARBCA, seek to prevent overdraft and the resultant disaster of divisive, protracted litigation and adjudication. Thus far, the effort has proven successful.

EAST BAY MUNICIPAL UTILITY DISTRICT/EAST SAN JOAQUIN PARTIES WATER AUTHORITY CONJUNCTIVE USE PROGRAM



Introduction

This case study reviews the efforts by the East Bay Municipal Utility District (EBMUD) and the East San Joaquin Parties Water Authority (ESJWPA) to jointly bank groundwater in Eastern San Joaquin County.

Physical Characteristics

SETTING

San Joaquin County is located at the northern end of the San Joaquin Valley, between the Sacramento-San Joaquin River Delta and the Sierra Nevada foothills. Eastern San Joaquin County is bounded by Sacramento County in the north; Amador, Calaveras and Stanislaus counties in the east; the Stanislaus River in the south; and the San Joaquin River and the San Joaquin River Delta in the west.[88]

San Joaquin County encompasses a total of 912,599 acres with about 600,000 acres of this area considered "Eastern San Joaquin County."[89] The majority of the land use in Eastern San Joaquin County is agricultural, and about six percent of the area is urban.[90] The major urban areas of Eastern San Joaquin County include the City of Stockton, City of Lodi, City of Manteca, Lathrop, Escalon and some unincorporated towns such as Lockeford, Clements and Thornton.

Water suppliers in Eastern San Joaquin County include the Woodbridge Irrigation District, the Stockton East Water District (SEWD), the North San Joaquin Water Conservation District, the Central San Joaquin Water Conservation District, the South San Joaquin Irrigation District, and the Oakdale Irrigation District. Additionally, San Joaquin County's Flood Control & Water Conservation District overlies the area.

Eastern San Joaquin County is traversed by the Mokelumne River in the north, the Calaveras River in the middle, and the Stanislaus River in the south at the San Joaquin/Stanislaus County line. Additionally, several small creeks cross the area. These include Dry Creek, Little Johns Creek, Lone Tree Creek, Duck Creek, Bear Creek, Mormon Slough, and Mosher Creek. Finally, six surface water reservoirs are operated within close proximity to the area: Camanche, Pardee, New Melones, New Hogan, Farmington, and Woodward Reservoirs.[91]

HYDROLOGY

San Joaquin County is within the northern portion of the San Joaquin River Hydrologic Region, as defined by the USGS, and overlies two groundwater basins—the Eastern San Joaquin County Groundwater Basin and the Tracy Groundwater Basin. The Eastern San Joaquin County Groundwater Basin is located east of the San Joaquin River and the delta and the Tracy Basin is west of the San Joaquin River. Sediments in the area are highly permeable.

Total agricultural consumption of water in San Joaquin County averages approximately 1,120,000 acre-feet per year. The municipal and industrial (urban) water demand is about 111,000 acre-feet per year.[92] Due to the relative lack of sufficient dry-year surface water rights in the San Joaquin County, the county has relied heavily on groundwater throughout its history. As a result, groundwater supplies approximately seventy percent of San Joaquin County's water needs.[93] The total groundwater usage in the county is estimated to be approximately 731,000 acre-feet per year, which exceeds the estimated safe yield of 618,000 acre-feet per year.[94] This mining of groundwater results in an estimated groundwater overdraft of 113,000 acre-feet per year.

Technical studies demonstrate that the groundwater overdraft problem has existed in Eastern San Joaquin County for several decades.[95] Two pronounced groundwater pumping depressions were observed in the region during the late 1940s and early 1950s. The largest of the two depressions is located in northeastern San Joaquin County between the Mokelumne and Stanislaus Rivers and is centered in the Stockton area. Here, groundwater levels are greater than seventy feet below sea level and as much as one hundred and fifty feet below pre-development levels.[96,97] One study indicates that the rate of groundwater withdrawal has exceeded recharge for at least fifty years. The overdraft has resulted in the intrusion of saline water into the aquifer below Stockton, with. some studies indicating that the saline water front is advancing at a rate of 140 to 150 lateral feet per year.[98,99] If the groundwater overdraft continues in the Stockton area, the saline migration will expand, resulting in a significant loss of Eastern San Joaquin County's groundwater resources.

The estimated overdraft for the northeastern part of the county is about 70,000 acre-feet per year, and a recent study shows that approximately 183,000 acre-feet per year is needed to overcome the impacts of the groundwater overdraft.[100,101] As a result, the ongoing overdraft has dewatered an estimated three million acre-feet and created considerable storage capacity in the Eastern San Joaquin County groundwater basin.[102]

The East Bay Municipal Utility District's 1993 Water Supply Management Program describes groundwater use as a key element of EBMUD's water supply reliability strategy. The District's engineering and environmental work clearly demonstrates the technical feasibility of recharging and extracting surface water in the Eastern San Joaquin County Groundwater Basin. The EBMUD literature also points out that, while it is technically feasible to bank water in the area, institutional issues need to be resolved before a project can move forward.[103] The following discussion provides a brief history of EBMUD's involvement in water banking in Eastern San Joaquin County.

Project History

Water officials and the public have been aware of the groundwater overdraft problem in Eastern San Joaquin for many years. In 1971, the serious nature of the situation prompted the California State Legislature to take special action. In recognizing the problem, the Legislature stated:

> *"The water supplies in the underground basin in the area of Stockton East Water District are insufficient to meet the water demands of the area, and, because of the geologic conditions peculiar to the area and because excessive pumping has seriously depleted the underground water storage, there has been an intrusion of saline waters into the underground water basin causing serious water quality deterioration and the destruction of the usefulness of a portion of the underground water basin. Further excessive pumping, without proper management of the underground water basin is certain to destroy the usefulness of a major portion of the underground water basin and endanger the health of and welfare of the district."*[104]

The Legislature found that the overdraft problem was broad and complex and that neither the urban nor the agricultural interests could solve the problem by themselves but instead must make a joint effort to reach a solution. Policymakers have recognized the overdraft problem in other forums as well. For example, Section 1011.5 of the Water Code mandates that the overdraft in the Eastern San Joaquin County Groundwater Basin be halted by 2007 as a condition for exportation of groundwater. And, the California Department of Water Resources (DWR) in Bulletin 118-80 identified the groundwater underlying Eastern San Joaquin County as subject to critical conditions of overdraft.

The recognition of the overdraft problem in Eastern San Joaquin County led to a number of proposals for dealing with the situation. Several options have been explored, including the reoperation of Farmington Reservoir to provide recharge water and a regional canal connecting the Folsom South Canal to the lower Farmington Canal to make use of water from the Calaveras and Stanislaus Rivers. One of the proposals involves participating in a conjunctive use project with EBMUD, where, during certain years, a portion of EBMUD's Mokelumne River Water or its CVP water would be banked in the Eastern San Joaquin County Groundwater Basin prior to being diverted into the Mokelumne Aqueduct.[105] This proposal was discussed in the EBMUD 1993 Water Supply Management Program (WSMP) and is the focus of this case study.[106,107]

EBMUD's involvement in Eastern San Joaquin County groundwater issues can be traced back to 1937 when concerns were raised about Mokelumne River diversions and groundwater in the Lodi area. EBMUD currently monitors groundwater levels as a part of an agreement with the City of Lodi. In 1981, the San Joaquin County Flood Control and Water Conservation District retained the firm of Brown and Caldwell to study groundwater conditions in Eastern San Joaquin County (Brown and Caldwell Study). The Eastern San Joaquin Water Users Association—composed of the North San Joaquin Water Conservation District, the Woodbridge Irrigation District, the Stockton East Water District, the Central San Joaquin Water Conservation District, the County Flood Control and Water Conservation District, and the Woodbridge Water Users Conservation District—supported the need for this study. Participants in the study Policy Advisory Committee included the City of Stockton, City of

Lodi, California Water Service Company, and EBMUD. The members of the Eastern San Joaquin Water Users Association, with the Cities of Lodi and Stockton (and the California Water Service Company as a non-voting member), eventually formed the East San Joaquin Parties Water Authority (ESJPWA) for the purpose of negotiating a groundwater recharge project with EBMUD.

The goal of the Brown and Caldwell Study was to determine the relative effects of various water supply alternatives on the Eastern San Joaquin County groundwater basin. Completed in 1985, the study found that development of a plan to optimize the use of surface water and groundwater supplies was technically feasible and economically attractive. However, the study notes that much technical, legal, economic, and institutional work would need to be completed before a conjunctive use program could be considered.[108]

The prolonged drought of 1987–1992 caused the groundwater levels in San Joaquin County to decline sharply.[109] This allowed the saline waterfront to encroach further eastward, degrading the quality of the groundwater in the eastern part of the county (Fall 1993 Groundwater Report). The drought also induced landowners to install wells in the southwest area of San Joaquin County for groundwater export via the adjacent CVP aqueduct facilities (the Delta Mendota Canal). These events, plus growth in the county, underscored the need to move forward with some form of supplemental water program.

The idea to actively pursue a recharge project for Eastern San Joaquin County originated with Stockton East Water District.[110] As a major water agency within Eastern San Joaquin County responsible for providing supplemental surface water supplies, SEWD recognized the seriousness of the overdraft problem and the need to explore regional solutions. The district's initiative, coupled with some active leadership within San Joaquin County and the development of EBMUD's Water Supply Management Program, led to negotiations between Eastern San Joaquin County water interests and EBMUD in 1994.[111,112]

In 1995–96, the Eastern San Joaquin County water interests, consisting of the San Joaquin County Flood Control and Water Conservation District, the Cities of Stockton and Lodi, SEWD, Central San Joaquin Water Conservation District, Woodbridge Irrigation District, North San Joaquin Water Conservation District, and the California Water Service Company (as an associate member), formed the East San Joaquin Parties Water Authority (ESJPWA), a joint powers authority.[113] The stated purpose of the ESJPWA is to plan a project or projects to meet the water deficiencies of Eastern San Joaquin County, either alone or in conjunction with EBMUD and/or other public entities.[114]

The ESJPWA negotiations with EBMUD resulted in a 1995 agreement to pursue jointly funded technical studies.[115] The technical studies were completed in 1996 and found that a mutually beneficial program would entail recharging 40,000 acre-feet per year in about half of all years into the basin, while extracting about 50,000 acre-feet of water in one out of four years.[116] The study looked at *in lieu* conjunctive use and injection/extraction as options. It concluded that the least expensive option would be to use dual-purpose aquifer storage and recovery wells located near EBMUD's Mokelumne River Aqueduct (MRA). Capital facilities for this option were estimated to cost $25 million, as opposed to $90 million for *in lieu* recharge facilities.[117] The MRA injection/extraction option would allow EBMUD to take advantage of normal weather and wet weather flows from the Mokelumne River.

The findings of the 1996 technical studies led to the execution of a 1997 Memorandum of Agreement (MOA) between ESJPWA and EBMUD to demonstrate the feasibility of the injection and extraction of surface water into the Eastern San Joaquin County Groundwater Basin.[118] The purpose of the proposed project was to test the reaction of the aquifer to injection and extraction, the water quality impacts and optimal rates of injection and extraction. The data generated by this pilot project would provide the necessary information for the design of full-scale injection/extraction facilities.

The proposed project, which became the Beckman Test Injection/Extraction Project (Beckman Test Project), was designed to inject 3,000 acre-feet of Mokelumne River Water from the MRA into a site adjacent to the MRA. Per the MOA, EBMUD would sell the water to ESJPWA; EBMUD would have the ability to recover up to fifty percent of the injected water (1500 acre-feet). The project was operated for a nine month period during 1997–1998 and demonstrated the feasibility of injecting up to 500 gallons per minute.[119] While the project performed as expected, the Beckman Test Project created an institutional controversy within San Joaquin County as a result of EBMUD filing an application for the export of water extracted from the project.

In 1996, in partial response to the groundwater overdraft in the southwest portion of the County that occurred during the drought, San Joaquin County adopted an ordinance establishing a permit process for exportation of groundwater. In 1997, EBMUD became the first entity to apply for a permit when it requested a permit for export of water from the Beckman Test Project site via the MRA.[120] Per the requirements of the County ordinance, the Advisory Water Commission of the San Joaquin County Flood Control and Water Conservation District reviewed the permit. The permit process includes the opportunity for public comment at the Commission review. Significant opposition to the permit application was voiced by the overlying farmer/landowners, including the San Joaquin Farm Bureau Federation, which was concerned about granting EBMUD access to the Eastern San Joaquin Groundwater Basin.[121] As a result, only three of the nineteen Commission members present (out of a total twenty-two members) voted to support the permit.[122,123] Thus, the permit was denied and no water was exported from the Beckman Test Project.

The application triggered nearly two of years of review of the protections afforded by the 1996 Ordinance. The ordinance was amended in June 2000 to incorporate measures to ensure that local groundwater users have enough water. The amendments adopted portions of the Kern Water Bank operating rules, modified to meet the needs of San Joaquin County. The amendment requires the submission of more detailed project information, the installation of at least three monitoring wells, a limit on the amount of water that can be exported to assure a net gain in usable water underlying the project, requirements for the spacing of extraction wells and buffer zones, limits on extraction times and periods, the formation of a monitoring committee, and a provision that the project shall not create conditions that are worse than conditions in the absence of the project (the so-called "Golden Rule"). The permit approval is made by the County Board of Supervisors. However, before approving any permit application, the Board of Supervisors must find that the proposed project will not operate to the injury of the reasonable and beneficial uses of the overlying groundwater users.[124]

With the adoption of the amended ordinance and the completion of the Beckman Test Project, ESJPWA and EBMUD proposed to move ahead with the Eastern San Joaquin Groundwater Bank #1 Project. This project would use both *in lieu* pumping and groundwater injection methods to bank Mokelumne River water. Injection/extraction wells would be constructed near the MRA in the North San Joaquin Water Conservation District area. The Eastern San Joaquin Groundwater Bank #1 Project proposed to recharge an average of 7,000 acre-feet per year and extract an annual average of 3,500 acre-feet of water per year. The estimated cost for this project was $25 million.[125]

ESJPWA began soliciting partners to provide water and/or funds to assist in advancing the project. This triggered the opposition of local interests who feared the encroachment of outside agencies into the Eastern San Joaquin Groundwater Basin, even with the protections provided by the amended County ordinance in place.

As of September 2000, the ESJPWA intended to move forward with the Eastern San Joaquin Groundwater Project, utilizing the lessons learned from the Beckman Test Project. The ESJPWA representatives believed, based on the ordinance revision process, that they understood what level of information is required to satisfy the Advisory Water Commission needs, and ESJPWA planned to develop the project along these lines. Also, ESJPWA intended to incorporate an ongoing public outreach effort regarding the project.[126] ESJPWA and EBMUD stated that they could work within the requirements of the amended County Groundwater Extraction and Exportation Ordinance. Eastern San Joaquin Parties Water Authority disbanded on June 30, 2000. The future of this project is therefore uncertain.

Table 2

EASTERN SAN JOAQUIN COUNTY/EAST BAY MUNICIPAL UTILITY DISTRICT GROUNDWATER BANKING PROJECT CHRONOLOGY	
EVENT	DATE
Brown and Caldwell are retained by San Joaquin County Flood Control & Water Conservation District to study groundwater conditions in Eastern San Joaquin County—EBMUD is a study participant.	1981
Brown and Caldwell study is completed. Study finds 200,000 af per year of surface water needed to stabilize groundwater basin, recommends Folsom South Canal option and/or New Melones be used as water source.	1985
Prolonged drought—farmers in Tracy area install wells for groundwater export.	1987–1992
San Joaquin County Flood Control & Water Conservation District groundwater monitoring demonstrates that saline front has encroached farther east towards Stockton (drought impact).	1993
Active negotiations begin between Eastern San Joaquin County water producers and EBMUD regarding a joint conjunctive use project.	1994
East San Joaquin Parties enter into an agreement with EBMUD to evaluate a joint groundwater storage conjunctive use program. Montgomery Watson, in conjunction with CH2M Hill, is selected to perform the study.	1995
East San Joaquin Parties Joint Exercise of Powers Agreement is executed. ESJWPA's stated purpose is to plan projects to meet water deficiencies of Eastern San Joaquin County.	1996
San Joaquin County adopts a groundwater extraction and export ordinance.	1996
Montgomery Watson issues Mokelumne Aquifer Recharge and Storage Project Final Report. Stanislaus & American River injection and *in lieu* options are presented. Folsom Canal South option plus Mokelumne River options are also presented.	1996
EBMUD and ESJWPA enter into a Memorandum of Agreement to demonstrate the feasibility of injection and extraction of surface water into the Eastern San Joaquin County Groundwater Basin. EBMUD will provide 3000 af of water to ESJWPA for $1/af. EBMUD can extract up 50% of the stored water.	1997
EBMUD files for an export permit pursuant to Division 7 of Title 5 of the Groundwater Extraction and Exportation Ordinance of San Joaquin County. Local interests strongly oppose issuing the permit. The Advisory Water Commission (AWC) approves environmental documentation, but the permit application subsequently fails.	1998
Beckman Test Injection/Extraction Project constructed and operated. Boyle Engineering Corp. is project consultant. Mokelumne River Aqueduct is used to supply water.	1997–1998
Boyle Engineering releases final report on Beckman Project. Report concludes that injection rates of 500 gallons per minute, or more, per well are feasible. Extraction rates were as projected.	1999
After a series of extensive reviews, the San Joaquin County Board of Supervisors approves an amendment to the Groundwater Extraction and Exportation Ordinance that limits groundwater exports, creates a monitoring committee for projects and requires groundwater banking projects to provide a net increase in groundwater in the basin.	May 2000
ESJWPA presents proposed Groundwater Bank No. 1 Project ("10 Well Project"). Information from the Beckman Project will be used for design. EBMUD will participate and Mokelumne River water is the proposed supply source. ESJWPA solicits partners for project.	August 2000
San Joaquin Farm Bureau Federation (SJFB) publicly opposes participation by outside interests in any groundwater banking/extraction project within San Joaquin County. The Farm Bureau states opposition to ESJWPA soliciting outside partners.	August 2000
ESJWPA charter formally expired June 2000—this is not recognized until November 2000.	November 2000
Members of former ESJWPA form northeastern San Joaquin County Groundwater Banking Authority.	February 2001

Institutional Arrangements

The proposed source of the banked water is the Mokelumne River and, potentially, water diverted from the Sacramento River. EBMUD has rights to 360,000 acre-feet per year of Mokelumne River water, but the district has inadequate storage and the Mokelumne River flows are highly variable, ranging from 80,000 to 1.8 million acre-feet per year.[127]

The Beckman Test Injection/Extraction Project was sited on land owned by Mr. Charles Beckman, near the Mokelumne River Aqueduct (MRA) to minimize conveyance costs. Similarly, the proposed Eastern San Joaquin County Groundwater Bank No.1 will be located near the MRA within the North San Joaquin Water Conservation District, in order to minimize costs of pipes for distribution and extraction. The proposal is for an aquifer storage and recovery (ASR) project, where banking would be accomplished by approximately ten injection/extraction wells. Water would then be conveyed to end-users via the Mokelumne River Aqueduct. Water remaining in the basin would be used for overdraft correction.

BENEFICIARIES

The project includes two groups of intended beneficiaries—EBMUD and the ESJPWA members. EBMUD will benefit by the addition of water storage to improve the reliability of its Mokelumne River supply. EBMUD is a participant due to its Mokelumne River rights and the proximity of its facilities (MRA) to Eastern San Joaquin County. The ESJWPA represents agencies in the Eastern San Joaquin County area that are most affected by the groundwater overdraft. Incidental beneficiaries will consist of overlying landowners who are groundwater users; groundwater users in Eastern San Joaquin County would benefit from the improved groundwater levels. The stored water would help to correct the overdraft created by agricultural pumping and municipal and industrial demands in Eastern San Joaquin County.

PROJECT OPPOSITION

For the most part, project opposition consisted of the San Joaquin Farm Bureau and Central Delta Water Agency. Their major concern was that it was too risky to bring in an outside agency and give that agency access to the local groundwater basin. Outside agencies were viewed as predatory organizations that would take the water when they needed it, without considering San Joaquin County's needs.[128] They also feared a loss of water rights if these agencies put a "straw in the aquifer." Paul Sanguinetti, past San Joaquin Farm Bureau President, member of the SEWD board and Stockton area farmer, expressed the essence of the local fears by stating that dealing with EBMUD was like "playing with a loaded gun" and that once the area experienced several dry years in a row, "there's no way we're going to stop them from exporting that water out of the county. No way. We'll have to stop pumping here."[129] The San Joaquin Farm Bureau Federation, representing the local farming interests, elaborated these concerns in public forums. The Executive Director, Russ Matthews, stated "everyone is in favor of recharging groundwater—as long as that water remains in the area and is not exported out of the county."[130]

In response to the ESJPWA call for partners, the San Joaquin Farm Bureau Federation interviewed local political leaders and Farm Bureau officers and members regarding the proposal. The Farm Bureau elicited responses to the effect that: solicitation of partners was premature until an export permit was obtained; banking by a local agency was preferable because "they'd have a stake in the groundwater situation and would work for both themselves and the area," overlooking the fact that the ESJPWA was comprised wholly of local agencies; San Joaquin county's needs should come first; "our" water rights might be lost; and the county should undertake groundwater banking itself for local control and benefit. It was also believed that, once involved, it would be expensive to get outside municipal water agencies out of the aquifer (invoking the Owens

Valley episode where MWD purchased overlying lands in order to appropriate the groundwater). In an earlier article, the San Joaquin Farm Bureau Federation discussed the SEWD technical study of recharging the Eastern San Joaquin County Groundwater Basin with winter run-off through percolation ponds. The article showed that local interests were supportive of the project due to the fact that a local San Joaquin County agency would be in charge, rather than an outside agency. The two articles, plus the statements of individuals interviewed for this study, indicated that the major issue was the fear of an outside entity gaining control of groundwater in San Joaquin County. However, the Farm Bureau did support an amended export ordinance that provided greater protections for overlying landowners.

STAKEHOLDER AND PUBLIC PARTICIPATION

For the most part, public participation took place at the Advisory Water Commission level and at the ESJPWA Board meetings. ESJPWA members reported project information back to their respective Boards and Councils. The ESJWPA Board was composed of the majority of the agency stakeholders in the northern portion of Eastern San Joaquin County (the southern agencies, such as the cities of Manteca, Lathrop, Escalon and the South San Joaquin Irrigation District are participating in a regional plan to use the District's surface water). Overlying landowners and other agencies could voice their concerns regarding the project through the San Joaquin County Water Advisory Commission and the Board of Supervisors. San Joaquin County is currently conducting a stakeholder/consensus building effort for the development of a county-wide Water Master Plan. This effort includes all of the stakeholders that are affected by the proposed groundwater banking project.

ENVIRONMENTAL REVIEW

If this project continues, the Beckman Test Project site and proposed project site will be located on farmland near the MRA. There are no environmental or water related issues that have been currently identified. The Beckman Test Project was carefully monitored to check for impacts to adjacent wells and the groundwater table. No detrimental impacts to adjacent wells occurred during the test project, and the ground surface was not impacted by injection.

A specific site for the proposed Eastern San Joaquin Groundwater Bank No. 1 has not been selected. The proposal calls for a site south of the Mokelumne River, adjacent to the MRA and within the North San Joaquin Water Conservation District area.

A Negative Declaration was approved by ESJWPA for the Beckman Test Project. Environmental compliance documentation has not been completed on the San Joaquin County Groundwater Bank No. 1 Project.

TECHNICAL STUDIES

There was no dispute regarding the various technical studies describing the overdraft problem in Eastern San Joaquin County. The Beckman Test Injection/Extraction Project Final Report prepared by Boyle Engineering Corporation was a very thorough and well-documented study. According to ESJWPA participants and published reports, the issue was not the thoroughness or validity of the technical studies—it was the distrust of an outside agency. The concern was that an outside agency could become overly reliant on the Eastern San Joaquin County groundwater basin, draining the region of its groundwater resources.[131] The issue is not a technical one; it is an institutional and political issue, and local interests must be assured that the potential third party impacts are mitigated before a project can move forward.[132]

Monitoring Program

The Beckman Test Project incorporated a thorough monitoring program to check groundwater levels and water quality impacts. Staff members of the ESJPWA performed daily monitoring of the Beckman Test Project. The Beckman Test Project also incorporated careful monitoring to determine if water quality problems might be encountered by injecting MRA water. The Technical Advisory Committee for the Beckman Test Project adopted a turbidity limit of 2.0 NTU to avoid well plugging. The project Final Report showed no water quality issues and recommended that the injection of surface water be suspended when MRA turbidities exceeded 2.0 NTUs.

The 2000 amendment to the San Joaquin County Groundwater Extraction and Export Ordinance required the establishment of a five-member monitoring committee for any permitted groundwater banking project within San Joaquin County. This requirement for a monitoring committee was modeled after the Kern Water Bank monitoring committee requirements and applies to any permitted project in San Joaquin County. Thus, the proposed San Joaquin County Groundwater Bank No. 1 will require the establishment of such a monitoring committee.

Per the ordinance, the monitoring committee will consist of representatives from the following agencies and stakeholder interests: the County Public Works; the County Public Health Services; the permittee; the local agency providing water within the project service area; and owners of land within two miles of the project location. The monitoring committee will set criteria to determine if there is well interference caused by the project and can engage the services of a professional groundwater specialist to provide assistance. The committee will also maintain records of the recharge and recovery activities related to the project and make recommendations to the San Joaquin County Advisory Water Commission for project modifications based on evaluation of monitoring data.[133]

Financial Characteristics

Costs for the design and construction of facilities—outside of the EBMUD right-of-way, permitting, right-of-way acquisition and environmental documentation for the Beckman Test Project—were borne by the ESJPWA. The design and construction of facilities within the EBMUD right-of-way were borne by EBMUD.[134]

The proposed San Joaquin County Groundwater Bank No. 1 will cost an estimated $25 million.[135] The cost shares are yet to be determined. The value of the water produced is estimated at $400 per acre-foot.

Issues and Risks

There is no full-scale project on line at present; therefore, hydrologic risks (e.g., aquifer leakage, pumping limitations, reduced infiltration) cannot be completely addressed. However, it should be noted that the San Joaquin County Groundwater Extraction and Exportation Ordinance does address these risks as follows:

- Extraction for export is limited to an amount that ensures that the project will result in a net addition to the usable groundwater underlying the project.
- Extraction wells may be spaced to limit impacts and an appropriate number of wells required to allow rotation.
- Buffer areas may be required between extraction wells and neighboring users.
- Annual, seasonal, or monthly limits and time restrictions can be placed on extraction rates.

- Pumping rates can be adjusted or terminated to reduce impacts.
- Exportation cannot result in lowering the average static water level in the project area by more than fifteen feet.
- A monitoring committee is required for each project.
- The project cannot create conditions that are worse than conditions absent the project.
- Lowering neighboring pump bowls to accommodate lower groundwater levels may be required to mitigate unavoidable adverse impacts.
- The cost of providing alternative water supplies to an impacted overlying user may be required of the project owner/operator.
- Financial compensation may be provided to an impacted overlying user by the project owner/operator.

The conditions and mitigation measures listed above are to be imposed by the County Board of Supervisors per the amended ordinance.

The ESPJWA and EBMUD 1997 Memorandum of Agreement provides that each party will indemnify the other. Both agencies agreed to equally share the costs of any permit challenges. It is assumed that similar contract provisions will be incorporated in future agreements.[136]

The Beckman Test Project and subsequent permit application did bring to the foreground the issues and concerns of the community regarding the EBMUD/ESJPWA partnership. This will allow the project participants to design the Eastern San Joaquin Groundwater Bank No. 1 Project in a way that responds to the concerns of the local community.

Conclusions

The ESJPWA/EBMUD experience in San Joaquin County is not unique in that the issues of local control of groundwater and the protection of overlying landowner rights to groundwater are a common theme in the San Joaquin Valley. As an example of this commonality, parallels can be drawn between this case and the Madera Ranch/USBR experience. Similarities between the two cases include:

- A groundwater basin in a state of overdraft, with potential capacity for recharge.
- Proximity to surface water conveyance features, providing for convenient put and take operations.
- An outside agency willing to consider banking within the county.
- Significant overlying landowner opposition to the proposed project.

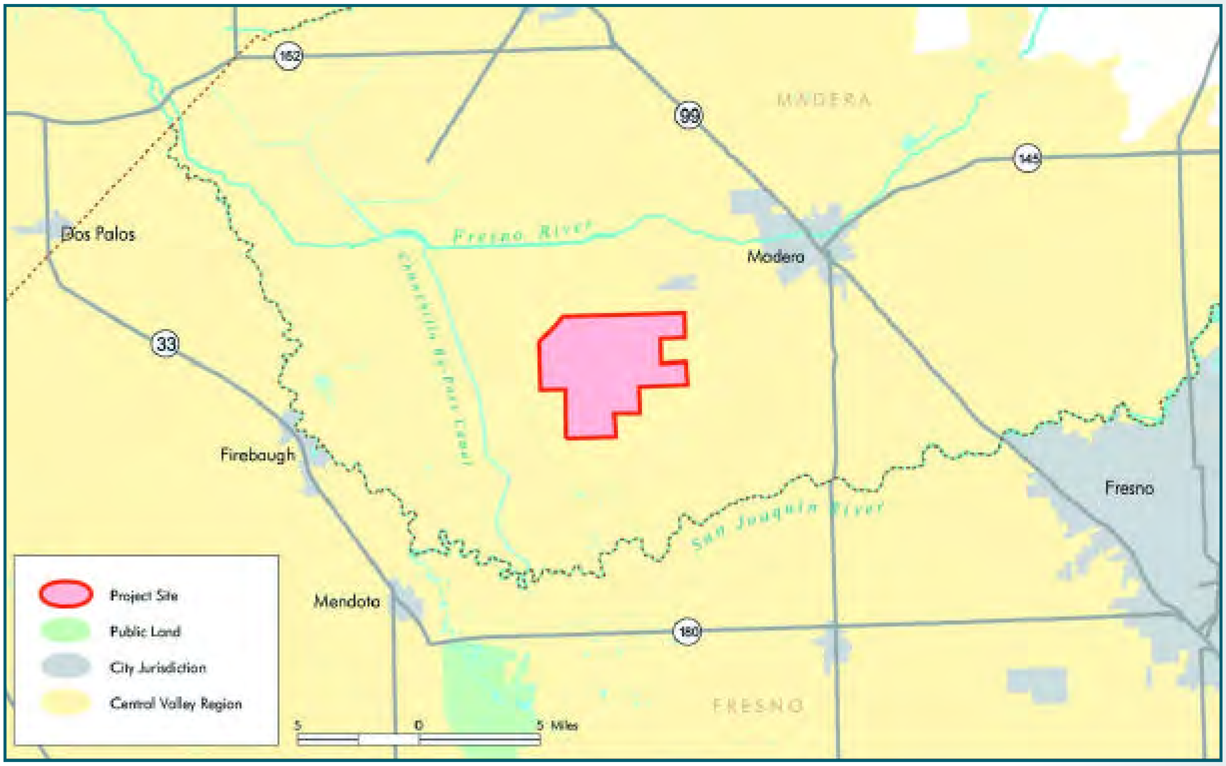
While the two cases appear to be essentially similar, there are significant differences. The differences can be summarized as follows:

- The presence in San Joaquin County of a groundwater extraction and exportation ordinance developed concurrent with, and in response to, the initial project proposal.
- The presence in San Joaquin County of a water advisory commission with authority to condition/approve/disapprove permits to extract and export groundwater.

> This commission also provides a forum for the multiple water interests within San Joaquin County, including agencies outside of the groundwater basin (this did not exist in Madera County).
>
> - The presence in San Joaquin of a joint powers authority made up of agencies in the area of overdraft, serving as project proponents.
> - The lack, in San Joaquin County, of a property transaction and time limit for pur chase (pending land sale) to make the project workable.
> - Multiple local water agencies investigating significant local groundwater banking projects within San Joaquin County (SEWD, San Luis Delta Mendota Water Users Authority, City of Tracy).

These differences create a different dynamic in San Joaquin County than the Madera case. The test of the ESJPWA/EBMUD will be the permit application for the proposed Eastern San Joaquin Groundwater Bank No. 1. The permitting process and decision will indicate how successful the ordinance amendment process was and whether or not local landowners are satisfied with its protections.

MADERA RANCH GROUNDWATER BANK PROJECT



Introduction

This case study reviews the Madera Ranch Groundwater Bank Project as proposed by Mr. Heber Perrett and the U.S. Bureau of Reclamation (USBR) prior to the purchase of the Madera Ranch property by the Azurix Madera Corporation in 1999.

Physical Characteristics

SETTING

Madera Ranch is a 13,600-acre property in Madera County, approximately eight to ten miles southwest of the City of Madera. Approximately 1,000 acres of the Madera Ranch property are irrigated, and the balance (12,600 acres) is used either for dryland farming or grasslands. The project site is located on the lower alluvial floodplain of the San Joaquin and Fresno Rivers in the southernmost portion of the San Joaquin River Hydrologic Region, (see Figure 2 on the following page). The Madera Ranch property overlies what is commonly referred to as the Madera Groundwater Basin.

The project site is situated in an unincorporated portion of Madera County. Madera Irrigation District overlies two sections (1,497 acres) on the eastern edge of the Madera Ranch property and is also directly north of and adjacent to the project site. Gravelly Ford Water District overlies two sections (1,282 acres) along the southeastern edge of the property.

HYDROLOGY

Ongoing monitoring and studies demonstrate that the Madera Groundwater Basin, including the groundwater table underlying the ranch, is in a state of overdraft that has been exacerbated by the drought periods of 1976–1977 and 1987–1992.[137] Groundwater levels in the Madera Basin dropped from 10 to 120 feet from 1960 to 1990[138] and the approximate average annual decline in static groundwater levels within the Madera Irrigation District is 1.25 feet per year.[139] Currently, the depth of groundwater in the Madera Basin is, on the average, 40 feet below pre-drought levels; thus, there should be space in the basin for groundwater recharge.[140]

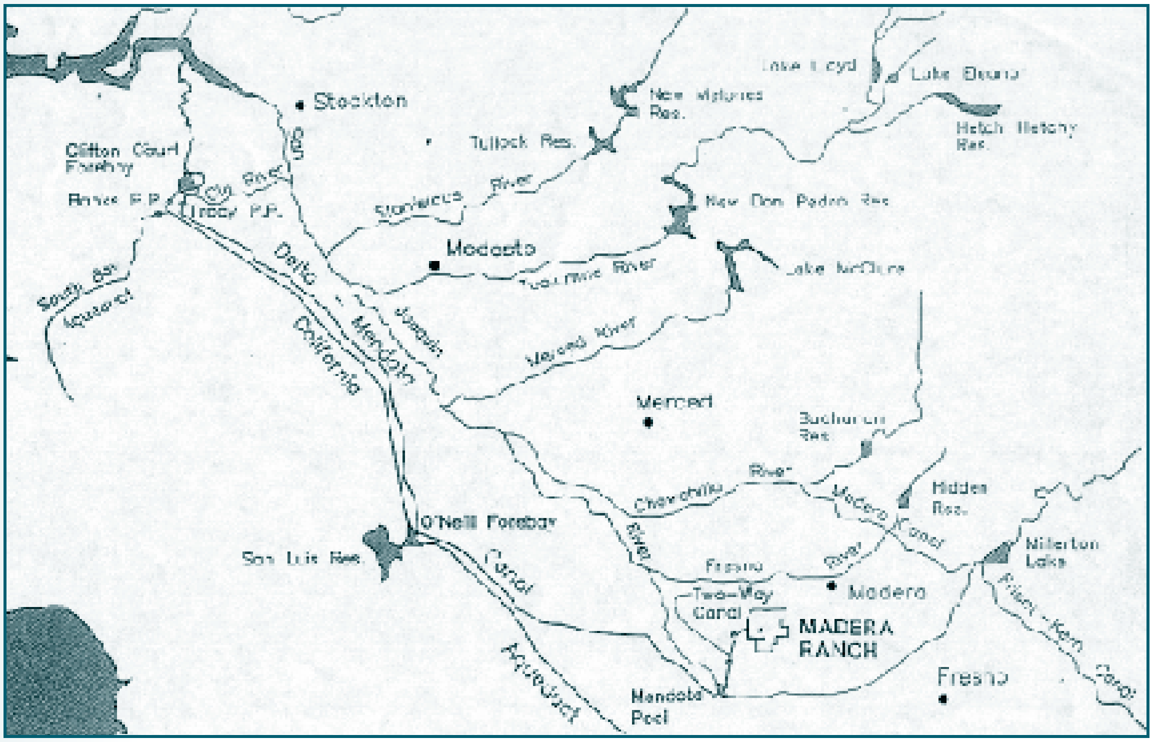
Groundwater pumping in the Madera Basin is estimated to supply about one half of Madera County's irrigation needs. The Madera Irrigation District provides surface water deliveries to a 128,294 acre service area adjacent to the Madera Ranch site. The ten year average of surface water deliveries to the Madera Irrigation District Service area is 95,557 acre-feet per year.[141]

The Madera Ranch Groundwater Bank Project site is ideally located to take advantage of existing water project facilities for the conveyance of recharge water to the site. The Madera Ranch site is situated near the southern portion of the Delta-Mendota Canal and Mendota Pool, potentially enabling surplus Central Valley Project (CVP) water to be conveyed to the project site—with the construction of minimal facilities—for percolation into the basin. Additionally, the project site location could also allow for the conveyance of water from the San Joaquin River via an improved Gravelly Ford, a canal facility that currently can deliver water from the San Joaquin River to lands adjacent to the Madera Ranch site.

The location of the Madera Ranch property above the Madera Groundwater Basin, its proximity to existing water project conveyance features, and the fact that the property is one of the last large unfarmed pieces of privately held land in the San Joaquin Valley make it a logical site to investigate for a potential groundwater banking project.

MADERA RANCH GROUNDWATER BANK

Figure 2



The original Madera Ranch project concept involved conveying surplus CVP water from the Delta to the Mendota Pool and then diverting this water to the Madera Ranch Project site. This could be augmented by additional water pumped under the joint point of diversion as part of a water reserve account proposed by USBR.[142] The CVP can only pump 4,200 cubic feet per second (cfs) from the San Joaquin River Delta due to conveyance capacity constraints downstream from the Tracy Pumping Plant. By utilizing the joint point of diversion, the 400 cfs not pumped by the CVP due to the constraints can be pumped by the State Water Project (SWP) at the Banks Pumping Plant and delivered for CVP uses, such as groundwater banking. Additional sources might include water purchased by the USBR as part of its Land Retirement Program and water from non-federal water users. Flood flows diverted from the Chowchilla Bypass flood channel were also considered but rejected because the operation would produce an average annual increase in yield of less than 3,000 acre-feet and the cost of the requisite additional facilities could not be justified.[143]

A gravity turnout and a two-way canal with pumping plants would be used to convey the water from the Mendota Pool to the Madera Ranch Project site and then percolated using recharge wetland ponds. Water extracted from the bank would be reconveyed to the Mendota Pool for delivery to end-users. Figure 3 shows a conceptual schematic of the conveyance, recharge and extraction facilities originally proposed for the project.

MADERA RANCH GROUNDWATER BANK / CONCEPTUAL DRAWING

Project History

On August 13, 1996, Mr. Heber Perrett, the owner of the Madera Ranch site at that time, presented the original Madera Ranch Groundwater Bank Project proposal to the USBR. The Bureau was interested in the Project to store water reserve account water. This reserve account is designed to assist the USBR in meeting the requirements of the Central Valley Project Improvement Act (CVPIA), improving CVP operations, and for drought year water supplies. An estimated maximum of 390,000 acre-feet of surface water was proposed for storage in the Madera Ranch Groundwater Bank Project, with 100,000 acre-feet reserved for critically dry years.[144]

The property owner's offer prompted the USBR to undertake a preliminary investigation to determine if fatal flaws existed in the Madera Ranch project proposal. The San Luis-Delta Mendota Water Authority (SLDMWA) and the Santa Clara Valley Water District (SCVWD), as potential groundwater bank partners, provided the information needed to model delivery and extraction operations at the project site. This preliminary investigation was also designed to evaluate the physical suitability of the Madera Ranch site for banking water.

The preliminary investigation, completed in July 1997, found no obvious fatal flaws and recommended a phased evaluation of the proposed banking project.[145] The first phase was initiated in July 1997 and completed in April 1998. The Phase 1 Investigation included the results of a geologic and hydrologic study by Bookman-Edmonson that was completed for Heber Perrett (February 1998). The investigation also provided a brief review of local issues, environmental concerns, operational concerns and financial issues. This preliminary investigation culminated in a Phase 1 Report that found that the Madera Ranch site has potential for groundwater banking development and is worth further investigation. However, it also pledged that further pursuit of the project would be halted if any fatal flaw, with no remedy, was revealed at any time by the Phase 2 Investigation.[146] The Phase 1 Report recommended proceeding with a more detailed Phase 2 Investigation of two project alternatives: a multi-year commitment by USBR to lease facilities and services developed by Mr. Perrett or an option for USBR to purchase the Madera Ranch Property for development of the project by USBR.[147] The Phase 2 Investigation also intended to also make recommendations on permit applications, public involvement, environmental compliance development under the California Environmental Quality Act (CEQA) and the National Environmental Policy Act (NEPA), necessary negotiated agreements and congressional authorizations.[148]

After the completion of the Phase 1 Report, opposition by the Madera County Board of Supervisors, the Madera City Council, the Madera Ranch Oversight Committee, area farmers, regional water districts and local stakeholders caused USBR to reconsider the project planning process.[149] The project timeline was extended an additional 18 to 24 months to give the Bureau time to address local stakeholder concerns.[150] A request by USBR to CALFED for $14.5 million in funding for the purchase of the property was rejected because of the local opposition, and CALFED indicated it would not reconsider the project until local concerns had been adequately addressed.[151]

Subsequently, USBR abandoned the project and the Madera Ranch property was sold to Azurix Madera Corporation (a Texas-based water development corporation owned in part by the Enron Corporation) in October of 1999 for a reported $31 million.[152] Azurix is currently pursuing the development of the Madera Ranch Groundwater Bank Project with the objective of providing banking participants with storage space for their water.[153]

A summary chronology of major project events is illustrated by Table 3 of this report.

Table 3

MADERA RANCH GROUNDWATER BANKING PROJECT CHRONOLOGY 1996–1999

EVENT	DATE
Mr. Heber Perrett purchases the Madera Ranch property	May 1991
USBR receives Madera Ranch Groundwater Banking Project Proposal	August 1996
Preliminary evaluation is completed (fatal flaws analysis, capacity analysis)	July 1997
Agreement for two-phase investigation is made	November 1997
Phase 1 Investigation starts	December 1997
USBR issues press release and holds two public briefings	January 1998
Bookman-Edmonston provides study results to Perrett and USBR	February 1998
Phase 1 Report completed (field tests, technical issues identified)	April 1998
Perrett conducts on-site tour of Madera Ranch for local landowners	May 1998
Area farmers and representatives of local water districts form grassroots Madera Ranch Oversight Committee to monitor project	August 1998
Oversight Committee gathers information and makes presentations opposing the project	September1998–March 1999
USBR releases Bookman-Edmonston study to the general public	September 1998
Emergency congressional appropriation attempts to fund land acquisition of Madera Ranch	September 1998
Various local agencies voice concerns and opposition to land acquisition prior to the completion of comprehensive studies	September/Oct 1998
CALFED rejects $14.5 million funding request by USBR due to local opposition	October 1998
USBR extends project timeline by 18 to 24 months due to local opposition	October 1998
USBR meets with Friant Users Authority and Oversight Committee	October 1998
Freedom of Information Act request is filed	December 1998
Madera County Supervisors pass groundwater ordinance and resolution opposing project	March 1999
Landowner sets deadline for USBR action	1999
Azurix purchases Madera Ranch site from landowner	October 1999

Institutional Arrangements

PARTICIPANTS

The proposed Madera Ranch Groundwater Bank Project sponsors and participants included Mr. Heber Perrett (owner), the USBR, SLDMWA, and SCVWD. Stakeholders included: local farmers and adjacent property owners; adjacent water and irrigation districts (Aliso WD, Gravelly Ford WD, Madera ID, Chowchilla WD); Madera County; City of Madera; California State Farm Bureau; Nisei Farmers League; Families Protecting the Valley; Tehipiti Chapter of the Sierra Club; Friant Water Users Authority; and the Regional Council of Rural Communities.[154]

The Phase 1 Report recommended that the choice between the two options that were under consideration—a multi-year lease of services and facilities or the purchase of the land and development of the facilities by USBR—be based on stakeholder consensus, partnership agreements, costs, contract negotiations and other factors.[155] However, no contractual arrangements for the use of the project were ever developed because the proposed Madera Groundwater Bank Project was not implemented beyond the Phase 1 Report recommendations.

BENEFICIARIES

As originally proposed, the water would be used to meet Central Valley Project (CVP) contract deliveries to agricultural water districts, as well as requirements to reduce pumping demands on the Delta to benefit wildlife refuges. USBR also proposed using the bank to implement a 100,000 acre-foot reserve account for drought relief in critically dry years. The non-federal project partners, the SLDMWA and SCVWD, participated in the project investigation to determine if possible banking opportunities existed for their agencies. Other potential uses included meeting unforeseen environmental needs and meeting general storage needs south of the Delta during certain critical periods.

STAKEHOLDER AND PUBLIC PARTICIPATION

According to stakeholder interviews, the Phase 1 Report, and other documentation, stakeholder participation during the preliminary investigation stage and the Phase 1 Investigation was limited to USBR, the property owner and the participating agencies (SLDMWA and SCVWD).

USBR issued a press release at the start of the Phase 1 Investigation to inform the public and identify interested stakeholders.[156] The press release was followed by the distribution of an information package to interested parties. Two public briefings were held and a list of interested parties compiled based on the telephone response to the press release and attendance at the public briefings.

Project Opposition

The Madera Ranch Groundwater Bank Project drew opposition from a variety of sources, most notably area farmers, local irrigation and water districts, Madera County and the City of Madera. The issues that triggered local concerns are summarized below:

> 1) Incomplete Information — opponents of the project characterize it as an example of USBR "getting the cart before the horse." Local stakeholders felt that the technical studies were very preliminary and incomplete, and thus the feasibility of the proposed project was not demonstrated sufficiently for policymakers to commit public funds to the project.[157,158,159] Some feel that the property owner's deadline for USBR action forced a premature commitment by the agency to move forward on the purchase of the property.[160] A Freedom of Information Act request for project information was filed by project opponents and Representative George Radanovich in 1998.[161,162] This request produced USBR internal documents and documents from other federal agencies that indicate potential flaws in the project as proposed.
>
> 2) Lack of Effective Public Involvement — due to the nature of the proposal, it was felt that USBR's public outreach came too late in the process and that local experts should have been consulted before, or at least during, the preliminary investigation. Utilizing local knowledge of the geography, aquifer response and historic water levels could have been beneficial to the evaluation. Additionally, CALFED officials and DWR Bulletin 160-98 characterized the project as feasible and beneficial before the technical studies were completed. As a result, the project was championed in several political arenas prematurely. This reinforced local concerns that the proposed project was political rather than technical in nature and a "top-down" driven project.[163] Community relations for the proposed Madera Ranch Groundwater Banking Project were a significant problem and local opposition is cited as the major factor in USBR's decision to abandon the project.[164,165]
>
> 3) Location near surface waters — the Madera Ranch Groundwater Bank Project site is in close proximity to the San Joaquin River, and adjacent property owners have observed immediate impacts to the unconfined aquifer based on fluctuations in the river levels. A 31.9-foot rise in water levels was observed over a twelve-month

period that included flooding and continuous river flows.[166] Based on these observations, local opponents to the project questioned the estimated storage capacity of the aquifer in the Madera Ranch area. Finally, the gradient and proximity to the river also raised concerns about a "topped off" aquifer and the outflow of stored water to the river.

4) Root Zone Flooding — local farmers adjacent to the Madera Ranch site have calculated that the area directly under the project site could only store a maximum of 130,000 acre-feet of water based on their observations of the variation of water levels in adjacent wells. Based on this calculation, the projects proposed storage of a maximum of 390,000 acre-feet would require about 10 square miles of surface area. Thus, local opponents believe stored water could move off of the project site, creating root zone flooding problems for neighboring orchards and other sensitive crops.[167]

5) Water Quality — Water quality consequences of groundwater banking were a concern for local farmers and adjacent landowners and were identified in the Phase 1 Report as an issue to be studied in the Phase 2 Investigation.[168] Local farmers state that the salinity of the Mendota Pool is approximately six times that of area groundwater; thus the introduction of Mendota Pool water might degrade water quality in the aquifer. This, coupled with the potential for stored water to move off-site, is a concern for farmers with wells and crops adjacent to the Madera Ranch site.[169] These concerns were echoed in comments by other agencies reviewing the preliminary studies, as evidenced in documents that were obtained by the Madera Ranch Oversight Committee through the Freedom of Information Act request referenced previously.[170]

6) Risk of Hydrologic Impacts on Groundwater Users — Proposed project well sites were upgradient of the infiltration ponds and close enough to the City of Madera wells that there was significant likelihood that water extracted may not be the water that was placed in storage. There was concern that the project could "exchange" lower quality banked water for higher quality native groundwater through the extraction process.[171] Additionally, area landowners were concerned about the accurate monitoring of the proposed project and its potential for extracting native groundwater in addition to the banked water (more "take" than "put). It should be noted that these hydrologic issues were expressed in communications by USBR staff, as evidenced in the Freedom of Information Act documents.[172]

7) Potential Loss of Local Control — the proposed project could present a means for outside interests to gain access to native groundwater and potentially other surface water entitlements (for example Friant water). In essence, local interests were concerned that the project represented a means for an outside entity to establish a foothold, or "pipeline," into the local water supply.[173,174,175]

Environmental Review

The CEQA process was not initiated for the proposed Madera Ranch Groundwater Banking Project. CEQA/NEPA compliance was to have been addressed in late 1998, according to the original project schedule. The Phase 2 Investigation would have identified whether or not a single CEQA/NEPA document would suffice for environmental compliance (as opposed to separate CEQA and NEPA documents).

The USBR Phase 1 Report indicates that the unfarmed area of Madera Ranch is "Priority 1" habitat "where actions must be taken to prevent the extinction or to prevent a species from declining irreversibly in the foreseeable future."[176] A reconnaissance survey of the site revealed the presence of vernal pools and the presence of sensitive terrestrial plant communities. Several species of halophytic (salt-tolerant) plants were found, and the presence or potential presence of several special status wildlife species was also noted.[177] Based on the reconnaissance survey, any groundwater banking facilities and operations at the Madera Ranch site would be required to minimize impacts on sensitive species and habitats. It should be noted that the reconnaissance survey in Phase I did not fully address the biological issues presented by the proposed Madera Ranch project and that additional site investigations would have been needed.[178]

Financial Characteristics

The options of leasing or purchasing the Madera Ranch were considered by USBR. The estimated cost of the proposed lease arrangement with Mr. Perrett was $14.8 million per year for a twenty year term. The option of purchasing the land was purported to cost from $43 million to $53 million.[179]

USBR estimated the annual cost for operations and maintenance of the facilities at $400,000. While the financing options were not fully developed, USBR did approach CALFED for $14.5 million to supplement the cost of purchasing the Madera Ranch site.[180] The Phase 1 Report identifies costs, cost allocations and repayment as items to be analyzed in the Phase 2 Investigation. Based on the term of the lease, the estimated value of the water produced was $226 per acre-foot at an annual yield of 70,000 acre-feet. The estimated value of the water under the scenario in which USBR would own and operate the facility is not available.

Issues and Risks

The proposed Madera Ranch Groundwater Banking Project did not proceed much beyond the Phase 1 Report phase, and thus the operational and administrative mechanisms for dealing with areas of risk were not fully developed.

The operational rules for dealing with the hydrogeologic risks of losing stored water were not developed. However, this was a significant issue that would have needed to be thoroughly addressed, both technically and institutionally, before the project could have been implemented.

As stated in the Phase 1 Report, landowners in the area were concerned about the location of the put and take conveyance features and the acquisition process for rights-of-way. They were especially concerned about the potential for parcels being split by infrastructure and land takes.[181] This issue was deferred to the Phase 2 Investigation. It was too early in the process to consider precise alignments and design of the conveyance features.

Potential crop damage associated with manipulating groundwater levels was a major concern of adjacent landowners, especially those with crops that are sensitive to high groundwater levels. This is an issue that would require significant study and the development of operational rules to avoid potential problems.

Summary of Issues

News articles and interviews with participants identify the lack of early stakeholder involvement and a clear public participation process, failure to incorporate the critiques of other federal agencies into the public process, the lack of sufficient technical analyses, the issue of local control, and the landowner-imposed deadline for USBR action as the key factors in galvanizing local opposition to the Perrett/USBR Madera Ranch Groundwater Banking Project.

Public and Stakeholder Involvement

The Madera Ranch Groundwater Banking Project chronology above indicates that the USBR took a logical approach to responding to the landowner's proposal by performing a preliminary analysis for potential fatal flaws. This step provided the Bureau with an indication of whether or not the project concept was worth pursuing further. The Phase 1 Investigation and Report were the next logical "due diligence" steps for the USBR.

The Phase 1 Report states that it is the USBR's policy to include public participation in decision processes that lead to federal actions, and it outlines a basic public involvement plan that includes identifying USBR and stakeholder roles, defining decision processes, holding briefing events, issuing a call for project partners and producing project status reports.[182] This process appears to comply with the USBR's Directives and Standards for public involvement in Reclamation activities.[183] If this is correct, then why is public/stakeholder involvement identified as a significant problem for the Madera Ranch Groundwater Banking Project?

As one commentator has noted: "a public interaction program, or the lack thereof, is often the sole or major reason for the failure to implement a water program."[184] Establishing and maintaining early, continuous—and most importantly, two-way—communications between the public, stakeholders and the water agency, preferably starting on "Day 1" of the project, is an essential element for building consensus and a successful program.[185,186] Based on comments by the local stakeholders that they would have preferred that USBR had consulted with them about the project at the conceptual stage, it appears that defining and communicating with potential stakeholders during the preliminary evaluation period would have been helpful to the overall process.

Keeping the process open and transparent by keeping all information "on the table" to the extent possible (outside of privileged negotiations) is another important element for gaining public trust and for effective communications. This appears to have been a problem for the Madera Ranch Groundwater Banking Project, based on the documented concerns of other federal agencies obtained through the Freedom of Information Act request by stakeholders.

Technical Analyses

The technical analyses of the Madera Ranch Groundwater Banking Project performed by USBR were preliminary in nature and designed to assist the agency in making decisions regarding the feasibility of the project. The Phase 2 Investigation would have addressed several outstanding technical issues, including the significant questions of compatibility of surface water from the Mendota Pool with native groundwater and the response of the aquifer under project operations. The major criticism of the preliminary and Phase 1 technical studies is that they were not sufficient to support the decision to commit public funds to the project.

It appears that the landowner-imposed deadline for USBR to commit to the project or acquire the project site may have contributed to the impetus to move ahead without the benefit of further technical studies.

Issues of Local Control

Many irrigation districts in the central, southern and eastern parts of the San Joaquin Valley have established effective conjunctive use programs in which water from wet years is stored in underground aquifers for dry year use.[187] Conjunctive use programs are widely viewed as an effective means for extending water storage in California, and Madera County stakeholders have stated that they support groundwater banking.[188,189] This poses the question of why the Madera Ranch Groundwater Banking Project met with significant local opposition.

In addition to the issues of insufficient public and stakeholder involvement and the need for more technical studies, the issue of local control, or the lack of local control, appears to be a major factor in the opposition to the Madera Ranch Groundwater Banking Project. The issue of local control can be exacerbated by the California water rights system. California's system of water rights does not require filing and licensing or quantification to establish rights to groundwater. A user only needs to begin use by drilling a well and making sure that the groundwater use is continuous.[190] Therefore, the concept of connecting the local groundwater basin to the rest of the California water system through extraction wells and a canal greatly enhances the fears of local stakeholders that local control could be taken away in the future. This, combined with the question of monitoring the quantities of banked water, makes it evident that a new, major non-local user of groundwater (in this case, USBR) would be viewed with suspicion, especially if that user were proposing a major extraction well field. Finally, no local benefits were identified by the project proponents, giving local stakeholders no incentives to support the project. Based on this situation, it can also be assumed that local interests would view local groundwater projects, controlled by local district boards and providing benefits to the community, more favorably.

In March 1999, a groundwater export and banking ordinance was passed in Madera County, along with a resolution opposing the Madera Ranch Groundwater Banking Project. This ordinance put in effect a permitting process for any groundwater project within the county and states that no groundwater extracted in the county can be exported without a permit. The groundwater exportation and banking ordinance was a direct response to the proposed Madera Ranch Groundwater Banking Project.[191] Also, Madera County officially appointed a Groundwater Oversight Committee in this time period.

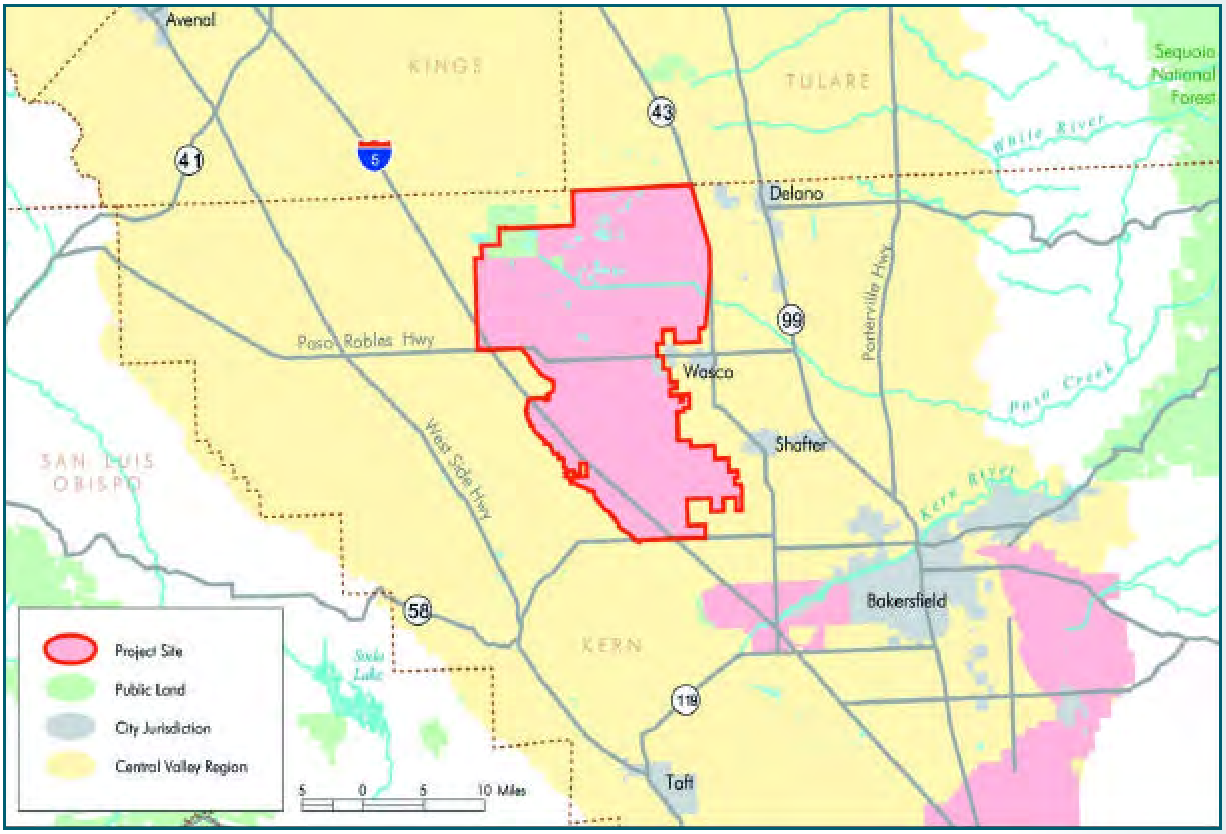
The concern over local control might have been effectively addressed through a public involvement process that established institutional and operational mechanisms to ensure local input and a measure of local control. As an example, an agreement could have been negotiated with Madera County to establish a stakeholder monitoring committee and set up enforceable operational rules for the project. This, coupled with an agreed-upon obligation to provide a quantity of banked water to alleviate conditions of overdraft, might have aided local support of the project proposal.

THE IMPORTANCE OF LOCAL SITE-SPECIFIC KNOWLEDGE

The subject of local site-specific knowledge is closely aligned with the issue of local control. Recent water policy research points out the need to integrate local site-specific knowledge with more generalized scientific understanding of hydrology in order to successfully address what one commentator called the "wicked water problems."[192] The assistance of people who work with and know the important site-specific factors that can impact a project must be effectively utilized when reviewing a project proposal. This need is clearly highlighted by the Madera Ranch Case.

In the Madera County setting, local farmers and water users with years of experience in using area groundwater and surface water are an excellent resource for evaluating the potential for a successful groundwater banking project. As cited in the section on local control, it is essential to involve these local experts in the initial project evaluation. It is recommended that local water organizations, in this case the irrigation districts, be used as a resource for engaging water users. These organizations often play a similar role interfacing between citizens, water users, and State and Federal agencies.

SEMITROPIC WATER STORAGE DISTRICT CONJUNCTIVE USE PROGRAMS



Introduction

This case study outlines the conjunctive use programs of the Semitropic Water Storage District.

Physical Characteristics

SETTING

Semitropic Water Storage District (Semitropic) contains 221,000 acres in the northern part of Kern County. Semitropic is surrounded on all sides by other water and irrigation districts including Lost Hills Water District, Buena Vista Water Storage District, Rosedale-Rio Bravo Water Storage District, Shafter-Wasco Irrigation District, North-Kern Water Storage District and the Southern San Joaquin Municipal Utility District.

HYDROLOGY

Semitropic is a primarily agricultural district that was originally developed with groundwater. The district has over 1,200 private wells. Continued use of these wells has caused significant overdraft in the basin underlying the district. To help alleviate this overdraft, the district started receiving surface water supplies in 1973 from the State Water Project. From 1973 to 1998 the district imported a total of 3,952,000 acre-feet of water. Other than its 155,000 acre-feet of State Water Project (SWP) entitlement (contracted through Kern County Water Agency) the district has no other significant surface water source. Rainfall is the district is also meager, averaging less than four inches per year.[193,194]

Of Semitropic's 221,000 acres, about 142,553 were irrigated before the district's groundwater banking program began. The "firm" contract surface water service area in the district compris-

es 42,343.65 acres and the groundwater service area in the district comprises 70,828.51 acres. An additional 29,381.99 acres has received temporary contract surface water service.[195]
Semitropic's total irrigation water demand exceeds 480,000 acre-feet per year, an amount greater than the district's SWP entitlement and other surface water supplies. Thus, the district still relies heavily on groundwater and the basin underlying the district is still in overdraft. In times of drought and/or minimal deliveries under its SWP contract (such as 1987–1992), the overdraft conditions in the district are severe and groundwater levels drop rapidly.[196,197,198]

Semitropic's Groundwater Banking Program began as a means of addressing several challenges that the district was facing in the late 1980s including an increasing groundwater overdraft, rising energy and water costs, and increasing unreliability of SWP contract water deliveries. The district sought a banking partner who was willing to finance such a program, with the goal that the additional money and facilities of the program would allow Semitropic to increase its own ability to take surplus waters when available, increase groundwater levels in the district, correct overdraft and reduce water costs to district landowners.[199]

Project History

Negotiations for Semitropic's banking program started in 1986 with Metropolitan Water District of Southern California (MWD). The Semitropic Groundwater Banking Program began as a Demonstration Project between the Department of Water Resources and the District. In 1990, the district and DWR entered into a contract, and DWR delivered 92,000 acre-feet of SWP water to Semitropic for underground storage via *in lieu* deliveries. The contract provided that the water would be returned to DWR via an exchange of the district's SWP entitlement wherein the district's landowners who would normally receive this SWP water would utilize groundwater substitution.[200]

In 1991, DWR wanted to recover its banked water by exchange of the district's SWP entitlement. Due to a very dry year and Delta pumping restrictions, no SWP water was available to the district that year, making the exchange impossible. These circumstances showed the District and others that a more successful groundwater banking program would include facilities to allow the district to directly deliver stored water back to the California Aqueduct, rather than having to rely on an exchange.[201,202]

MWD had been watching the DWR demonstration project in Semitropic with great interest and had been discussing a similar project with the district. However, in order for the project to be worthwhile from MWD's perspective, it had to include a pumpback component. While landowners in the district were originally apprehensive about this idea,[203] MWD and Semitropic started serious discussions and entered into a final banking agreement in 1994. Four additional Banking Partners have also contracted with Semitropic to participate in the banking program: Alameda County Water District, Zone 7 Water Agency, Vidler Water Company and Santa Clara Valley Water Agency.[204,205,206]

The basic concept of Semitropic's Groundwater Banking Program is that Banking Partners can purchase a proportionate share of the available space in the aquifer underlying the district by paying the district and delivering water to the district for storage. Banking Partners also pay to establish rights to use a proportionate share of the new facilities constructed to "put" water in storage and "take" it out at a later date.[207]

Engineering studies estimate that the basin beneath the district has at least 2,000,000 acre-feet of storage space.[208,209] To date, 1,000,000 acre-feet of space has been allocated between Semitropic's Banking Partners as follows: Metropolitan Water District of Southern California (MWD) 350,000 acre-feet; Santa Clara Valley Water District (SCVWD) 350,000 acre-feet; Vidler Water Company, Inc. 185,000 acre-feet; Zone 7 Water Agency 65,000 acre-feet; and Alameda County Water District 50,000 acre-feet.[210,211] These Partners have also allocated among themselves through contract the 91,000 to 315,000 acre-feet/year "put" capacity of the Program, the 90,000 acre-feet/year maximum pumpback capacity of the Program and the zero to 133,000 acre-feet/year maximum SWP Entitlement Exchange capabilities (for a total maximum "take" capacity of 233,000 acre-feet) of the Program. The source of water for the banking program consists primarily of SWP contract supplies of the Banking Partners.[212,213]

The percolation rates in the district are not high. Thus, water is banked via *in lieu* delivery arrangements with individual landowners. Banking Partners have financed the additional facilities necessary to expand this "put" capacity through fees paid when water is "put" in or "taken" out of the basin. The district has entered into individual contracts with landowners who receive *in lieu* water that specify how payment and operations will occur. Generally these contracts provide that the landowner will take *in lieu* surface water deliveries when made available from the district instead of pumping groundwater. These same agreements provide that the district may utilize the landowner's well (if it is not needed for irrigation of the landowner's property) to extract stored water for return to a Banking Partner, with full compensation.[214]

In 1999, the Banking Partners and Semitropic began studying an expansion of the original Semitropic Groundwater Banking Program that would increase the put and take capacity of the system so that full capacity of storage could be returned within a three-year period. This expansion plan was analyzed in a Draft and Final Supplement Environmental Impact Statement in 1999 and 2000 but has yet to be implemented.[215,216,217]

Institutional Arrangements

No new institutions were created to implement Semitropic's water banking program. Rather, the program operates through contractual arrangements between the banking partners, with surrounding landowners and with necessary agencies. These agreements are explained in detail below.

Financial Characteristics

Semitropic's Groundwater Banking Program is designed so that the district is fully compensated for the costs of construction and operation of the program by its Banking Partners. The Banking Partners' payments to Semitropic include the following kinds of payments: when water is stored; when water is returned from storage; with respect to energy used to recover water from the basin and deliver it to the Aqueduct; and for operation and maintenance expenses. The total cost to Banking Partners to store their supplies is approximately $175.00 per acre-foot (in 1994 dollars). Semitropic has structured the payments for Banking Partners so that there is an incentive to make larger payments upfront in order to achieve a permanent allocation of capacity in the system. These options are outlined in Table 4 on the following page.[218,219]

Table 4

*** All costs are in 1994 dollars, which began to escalate in 1995.*

	Option 1	Option 2	Option 3	Option 4	
Put	$110.00	$90.00			Per af in year water stored
Take	$20.00	$40.00	$10.00	$10.00	Per af plus actual power in year water is recovered
Annual O&M	$3.98	$3.98	$3.98	$3.98	Per af of vested storage capacity
Cycling Incentive	$20.00				Per af per year for water in storage longer than 5 years if capacity not vested
Capital Contribution			$12.40		Per af of storage capacity per year for the first 10 years
Capital Contribution				$120.60	Per af of storage capacity

Banking partners who use Option 1 have their capacity rights vested as water is put into storage. For those that use Option 2, storage and withdrawal capacity is specified at the outset and reserved during a ten-year vesting period. Only ten percent of total project capital is due within sixty days of signature. For those that want their storage and withdrawal capacity fixed at the outset, regardless of the amount of water stored in the initial years, Options 3 and 4 provide this benefit.[220]

The options outlined above apply to "first tier" water, or the amount of water required to establish capacity rights in the project. Recharge and withdrawal capacity rights are proportional to storage capacity rights. Once a banking partner has stored the amount of water represented by its specified storage capacity, any additional water put into storage is considered "second tier" and subject to a standard payment scheme.[221]

Interestingly, the banking agreements between Semitropic and its partners do not require that the district have the first right to use the new facilities constructed for the program. Rather, this first right is given to the Banking Partners for the duration of their banking agreements with the district. The district can use these facilities for its own operational flexibility, and to take surplus waters, when the facilities are not in use by the banking partners. The facilities will remain the property of the district.[222,223]

MWD advanced $1.35 million in early 1995 to Semitropic to begin design and construction of the banking facilities. In return, after the first five years of the Agreement, MWD is accorded a first priority to a certain storage capacity in the project. The "front-end" investment by MWD has been repaid through reductions in storage payments required under its banking agreement with the district.[224]

Issues and Risks

POLITICAL ISSUES

The district's President, Vido G. Fabbri, converted some of the landowners' original apprehension to a banking program with MWD into support through landowner meetings and a lot of "legwork". The district's General Manager, Will Boschman, was also instrumental in helping the district's board of directors and landowners visualize how the program would work. Before becoming the district's general manager, Mr. Boschman spent numerous years working for the Bookman-Edmonston engineering firm. The firm designed and constructed most of the water-related facilities in Kern County, including the recharge ponds and delivery system already in place in Arvin-Edison Water Storage District.[225]

In 1992, a temporary banking agreement was reached between MWD and Semitropic, which was converted into a long-term agreement in 1994. The agreement triggered CEQA, and an EIR was prepared in July of 1994. Surrounding landowners used the EIR process to address their concerns about potential third party impacts that a Semitropic Groundwater Storage Program might cause. Attorneys for Semitropic and the surrounding districts immediately started working together to resolve these concerns to gain the necessary support for the project. At the same time, districts adjacent to other new groundwater banking programs in Kern County were addressing the same concerns.[226,227,228]

Representatives of many of the affected parties had previously participated in a process to delineate the technical issues associated with the Kern Water Bank's groundwater monitoring program.[229] This process resulted in recommendations on rules to be incorporated in a Memorandum of Understanding between the project participants of the Kern Water Bank Authority and the Adjoining Entities, entered into in October of 1995, and for the MOU between Semitropic Water Storage District and the Adjoining Entities on September 14, 1994 (MOU).[230]

When the district and its Banking Partners proposed the expansion of the put and take capacity of the program in 1999, surrounding landowners again expressed their concerns through the Supplemental EIR process. Semitropic addressed these concerns by completing additional studies and maps as requested by the surrounding districts and by adding additional elements to its Mitigation Monitoring Plan as part of the Final Supplement EIR completed in January 2000.[231,232,233]

HYDROLOGICAL CONCERNS

The MOU for the Semitropic Groundwater Banking Project focused primarily on the hydrological concerns of surrounding landowners. The landowners were concerned about the following issues:

- Banked water would have recharge, evaporation and migration losses that needed to be accounted for to avoid withdrawal of more water than was actually banked.
- Groundwater migration could cause adverse impacts on groundwater quality or make it impossible to recover stored water, creating the risk that recovery of banked water would increase the pump lift for surrounding landowners.
- The placement and number of the extraction wells had to be planned so that the cone of depression around these wells would not adversely affect surrounding landowners dependent on groundwater.
- The program had to be closely monitored to prevent obstruction of natural recharge to the basin or an increase in basin overdraft.[234]

With these concerns in mind, Semitropic and the surrounding landowner districts hired Kenneth D. Schmidt, a groundwater quality consultant, to prepare a monitoring plan and detailed maps of "Well Location, Water Quality Network" and "Well Location, Water Level Network" that could be used as benchmarks for the monitoring program. In the meantime, the attorneys for the district worked on drafting the MOU. The primary elements of the MOU include the following:

- The MOU is based on the maximum project design as of 1994. Major changes or additions to this design are subject to additional environmental review.
- A monitoring committee, consisting of representatives from Semitropic and each of the surrounding districts and one ex officio non-voting representative of each of the Banking Partners, was created.
- A monitoring well network was established that would be modified as needed based on the committee's recommendations. Semitropic bore the cost of the installation of the original monitoring wells.
- Other costs of the monitoring program are borne 50% by Semitropic and 50% by the adjoining districts.
- "Fifteen-Foot/Three-Year Rule:" Semitropic will not make groundwater withdrawals that cause the average groundwater levels in an area to decline more than fifteen feet over a three-year period compared to the average groundwater levels that would have occurred without the project.
- If Project pumping causes well interference, Semitropic must stop pumping or compensate for the interference. The Monitoring Committee must establish criteria to determine if well interference is due to Project pumping.
- The MOU provides a dispute resolution procedure via the Monitoring Committee. If this procedure is not successful, any party may still pursue any remedy for injunctive relief or damages, with one exception. If all parties to the dispute agree that a factual dispute exists regarding any recommendation of the Monitoring Committee, the dispute shall be submitted to binding arbitration before a registered civil engineer with a background in groundwater hydrology. The MOU specifically states that nothing in the agreement prevents any landowners within the boundaries of any party from pursuing any legal remedy in the event the landowner is damaged as a result of the project.

Interestingly, the Semitropic MOU was the first finalized in Kern County between a banking district and surrounding districts. The Semitropic MOU was used as a model for the first draft of the more comprehensive MOU developed in 1995 for the Kern Water Bank, on direction by the Kern Water Bank Authority, and later to other Kern River Fan Projects.[235]

In addition to the MOU, The Final EIR approved by Semitropic and MWD under CEQA contains a Mitigation Monitoring Plan that addresses many of these same hydrological concerns and provides monitoring criteria for the project. The banking agreements between Semitropic and each Banking Partner also contain criteria to address hydrological concerns such as:

- Evaporation, migration and other losses for banked water are collectively assumed to be 10% of the amount of water furnished for storage. This loss percentage may be increased or decreased with evidence gained from monitoring.
- When water is returned via direct pumpback, it must be returned during Semitropic's off-peak irrigation season.
- Semitropic will seriously consider reducing or terminating groundwater pumping to return stored water to a Banking Partner if required by the MOU.[236,237]

To date, the Monitoring Committee has not had to resolve any disputes and no one has brought suit under the MOU or the Mitigation Monitoring Plans for either the original or Supplement EIRs for the project.[238,239]

ENVIRONMENTAL CONCERNS

From an environmental standpoint, implementation of Semitropic's Groundwater Banking Program has been relatively easy. The program does not utilize any natural stream systems or involve use of a significant amount of critical habitat. Environmental impacts identified in the 1994 EIR were mitigated pursuant to the Mitigation Monitoring Plan that was part of the Final EIR. In addition, the district was able to certify a Negative Declaration in May of 1996 that addressed the additional environmental impacts relating to the program that were not addressed in the 1994 EIR.[240] The district did not have to comply with NEPA because no federal agency approval is required to implement the program.[241]

WATER QUALITY ISSUES

The groundwater that is extracted for Banking Partners is delivered to them via the California Aqueduct. This required that Semitropic enter into an agreement with DWR for "Introduction of Local Water into the California Aqueduct." This agreement imposes strict quality criteria on the water that is introduced into the Aqueduct.[242] To date, the water withdrawn from Semitropic has met these criteria. If the criteria become more stringent, the water may have to be treated before it is pumped into the Aqueduct or returned via an exchange instead.[243] Any additional costs imposed due a change in water quality standards for the California Aqueduct must be borne by the Banking Partners pursuant to the Agreements between Semitropic and each Partner.[244,245]

Groundwater quality was one of the concerns addressed by surrounding landowners at the inception of Semitropic's program. To date, the program appears to have actually prevented the migration of lesser quality groundwater from west to east.[246]

Conclusions

To date, Semitropic's Banking Partners have stored over 675,000 acre-feet of water in the district. However, the only water recovered under Semitropic's program has been by DWR in 1992 and 1997.[247] Thus, the withdrawal capabilities of the program—and its potential third-party impacts—have yet to be tested.

From a financial perspective, however, the program has been very successful for Semitropic. The program will allow the district to finance $134 million worth of new facilities to increase its own operational flexibility. To date, over $70 million in new facilities have been constructed. In addition, revenue generated from Semitropic's banking program has, in part, allowed the district to reduce water charges to its landowners from almost $60 per acre-feet in 1995 to less than $50 per acre-feet in 1998. Pump lifts in the district have also decreased since the inception of the program by about 33 feet, representing additional savings in energy costs for landowners who utilize groundwater wells.[248]

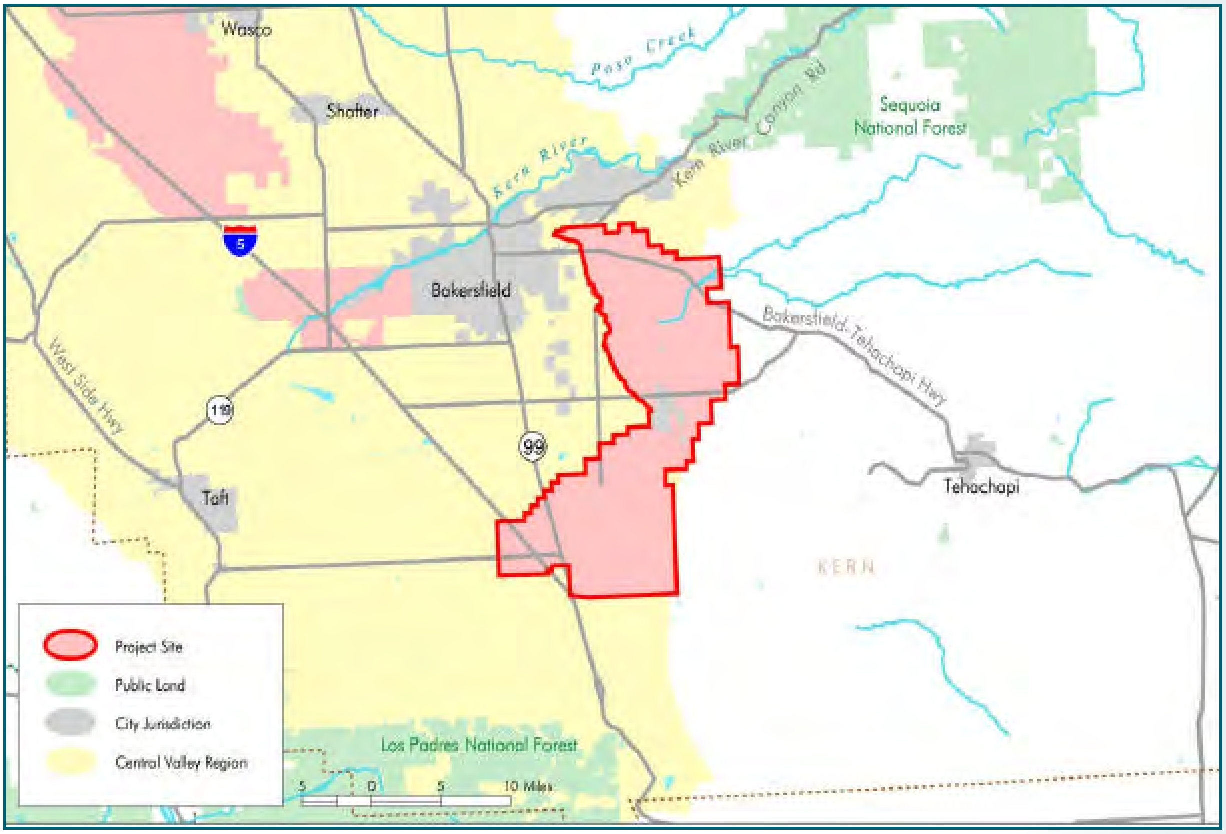
To date, the Semitropic Groundwater Banking Program has been successful due to the following factors:

- The program is not anticipated to affect the hydrogeologic conditions of a significant number of surrounding landowners.
- The landowners in Semitropic and surrounding districts that could be affected by

the program were generally cooperative in working with the district to resolve their concerns via a monitoring agreement and committee.

- The program was environmentally easy to implement.
- The district itself is a landowner-voting district where the larger landowners in the district are either represented on the board or trust those landowners who are board members. The banking Project was approved by a 97% favorable landowner election in November of 1991.
- The landowners in the district all have a common interest, as the district is primarily agricultural.
- The district has been in charge of the project since its inception and controls the operations in a manner that makes the landowners within and adjoining the district comfortable.
- Semitropic's Banking Partners have made the project essentially cost and risk free for Semitropic, while providing the district with numerous benefits and facilities.
- The district's general manager and president understood and supported the program and did a good job of explaining it to the members of the district and surrounding landowners.

ARVIN-EDISON WATER STORAGE DISTRICT CONJUNCTIVE USE PROGRAMS



Physical Characteristics

SETTING

Arvin-Edison Water Storage District (Arvin) consists of 132,000 acres in the southeastern corner of the San Joaquin Valley, entirely within Kern County. Arvin is bordered by the foothills of the Sierra Nevada on the east and the Tehachapi Mountains on the southeast. Farming began in the area now included in the district in the early 1900s. Today, the district is known for its high quality soils and high value crops such as grapes, citrus, potatoes, carrots, cotton, orchard fruit and truck crops.[249] The area is almost entirely agricultural, with only small areas of urban development.

HYDROLOGY

No significant streams or rivers are located within the district and the region receives only 8.3 inches of rain in an average year. Historically, farmers in Arvin relied primarily on groundwater to cultivate the region. Evidence of groundwater overdraft appeared as early as the 1930s. Prior to the importation of surface water to the area, depth to groundwater exceeded 600 feet in some areas of the district. In addition, the receding water table had induced the subsurface movement of water with high boron concentrations from the east into the aquifers underlying the district.

The district's groundwater basin can be divided into three distinct areas—a large central area and two smaller areas to the northeast and southeast. Two faults running through the district affect the movement of groundwater and create the three areas. However, in practice, the district is regarded as one groundwater management area.[250]

Project History

In 1942, the Arvin-Edison Water Storage District was formed to obtain a supplemental surface water supply in order to alleviate groundwater overdraft. The district secured Federal water contracts from the Central Valley Project (CVP) in the 1960s. In the meantime, agricultural operations expanded in the district, with approximately 100,000 acres in irrigated agriculture by the mid-1960s.

In 1966, the district began importing surface water from the Friant-Kern Canal under its CVP contract. A federal loan enabled the district to construct the Arvin-Edison Canal (which conveys water from the terminus of the Friant-Kern Canal into the district), 1,000 acres of spreading works, and 55 recovery wells. Thus, the district was able to store surface water underground via recharge ponds or by delivering surface water to landowners in lieu of their customary use of groundwater. To achieve economies of scale with the infrastructure, the district concentrated its surface water delivery facilities to serve 52,000 acres of the district with the poorest quality groundwater at the greatest depths. Thus, much of the district (about 80,000 acres) is still totally dependent on groundwater but has benefited from the district's programs in the form of reduced depth to groundwater (and associated reductions in pumping costs) and higher quality groundwater.[251]

The district's CVP contract includes 40,000 acre-feet of Class 1 priority water and 311,675 acre-feet of Class 2 priority water.[252] However, water deliveries under the contract are highly variable. Average demand for surface water in the district (exclusive of demand for groundwater) is 160,000 acre-feet. Deliveries under the contract have ranged from a low of 10,000 acre-feet in 1977 to a high of 351,675 acre-feet in 1978.[253,254]

The district has attempted to realize maximum benefit from its highly variable surface water supply, in part, through its conjunctive use system. The district deep percolates supply in excess of coincident irrigation demand when it can. The district has banked over 1.5 million acre-feet in this manner since 1966. The results are evident: in the 1950s, average overdraft in the district was 200,000 acre-feet per year; today overdraft averages only 5,000 to 10,000 acre-feet per year.[255,256,257]

Beginning in the 1970s, the district entered into exchange programs with other CVP contractors on the Friant-Kern Canal in an effort to further regulate its surface water supply. Through an exchange agreement, six exchange agencies located along the Friant-Kern Canal on the east side of the San Joaquin Valley receive up to 70,984 acre-feet per year of the district's highly variable Class 1 Friant water. In exchange, the district receives up to 66,096 acre-feet of non-Friant CVP water from the California Aqueduct (west of the district) on an irrigation demand schedule. The water that Arvin receives via this exchange is available almost every year, as opposed to the district's much less reliable Class 1 Friant water. Delivery of water to the district via the California Aqueduct is made possible by the Cross Valley Canal, which connects the Arvin-Edison Canal to the Aqueduct.[258,259]

In the mid-1980s, the district sought financing for additional water banking facilities that would allow further regulation of its erratic surface water supply and increased water availability to district landowners. These additional facilities would allow Arvin to take more of its Class 2 CVP water, when available, and store the supply in the underground aquifer for subsequent recovery during high demand/low supply periods. Thus, the district sought a partner that would provide financial assistance for these additional facilities in exchange for temporary storage of water in the groundwater basin underlying the district. By the late 1980s, a tentative agreement had been reached with Metropolitan Water District of Southern California (MWD). Although that initial agreement was never implemented, the concept resurfaced again in 1995, and a final agreement for a Water Management Program between Arvin and MWD was signed in 1997.[260,261]

In this original proposal, the Arvin/MWD program required approval by the United States Bureau of Reclamation (USBR) for the transfer/exchange of the Delta-CVP water to MWD; by the California Department of Water Resources (DWR) for use of the California Aqueduct to wheel CVP water to MWD under MWD's SWP contract and by the State Water Resources Control Board (SWRCB) for amendment to USBR's Delta-CVP water rights permits to include portions of MWD's service area as a permitted place of use and for changed points of diversion. Originally, the CVP Water Users Association opposed the concept of amending the Delta-CVP water rights permits. However, Arvin and MWD were able to resolve issues through negotiation with other Delta-CVP users and by agreeing to seek a very limited permit amendment that would facilitate only the proposed project.[262,263]

Federal and State approvals required environmental compliance pursuant to the California Environmental Quality Act (CEQA) and National Environmental Policy Act (NEPA), and a joint EIR/EIS was prepared in 1992. Public and agency comments on the Draft EIR/EIS reflected concerns that the project would result in increased deliveries from the delta that would damage the estuary and adversely affect fisheries. Pumping restrictions in place at the time rendered delta deliveries to the west side of the valley extremely unreliable. Because of the increasing uncertainty of delta deliveries, MWD determined that it was only interested in pursuing a banking program that included the option of direct pumpback of banked water. Thus, the program as planned was abandoned for the time being, and the SWRCB change petition that would have amended the Delta-CVP water right permits was never filed.[264]

After shelving the original banking program concept with Arvin, MWD negotiated and entered into a banking agreement with Semitropic Water Storage District that included a direct pumpback component. The Semitropic/MWD program addressed the concerns of neighboring landowners through an agreement that placed operational criteria on the project to limit third party impacts and required a formal groundwater monitoring committee.[265]

In light of the success of the Semitropic/MWD project, Arvin and MWD reinitiated discussions and developed a project that included a pumpback component. Under this arrangement, MWD would deliver its SWP water to Arvin for subsurface storage. At some future date, Arvin would recover the water and deliver it to MWD via a new 4.5-mile pipeline intertie between the Arvin-Edison Canal and the California Aqueduct.[266]

Under the twenty-five year agreement with MWD, substantial new groundwater banking facilities were constructed in the district including 500 additional acres of spreading ponds, 15 new groundwater wells, and a 4.5-mile bi-directional intertie pipeline connecting the terminus of the district's canal with the California Aqueduct. Facilities are expected to cost approximately $25 million. It is anticipated that MWD will store a minimum of 250,000 acre-feet of water in Arvin within the first seven years. Maximum storage levels over the life of the program are not specified, but MWD cannot store more than 350,000 acre-feet of water in the district at any one time without amendment of the agreement by both parties. The new spreading grounds constructed for the project have the capacity to recharge 45,000 acre-feet per year. The recovery capacity of the project ranges from 40,000 to 75,000 acre-feet per year.[267,268] To date, MWD has banked water in the district but has not yet withdrawn water from the district.[269,270] The agreement characterizes Arvin as holding MWD's water in "trust" while the water is stored in the district.[271]

The restructuring of the project obviated the need for USBR to approve the transfer, as Arvin's CVP water was no longer involved. Without USBR involvement, NEPA compliance was not required, and the project had only to comply with CEQA. After the Monterey Agreement, the water rights held by the State of California for the State Water Project allowed off-stream storage. Thus, the proposed project was already an approved use under project partners' SWP contracts and only required ministerial approval by DWR for changes in points of diversion. The parties adopted a Mitigated Negative Declaration in July of 1996, and the project was approved without substantial public or agency controversy. The agreement between Arvin and MWD for a Water Management Program was signed December 19, 1997.[272,273]

Currently, source water for the banking program includes only MWD water from its SWP contract and other sources. However, the Arvin/MWD agreement also contemplates acquisition and banking of 150,000 acre-feet (over twenty five years) of Friant flood flows as an additional source of water for MWD.[274] This aspect of the Arvin/MWD program was sought by MWD as an incentive to invest the many millions needed to construct the additional conjunctive use facilities in Arvin. It was also the most controversial part of the program.[275]

Friant flood flows are currently available to all Friant contractors. However, because they are available in times of very low demand and most districts do not have the facilities to capture and store the water, flood flows are not often utilized. The Arvin/MWD Agreement provides for flood flow purchase by Arvin for storage and transfer to MWD.[276] Theoretically, this transfer would have required that the Friant CVP water right permits be amended to add portions of MWD to the permitted service area. Other Friant water users and districts adamantly opposed the idea of expanding the permitted place of use to include MWD, fearing that MWD's domestic water uses would take priority over the needs of east side farms in times of shortage in the Friant system.[277]

This opposition led to negotiations between the Friant Water Users Authority, the Central Valley Water Coalition, MWD and Arvin.[278,279] The result of these negotiations was a Principals Agreement between the four groups that allows MWD to capture 150,000 acre-feet of additional water supply without the need to amend the Friant CVP permits. The Principals Agreement allows Arvin to purchase flood flows in the form of "Conservation Credits." Arvin can transfer these flood flows to Kern County Water Agency (KCWA) in exchange for a like amount of KCWA's SWP water which, in turn, can be sold to MWD and stored in Arvin's underground aquifer. MWD can request return of its stored water and the SWP water would be pumped back to MWD via the California Aqueduct.[280]

The concerns of the Friant Water Users and Central Valley Water Coalition were addressed by imposing specific operational criteria on when "Conservation Credits" may accrue and when water may subsequently be delivered to MWD. Under the Principals Agreement, Conservation Credits accrue to the extent that Arvin's new water banking facilities can conserve additional water supplies at times and under conditions that do not adversely affect other Friant Water Users. Thus, if Arvin shows that its new facilities can conserve up to 45,000 acre-feet of water per year, Arvin accrues 45,000 acre-feet of Conservation Credits and may transfer up to 45,000 acre-feet of non-CVP water to MWD.[281]

The Principals Agreement also explains that Conservation Credits can only be accrued if the following conditions are met:

- Water is being released from Friant Dam for flood control and can be diverted without unreasonably affecting downstream water quality requirements;
- Capacity exists in the Friant-Kern Canal, above all other demands for water delivery which will be used in the San Joaquin Valley, to deliver the water to Arvin; and
- The new water banking facilities in Arvin are recharging water.[282]

The Principals Agreement also requires that no land be fallowed for the purpose of transferring water outside of the San Joaquin Valley. These requirements provide protection to other Friant water users.[283]

The agreement expressly prohibits Arvin from delivering CVP water directly to MWD, which would have necessitated adding MWD as a place of use under the CVP water right permits. Thus, to put this component of the program into place, the additional exchange described above is required. MWD has also agreed that it will not pursue any future program involving Friant Division contract supplies that is inconsistent with the Principals Agreement without the prior written approval of the Friant Water Users Authority.[284]

Although Arvin and MWD made great strides in negotiating a solution to the opposition of the Friant Water Users Authority to this portion of their banking program, it is still not operational. This component of the program has been stalled by the USBR's interpretation that the contemplated transaction involving the conservation credits and subsequent transfer of non-CVP water to MWD would require the $25 per acre-foot M&I surcharge provisions of the CVPIA.[285] The negotiated Principals Agreement conditions the transfer to MWD on USBR approval of the long-term exchange/transfer, and on the exchange/transfer not being subject to the CVPIA. To date, USBR has stated that the transfer is subject to the CVPIA (notwithstanding that CVP water would be delivered to KCWA, which is not a CVPIA transfer), and that the $25 per acre-foot surcharge would apply. Because of this additional cost, the parties have not yet pursued this component of the project.[286]

Arvin intends to expand its banking program to third parties in the future, but no final agreements have been reached to date.[287] The MWD/Arvin Agreement contemplates such program expansion, however, and grants MWD certain rights of priority to banking and conveyance capacity in the new facilities.[288]

Institutional Arrangements

No new institutions have been formed to implement Arvin's banking program with MWD. Rather, the districts have formed the program through contractual arrangements between the districts themselves and between the districts and the Department of Water Resources. Negotiated principles with local interest groups have been used to overcome initial apprehension about controversial aspects of the program. For example, the contract between MWD and Arvin incorporates the Principles of Agreement between the district, MWD, the Friant Water Users Authority and the Central Valley Water Coalition. The contract between MWD and the district also requires certain monitoring activities and rules that are designed to protect local groundwater users.

Financial Characteristics

As noted above, the district's original facilities were constructed with a federal loan, which has since been repaid. The Arvin/MWD agreement provides that the $25 million to construct the facilities for the project will come from fees charged by Arvin to MWD for banking its water. Arvin will also recoup all of its costs through operation and maintenance fees, energy cost fees and conveyance facility use fees. The bottom line cost to MWD is about $250 per acre-foot.[289,290]

To finance construction of the necessary facilities, MWD advanced the district $12 million in fees. To recoup this investment, MWD will pay proportionately reduced rates per acre-foot when it stores and extracts water—in effect creating a $12 million interest-free loan from MWD to Arvin.[291,292]

Arvin is further protected financially because the agreement with MWD requires a minimum of 277,778 acre-feet of water to be stored by MWD in the district within seven years. This minimum level is tied to the estimated cost of facilities to be constructed so that the fees paid at this level will generate sufficient funds to pay for the cost of the necessary facilities. The Agreement contemplates that additional water may be stored by MWD, up to 350,000 acre-feet at any one time, upon mutual agreement of the parties. The parties may also amend the agreement to exceed this limit.[293,294]

Arvin's cash flow position in constructing the project is further protected in that MWD has agreed to advance additional funds to Arvin under certain conditions. Specifically, if at any time Arvin has expended $3 million more in constructing the necessary facilities than it has earned in water management fees, MWD will advance additional funds so that Arvin is never more than $3 million "upside down."[295,296,297]

The facilities constructed for the project are owned and operated by Arvin and allow the district the benefit of being able to increase its dry year supplies, expand its surface water delivery capabilities to additional acreage and increase its overall operational flexibility. Notably, the additional facilities that Arvin will own as a result of its banking program with MWD will allow the district to conserve about 8,000 to 10,000 acre-feet of its own contract entitlement per year. However, at an estimated cost of $25 million, it never would have been cost effective for Arvin to build these same facilities without the financing of a banking partner such as MWD.[298] MWD's use of the facilities will always be subject to Arvin's superior right to use the facilities for its own benefit. However, MWD will have a first priority to use a certain capacity of the new facilities in front of other bankers that enter the program in the future.[299]

MWD is responsible for dealing with DWR to schedule deliveries of returned water from Arvin to MWD via the California Aqueduct. Thus, MWD must incur the costs of these arrangements and meet the water quality standards necessary to put the returned water into the aqueduct.[300]

The financial risk that the project will not succeed has been primarily placed on MWD. There are several reasons why it could become impossible for Arvin to return stored water to MWD, including changes in water quality or water quality standards or other reasons beyond its control. If this were to happen, Arvin could buy the water that MWD has stored. The purchase would be arranged so that Arvin would buy the water from MWD for an amount equal to the costs that Arvin would have incurred to purchase the same amount of water as Class 2 supplies from the Friant-Kern Canal, under its contract with USBR in the year that the water was delivered to storage by MWD.[301]

Issues and Risks

POLITICAL ISSUES

Arvin's local benefit program Political opposition to Arvin's internal conjunctive use program has been non-existent. Notably, Arvin is a district that was originally formed to conduct conjunctive use operations for the benefit of its own landowners. Thus, the concept of conjunctive use and/or groundwater banking was never new or foreign to landowners in the district. Rather, those landowners surrounding the district's original spreading ponds and collection wells historically have experienced fluctuating pump lifts due to the district's operations.[302,303] Political opposition to Arvin's new banking program with MWD has come primarily from outside of the district and has not prevented implementation of the program.[304,305,306]

When MWD and Arvin first began negotiating a banking program in the 1980s, the district's consultants, attorneys and board members anticipated political opposition to any program that included pumping groundwater from the valley and conveying it to MWD.[307,308] Therefore, the program was structured so that MWD would receive its banked water only via exchanges on the California Aqueduct and never through a direct pumpback from the district. As originally envisioned, the proposal would have worked as follows:

- MWD would bank water in Arvin by delivering surplus water under its State Water Project (SWP) contract to Arvin for either direct recharge or delivery to farmers *in lieu* of groundwater pumping. MWD would accrue a like amount of groundwater credits.

- Recovery of banked water by MWD would involve transfer by Arvin of a portion of its Delta-CVP water received via the California Aqueduct (from the exchange agreement with the Cross Valley Contractors) to MWD. MWD would take delivery of water from the California Aqueduct that would otherwise be diverted at the Cross Valley Canal for use by Arvin. Farmers in Arvin would pump groundwater in place of the CVP surface water they would normally receive. MWD banking credits in Arvin would be reduced accordingly.[309,310,311]

HYDROLOGICAL CONCERNS

The concerns of adjoining landowners were addressed rather easily in the Arvin case. The only adjoining district affected at all by Arvin's manipulation of the groundwater table is Kern-Delta Water District, located to the west of Arvin. None of Arvin's recharge ponds or wells are located near the boundary with Kern-Delta, and thus groundwater levels in the neighboring district are not affected by Arvin's operations. However, there is a slight gradient of groundwater movement west to east from Kern-Delta to Arvin, with groundwater levels higher in Kern-Delta. Over the long term, it is conceivable that Kern Delta's water levels could be affected by a concentration of pump-back operations in Arvin over a multiple year period. To alleviate this concern, Arvin worked with Kern-Delta to adopt groundwater monitoring and operational criteria that became provisions of the contract with MWD. Although these criteria do not establish a contract between Kern-Delta and Arvin and/or MWD, they do set up project operating parameters that are acceptable to Kern-Delta and that protect landowners within Arvin.[312]

The contract between Arvin and MWD also provides the following protections for the basin:

- MWD may only request return of water to the extent that there is water in its account balance.

- A 10% loss is imposed on all water banked under the program; i.e., to recover 250,000 acre-feet of banked water, MWD must deliver 277,778 acre-feet to the district.

- Return of regulated water by the district to MWD must not interfere with deliveries to the district's contract users or other "normal and customary uses" by the district of its available supplies. Water will generally be returned to MWD "off-peak" and will not compete with Arvin's need for dry year water.

- Arvin will reduce or terminate groundwater pumping for purposes of returning water to MWD as necessary to comply with the groundwater monitoring program and operating criteria discussed above.[313]

ENVIRONMENTAL CONCERNS

As originally envisioned, some parties were concerned that the Arvin/MWD project would cause increased diversions from the delta at times that would injure fish or water quality.[314] Restructuring the project to include a pumpback rather than an exchange alleviated these concerns. Endangered species concerns were raised with regard to construction of the 500 new acres of spreading ponds and ancillary facilities necessary to operate the project, however, these concerns were addressed through mitigation or otherwise resolved through the CEQA process.[315] No natural stream systems were utilized as part of the project, and the isolation of the Arvin groundwater basin makes hydrologic interaction a minor issue.[316]

The groundwater produced in the district currently meets the state standards necessary for water to be pumped into the California Aqueduct for transport to MWD.[317] The agreement also requires that water delivered to Arvin by MWD for storage meet specific quality criteria.[318] The project has raised groundwater levels, which has reduced the migration of boron concentrations from the eastern hills surrounding the district.[319] Should any water quality problem arise, the Agreement puts the burden on MWD to solve the problem with DWR.[320]

Conclusions

The Arvin/MWD project has to date only operated to bank MWD's SWP water in Arvin. The recovery aspect of the project has yet to be tested. The other components of the project, including the use of Friant water and/or exchanges with CVP water, have also yet to be finalized because of outstanding cost issues associated with implication of the CVPIA.

To date, Arvin has not experienced any adverse third party impacts as a result of its own conjunctive use programs or as a result of banking water for MWD. This is so even though Arvin resorted to significant groundwater pumping for its own use during the late 1970s and early 1990s.[321]

Arvin's own conjunctive use program appears to have been extremely successful since its implementation in 1966 for the following reasons:

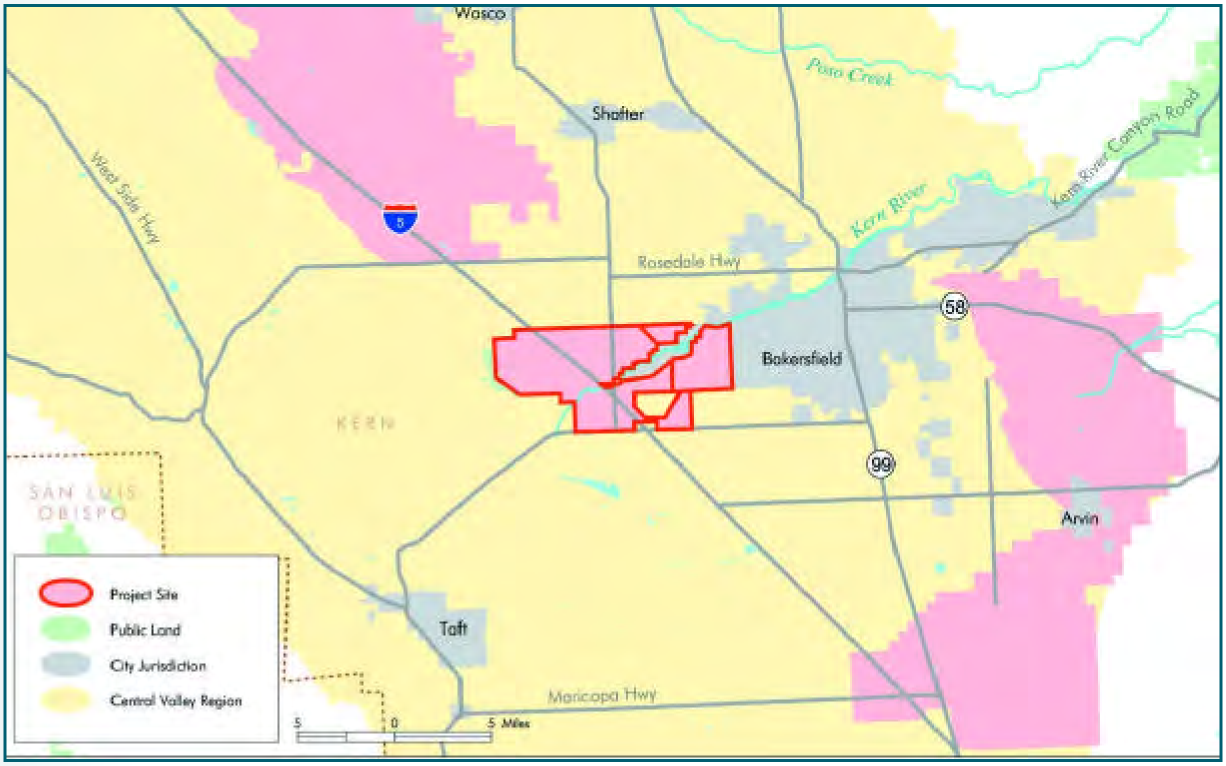
- Soils in the region are excellent for recharge ponds and have never had subsidence problems.
- Nearly half of all supplies banked in Arvin-Edison have remained to mitigate groundwater overdraft, and half has been extracted during critically dry periods.
- The program has had years of extreme pumping that greatly mitigated drought conditions without resulting in extreme impacts on pump lifts for surrounding landowners.
- The basin is relatively isolated geographically and does not interact specifically with surrounding basins or districts.

- History has shown that the program has resulted in a reduction in annual overdraft and much more plentiful and regulated supply of water for the landowners in the district.

Arvin’s project to bank water for MWD also appears to have been implemented in a rather painless fashion because of the following factors:

- The program will not hydrologically affect a significant number of surrounding landowners, if any.
- The landowners in the district are already familiar with conjunctive use and have seen it operate successfully in their district for almost fifty years.
- A board elected by the members governs the district whose votes are in proportion to their land holdings. Thus, the larger landowners in the district are either represented on the board or trust those landowners who are board members.
- The landowners in the district all have a common interest, as the district is primarily agricultural.
- The district has been in charge of the project since its inception and its control makes the landowners within and adjoining the district comfortable.
- USBR did not need to be involved in the project as currently approved.
- The project only had to comply with CEQA, not NEPA, and was able to be implemented with an Initial Study and Negative Declaration instead of an EIR or EIS.
- MWD was willing to make the project essentially cost and risk free for Arvin, while providing the district with numerous benefits.

KERN WATER BANK



Introduction

This case study reviews the Kern Water Bank (KWB) and provides an overview of the project development, interest group interactions, financing and performance. The KWB's objective is to enhance the water supplies of the southern San Joaquin Valley while providing exceptional upland and wetland habitat.[322] The beneficiaries include the KWB project participants, SWP contractors and Improvement District 4, which encompasses the City of Bakersfield located immediately east of the KWB site, the Rosedale-Rio Bravo Water Storage District immediately north of the site, and the Kern Delta WD to the south. The banked water is used primarily in agriculture.

Physical Characteristics

SETTING

The KWB is located on 19,883 acres of land in Kern County, California, at the extreme southern end of the San Joaquin Valley. The Kern River flows through the southeastern portion of the site from northeast to southwest. The KWB is on the lower part of the Kern River Fan.

The primary land use in the vicinity is agriculture. Approximately 835,000 acres of irrigated land exists in Kern County.[323,324] The SWP and the Friant-Kern Canal, linked by the locally-constructed Cross Valley Canal, serve the area. The City of Bakersfield is located to the east of the KWB site and is the major municipal water user in the area.

Approximately half of the 19,883 acres of the KWB project area has been set aside for habitat as part of the KWB Habitat Conservation Plan. More than forty species of birds have been sighted at the KWB, including the Caspian tern, white-faced ibis, and freshwater pelicans.[325] ESA listed species found on the KWB site include the San Joaquin kit fox (Vulpes macrotis mutica), Tipton's kangaroo rat (Dipodomys Tiptonsi), and blunt-nosed leopard lizard (Gambelia sila).[326]

HYDROLOGY

Groundwater pumping in the area serves agricultural and municipal uses. Median groundwater use for irrigation is 1.2 million acre-feet per year, while drought year use increases to 1.9 million acre-feet per year. In 1998–1999, the City of Bakersfield, with a population of over 210,000, used approximately 59,511 acre-feet of groundwater per year to meet its annual water demand of 73,500 acre-feet.[327] The balance of its demands are met by treated surface water supplied by Kern County Water Agency, KCWA.[328]

Bakersfield owns and operates a 2,800-acre groundwater recharge project that follows the path of the Kern River through the easternmost portion of the Kern Water Bank site. In addition, the Kern County Water Agency Pioneer Project recharge areas (North Pioneer, Central Pioneer and South Pioneer) are adjacent to the KWB on the east and northeast. Neighboring water districts include the Rosedale-Rio Bravo WSD immediately north of the KWB site and the Kern Delta Water District and Wheeler Ridge-Maricopa WSD located to the south of the site.

A unique combination of water supply, delivery infrastructure and geology place the KWB in an ideal location for water banking. The KWB can take advantage of water deliveries from three sources—the Kern River, the California Aqueduct (State Water Project), and the Friant-Kern Canal.[329] The Kern River and the California Aqueduct converge near the KWB, and the Kern River is the terminus of the Friant-Kern Canal, which is a facility of the federal Central Valley Project (CVP).[330]

The KWB is located in the Tulare Lake Hydrologic Region, which has an aquifer system with the capacity to store an estimated 50,000,000 acre-feet of water.[331] As a sub-section of the Tulare Hydrologic Region, the 19,883 acre KWB has the ability to store an estimated 1,000,000 acre-feet of water at an estimated annual recharge capacity of 450,000 acre-feet per year.[332] The recovery capacity is estimated to be 240,000 acre-feet per year at project completion.[333]

Approximately 7,000 to 7,200 acres of the KWB are used as active recharge basins.[334] There are 61 shallow (2 feet deep) recharge basins at the site, with approximately 63 miles of levees.[335] The areas between the recharge basins are managed as habitat. The habitat areas are approximately 6,800 acres and are used to regenerate native grasses and plants to provide habitat for local threatened and endangered species. Additionally, the water recharge process has created intermittent wetlands, with willows and tules growing at the edges of the recharge basins, thus providing habitat for a variety of waterfowl.[336]

The Kern River (winter floodwaters) and the SWP are the major sources of water banked in the KWB. The location of the KWB also allows for delivery of water from the Friant-Kern Canal. Construction of a six mile long, two-way conveyance canal connecting the SWP and the Kern River to the KWB was initiated in August 1999.[337]

The water is banked in what is known as the Kern Fan Element. This river fan consists of sandy soil created by years of alluvial deposits. KFE sediments are capable of percolating up to six inches of water per day. Recharge is accomplished utilizing 800 cubic feet per second (cfs) flow from the Kern River and 750 (cfs) from the SWP (California Aqueduct).

Banked water will be recovered by thirty new recovery wells and fifteen old wells that have been rehabilitated. These are located on the site, and an additional thirty wells are proposed as part of the KWB Master Plan Facilities. Other Master Plan Facilities include: a two-way canal connecting the KWB and the SWP; approximately 21 miles of transmission pipeline; and a 545 cubic feet per second (cfs) pump station and meter structures.[338,339] As of August 2000, the two-way canal, turn-outs, pipeline and meter structures were nearly complete.[340]

The new two-way canal will have a capacity of 800 cfs. Drilling started on thirty new extraction wells during 2000 and eighteen existing wells were slated for rehabilitation.[341] Recovery is anticipated to be 375 cfs (240,000 acre-feet per year) to the SWP. [342]

Project History

The original proposal to bank water at the KWB dates to the 1970s when Tenneco West, Inc., the owner of the land where the KWB is now located, and the Wheeler Ridge-Maricopa WSD entered into an agreement to explore banking water on the 46,000 acre Tenneco West parcel. Wheeler Ridge-Maricopa WSD recognized that the scope of the proposed project would require the participation of other entities and began to solicit potential partners in the Kern County area. However, most districts and entities in the Kern County area looked to the completion of the State Water Project (SWP) for additional water supplies and, therefore, chose not to participate in the Wheeler Ridge-Maricopa/Tenneco West project.[343] As a result, Tenneco West eventually terminated the agreement with Wheeler Ridge-Maricopa WSD. Subsequently, Tenneco West sold the future KWB land to the Department of Water Resources (DWR) in 1988, as discussed below.[344,345]

By the early 1980s it became apparent that the SWP would not be completed as anticipated. Consequently, in years of short water supplies in the SWP, water contractors in Kern County receive substantially less water from the SWP than their initial expectations.[346] As a result, a groundwater overdraft of approximately 250,000 to 300,000 acre-feet per year persisted in Kern County.

Thereafter, a series of technical studies, such as "Water Resources Management in the Southern San Joaquin Valley California (1979)" and the "Report on the Investigation of Optimization and Enhancement of the Water Supplies of Kern County (1983)," illuminated opportunities to integrate available surface water supplies into groundwater recharge operations. The reports also underscored the adverse impacts of continued groundwater overdraft in Kern County. These factors, combined with the opportunity to increase SWP water supply reliability during dry years, provided the incentive for DWR to initiate the KWB project in 1988 with the purchase of 19,883 acres of the Tenneco West property.

With that acquisition, DWR phased out farming leases on the KWB land. In 1991–1992, the California Department of Fish and Game identified endangered species on the fallow land, and it became subject to Endangered Species Act requirements.[347] Subsequently, DWR's process of developing the KWB project stalled due to high costs, habitat regulations, complicated negotiations over local use of the bank and uncertainty over the volume of water that could be diverted from the delta for storage.[348,349] The estimated cost of banked water was approximately $400 to $450 per acre-foot, which was unacceptably high for local users.[350] Over $28 million was spent on proposal studies without any project development.

In 1990, local water district managers formed the Kern County Future Water Supply Committee to evaluate future water supply options including groundwater banking in the southern Kern area.[351] The Committee was spurred along by the prolonged drought from 1987 to 1992, which resulted in significant impacts to SWP water users in Kern County. Reductions in SWP allocations and major increases in groundwater pumping for local use and export during 1990–1991 underscored the need for the KWB project. In 1992, an Issues Resolution Committee was appointed to produce a draft set of rules for the joint operation of the KWB and to resolve monitoring issues.

The existing KWB project (under the Kern Water Bank Authority) was initiated on August 4, 1994, when DWR staff, Kern County Water Agency staff, and representatives of the Westside Mutual Water Company met to discuss the potential for transferring the KWB property from DWR to Kern County interests in exchange for 40,000 acre-feet of SWP annual entitlement. Subsequently, representatives of the State Water Contractors and DWR executed the Monterey Agreement ("Statement of Principles for Potential Amendments to the State Water Supply Contracts") on December 4, 1994. The Agreement established principles for making changes in the SWP water supply contracts by modifying each contractor's SWP contract.[352] The Agreement allowed for an amendment to local SWP contracts that facilitated the exchange of the KWB lands from DWR to Kern County Water Agency and Dudley Ridge Water District in return for 45,000 acre-feet of SWP entitlement.[353] Subsequently, DWR agreed to allow the KWB project participants, under Kern County Water Agency, to use the KWB in April of 1995.

After the execution of the Monterey Agreement, Kern County Water Agency, Dudley Ridge WD, Semitropic WSD, Wheeler Ridge-Maricopa WSD and the Westside Mutual Water Company agreed to a Statement of Principles for the Development, Operation and Maintenance of the Kern Fan Element of the KWB. This group, with the addition of the Tejon-Castaic Water District, became known as the Project Participants.

By the end of 1995, the Project Participants had formed the Kern Water Bank Authority (KWBA), executed a "Memorandum of Understanding Regarding Operation and Maintenance of the Kern Water Bank Groundwater Banking Program," established a Monitoring Committee with non-participating districts adjoining the KWB to ensure avoidance or mitigation of potential adverse impacts resulting from KWB operations, and executed a transfer and exchange agreement for the transfer of the KWB from the Kern County Water Agency to the Kern Water Bank Authority. Thus, in 1995, the KWB officially became a locally operated project under a joint powers authority formed for the purposes of recharge, storage, and recovery of water to supplement State Water Project supplies to agricultural and urban communities within Kern County.[354]

Prior to the transfer of the KWB from the Kern County Water Agency to the Kern Water Bank Authority, the KWB Project Participants had received a 2081 Permit from the California Department of Fish and Game for interim operation of the KWB and a Section 7 Permit from the U.S. Fish and Wildlife Service (USFWS) for interim operations. KWB participants began recharge operations with floodwaters in 1995 under an emergency declaration to prevent flooding (Kern County Water Agency operated the KWB facilities for project participants). This declaration expedited the USFWS permit process and freed the Water Agency from California Environmental Quality Act (CEQA) compliance requirements. Environmental effects of recharge with regulated non-emergency flows were addressed in an adopted mitigated negative declaration.[355] By the end of 1995, over 222,000 acre-feet of water had been recharged into the KWB.[356]

On August 9, 1996, the KWB property was officially transferred from the Kern County Water Agency to the Kern Water Bank Authority. In 1997, the KWBA filed a CEQA Notice of Determination and completed the 75-year KWB Habitat Conservation Plan/Natural Community Conservation Plan. Construction of Master Plan Facilities, consisting of a six mile long, two-way conveyance canal connecting the SWP and the Kern River to the KWB, turnout facilities on the SWP and Kern River, 30 new recovery wells, 15 rehabilitated recovery wells, approximately 21 miles of transmission pipeline, and metering structures, commenced in 1999. During the 1995–2000 period, the KWBA recharged a total of 871,502 acre-feet of water into the KWB, nearly reaching the 1,000,000 acre-feet of estimated banking capacity.

The chronology of significant KWB project events, up to and following the Monterey

Agreement, is summarized below:[357,358]

1986 — DWR begins to explore the possibility of developing a Kern Water Bank for the purposes of augmenting the SWP.

May 1986 — DWR issues a draft program Environmental Impact Report (EIR) on the proposed KWB.

December 1986 — DWR issues the Final Program EIR.

March 1987 — DWR enters into a memorandum of understanding with the KCWA to develop and operate the KWB.

April 1987 — DWR issues a Preliminary Technical Report describing the features, facilities, costs, and operation of a direct recharge program.

August 1987 — DWR accepts a report from a consultant evaluating toxics in the area of the Kern River Fan.

September 1987 — DWR makes an offer to Tenneco West, Inc., to purchase approximately 24,000 acres of Tenneco West land for the purposes of establishing the KWB.

May 1988 — DWR contracts with the Kern County Water Agency to assist in the development of the KWB. DWR and the Water Agency solicit proposals from local districts to participate in the KWB. Seven local districts express interest in participating; DWR and the Water Agency analyze the proposals.

August 31, 1988 — escrow closes on the purchase of 19,833 acres of Tenneco West land by DWR. The land is purchased by DWR for $31,115,168.74 (approximately $1,565 per acre).

1989 — DWR installs monitoring wells and implements water level and water quality monitoring program. DWR starts the five-year phase out of 20 agricultural leases on approximately 16,000 acres of the KWB land. Planning activities for the KWB are implemented by DWR. Land management activities are started, as is the clean up of contaminated soils.

1989 through 1994 — DWR spends approximately $28–$30 million on studies. ESA issues emerge. Participants note that the cost of banked water is increasing to around $400 to $450 per acre-foot already with no physical banking project yet in place.

1990 — Kern County Future Water Supply Committee is established and provides the forum for discussion of operating criteria for banking projects in Kern County.

1991 — drought impacts begin to underscore the need to move ahead with the KWB. Agricultural allocations of water from the SWP are reduced to zero acre-feet, and municipal and industrial users are reduced to 35 percent of their allocation. Exportation of groundwater out of the Kern area basin accelerates.

1991 — due to lack of water, 101,400 acres in the entire San Joaquin portion of Kern County are fallowed; 9,700 acres are abandoned after crops (primarily, cotton and almonds) are planted; and 101,700 acres of crops suffer reduced yields.

August 1992 — Kern County Future Water Supply Committee appoints an Issues Resolution Committee for the purpose of identifying resolutions to issues surrounding the monitoring and operations of a joint water bank project.

1993 — SWP contractors and the DWR enter into negotiations to resolve dry year water allocation issues.

August 4, 1994 — DWR staff, Kern County Water Agency Staff and representatives of the Westside Mutual Water Company meet to discuss the potential for transferring the KWB property from DWR to Kern County interests in exchange for 40,000 acre-feet of SWP annual entitlement.

August 22, 1994 — the Issues Resolution Committee issues its Draft Groundwater Management Rules. Attorneys Committee begins to investigate the formation of a Joint Powers Authority to operate the KWB.

October 6, 1994 — the Issues Resolution Committee issues a memorandum describing six major areas where disagreements remain regarding the Groundwater Management Rules for banking projects.

December 1994 — the Monterey Agreement between the DWR and the SWP water contractors is executed to resolve dry year allocation issues. This agreement sets forth principles for making changes in SWP water contracts, which would be implemented by amendment. The Monterey Agreement allows for an amendment to the Project Participants contracts to allow the title to the Kern Water Bank to be transferred to local SWP contractors in exchange for 45,000 acre-feet of their annual SWP entitlements. The Kern County Water Agency is to assume operation of the bank.

March 1995 — the Kern County Water Agency, Dudley Ridge Water District, Semitropic Water Storage District, Wheeler Ridge-Maricopa Water Storage District and the Westside Mutual Water Company agree to a Statement of Principles for the Development, Operation and Maintenance of the Kern Fan Element of the Kern Water Bank.

April 13, 1995 — DWR agrees to allow KWB participants use of the Kern Water Bank for water banking, with the Kern County Water Agency managing operations until the Kern Water Bank Authority is officially chartered in October 1995.

May 16, 1995 — California Department of Fish and Game (CDFG) issues a 2081 Permit for the interim operation of the Kern Water Bank.

May 22, 1995 — U.S. Fish and Wildlife Service (USFWS) issues a Section 7 Permit for Stage 2 1995 Interim Operation of the Kern Water Bank.

May 1995 — the KWB Project Participants start recharging water at the KWB.

June 27, 1995 — USFWS and CDFG meet with KWB participants regarding the outline for the Habitat Conservation Plan and to discuss master permit and Natural Communities Conservation Program issues.

October 16, 1995 — Project Participants officially form the Kern Water Bank Authority, which incorporates prior participant agreements.

October 26, 1995 — a Memorandum of Understanding Regarding Operation and Maintenance of the Kern Water Bank Groundwater Banking Program (MOU) is entered into between the Project Participants in the KWB and the Adjoining Entities (agencies not participating in the KWB). This MOU addresses and resolves the six major issues identified by the Issues Resolution Committee. The Monitoring Committee is established.

December 13, 1995 — the Transfer and Exchange Agreement between the Kern County Water Agency and the Kern Water Bank Authority is executed. Upon close of escrow, this agreement will allow the transfer the KWB property from the Water Agency to the Kern Water Bank Authority.

December 31, 1995 — a total of 222,377 acre-feet of water is recharged into the KWB.

August 9, 1996 — the KWB property is transferred from Kern County Water Agency to the Kern Water Bank Authority.

June 4, 1997 — Kern Water Bank Authority posts CEQA Notice of Determination.

October 2, 1997 — signing ceremony takes place for the completion of the KWB Habitat Conservation Plan.

August 30, 1999 — construction is started on the KWB Master Plan Facilities, including a two-way canal, 72,000 feet of transmission pipeline, a pump station, and new recovery wells to allow an estimated recovery of 236,430 acre-feet of water per year.

April 2000 — 871,502 acre-feet of water has been recharged into the KWB.

August 2000 — most of the Master Plan Facility construction is complete. Installation of new recovery wells and distribution piping are the major facilities remaining to be completed.

STAKEHOLDERS AND BENEFICIARIES

Participants in the KWB (referred to as Project Participants) include: Dudley Ridge Water District, KCWA, Semitropic Water Storage District, Tejon-Castaic Water District, Westside Mutual Water Company and Wheeler Ridge-Maricopa Water Storage District. Project Participants entered into a Joint Powers Agreement to form the KWBA.

Additional stakeholders include: Rosedale-Rio Bravo Water Storage District, the Buena Vista Water Storage District, the Henry Miller Water District, the West Kern Water District and the Kern Delta Water District. These agencies are not participants in the KWB, but, due to the proximity of their agency boundaries to the KWB, they are stakeholders. The special districts listed above (referred to as "Adjoining Entities") entered into a Memorandum of Understanding with the KWBA regarding the operation and maintenance of the KWB so as to prevent significant adverse impacts and to create a monitoring committee and forum for dispute resolution.

Paramount Farming Co., a major landowner and farming operation in the area, is another stakeholder. Paramount Farming Co. played a key role in working with DWR and the participants to facilitate the transfer of the KWB land from DWR to the Kern Water Bank Authority.[359] The Kern County Water Agency acted as the intermediary in the transfer of the KWB land to the Kern Water Bank Authority.

Outside agencies can purchase KWB water from Project Participants per the JPA. The JPA contains a "right of first refusal" clause, wherein a Project Participant proposing to transfer (sell) water must first notify the other Participants of the offer and allow them the opportunity to purchase before selling to a third party.[360,361] KWB recently concluded one-year sales of water to USBR for 70,000 acre-feet and the Westlands Water District for 45,000 acre-feet of water.

It should be noted that the KWB project priority is to enhance water supplies for the KWB project participants and SWP contractor needs (when possible). Kern County Water Agency member units and the Kern County Water Agency have a second priority.

Project Opposition

The Adjoining Entities had six concerns regarding the KWB that needed to be resolved before an agreement to proceed could be reached. These issues were as follows:[362]

- The level of authority of an oversight committee (Project Participants say it functions as a forum and for record keeping; Adjoining Entities propose authority power to modify programs for compliance with groundwater management plans).
- The right to reserve the recharge capacity of the basin for local water supplies (avoidance of reduction in the capability of the basin to recharge both imported and native water).
- Recognition of the possible benefits to the basin (bankers would like recognition of enhancements to the basin due to banking).
- Recognition of mitigation credit for fallowed land (adjoining entities propose no credit, Project Participants propose a credit).
- Definition of adverse impacts to prevent recovery.
- Definition of migration losses.

Local water users' fear of adjudication was an incentive to develop an agreement to resolve these six major issues. A sixty day negotiation process resulted in the execution of a "Memorandum of Understanding Regarding Operation and Monitoring of the Kern Water Bank Groundwater Banking Program" between the Project Participants and the Adjoining Entities.

STAKEHOLDER AND PUBLIC PARTICIPATION

The KWB project engaged local stakeholders through the Future Water Supply Committee process and the Issues Resolution Committee process. The Kern Water County Agency represents many of the water agencies in the area, as they are member units of the Agency. This helps to provide some cohesiveness among the stakeholders. Public participation was accomplished through the environmental compliance (CEQA) process.

ENVIRONMENTAL REVIEW

The original Environmental Impact Report for the KWB was completed by DWR in December 1986 for the purpose of acquiring the Tenneco West land (Final Environmental Impact Report, Artificial Recharge, Storage and Overdraft Correction Program, Kern County, California—Kern Water Bank). The EIR adequately analyzed potential operations of the KWB and identified potential groundwater impacts, in this case interference with neighboring banking projects. Monitoring and rotating recharge areas to minimize impacts was recommended. It should be noted that the issue of endangered species at the site was not identified until 1992.[363] A mitigated negative declaration was issued in 1995 to address recharge operations utilizing non-emergency regulated flows.

Financial Characteristics

As mentioned earlier, the KWB was purchased from the DWR through an entitlement transfer. Major construction costs for the KWB project were obtained through a Proposition 204 loan ($5 million) and a private loan ($20 million).[364]

The expenses for the operation and maintenance of the KWB for FY 2000–2001 are budgeted at $1,645,100. These expenses include the cost of monitoring, operations and maintenance, land management and administration. Income to the Kern Water Bank Authority from banking operation assessments, mitigation credit sales, grazing, third party banking and interest earnings is estimated to balance with the budgeted expenses.[365]

Monitoring costs via the KWB Monitoring Committee are shared equally between the KWB Project Participants and the Adjoining Entities.[366] Costs for construction of monitoring wells are borne by the project participants. Each of the parties is responsible for the personnel costs of their representatives to the KWB Monitoring Committee.[367]

The costs of operations and maintenance for the KWB are recovered by the Kern Water Bank Authority through assessments levied against the Project Participants per their share of the project.[368]

The KWB project water uses the market value of water to establish the base value of the water put into storage.[369] Thus, in 2000, the value of the water was approximately $138 per acre-foot, based on recent transactions with the USBR and Westlands Water District.[370] However, it should be noted that the value of water is dependent on the hydrologic cycle, and the cost of $138 per acre-foot would be more typical of the minimum cost or "value" of KWB banked water.

The price of water to third parties outside of Kern County could be in the range of $350 to $400 per acre-foot, depending on variable costs.[371]

Issues and Risks

Hydrogeologic risks are addressed in the 1995 "Memorandum of Understanding Regarding Operation and Monitoring of the Kern Water Bank Groundwater Banking Program (MOU)." This MOU creates a Monitoring Committee made up of one representative from each of the Adjoining Entities and one representative from each of the Project Participants. The Monitoring Committee oversees a comprehensive monitoring program to determine groundwater levels and water quality under project and non-project conditions. The Monitoring Committee has the authority to retain an independent expert consultant to assist in the data collection and analysis necessary for monitoring the banking operation. The Monitoring Committee, assisted by the consultant, prepares a monitoring plan, maps well locations and specifies additional monitoring wells as needed for a monitoring network. The consultant prepares annual water balance studies, develops criteria to define excessive groundwater mounding, and develops recommended KWB Project operating criteria for the purposes of avoiding significant adverse impacts. The Monitoring Committee deals with all banking projects operating in the Kern Fan Area and is the body charged with resolving disputes regarding the KWB Project operations. Meetings of the Monitoring Committee are held monthly or at regular intervals as deemed necessary.

The MOU states that the banking project will be operated by the "golden rule," meaning that, unless acceptable mitigation is provided, the banker may not operate so as to create conditions that are worse than would have prevailed absent the banking project. Also, the MOU states, "operators of projects in the Kern Fan area will avoid operating recharge projects in such a fashion so as to significantly diminish the natural, normal and unavoidable recharge of water native to the Kern Fan Area as it existed in a pre-project condition."[372] Per the MOU, mitigation measures for hydrogeologic risks include the following:

- A spread-out recovery area and the provision of adequate well spacing.
- Buffer areas between recovery wells and neighboring overlying users.
- Limits on the monthly, seasonal, and/or annual recovery rate.
- Provision of sufficient recovery wells to allow the rotation of recovery wells.
- Adjustment to pumping rates and/or termination of pumping to reduce impacts.
- Time restrictions between recharge and recovery to allow for downward percolation of water to the aquifer.
- Provision of water that would not otherwise be available to recharge the Kern Fan Basin.
- Lowering of well pump bowls or deepening wells for impacted overlying users.
- Provision of alternative water supplies to impacted overlying users.
- Financial compensation to impacted overlying users.

The MOU assigns losses of water during the recharge process at 6% for evapotranspiration, and 4% for migration. Thus, the assigned loss rates help to dedicate water to the basin for overdraft correction. Finally, the operation of the recharge basins is deliberately designed to create intermittent wetlands to provide habitat for waterfowl.

CONVEYANCE CAPACITY

Conveyance capacity in the SWP (California Aqueduct) is conditioned through a Point-of-Delivery Agreement. Put and take conveyance is accomplished in accordance with a schedule approved by DWR. A Use-of-Facilities Charge is applied for each reach of the California Aqueduct in which the users are not participating in a repayment of charges.[373]

GROUNDWATER RIGHTS

Recovery has not preceded recharge due to the fact that the KWB may only recover water that it has recharged. With regard to protection of banked groundwater, the monitoring program described above provides such protection, as it is composed of the adjoining agencies that utilize groundwater in the Kern River Fan.

WATER QUALITY

The 1995 "Memorandum of Understanding Regarding Operation and Monitoring of the Kern Water Bank Groundwater Banking Program" provides for water quality monitoring and has specific requirements for the operation of the KWB to enhance water quality. Recharge water must be of high quality and cannot degrade the groundwater basin.

Financing is allocated by the percentage of base shares of the Project Participants, and operating costs are pooled and shared in a similar fashion. Using the base share formula, the costs are allocated as follows:

Table 5

Agency	Percentage Share of Costs and Benefits Based on Entitlement Contributed
Kern County Water Agency	9.62%
Dudley Ridge	9.62%
Semitropic	6.67%
Tejon-Castaic	2.00%
Westside	48.06%
Wheeler Ridge	24.03%

POLITICAL RISKS

The political risks associated with adverse community reactions for this project are minimal because:

- Water banking projects are common in the area and tend to be accepted as required to preserve and enhance the economy of the area.
- The KWB project has done an effective job of creating habitat and enhancing the natural environment.
- The Monitoring Committee structure offers a forum for addressing the concerns of overlying users adjacent to the project.

Conclusions

KWB participants cited the following factors as having contributed to the success of the Kern Water Bank:

- Kern County has a long history of water banking programs; therefore, it is not a new concept but rather considered a "tried and true" method for water resources management.

- The water agencies within the southern Kern County area are fairly cohesive. The Kern County Water Agency serves as an umbrella organization and a forum for water agencies dealing with the DWR on SWP contracts. The Water Agency also serves as an important intermediate "linking" and resource organization for representing local interests at the state level.

- Leadership within the local water interests recognized the need to develop committees or other mechanisms to reach out and include stakeholders in the program development process. The "glass house" theory was used extensively—in other words, invite and include as many participants into the project as possible (they are less likely to "throw stones" if they are involved in the project).

HYPOTHETICAL ARRANGEMENTS

Based on the lessons learned from the case studies, we propose the following design features for successful and locally acceptable conjunctive use projects. These elements are posed for detailed discussion and reaction by focus groups comprised of knowledgeable and constructive groundwater users, water managers, local officials and opinion leaders in the communities that appear on the basis of hydrogeologic criteria to be particularly well-suited for groundwater banking. The Natural Heritage Institute intends to conduct such focus group reviews as a future phase of the "System-Wide Investigation of the Opportunities for Conjunctive Water Management in the Central Valley" project, out of which this case study report itself emanated.

OVERALL PROJECT DESIGN:

- Banked water would be imported. Thus, aquifer would be actively recharged with water not otherwise available;
- Recharge and extraction facilities would be sited within an existing water district service area or within an AB-3030 planning area;
- The banking operations (recharge and recovery) would be performed by (under the control of) the overlying water district or groundwater management authority;
- Local benefits in the form of water or cash payments would be obligated in enforceable contracts. These commitments could take the form of rights of first refusal in favor of the local water district or authority that is operating the bank (or its individual members) to utilize either the banked water or the aquifer storage capacity or both;
- For unincorporated areas (e.g., for *in lieu* projects), create a local water management authority by special act or county ordinance; and
- Issues, alternatives, and mitigations would be routinely analyzed in NEPA/CEQA documents with full public participation.

IMPROVEMENTS IN HYDROGEOLOGIC INFORMATION

- Measures to improve baseline data in the project area would be undertaken. Local groundwater users would be included in the process of collecting, interpreting, and modeling the data. Efforts would be made to prompt DWR to aggressively improve aquifer baseline information in the areas most suitable for banking.

HYDROLOGIC ASSURANCES

- "Groundwater substitution" projects would only be conducted where subsequent recharge is assured—perhaps through escrow arrangements;
- *In lieu* banking would be conducted only where substitute surface water deliveries are assured—perhaps through escrow arrangements;
- Groundwater substitution arrangements and *in lieu* arrangements should be avoided in areas with shallow wells unless the project is operated within tolerance limits or it pays for deepening the wells or it provides a substitute water supply out of the bank to neighbors with shallow wells;
- The project would commit to recharge more water than it recovers by a specified percentage to provide a buffer against hydrogeologic uncertainties, or the

project would provide some other type of hydrologic assurance;

- The project would be operated within specific water table elevation limits to avoid inundating root zones or structures;
- The recharge and extraction facilities would be located near the center of the overlying water district of groundwater management authority to avoid or minimize effects on external groundwater users;
- The project would cease pumping or provide automatic compensation whenever monitoring wells indicate interference with neighboring wells. Where this potential is significant, the project would allow neighboring groundwater users to order cessation pending investigation of the impacts;
- The project would extract water on a schedule designed to avoid impacts on irrigators. The schedule could be subject to modification by the monitoring committee. For example, the extraction schedule would be limited to seasons or days when neighboring wells are not in operation such as nights, weekdays or before or after the peak irrigation season;
- The groundwater bank should be located as far as possible from surface streams (unless interaction is desired);
- The contract terms should assure that water deliveries to beneficiaries will cease at the termination of the contract period. Enforcement mechanisms might include export permits of limited duration or substantial liquidated damages; and
- Where recharge water is routed through the delta (or otherwise degraded en route), it will be subject to water quality criteria that will assure that the recharge water is of higher quality than the *in situ* groundwater.

FINANCIAL ASSURANCES

- Costs incurred by neighboring landowners due to increases in power requirements to lift groundwater—for any reason—will be compensated out of project revenues. Such compensation arrangements will feature streamlined and simplified claims processing procedures; and
- The customers of a groundwater banking project will defray the costs incurred by the water district or groundwater management authority that is providing the banking services even if delivery constraints beyond the control of such banker prevent the delivery of water to such customers. The customers may also be required to pay those costs in advance. If the banked water cannot be delivered, banking district can purchase that water at their marginal costs of substitute supplies.

LEGAL ASSURANCES

- In groundwater basins that are in a condition of chronic overdraft, groundwater users' historic rates and volumes of pumping would be immune from legal action by groundwater bankers. Unless the basin is adjudicated, the formula for defining "historic use" would be specified in the contract setting up the groundwater bank;
- In groundwater basins in which current extractions are less than natural recharge, groundwater users' would also be immune from legal action to the extent of the "safe yield" surplus in the basin. Unless the basin is adjudicated,

the formula for defining "safe yield" and surplus would be specified in the contract setting up the groundwater bank;

- For *in situ* projects, either all of the local groundwater users would be brought into the project via contract (probably unrealistic), or the program will have to be operated in a manner that avoids injury—perhaps by allowing "take" only after a period of "put"; and
- A groundwater banking project will have the burden of proving that its operations will not cause injury to legal users of water, including groundwater users, where the project is required to obtain a permit or order from the State Water Resources Control Board or a local groundwater management authority.

MONITORING PROGRAM

- A banking project will establish a groundwater monitoring program directed by committee representing the local groundwater users as well as project participants. The program will include perimeter monitoring wells and adequate monitoring infrastructure. The program will monitor specified quantity and quality parameters. The committee will possess the power to modify the pumping regime when specified thresholds are exceeded; and
- The committee will also be vested with authority to resolve disputes regarding project operations either directly or by referring the dispute to an arbitration panel comprised of technical experts.

LOCAL PARTICIPATION

- The overlying water district or groundwater management authority that will provide the banking services will consult with the local groundwater community, involve it in the project design and operations, and solicit and use "local knowledge" of groundwater conditions;
- Where possible, the project will be located in areas where groundwater banking is already an established practice;
- The project proponents will make all technical investigations transparent and provide ample opportunities for early review and comment;
- The proponents will complete all technical investigations and public review before implementation steps are taken; and
- That will include thorough and convincing NEPA/CEQA compliance.

ENDNOTES

INTRODUCTION

[1] For the purposes of this paper, "imported water" refers both to "foreign water imported from a different watershed" or water that comes from an in-basin source that is not hydrologically connected with the banking site within a relevant period of time (e.g. flood flows of a river). City of Los Angeles v. City of San Fernando, 14 Cal. 3d 199, 261 n.51 (1975). Note that this definition would include water that originates within the same hydrologic basin as the banking site, provided that it would not be available for extraction at that site but for the physical act of bringing it to that location as recharge water.

[2] We use the term "rent" figuratively for, as we shall see in the section of this document on "Outstanding Issues", overlying landowners probably do not have a right to charge rent for the use of the subsurface aquifer. Nonetheless, the landowner or groundwater management entity that provides and operates the recharge and recovery facilities will want to participate in the benefits of the groundwater bank. When that inducement takes the form of a cash payment, it may resemble "rent", a term of art we employ with the above caveat.

[3] The potential for groundwater export and refill projects adversely affecting streamflows is a function of the transmissivity of the groundwater, the proximity to surface streams, and the interval between extraction and refill. These are parameters that are not difficult to control if the baseline information is adequate. We envision projects where extraction and refill both occur annually, and where the bank is located remotely from surface streams. Under those circumstances, uncertainties in the current understanding of the linkage between surface water and groundwater systems in the northern Sacramento Valley should not pose an unmanageable risk.

[4] The courts, using their equitable powers, and the State Board, though Cal. Wat. Code § 275, can fashion and enforce physical solutions to ensure more efficient use of water, provided that the legal rights of the parties are protected and senior rights holders are not required to incur any material expense. See generally City of Barstow v. Mojave Water District, 23 Cal. 4th 1224 (2000). (Examples of State Board enforcement of physical solutions include SWRCB Decision 1631 and Order WR 98-05, D 1600 and Order 88-20, and Orders WR 2000-13, WR 96-002, WR 94-2 & 93-8, and WR 90-16.)

SCOPE AND METHODOLOGY

[5] The storage of Friant flood releases at Arvin-Edison comes closest to the system-wide approach. However, it does not entail reoperation of Friant Reservoir to capture such flood events.

FINDINGS AND CONCLUSIONS

[6] E.g., the Semitropic and Arvin-Edison programs have allowed these districts to finance new facilities that increase their internal operational flexibility to the substantial benefit of the districts' members.

[7] The Kern Water Bank MOU includes the following provisions:

A spread out recovery area and the provision of adequate well spacing.
Buffer areas between recovery (extraction) wells and neighboring overlying users.
Limits on the monthly, seasonal, and/or annual recovery rate
Provision of sufficient recovery wells to allow the rotation of recovery wells.

[8] That monitoring committee prepares annual water balance studies, develops criteria to define excessive groundwater mounding, and develops operating criteria to avoid adverse impacts. It is also charged with resolving disputes concerning project operations.

OUTSTANDING ISSUES

[15] See, e.g., Niles Sand and Gravel Co. v. Alameda County Water Dist., 37 Cal. App. 3d 924 (1974).

[16] Unless already authorized, groundwater banking usually involves both a new place of storage and a new or expanded place of use (when the water is pumped back out of the aquifer). The State Board exercises jurisdiction over both. See California Water Code § 1266, Cal. Code Regs. tit. 23, § 722.

[17] For instance, the groundwater banking authority must avoid raising the groundwater table to a level that might invade the root zones of neighboring crops or structures. It must avoid lowering the groundwater table below the level

that would exist in the absence of the project, thereby dewatering nearby wells or increasing the power requirements for pumping. The banking authority must also avoid degrading the quality of the *in situ* groundwater.

[18] For example, water users could be made whole through delivery of an alternate source of water of equal quality and quantity. Additionally, a well owner who has to deepen her well to respond to a declining water table (as occurs with a groundwater substitution project) might be reimbursed for the increased well construction and pumping costs. Depending on the nature and severity of the change, adverse impacts on groundwater quality may not be allowable even if the affected well owners accept compensation.

[19] By their terms, the county and watershed of origin statutes apply only to water that originates in the county or watershed of origin. However, if this water is banked within the county or watershed of origin and then extracted and exported, it would seem that the doctrines would apply.

[20] City of Los Angeles v. City of San Fernando, supra note 1.

[21] The importer would lose rights to the water only if it is abandoned, which would be contrary to the intent of a groundwater banker, or is acquired by "adverse possession", also known as prescription. Prescriptive rights cannot be obtained as against a public agency, however. City of Los Angeles v. City of San Fernando, 14 Cal. 3d 199 (1975). This is yet another reason why water districts are the preferred operators of a groundwater bank.

[22] The California Supreme Court has affirmed the paramount rights of the importer to recapture foreign water intentionally lost to groundwater basins and unintentionally lost to surface waters. See, Stevens v. Oakdale Irr. Dist., 13 Cal. 2d 343 (1939); City of Los Angeles v. City of Glendale, 23 Cal. 2d 68 (1943); City of Los Angeles v. City of San Fernando, 14 Cal. 3d 199 (1975). Some water law practitioners contend that the Stevens rule permitting recapture of unintentionally lost imported water should not be extended to deep percolation from irrigation. They are concerned that if the right to recapture percolation losses is extended to large importers like the SWP or CVP, they could effectively control every groundwater basin in the Central Valley. Others point out that groundwater users who are the incidental beneficiaries of irrigation imports contribute nothing to the capital or maintenance costs of such projects, and are not entitled to insist on the continuation of that gratuity.

[23] This issue is emerging in discussions over the reoperation of Friant Dam to restore the downstream anadromous fishery. The increased releases will increase infiltration in the Gravelly Ford reach. Groundwater pumpers in that area are likely to benefit from the increased recharge—if it is theirs to pump. Is a change in dam operations of this sort an act of importation, utilizing a natural channel to bring in water that would not otherwise be available to the aquifer but for the reoperation, if part of the intended purpose is to bank groundwater downstream? If so, shouldn't the USBR be entitled to pump that increased recharge and deliver it to, for instance, the San Joaquin exchange contractors in exchange for Mendota Pool water that could be wheeled to the Friant Water Users to make them whole? On the other hand, the Gravelly Ford groundwater users point out that that increased flow to more closely mimic the natural hydrograph is water that would have been available to them as recharge water if Friant Dam had not been built. Thus, the reoperation merely restores a degree of the natural conditions to which they are entitled. The issue of the hydrologic and temporal baselines for determining what constitutes "imported water" permeates this paper and is a matter on which we recommend clarifying legislation.

[24] Katz v. Walkinshaw overturned the rule of absolute ownership of groundwater traced back to Acton v. Blundell, 12 Mees. & W. 324 (Exchequer) (1843), and rejected the notion that a landowner owns everything from the "heavens to the center of the earth." It made groundwater a common property resource in that groundwater resources must be shared in a correlative fashion by the overlying landowners. But Katz did not consider whether an overlying landowner may restrict a water importer from using the free space in an aquifer.

[25] If overlying users own a correlative share of the aquifer storage space, they arguably would have to be compensated for use of that space, whether or not they are injured. The City of Los Angeles v. City of Glendale and City of Los Angeles v. City of San Fernando holdings make no provision for compensation for use of aquifer storage space.

[26] City of Los Angeles v. City of Glendale and City of Los Angeles v. City of San Fernando uphold Los Angeles DWP's importation and storage of water underground despite Los Angeles' status as an appropriator and lack of any statutorily authorized groundwater management authority.

[27] See Slater, California Water Law and Policy (1998); City of Los Angeles v. City of San Fernando, 14 Cal. 3d 199 (1943).

[28] Correlative rights are like riparian rights: they are neither quantified nor prioritized by historic use. The only limitation on their exercise is the mutual avoidance of harm. The problem that emerges is illustrated by the following hypothetical: Suppose a groundwater bank is recharged for two years and then water is extracted in the third year. Suppose there are three overlying groundwater users, A, B and C. In the first two years (of recharge), A and B greatly exceed their historic rates of pumping to take advantage of the new recharge, and in the third year they revert to historic levels. In that third year, the program also seeks to extract. The combined pumping increases C's lifting costs above the historic baseline. May C sue to prevent the project from extracting its water? May the project sue in the first two years to prevent A and B from increasing their rates of pumping?

[29] There is an enforcement problem, however. Water users are typically aware when pumping exceeds safe yield, but the costs of curtailing pumping and/or initiating an adjudication inhibit legal action for abatement. Also, an individual user has at least a theoretical argument that it can increase its pumping as its needs increase, even when the basin is in overdraft. The fact that total use exceeds the safe yield does not rule out the possibility that some of the overlying users are entitled to increase their pumping (i.e. their correlative share happens to be higher than their current pump-

ing, because their needs have substantially increased). See City of Barstow v. Mojave Water Agency, 23 Cal. 4th 1224 (2000). Of course, the total basin pumping cannot legally increase, but they could argue that others' correlative share must be reduced to accommodate their increased need.

[30] However, the fact that the land is within the boundaries of a district that delivers surface water doesn't necessarily mean that the district is doing anything to regulate groundwater extractions.

[31] Some water lawyers argue that the State Board has no jurisdiction over water in underground basins because it is not water flowing in "surface streams" or in "known and definite channels." The argument suggests that, once surface water is put into aquifer storage, it becomes groundwater outside of the State Board's authority to regulate. Also, county ordinances define "groundwater" subject to their jurisdiction as "all water below the surface not in known and definite channels."

[32] See, e.g., In the Matter of Application 17002, Decision No. D. 894, at 3 (Mar. 25, 1958)(approving an application for water that, after appropriation, will be placed into underground storage and later released for municipal, domestic, irrigation, and recreation purposes over 18,100 acres of land); In the Matter of Application 20621, Decision No. D. 1235, at 3, 29 (Aug. 25, 1965)(approving the Navy's application to store 4,000 afa underground from which it will be pumped for military, domestic, municipal, and agricultural purposes, both within and without the watershed.)

[33] For example, In the Matter of Application . . . to Appropriate Water from Sespe Creek In Ventura County, Decision No. D 1129 (Apr. 29, 1963), the State Board weighed competing permit applications for development of certain water resources in the Santa Clara River basin near Oxnard. The United Conservation District planned to appropriate water year-round for domestic, industrial, irrigation, and salinity control purposes, with a portion of the water first being placed in underground storage. In approving United's application, the board, as a condition of United's permit, held that it retained authority to ensure the use of the water was consistent with the permit. We note that these orders pertain to water right applications. It is not certain that the same holdings would apply to change orders.

[34] The ultimate use of the water is subject to the reasonable and beneficial use requirement of Article X, §2 of the California Constitution. Under Water Code §1242, the storage of surface water underground is considered a beneficial use if the water provided that the water so stored is thereafter applied to a beneficial purpose.

[35] The State Board retains authority over the use of water diverted from a natural watercourse even if it is first diverted to storage in an offstream reservoir. Its jurisdiction does not depend on whether the reservoir is characterized as a "natural channel" as long as the water diverted into the reservoir was diverted from a stream lake or other body of water. For purpose of State Board jurisdiction over rediversion and use of water first stored to a reservoir, the Water Code does not distinguish between surface and underground reservoirs. See California Water Code § 1201.

[36] California Water Code §§ 10750-10753.9.

[37] See California Water Code § 10753.8(c).

[38] The ten special districts are Willow Creek Groundwater Management Agency (Lassen Co.), Honey Lake Groundwater Management District (Lassen Co.), Long Valley Groundwater Management District (Lassen Co. and Sierra Co.), Sierra Valley Groundwater Management District (Sierra Co.), Mendocino City Community Services District (Mendocino Co.), Mono County Tri-Valley Groundwater Management District, Pajaro Valley Groundwater Management Agency (Santa Cruz), Ojai Groundwater Management Agency (Ventura Co.), Fox Canyon Groundwater Management Agency (Ventura Co.), and the Monterey Peninsula Water Management District (Monterey Co.). See California Department of Water Resources, Water Facts: Groundwater Management Districts or Agencies in California (1996).

[39] Such as the Orange County Water District, Santa Clara Valley Water District, and the Monterey County Water Resources Agency.

[40] See In re Mass, 219 Cal. 422, 424-25 (1933); Ex parte Elam, 6 Cal. App. 233, 237 (1907).

[41] Baldwin v. County of Tehama, 31 Cal. App. 4th 166, 173-74 (1994, 3rd Dist.); review denied, Cal. Sup.Ct., March 17, 1995. Baldwin held that state law, namely AB 3030, specially enacted local districts and California Water Code Section 1220 (about which more, later) do not preempt city and county management of groundwater resources. State law preempts local ordinances only when "the subject matter has been so fully and completely covered by general law as to clearly indicate that it has become exclusively a matter of state concern . . ." or "the subject matter has been partially covered by general law couched in such terms as to indicate clearly that a paramount state concern will not tolerate further or additional local action. . . ." .

[42] The following counties have passed groundwater management ordinances that govern the extraction and exportation of groundwater (dates of the most recent amendment are noted): Butte Co. 1996; Colusa Co. 1998; Fresno Co. 2000; Glenn Co. 2000; Imperial Co. 1998; Inyo Co. 1998; Kern Co. 1998; Lake Co. 1999; Madera Co. 2001; Modoc. Co. 2001; Napa Co. 1999; Sacramento Co. 1952 Water Act (Sec 32 on GW mgmt added 1985); San Benito Co., 1995; San Diego Co. 1991; San Joaquin Co. 1996; Shasta Co. 1998; Siskiyou Co. 2001; Tehama Co. 1994; Yolo Co. 1996. Ordinances have been proposed or are pending approval in a number of other counties.

[43] Groundwater is generally defined as "all water below the surface not in known and definite channels." Since none of the ordinances exempt imported water from this definition, the ordinances arguably apply to banked, imported water.

[44] For example, see Colusa County Code §§ 43-3, 43-4 and Shasta County Ordinance No. SCC 98-1, §§ 18.08.030, 18.08.040.

[45] The Board must make an injury determination when approving the change order to transfer water into the aquifer and likely retains jurisdiction over the subsequent rediversion of the stored water. Parties potentially affected by the banking

operation would have the opportunity to protest the project as well as seek protection from the Board if the project operation affects their rights. On the other hand, the Board's authority to protect the banker is not symmetrical; the Board does not have the power to prevent groundwater pumpers from taking the banked water. Legal counsel to the State Board suggests that the instances of actual conflict may not be frequent in that, in situations where there is a competent county regulatory regime, the Board would likely defer to the county and exercise its authority only when necessary.

[46] The County of Origin and Watershed of Origin statutes by definition only apply to water that originates in the county or watershed of origin.

[47] California Water Code § 1220: "(a) No groundwater shall be pumped for export from within the combined Sacramento and Delta-Central Sierra Basins . . . unless the pumping is in compliance with a groundwater management plan that is adopted by ordinance pursuant to subdivision (b) by the county board of supervisors, in full consultation with affected water districts, and that is subsequently approved by a vote in the counties or portions of counties that overlie the groundwater basin, except that water that has seeped into the underground from any reservoir, afterbay, or other facility of an export project may be returned to the water supply of the export project. . . ."

[48] Injury to groundwater appropriators is unlikely, however, as their rights are subordinate to the overlying parties who are participating in the *in lieu* banking project.

[49] California Water Code § 1005.2 and 1005.4 states that where a nontributary source of water (imported foreign water or conserved water otherwise unavailable to the aquifer) is used *in lieu* of groundwater pumping, a reduction or cessation of groundwater pumping to permit groundwater replenishment is deemed a beneficial use of water and will not result in loss, reduction or forfeiture of the groundwater rights.

CASE STUDIES

[50] More recent geologic investigations by the Department of Water Resources Northern District Office suggest that the western boundary of the basin may not coincide with the Sacramento River. The southern boundary is likewise in question due to limited hydrogeologic characterization of the stratigraphy surrounding the Sutter Buttes. A further complication related to the southern boundary is that the greater reliance on groundwater south of the Sutter Buttes has created a net outflow of regional groundwater from the Butte Basin.

[229] Issues relating to groundwater management in Kern County were presented to Kern County's Future Water Supply Committee in July of 1992. This Committee appointed an Issues Resolution Committee to recommend possible solutions to these issues. The Issues Resolution Committee tried to develop groundwater management rules regarding banking projects. In October of 1994 the Issues Resolution Committee presented their draft rules to the Kern County Water Agency. On issues where the committee could reach resolution between groundwater districts and bankers, a specific rule was outlined. On issues where the committee could not reach resolution between groundwater districts and bankers, the Committee outlined the positions of each group.

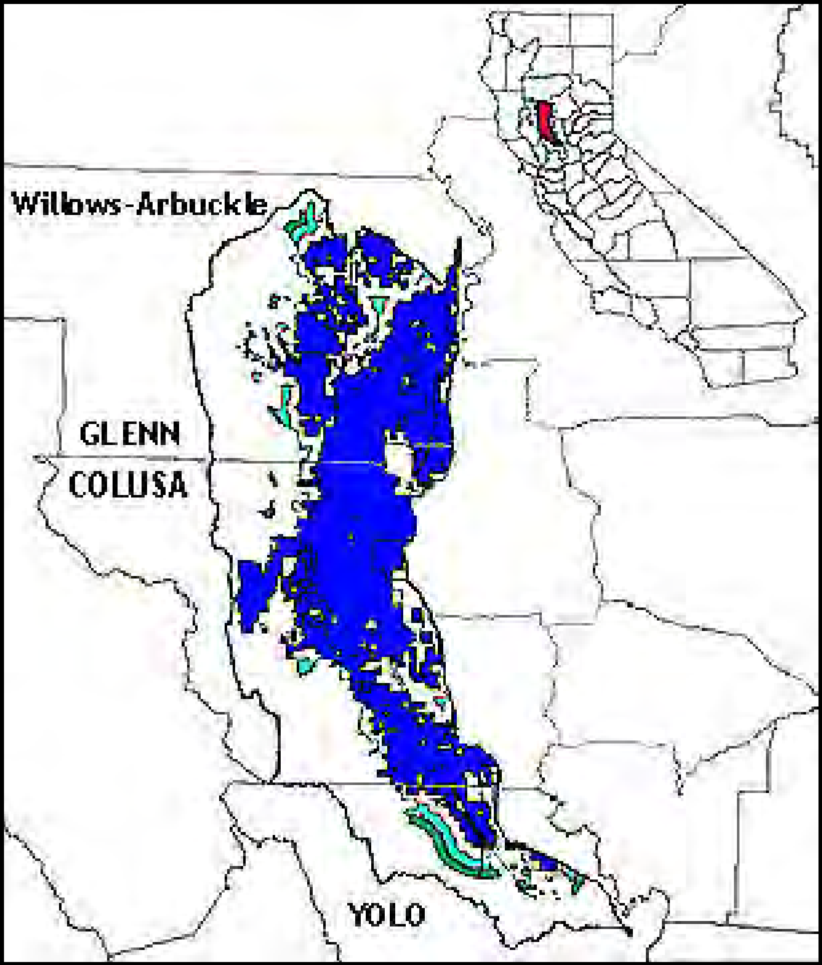
SYSTEM-WIDE CONJUNCTIVE WATER MANAGEMENT

ESTIMATING THE POTENTIAL FOR IN LIEU CONJUNCTIVE WATER MANAGEMENT IN THE CENTRAL VALLEY OF CALIFORNIA



THE NATURAL HERITAGE INSTITUTE

David R. Purkey, Ph.D.
Elizabeth M. Mansfield

February 2002

This report is one of several technical studies prepared by the Natural Heritage Institute as part of a System-Wide Investigation of Conjunctive Water Management Opportunities in the Central Valley of California under a cooperative agreement (99FC200189) with the U.S. Bureau of Reclamation. That project, in turn,0 is part of a larger program of activities to Enable Water Transactions to Restore Landscapes and Aquatic Habitats in California's Central Valley with support from the David and Lucile Packard Foundation, the Dean Witter Foundation and the William and Flora Hewlett Foundation.

This report and others from this project are available on-line from NHI's website at www.n-h-i.org or contact the Natural Heritage Institute at the address below.

THE NATURAL HERITAGE INSTITUTE

The Natural Heritage Institute is a non-profit natural resource conservation organization composed of technical and legal specialists and dedicated to the improvement of the laws and institutions that manage our natural heritage both domestically and internationally.

TABLES

FIGURES

1.0 Introduction

Over the course of the past several years conjunctive use has emerged as a key element of California water management strategy. This fact is most prominently embodied in the call for 500,000 to 1,000,000 acre-feet of additional groundwater storage made in the CALFED Record of Decision (RoD). In response to this call efforts are underway across the state to design and develop conjunctive use programs—efforts that are being supported financially by CALFED and by a number of other State and Federal agencies. In keeping with the current agency philosophy that groundwater management initiatives should grow out of local initiatives, the vast majority of these efforts focus on projects with a well-defined local geographic scope.

While these projects, when viewed as a whole, will surely produce important water management flexibility in the future, they represent a change in focus from historical surface water development efforts in California that often adopted a more statewide geographic perspective. The impact of this history is now manifest in the far-flung distribution of reservoirs, canals and water users that characterize the California water system. While this system has dramatically altered the natural hydrology of the Sacramento and San Joaquin Basins, it also offers remarkable opportunities for management integration and innovation, including the possibility of regional and system-wide conjunctive water management initiatives that may offer benefits that would be missed by adopting a purely local conjunctive use planning perspective.

In recent years, the Natural Heritage Institute (NHI) has been exploring the role that system-wide conjunctive use and groundwater banking focused on the reservoirs and aquifers in the Central Valley can play in balancing the water needs of California's agricultural, urban and environmental interests. The starting point of each element of this analysis is that the interests of groundwater users overlying individual groundwater basins in the Central Valley must be protected, or even enhanced, when evaluating any system-wide conjunctive use initiative. If system-wide integration of a groundwater basin causes harm to the historic users of the resource, no amount of cajoling can compel the basin's managers to pursue this option. The rules governing the use of groundwater in California simply do not accommodate this possibility. However, determining whether system-wide integration of a groundwater basin can generate a broad spectrum of benefits that accrue both locally and across the state requires analysis. The System-Wide Conjunctive Management Series published by NHI, which has been supported by the U.S. Bureau of Reclamation and a consortium of other public water management agencies, attempts to respond to this need.

Previous reports that have been published in the Series include:

- *A Feasibility Study of Maximal Scale Program of Groundwater Banking in California* (NHI 1999), which dealt with the technical feasibility increasing the yield of the California water system through the re-operation of the State's major surface water reservoirs as part of a system-wide groundwater banking program, and included three case studies.

- *Designing Successful Groundwater Banking Programs in the Central Valley* (NHI 2001a), which described in detail the legal and institutional opportunities and constraints suggested by the successes and failures encountered during earlier attempts to implement ambitious groundwater management projects.
- *The Hydrogeologic Suitability of Potential Groundwater Banking Sites in the Central Valley of California* (NHI 2001b), which proposed an index to rank the hydrogeologic suitability of various groundwater basins in the Central Valley as targets for direct recharge groundwater banking based on geologic, groundwater quality, soils and hydrologic considerations.

Others will follow, subject to the availability of financial resources, on:

- Design specifications for local groundwater management institutions;
- The potential for integrating conjunctive use into reservoir re-operation strategies that are also intended to enhance downstream fluvial processes;
- The analysis of institutional, land use, infrastructure, and environmental and other factors bearing upon siting decisions for groundwater banks;
- The results of “gaming” analysis of a series of conjunctive use configurations in the Central Valley;
- Economic optimization analysis; and
- The final feasibility of and strategic plan for an appropriate system-wide conjunctive water management initiative.

The current report contains analysis on the potential role that *in lieu* conjunctive water management in the Central Valley could play in a system-wide conjunctive water management initiative. This conjunctive use strategy relies upon offsetting historical groundwater pumping with surface water deliveries from project participants during times of excess surface water supply. These extended deliveries of surface water could also be part of a reservoir re-operation strategy designed to enhance the overall yield of the major water supply reservoirs in the Central Valley (NHI 1999). Any foregone groundwater pumping that results from the delivery of surplus surface water or reservoir re-operation is, in turn, considered to be stored groundwater water that can be reclaimed by project participants during times of surface water shortfalls. This strategy, which obviously rests heavily on institutional and accounting arrangements, is an alternative to direct aquifer recharge of surface water either during years of surplus or as part of the reservoir re-operation that was the focus of previous analyses published in the System-Wide Conjunctive Management Series (NHI 2001b).

In theory, any historic user of groundwater, either municipal or agricultural, could receive surface water deliveries *in lieu* of groundwater pumping. An interesting example of urban *in lieu* conjunctive use is emerging in the Sacramento Region north of the American River, where several municipal water districts have formed a joint powers authority to coordinate the use of their individual American River surface water rights and pumping from their common underlying aquifer (Winkler 2002). In addition, the delivery of surface water to offset groundwater pumping does not necessarily require water delivery outside of the jurisdiction of the original surface water rights holder.

In many, perhaps most, water districts irrigators draw upon both surface water and groundwater to meet crop water requirements based on water availability, delivery timing and overall cost considerations. In this setting, however, realizing viable *in lieu* conjunctive water management opportunities is likely to occur as part of standard internal water district planning.

Outside of urban regions and water districts endowed with surface water supplies, there remains a substantial opportunity to carry out *in lieu* conjunctive use by delivering available surface water to irrigated lands lying outside of the boundaries of established surface water delivery districts. These are lands that rely completely on groundwater pumping as a source of irrigation water. While water districts are both common and extensive in the Central Valley, there remain vast tracts of land that fall into the land use category of "unincorporated irrigated agriculture". Evaluating the extent of delivering surface water to these lands as part of an *in lieu* conjunctive use program, either during years of surplus or as part of an overall reservoir re-operation strategy, is the focus of this report.

The report continues in Section 2.0 with a brief discussion of the evaluation criteria that can be used to evaluate where in the Central Valley an *in lieu* conjunctive water management program could be implemented. Subsequently, in Section 3.0, the analytical methodology used to examine these evaluation criteria is presented, including a discussion of the data collected and tools used. Section 4.0 presents the results of analysis of the evaluation criteria and an estimate of the scale of potential *in lieu* conjunctive water management in the Central Valley. The report closes with some thoughts on the implications of this work on the System-Wide Conjunctive Water Management Initiative.

2.0 Evaluation Criteria for Assessing *In Lieu* Conjunctive Use Opportunities

As mentioned in Section 1.0, this report explores the potential for implementing *in lieu* conjunctive water management projects on agricultural land in the Central Valley that has historically relied solely on groundwater pumping to supply irrigation water. One consideration in developing such a program is the availability of surface water for delivery to these lands. The possibility of generating new surface water was discussed in an earlier publication in the System-Wide Conjunctive Water Management Series (NHI 1999). Other hydrologic modeling exercises have also focused on enhancing the storage capacity available to manage surface water in the Central Valley. What has been missing, at least in the context of *in lieu* conjunctive water management, is an inventory of the magnitude of the opportunity for historic agricultural users of groundwater to accept any available surface water supplies.

While the willingness of historic groundwater users to participate in such a program will turn primarily on local considerations related to cost and assurances, there are some physical characteristics that can make a particular region attractive for *in lieu* conjunctive use. In pursuing this investigation, three evaluation criteria that will influence the viability of this water management strategy were identified.

- The relative contribution of surface water and groundwater to irrigated agriculture in an area of interest. Ideally *in lieu* groundwater banking will occur in areas where significant amounts of groundwater pumping for irrigation takes place in the same locale where significant amounts surface water are available to offset groundwater pumping.
- The physical proximity of lands irrigated solely with groundwater to water districts that own the surface water distribution network that would be extended to deliver surface water in lieu of groundwater pumping.
- The amount of available aquifer storage space to accommodate the "stored" groundwater that will be left behind by delivering surface water to land historically dependent on groundwater pumping.

The analytical methodology used to evaluate each of these parameters is found in the following section.

3.0 Analytical Methodology

Having selected three criteria for evaluating the potential for *in lieu* groundwater banking in the Central Valley, we developed an analytical methodology that would allow for comparisons among different parts of the region. These are discussed below.

3.1 Relative Contribution of Surface Water and Groundwater

This evaluation criterion relates to local balance between the use of surface water and groundwater to meet crop water requirements on irrigated lands. If all of the land in a particular area has access to adequate surface water, then there is little possibility to increase groundwater storage by offsetting groundwater pumping. Conversely, in an area characterized uniquely by groundwater pumping there is no surface water to more widely distribute, either in times of excess supply or as part of reservoir re-operation. This suggests that *in lieu* conjunctive water management is a strategy best suited for areas where both groundwater and surface water contribute to the overall agricultural water supply.

The question becomes, however, how to define the boundaries of an area for analysis. An area such as the Central Valley certainly relies upon a mix of surface water and groundwater to meet crop water requirements. According to the most recent State Water Plan Update (DWR 1998), 28.3 MAF of surface water and 9.2 MAF of groundwater are used during average water years in the Central Valley. At this scale it is possible to imagine that surface water supplies might be available to offset groundwater pumping as part of *in lieu* conjunctive water management. This conclusion, however, does little to help in identifying where the most promising opportunities for this arrangement lie. To achieve this objective some more refined characterization of the mix of available surface water and groundwater for irrigation is required.

The State Water Plan Update (Bulletin 160), published once every five years by the Department of Water Resources (DWR), was identified as the logical source of information for developing this more refined characterization. Bulletin 160 reports on the composition of water supplies and demands at the level of 10 Hydrologic Regions in the State (Figure 3.1) and uses this data to anticipate the evolution of the statewide balance of water supply and demand over a planning horizon of several decades.

Figure 3.1: Hydrologic Regions Defined by California Department of Water Resources for the Purpose of Statewide Water Planning (DWR 1998)

In actuality, however, the data published in Bulletin 160 are aggregated up from water balance calculations performed at the level of 280 Detailed Analysis Units (DAU) defined by DWR (Figure 3.2). These range in area from roughly 11 mi^2 up to over 3600 mi^2. While the actual logic used to delineate these DAUs is not included in Bulletin 160, they appear to be based largely on the location of local important physical (mountains, rivers, distribution canals) and political (local government and water district boundaries) features.

Figure 3.2: Detailed Analysis Units Defined by California Department of Water Resources for the Purpose of Conducting Water Balance Calculations

Given their foundational role as the level at which water supply and demand data are actually assembled and analyzed, the DAUs were deemed the most appropriate unit for evaluating the local mix of surface water and groundwater used by irrigated agriculture. As the scope of the current investigation was limited to *in lieu* conjunctive water management opportunities in the Central Valley, a set of 56 DAUs was identified for further analysis (Figure 3.3). The logic used for selecting these DAUs was that the most significant portion of the DAU lies within the relatively flat, heavily agricultural region lying between the Coast Range Mountains and the Sierra Nevada Foothills. This logic also appears to have driven the original definitions of the DAUs, as those selected generally lie entirely within this zone. Details regarding the identifying code number, name, Hydrologic Region and surface area of the 56 selected DAUs are presented by identifying code number in Table 3.1.

Figure 3.3: Detailed Analysis Units in the Central Valley Selected for Analysis of the Potential for *In Lieu* Conjunctive Water Management

DWR's regional offices maintain databases for the various DAUs around the state. 1995 and 1996 data for the Central Valley DAUs shown in Figure 3.3, which presumably were used to develop the 1998 edition of Bulletin 160, were obtained directly from DWR personnel in the Redding, Sacramento and Fresno offices. A number of different data sets were extracted from these Excel spreadsheets, some of which were used to perform calculations designed to evaluate the relative contribution of surface water and groundwater to the irrigation water supply in the DAU.

Table 3.1: Relevant Details Pertaining to the 56 Central Valley DAUs Selected for Analysis of the Potential for *In Lieu* Conjunctive Water Management

ID No.	Name	Hydrologic Region	Area (mi^2)	ID No.	Name	Hydrologic Region	Area (mi^2)

The extracted data sets included:

- Reported applied water to agriculture (AGAW)
- Reported evaporation of applied water (ETAW)
- Reported applied surface water to agriculture (ASW)
- Reported applied groundwater to agriculture (AGW)

These values are considered to be reported because it was generally not clear from the spreadsheets how the numbers were developed and in several cases it was evident that the numbers were calculated from other variables (see the text box on the following page). As they represented the best available data, however, these values were used to calculate the following variables:

- Irrigation Efficiency (E) = ETAW/AGAW
- Agricultural Surface Water Contribution (%SW) = ASW/AGAW
- Agricultural Groundwater Contribution (%GW) = 1 - %SW

The values of ETAW, ASW, AGW, %SW and %GW were then tabulated and graphed in order to identify DAUs with the proper mix of surface water and groundwater use to make them attractive candidates for *in lieu* conjunctive water management. The results of this analysis are presented in Section 4.0. The estimated irrigation efficiency was used to examine where improvements in irrigation water management might allow for a wider distribution of available surface water. This opportunity is also discussed in greater detail in the Results section below.

3.2 Physical Proximity of Lands Irrigated Solely with Groundwater

In addition to having an appropriate mix of surface water and groundwater use for irrigation, in order to implement an *in lieu* conjunctive use program it is desirable if much of the land irrigated solely with groundwater lies in close proximity to water districts. These are the entities endowed with the surface water delivery networks that would presumably be expanded to deliver surface water to these lands *in lieu* of groundwater pumping. This criterion was evaluated by carrying out spatial analysis on databases describing the location of water districts and the distribution of agricultural lands within the 56 Central Valley DAUs.

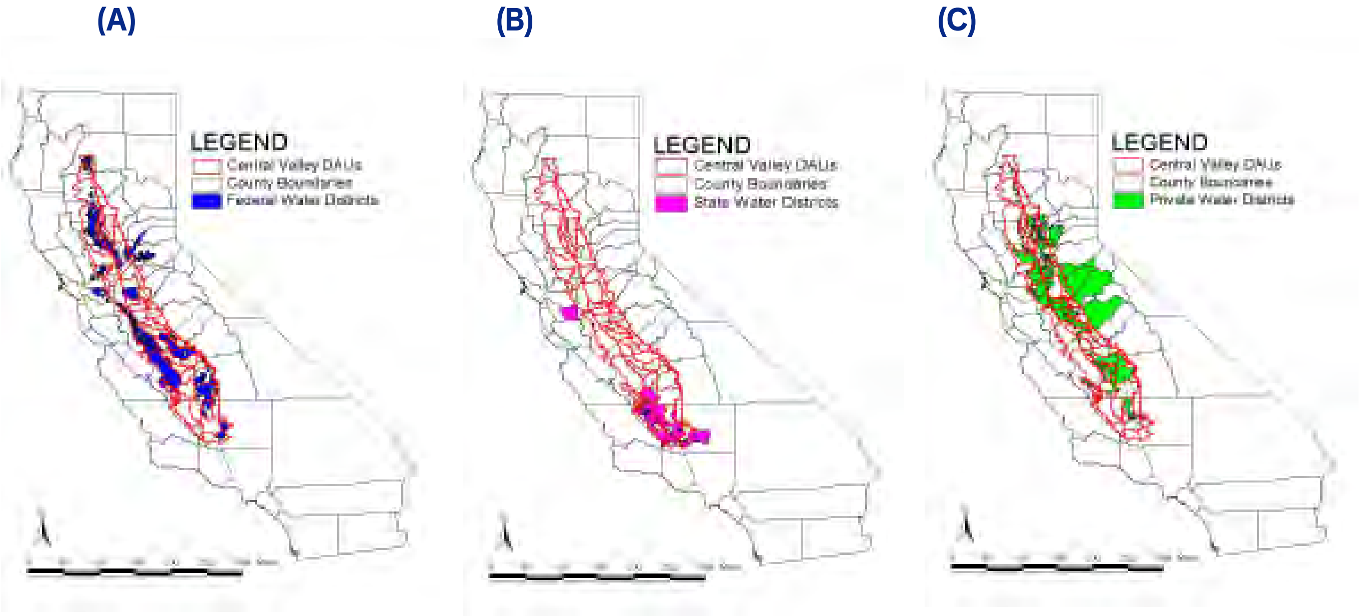
The U.S. Bureau of Reclamation's (USBR) Mid-Pacific Region originally developed the water district databases used in this exercise. The database differentiated water districts into three categories: Federal districts that contract with the USBR for water, State districts that contract with the State Water Project for water, and private districts that own and operate their own surface water supply systems. Districts lying at least partially within the Central Valley DAUs that are the basis of the current analysis are shown in Figure 3.4.

Observations on the DAU Databases

Given their foundational role in developing the aggregate Hydrologic Region water supply and demand numbers reported in Bulletin 160, it was surprising to discover that the DAU databases are neither easy to acquire nor uniform in format. The following observations regarding the DAU databases are offered in the hope that they may assist in expanding the utility and integrity of this important dataset.

1. DAU databases for the entire State should be available from a single source, preferably on-line.
2. DAU databases should follow a single transparent format so that interested parties outside of DWR can easily use them.
3. Detailed meta-data descriptions of the numbers included in the DAU databases should be developed. This meta-data should draw a clear distinction between what has been measured and what has been estimated. For estimated data, the methodology used to arrive at the estimate should be included.
4. For DAUs in the San Joaquin River and Tulare Lake Hydrologic Regions, a groundwater use is estimated to be a closure term in a mass balance that relies upon several coarse assumptions. Given the importance of groundwater in California, a better method of estimating groundwater use must be developed.
5. Bulletin 160 should include an appendix that clearly lays out how the uncertainty in the DAU water budget calculations can aggregate up into the reported Hydrologic Region supply and demand numbers.

Figure 3.4: Location of Federal (A), State (B) and Private (C) Water Districts Located at Least Partially within the 56 Selected Central Valley DAUs

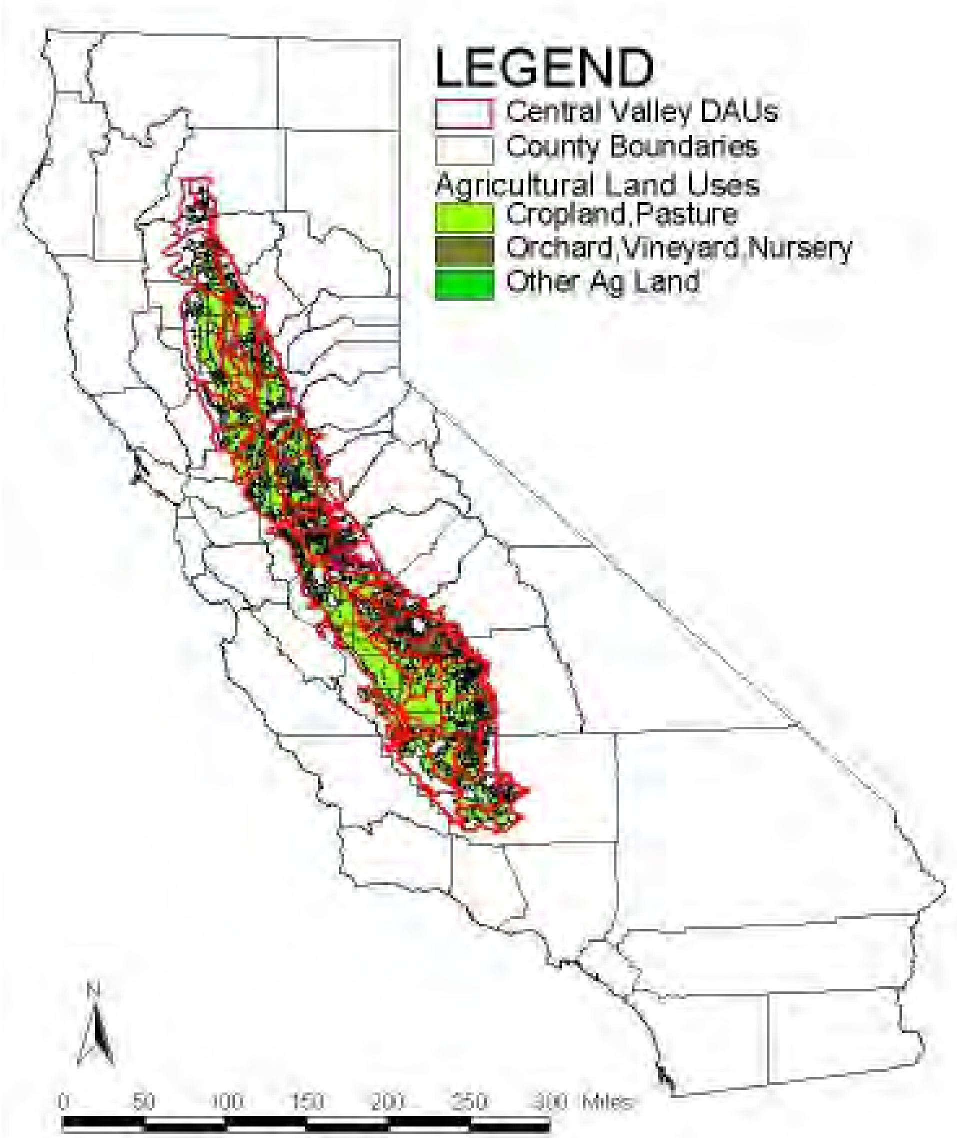


In order to estimate the amount of irrigated land historically irrigated solely with surface water that lies in close proximity to these districts, a land use/land cover database developed by the U.S. Geological Survey (USGS) at a scale of 1:250,000 was obtained. This database was edited so that it contained only land that would be under irrigation by removing all urban, industrial, non-irrigated agriculture and natural land use areas. The resulting database is found in Figure 3.5.

ArcView 3.2 buffers of 1, 2 and 3 miles were drawn around the portion of the Federal, State and private districts found within each of the 56 Central Valley DAUs. This buffering was performed separately for each of the three categories of water districts. Any land within the buffers of a particular water district category but inside the boundaries of another category of water district was eliminated from consideration. The remaining buffers were subsequently clipped to find those areas that contained irrigated agricultural land use types where groundwater pumping would presumably occur. The area of the remaining land was then calculated to evaluate the physical proximity of lands irrigated solely with groundwater to established water districts.

By treating the different categories of water districts separately, some of the irrigated lands located outside of the boundaries of incorporated water districts could be included in more than one set of buffers. As such the total amount of land irrigated by groundwater in a DAU within a given distance of any water district cannot be calculated by summing the area of buffers around the different categories of water districts. The analysis was carried out in this manner because the Federal, State and private districts are managed by different entities that generally make their own planning decisions.

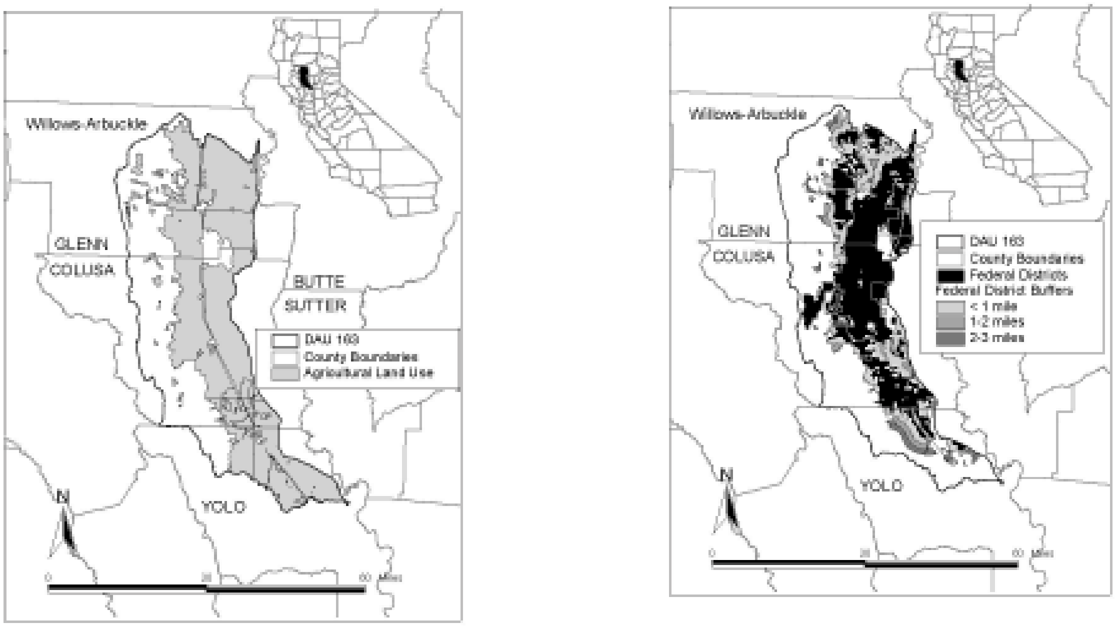
Figure 3.5: Irrigated Agricultural Land Use Type Located within the 56 Selected Central Valley DAUs



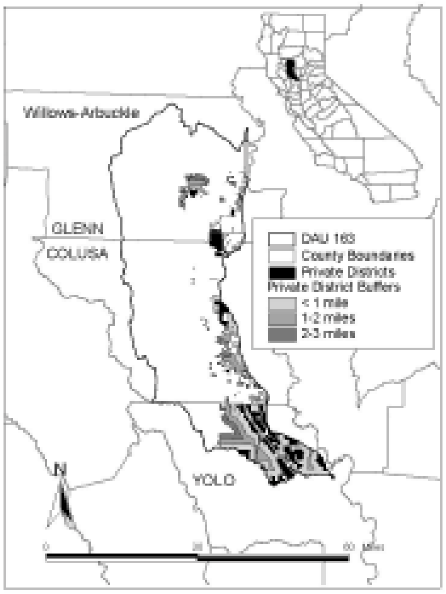
The basic framework for the spatial analysis used to evaluate this criterion is shown in Figure 3.6 for DAU 163, Willows-Arbuckle, which includes Federal and private water districts as well as substantial areas of irrigated land lying outside of district boundaries.

Figure 3.6: Spatial Analysis Framework for DAU 163, Willows-Arbuckle, with Area of Irrigated Agriculture (A), Federal Districts with 1-, 2- and 3-Mile Buffers (B), Private Districts with 1-, 2- and 3-Mile Buffers (C), and Tabulated Results (D)

(A) (B)



(C) (D)



Buffer Distance (miles)	Area Relative to Federal Districts (miles)	Area Relative to Private Districts (miles)
< 1	180.3	92.1
1-2	30.1	40.8
2-3	21.3	21.1

Maps similar to those shown in Figure 3.6 are shown for all of the Central Valley DAUs in Appendix A. The results of the spatial analysis of this criterion are discussed in Section 4.0.

3.3 Amount of Available Aquifer Storage Space

When groundwater pumping is foregone as a result of *in lieu* surface water deliveries, the result is that more water is left in aquifer storage than otherwise would have been present. Given ample substitution of surface water, the increase in aquifer storage will translate to higher water levels in the unused wells. If the well is tapping an unconfined aquifer where the water table already lies close to the ground surface, then the additional groundwater storage may be problematic. High water tables can create drainage problems for agricultural crops and cause damage to structures with deep foundations. In addition, high water tables can result in increased seepage to streams and rivers meaning that some portion of the water stored in the aquifer as a result of *in lieu* surface water deliveries may be lost. Wells tapping deeper, confined aquifers are less prone to the problems associated with high water tables although increases in the piezometric surface in these wells may reduce seepage from overlying unconfined aquifers, leading indirectly to a rising water table.

Both types of aquifers are tapped by agricultural wells in the Central Valley. In the San Joaquin and Tulare Lake Basins in particular, much of the groundwater used for irrigation is pumped from the confined aquifer below the Corcoran Clay. In either case, *in lieu* conjunctive use becomes less attractive if either the water table or the piezometric surface is already close to the ground surface prior to the delivery of surface water to historic groundwater users. Identifying regions with ample available aquifer storage space was carried out using data available in the Fall 1999 DWR water level survey of wells in the Central Valley (the latest complete data set available on-line). Figure 3.7 depicts the wells included in the survey that lie within the 56 Central Valley DAUs selected for analysis.

While DWR includes some agricultural wells in its semi-annual water level survey, the vast majority of wells in the survey are used for irrigation. In order to further focus on these irrigation wells, only the wells located within the irrigated agricultural land-use types of each of the Central Valley DAUs were selected for analysis (see Figure 3.5). For example, Figure 3.8 shows the wells located within areas defined by an irrigated agricultural land-use type in DAU 163, Willows-Arbuckle. No attempt was made to differentiate between wells that were tapped in the surface unconfined aquifer and were recording the depth to water table and those recording the piezometric surface in a deeper confined aquifer. The fact that either surface lies close to the ground surface would detract from the attractiveness of this DAU, or any other DAU, for *in lieu* conjunctive use. Using the ArcView 3.2 Statistics tool, the average depth to water (DTW) reported in the Fall 1999 water level survey was found to be 35 feet in DAU 163. A similar calculation was carried out for each of the 56 Central Valley DAUs. While it may have been more accurate to contour the water level data in order to estimate the average depth to water, trial calculations on a few DAUs revealed that the results were not significantly different to merit the substantial increase in effort required for contouring. The results of this analysis for the entire Central Valley is presented in Section 4.0.

Figure 3.7: Location of DWR Water Level Survey Wells Located within the 56 Selected Central Valley DAUs

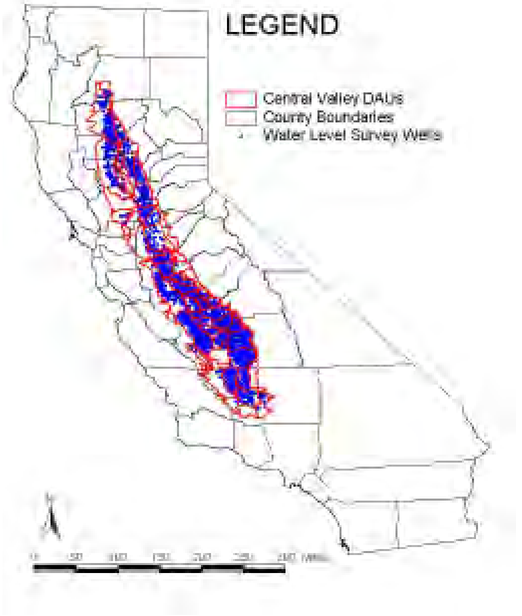


Figure 3.8: Location of DWR Water Level Survey Wells Located within Irrigated Agricultural Areas of DAU 163, Willows-Arbuckle

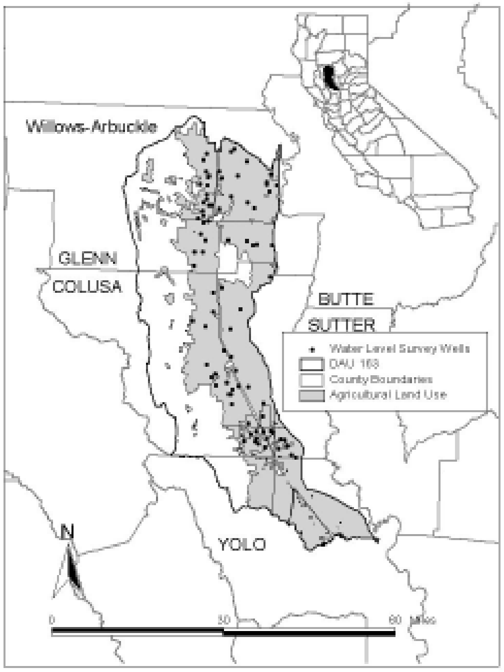

4.0 Results

Figures 4.1 through 4.3 present the results of the analysis to determine the current mix of surface water and groundwater utilization in DAUs located within the Sacramento River, San Joaquin River and Tulare Lake Hydrologic Regions. In each region the DAU have been sorted by the sum of the surface water (ASW) and groundwater (GSW) applied in the agricultural sector. The recorded value of evapotranspiration of applied water (ETAW) is also plotted on the left-hand volumetric scale. Calculated values of the irrigation efficiency (E) and agricultural surface water contribution (%SW) are plotted on the right-hand percent scale.

In examining these figures, the most attractive DAUs are those that utilize a mix of surface water and groundwater for irrigation, as this suggests that groundwater pumping could be replaced by *in lieu* deliveries of locally available surface water. The absolute amount of water used in agriculture is also important as it corresponds with the magnitude of the *in lieu* conjunctive use program that could occur. DAUs with low irrigation efficiencies are areas where improved water management might allow for a wider distribution of available surface water. DAUs in the San Joaquin River and Tulare Lake Hydrologic Regions with negative values of applied groundwater reflect the fact that AGW is calculated as a closure term in the water balance conducted for these regions combined with the fact that ASW exceeds ETAW in these units. DAUs without data are those for which no data could be obtained from the associated DWR regional office.

Figure 4.1: Relative Contribution of Surface Water and Groundwater to Irrigated Agriculture for DAUs in the Sacramento River Hydrologic Region

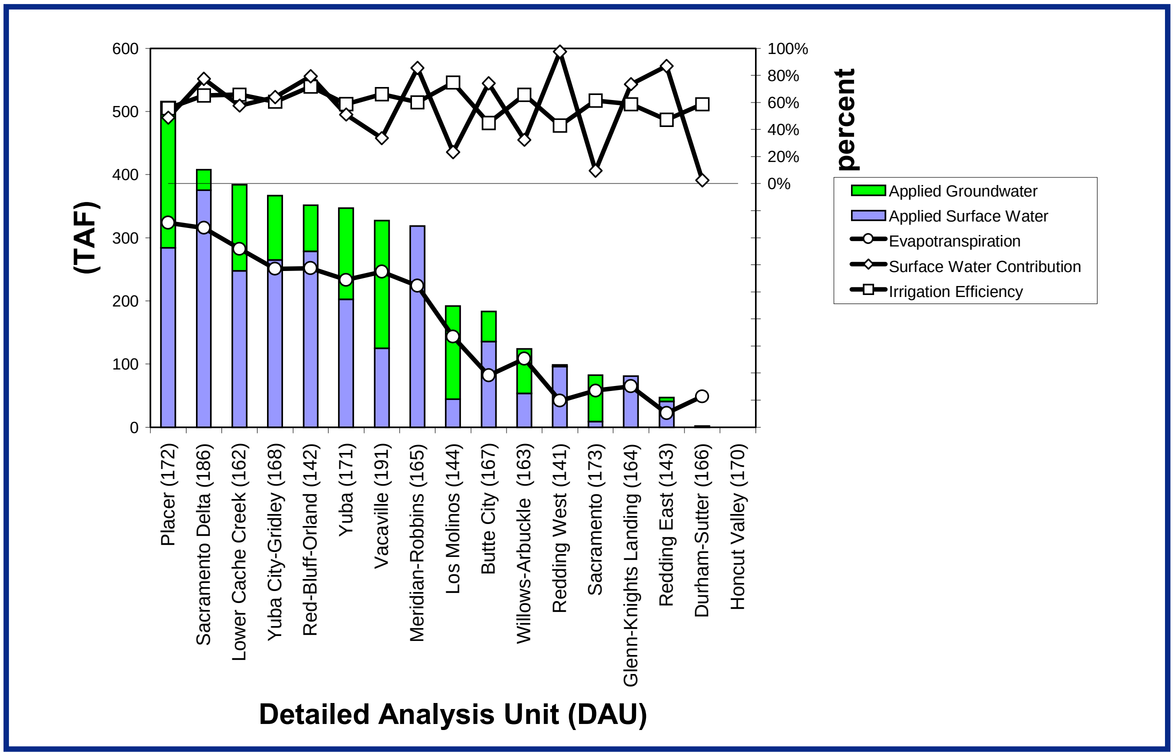

Figure 4.2: Relative Contribution of Surface Water and Groundwater to Irrigated Agriculture for DAUs in the San Joaquin River Hydrologic Region

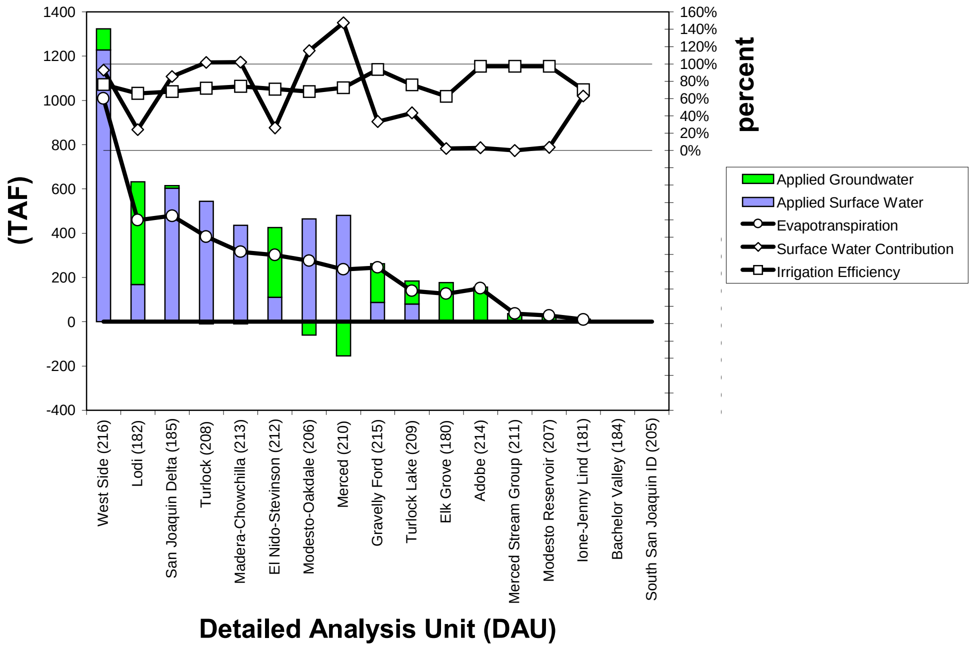

Figure 4.3: Relative Contribution of Surface Water and Groundwater to Irrigated Agriculture for DAUs in the Tulare Lake Hydrologic Region

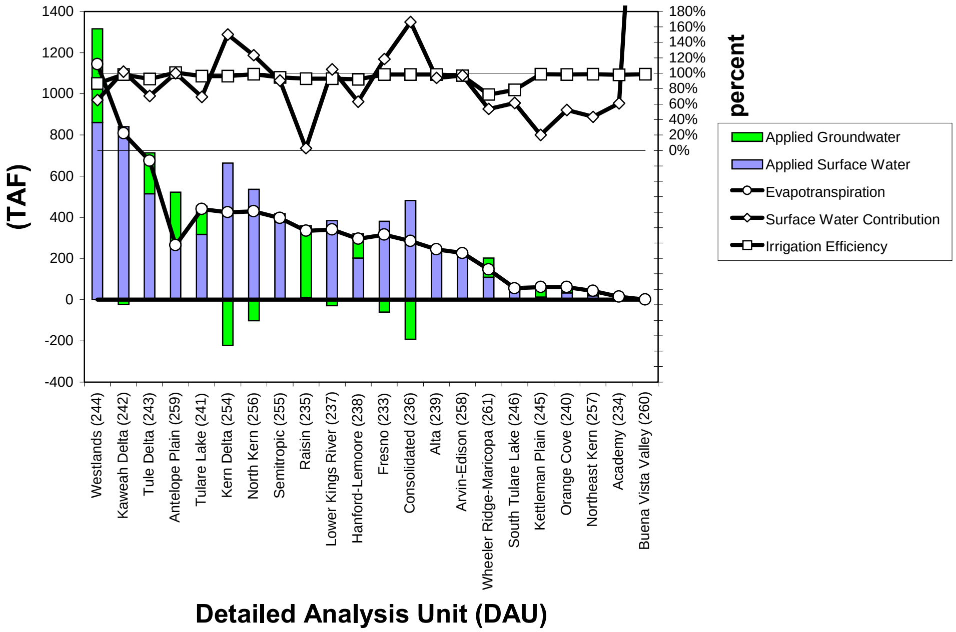

Figures 4.4 through 4.6 contain the results of the spatial analysis on the proximity of unincorporated irrigated land to Federal, State and private water districts for the Sacramento River, San Joaquin River and Tulare Lake Regions. Only the area of the 1-mile buffers around water districts are included in these figures as these are the lands that could most easily receive surface water deliveries in lieu of groundwater pumping. Areas contained within the 2- and 3-mile buffers are reported in Appendix B, along with the data used to develop Figures 4.4 through 4.6. The DAUs are sorted by the amount of land in close proximity to Federal water districts in order to reflect the support that the USBR has provided to the effort. State water districts are not found within the Sacramento River Hydrologic Region, and the only one in the San Joaquin River Hydrologic Region, DAU 216 West Side, has virtually no unincorporated irrigated land in its immediate vicinity.

Figures 4.7 through 4.9 depict the results of the depth to water analysis for DAUs in the Sacramento River, San Joaquin River and Tulare Lake Hydrologic Regions. The very large DTW values observed in the Tulare Lake Hydrologic Region are probably due to the fact that many of the agricultural wells in this region are screened in the confined aquifer below the Corcoran Clay. A table summarizing the data found in these figures is summarized in Appendix C.

5.0 Analysis and Conclusions

Based on the results of analysis of the three evaluation criteria, several DAUs in each of the Hydrologic Regions emerge as attractive candidates for *in lieu* conjunctive water management. The first filter that was applied to identifying target DAUs was the mix of surface water and groundwater used in the agricultural sector. Table 5.1 includes DAUs where 20 to 70% of irrigation water is supplied by groundwater pumping. This level has been established because it reflects the fact that there is a significant reliance on groundwater pumping in the vicinity of the water districts endowed with locally important surface water rights that could potentially be managed to offset some groundwater pumping. The DAUs in Table 5.1 have also been screened to include only those that reported more than 20 TAF of total agricultural water use. Areas with smaller amounts of total agricultural water use were eliminated because they do not represent a significant opportunity from the perspective of system-wide conjunctive water management planning. The DAUs shown in bold have an estimated irrigation efficiency of less than 70%. These are areas where water management improvements may create the opportunity to expand the delivery of existing surface water supplies, although detailed analysis will be required to evaluate this opportunity since some percentage of the water not consumed by crops may be collected and used by other irrigators.

The second filter allied to the results was the proximity of water districts whose surface water delivery infrastructure would likely be extended to supply surface water in lieu of groundwater pumping.

Those DAUs listed in Table 5.1 with more than 10 miles^2 of unincorporated irrigated land within 1 mile of either Federal, State or private water districts in the DAU are listed in Table 5.2.

Table 5.1: Central Valley DAUs with > 20% and < 70% Reliance on Groundwater Pumping in the Agricultural Sector and > 20 TAF of Total Agricultural Water Use

DAU	Hydrologic Region	SW Contribution (%)	GW Contirbution (%)	ASW + AGW (TAF)
Red-Bluff-Orland (142)	Sacramento River	79.4%	20.6%	351.2

South Tulare Lake (246)	Tulare Lake	2.7	30.2	6.3
Northeast Kern (257)	Tulare Lake	30.8	0.0	3.0

Finally, for the DAUs listed in Table 5.2, the depth to water evaluation criterion was applied. Table 5.3 lists those DAUs where the estimated depth to water in agricultural wells was at least 20 feet below ground surface. This value was selected to represent the fact that higher water levels associated with *in lieu* conjunctive water management should not be allowed to rise too close to the ground surface. If the starting water level is less than 20 feet, there may not be much opportunity to increase the amount of groundwater storage within the DAU.

Table 5.3: Central Valley DAUs where the Estimated Depth to Water in Agricultural Wells is at Least 20 Feet Below Ground Surface

DAU name	Hydrologic Region	DTW (ft)
Red-Bluff-Orland (142)	Sacramento River	48.9
Lower Cache Creek (162)	Sacramento River	50.3
Willows-Arbuckle (163)	Sacramento River	35
Glenn-Knights Landing (164)	Sacramento River	23.9
Yuba (171)	Sacramento River	26.4
Placer (172)	Sacramento River	46.1
Turlock Lake (209)	San Joaquin	95.3
Gravelly Ford (215)	San Joaquin	80.6
Hanford-Lemoore (238)	Tulare Lake	65.2
Tule Delta (243)	Tulare Lake	103.8
South Tulare Lake (246)	Tulare Lake	134.1
Northeast Kern (257)	Tulare Lake	343

The map in Figure 5.1 depicts the location of the Central Valley DAUs that have been identified as attractive locations for *in lieu* conjunctive water management based on the application of the three selected evaluation criteria. This map suggests that opportunities for *in lieu* conjunctive water management exist in all three of the Hydrologic Regions in the Central Valley, although the Sacramento River and Tulare Lake regions have larger amounts of land that could be easily incorporated into a program (see Table 5.2).

Based on the values of the various evaluation criteria, it is possible to develop a very rough estimate of the scale of the *in lieu* conjunctive use program that could be implemented in the DAUs identified in the screening process. This can be done in two ways. First the estimated available aquifer storage can be calculated as the product of the difference between the depth to water and a plane 10 feet below the land surface and the area of land within 1 mile of water districts adjusted by a specific yield in the case of wells with a DTW of less than 100 ft (assume 0.1) and the specific storage in wells with a DTW in excess of 100 ft (assume 0.01). The second estimate can be made by assuming that up to 10% of the allied surface water in a DAU could be used to offset up to 50% of groundwater pumping. The results of this analysis are found in Table 5.4. The first number is a proxy for the total available storage while the second number is a proxy for the amount of water that could be delivered to storage in a typical water year. Even given the coarse nature of these calculations it is evident that the scale of potential *in lieu* conjunctive water management opportunities in the Central Valley is very substantial. Further analysis of aquifer characteristics and water supply opportunities in these DAUs would help to refine these estimates.

Figure 5.1: Locations of Promising DAUs in the Central Valley

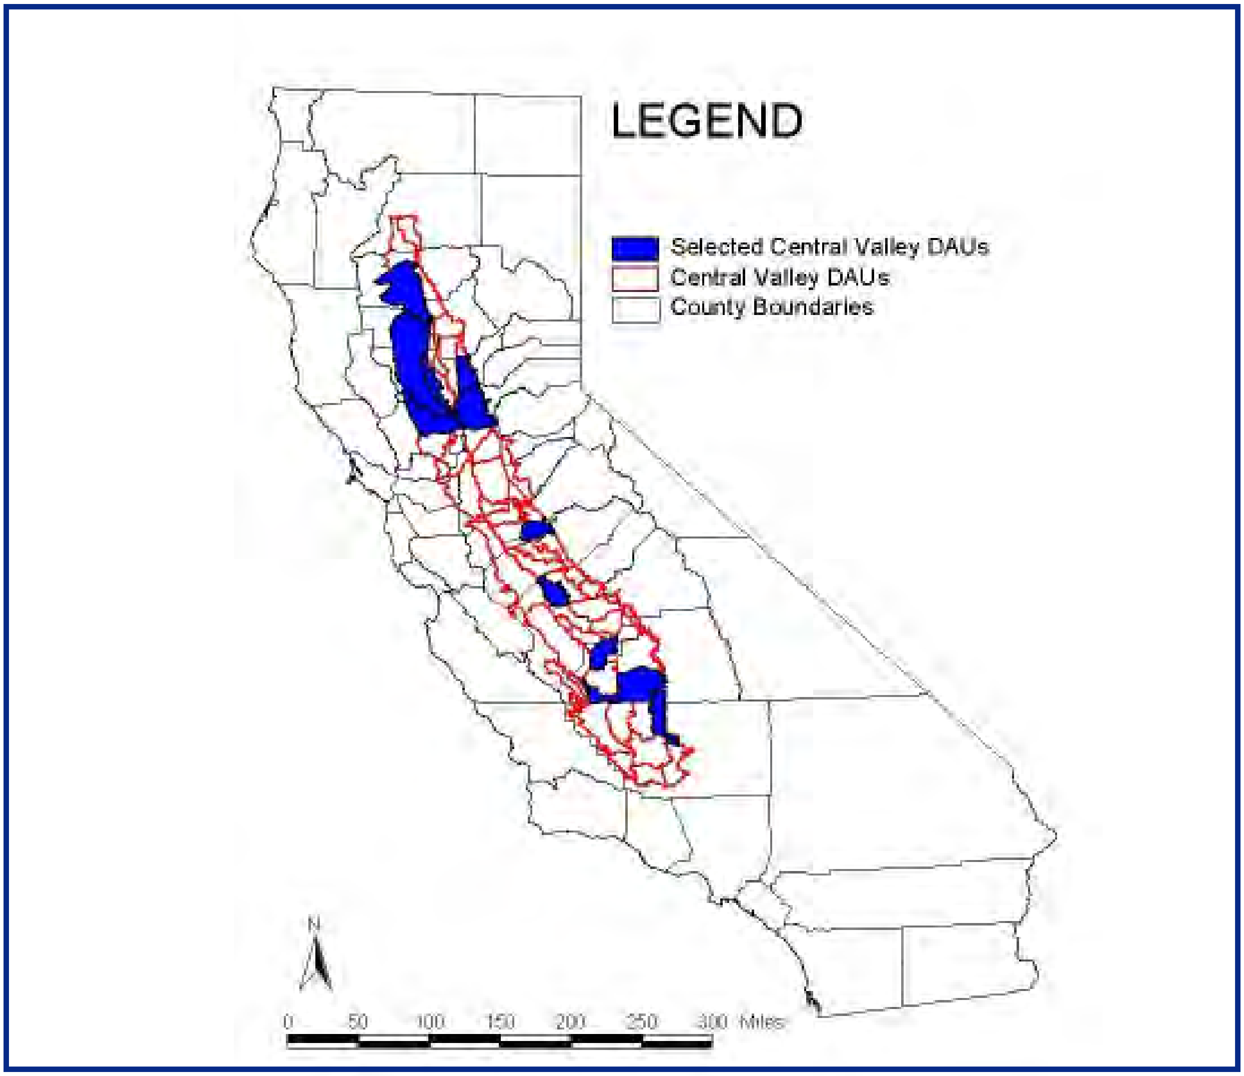

Table 5.4: Analysis of the Scale of Potential *In Lieu* Programs in the Central Valley

		Area within 1 mile				Estimated Available Storage			
DAU name	**Hydrologic Region**	**Federal (miles^2)**	**State (miles^2)**	**Private (miles^2)**	**DTW (ft)**	**Federal (TAF)**	**State (TAF)**	**Private (TAF)**	**Available Water (TAF)**
Red-Bluff-Orland (142)	Sacramento River	69.0	0.0	56.0	48.9	343.74	0.0	278.87	36.2
Lower Cache Creek (162)	Sacramento River	0	0.0	41.0	50.3	0.00	0.0	211.72	81.1
Willows-Arbuckle (163)	Sacramento River	180.3	0.0	92.1	35	577.09	0.0	294.57	41.9
Glenn-Knights Landing (164)	Sacramento River	51.5	0.0	34.9	23.9	91.66	0.0	62.01	10.7
Yuba (171)	Sacramento River	0	0.0	34.2	26.4	0.00	0.0	71.90	84.9
Placer (172)	Sacramento River	39.4	0.0	55.6	46.1	181.87	0.0	256.71	132.0
Turlock Lake (209)	San Joaquin	0.0	0.0	14.7	95.3	0.00	0.0	160.46	52.1
Gravelly Ford (215)	San Joaquin	31.7	0.0	11.4	80.6	286.03	0.0	103.33	86.9
Hanford-Lemoore (238)	Tulare Lake	0.0	0.0	46.2	65.2	0.00	0.0	326.58	58.9
Tule Delta (243)	Tulare Lake	69.9	0.0	20.1	103.8	4.20	0.0	1.21	104.4
South Tulare Lake (246)	Tulare Lake	2.7	30.2	6.3	134.1	0.21	2.40	0.50	13.6
Northeast Kern (257)	Tulare Lake	30.8	0.0	3.0	343	6.57	0.0	0.64	12.1
					Total =	**790.87**	**24.01**	**900.82**	**209.39**

Given the magnitude of the potential for *in lieu* conjunctive water management in the Central Valley, this component of a system-wide conjunctive water management strategy certainly merits further consideration. Information on this opportunity will be factored into future analyses conducted as part of this series, most notably, the evaluation of the potential for integrating conjunctive use into reservoir re-operation strategies that are also intended to enhance downstream fluvial processes, the “gaming” analysis of a series of conjunctive use configurations in the Central Valley, the economic optimization analysis, and the final feasibility study of and strategic plan for the initiative. In conclusion, however, even taken as a stand-alone piece of research, this analysis suggests that *in lieu* conjunctive water management can contribute to enhancing the performance of Federal, State and private surface water supplies in the coming decades.

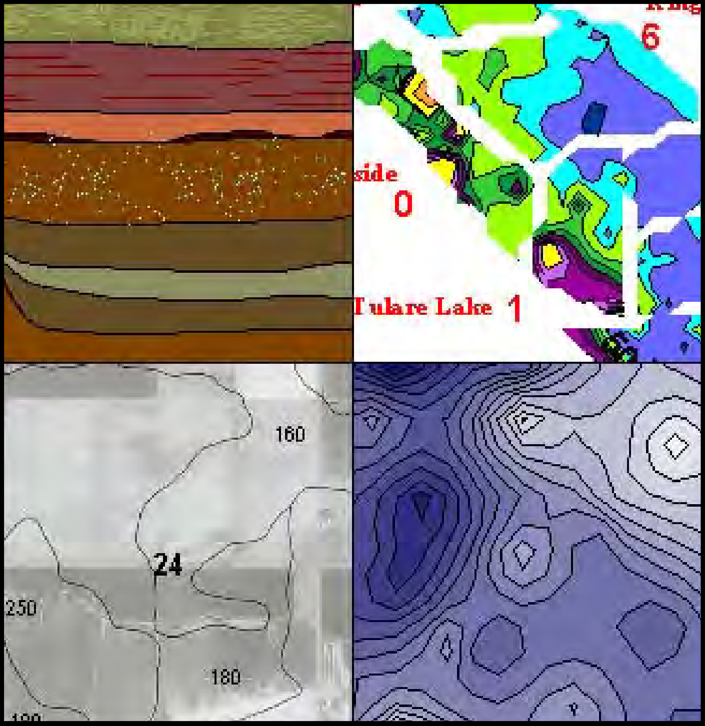
SYSTEM-WIDE CONJUNCTIVE WATER MANAGEMENT

THE HYDROGEOLOGIC SUITABILITY OF POTENTIAL GROUNDWATER BANKING SITES IN THE CENTRAL VALLEY OF CALIFORNIA



THE NATURAL HERITAGE INSTITUTE

David R. Purkey, Ph.D.
Gregory A. Thomas, J.D.

with research by:

Shannon Byrne
Ann M. Cheng
Nathan E. Harrison

September 2001

This report is one of several technical studies prepared by the **Natural Heritage Institute** as part of a System-Wide Investigation of Conjunctive Water Management Opportunities in the Central Valley of California under a cooperative agreement (99FC200189) with the U.S. Bureau of Reclamation. That project, in turn, is part of a larger program of activities to Enable Water Transactions to Restore Landscapes and Aquatic Habitats in California's Central Valley with support from the David and Lucile Packard Foundation, the Dean Witter Foundation and the William and Flora Hewlett Foundation.

The methodology and results in this study benefited greatly from a peer review by the following panel of experts who graciously donated their time and knowledge to this effort:

- Sydney Coatsworth, EDAW, Inc.
- Mark Cowin, CALFED Bay-Delta Program
- Toccoy Dudley, California Department of Water Resources
- John Fielden, California Department of Water Resources
- Jan Fleckenstien, University of California at Davis
- Graham Fogg, University of California at Davis
- David Fullerton, Natural Heritage Institute
- Carl Hauge, California Department of Water Resources
- Karen Hoover, California State University at Chico
- John Jenkins, US Bureau of Reclamation
- George Mantanga, US Bureau of Reclamation
- Doug Osugi, California Department of Water Resources
- Steven Phillips, US Geological Survey
- Anthony Saracino, Saracino, Kirby & Snow
- Walter Swain, US Geological Survey
- John Woodling, California Department of Water Resources

This report and others from this project are available on-line from NHI's website at www.n-h-i.org or contact the Natural Heritage Institute at the address below.

THE NATURAL HERITAGE INSTITUTE

1.0 Introduction

This report is one product of a technical investigation to design a **Central Valley System-Wide Conjunctive Water Management Program** under an emerging partnership that includes the U.S. Bureau of Reclamation and a consortium of other public water management agencies. As envisioned by this program, conjunctive use entails the integration of groundwater banking with reservoirs that would be reoperated to generate the source water. Other products of the investigation that are now available include:

- ***Feasibility Study of a Maximal Program of Groundwater Banking in California*** (January 1999), which includes an overview of the project and three pilot feasibility studies.
- ***Designing Successful Groundwater Banking Programs In The Central Valley: Lessons From Experience*** (August 2001), which includes extensive analysis of legal and institutional constraints and solutions.

These and other project documents can be viewed and downloaded from the Natural Heritage Institute's website at www.n-h-i.org.

Subject to the availability of financial resources, forthcoming products will include reports on:

- "*In lieu*" groundwater banking site analysis
- Design specifications for local groundwater banking institutions
- The potential for reoperating reservoirs to generate source water for groundwater banking and to restore downstream fluvial processes
- Analysis of institutional, land use, infrastructure, environmental and other factors bearing upon siting decisions for groundwater banks
- Results of "gaming" analysis of a series of conjunctive use configurations in the Central Valley
- Economic optimization analysis
- A final feasibility report and strategic plan

This work is animated by the widespread realization that conjunctive water management will be a prominent feature of California's water future because it is an environmentally acceptable (indeed, environment-enhancing) and cost-competitive way to improve the reliability of water supplies for all sectors. Thus, groundwater banking has emerged as a management concept that can garner broad-based support. As a storage enhancement strategy, groundwater banking is an attractive alternative to many who are reluctant to endorse an ambitious expansion of the state's surface storage infrastructure. Storage increases associated with groundwater banking offer the potential to increase the yield of the California water system—an attractive prospect to the state's water user community. Indeed, the CalFed Record of Decision assigns a larger role to groundwater storage (500,000–1,000,000 acre-feet) than to any of the surface storage options in its plan to increase water supplies. Notably, however, the RoD gives priority to conjunctive use projects that are developed for local benefit and is silent regarding the source of the water to be banked. It is difficult to see how that vision would create new yield not otherwise available in the system. By contrast, the system-wide investigation, of which this report is a part, is oriented toward system-wide benefits (including benefits that accrue in the locale where groundwater banking occurs) and would generate new yield by integrating the water storage with existing reservoirs that would be reoperated so as to increase the space available to capture a larger fraction of annual runoff.

Groundwater banking must, as a practical necessity, be developed with the cooperation and consent of overlying landowners, groundwater appropriators, water districts and groundwater management authorities. Indeed, the recharge and recovery operations will generally be conducted by such local interests. Increasingly those communities that have historically relied on groundwater pumping to meet their needs realize that the best way to assure that local benefits flow from potential groundwater banking projects is to be involved in the project selection and design processes. The apparent convergence of interest between those charged with assuring California's future water supplies and those charged with managing local groundwater resources creates a climate where attempts are being made to identify the most promising groundwater banking opportunities in advance of the design and implementation of actual projects.

As with any water management initiative, the translation of a promising concept into a viable project relies upon a rigorous analysis of site-specific opportunities and constraints. To determine how best to link reservoirs that would provide the recharge water, with groundwater banking sites that would store it, with project beneficiaries who would use it, in a way that proves universally beneficial, it is of course necessary to investigate the most suitable groundwater banking sites. There are many dimensions to that puzzle. To itemize the most prominent factors, the most suitable sites will be those where:

- The target aquifer has the best physical characteristics for the storage and retrieval of banked groundwater;
- The aquifer does not interact with surface water bodies (unless such interaction is a desired characteristic);
- The overlying water districts or groundwater management authority is willing to operate the banks and where effects on unincorporated groundwater users can be avoided;
- The existing patterns of groundwater use in the vicinity of the project are compatible with groundwater banking;
- The legal and institutional setting governing groundwater management, use and export is most congenial;
- The recharge, extraction and conveyance facilities will not conflict with existing land uses;

- The manipulation of groundwater levels will not adversely affect important habitats, crops or structures;
- The project can be easily linked to a water distribution network;
- The project is located down gradient of river reaches through which it is feasible to re-establish geomorphically beneficial peak flows;
- The project is located within the same sub-basin as the demand center that it is intended to serve (so as to minimize the need to transfer the banked water across the delta); and
- The costs of storing and recovering water are relatively attractive.

This report focuses on the first factor only, namely the hydrogeologic suitability of potential groundwater banking sites in the Central Valley. In limiting the scope of the report to this factor, we fully recognize that hydrogeologic suitability may not be the ultimate arbiter of where groundwater banking projects will prosper. The full suite of opportunities and constraints that will bear on any final project selection, as itemized above, will be the subject of other reports emanating from this project. Perhaps most predominant of those is the local receptivity as shaped by the legal and institutional settings of current groundwater utilization—this is treated at length in the companion report, ***Designing Successful Groundwater Banking Programs in the Central Valley: Lessons from Experience***, published by the Natural Heritage Institute in 2001.

Also, in limiting our scope to the Central Valley, we acknowledge that promising groundwater banking opportunities exist both in the Bay Area and on the Southern California Coastal Plain. Our assumption is that these opportunities will be pursued by the water management agencies that overlie those sites as part of their own local resource planning efforts. Here we are attempting to focus on potential groundwater banking projects that through integration with the overall California water system could improve that system's performance, but which are less likely to be included in purely local resource planning initiatives. These sites are located primarily in the Central Valley.

We also need to be clear that the scope of this hydrogeologic suitability analysis is limited to one of several modes of recharging groundwater: active recharge through percolation of water from ponds at the land surface that overlie the aquifer in which water will be stored. Water introduced to these ponds will percolate under gravity through any intervening unsaturated material prior to entering into groundwater storage. Another strategy, which is not treated in this report, involves introducing banked water directly to groundwater storage via wells screened in the target aquifer material. A third approach to groundwater banking is called *in lieu* groundwater banking. Under this approach, historic users of groundwater are provided with a new or expanded supply of surface water that decreases their need to pump groundwater. Groundwater that goes unpumped is considered banked (site suitability analysis for this type of groundwater banking technique will be the subject of a forthcoming report from this investigation). A fourth emerging concept focuses on rivers that will undergo dramatic shifts in their flow regimes as part of ecosystem restoration efforts. In theory, any additional seepage through the bed of these rivers that percolates down to the underlying aquifer system could be considered banked.

Each of the approaches is characterized by technical considerations that define its suitability for a particular location. If, for example, the aquifer targeted for groundwater banking is located below layers of low permeability material, injection wells would represent a more viable option for conveying water to storage than recharge ponds. If such an area has already experienced substantial development of groundwater wells, it might be particularly well-suited for an *in lieu* banking arrangement. For instance, the Tuscan formation below Butte County is highly suitable for *in lieu* groundwater storage because it is overlain with a thick layer of tight geologic material and is already utilized for irrigation. This report focuses exclusively on groundwater banking via recharge ponds. We have limited the scope of our analysis in full recognition that other types of groundwater banking projects are possible, and potentially important, in California. However, we chose to focus on recharge ponds based on several factors:

- The largest existing groundwater banking projects in California, of which the Kern Water Bank is the best known, have generally employed recharge ponds.
- Soil assemblages in the Central Valley, derived largely from the deposition of alluvial fans, often contain soils coarse enough to support recharge ponds.
- While vertical stratification of thin water bearing and flow retarding aquifers does exist in parts of the Central Valley, deep alluvial aquifers receiving recharge from overlying percolation are fairly widespread.

Within this limitation in scope, however, this report provides a methodology to compare sites in the Central Valley in terms of their hydrogeologic suitability for groundwater banking via recharge ponds. Our methodology relies upon utilizing a core set of available data related to geology, groundwater quality, soils and hydrology to develop a Hydrogeologic Suitability Index, which like all indices is the product of both analysis and judgment. In developing this index we were driven by the desire to create a uniform template against which all potential groundwater banking sites could be compared—tempered by the recognition that site-specific factors and data limitations generally complicate the application of a uniform standard. We acknowledge these complications, and make appropriate assumptions in response, because waiting until the definitive information is available to complete our analysis, if ever, is unacceptable in the accelerated state of water planning initiated by the RoD.

One significant complication in applying a single index across the Central Valley stems from the fact that hydrogeologic conditions in the Sacramento and San Joaquin Valleys differ. While regions of prolonged groundwater overdraft characterize the San Joaquin Valley, resulting in the creation of substantial cones of depression, aquifers in the Sacramento Valley are not typically impacted by overdraft and large cones of depression are less common in this region. This difference has implications for the sequence of water storage and recovery that could be implemented as part of a program of groundwater banking. In general, dewatered aquifer space is available for immediate groundwater storage in portions of the San Joaquin Valley while aquifer storage in the Sacramento Valley would generally have to follow the groundwater recovery required to create storage space. The hydrologic parameters useful in evaluating the hydrogeologic suitability of groundwater banking under these two conditions are not identical. As a result, we developed a core index that includes information on geology, groundwater quality and soils that can be applied in both the Sacramento and San Joaquin Valleys, and an extended index that draws upon hydrologic information for use solely in the San Joaquin Valley.

Even in applying the index within the Sacramento or the San Joaquin Valley, however, we confronted the challenge of assigning appropriate weighting factors for the parameters under consideration. These assignments are certainly open to alternative interpretations. To allow for that, we have crafted a methodology that allows others to insert weighting factors that reflect their own judgments or preferences. The result is a spreadsheet that can be manipulated based on any number of assumptions regarding appropriate weighting factors. If suitably disaggregated data is available, the index is also scalable so that it could be applied to the comparison of promising groundwater banking sites within a single county as easily as it has been applied across the Sacramento or San Joaquin Valleys in this report.

We hope this flexibility and scalability will make the index useful to a range of potential users in California. These could include: agency staff charged with prioritizing the range of potential groundwater banking sites across the Central Valley, researchers examining the interactions between groundwater banking and other water management objectives such as flood control and ecosystem restoration, local and private resource managers deciding whether or not a groundwater banking project they are contemplating offers strategic advantages to statewide water planners, and reservoir operators attempting to develop groundwater banking strategies that take into consideration all of the constraints and opportunities listed above. Thus, despite the limitations inherent in adopting an index approach, we trust that our study will provide information useful to all of these actors as they attempt to move the analysis of groundwater banking to a point where consideration of more refined site-specific details of promising sites becomes both necessary and appropriate.

This work is properly viewed as a first screen in identifying the most suitable groundwater banking sites. The scale of analysis is too coarse and the data uncertainties too significant to permit specific parcels of land to be specified as the best locations to construct groundwater recharge or extraction facilities. Nor would we presume so far without the assent of such landowners. Indeed, the uncertainties inherent in the analysis point out areas where additional research carried out with limited public resources would prove beneficial. Refinement of the information on the heterogeneity of geologic and associated aquifer hydraulic properties in the areas that appear most suitable for groundwater banking is a direct benefit that can flow from the development of the index. Continued investment in water quality data acquisition may also be warranted at promising sites as much of the information currently available is decades old. Finally the analysis can lend focus to more targeted analysis that includes the other factors, itemized above, that will necessarily bear upon the selection of optimal sites. With the funds earmarked for conjunctive use beginning to flow from the CalFed Program,Proposition 13 funding, and other federal and state resources, the analysis behind the development of the index can provide useful on where to utilize research dollars intended to facilitate the increasing adoption of conjunctive use as a viable water management strategy.

Two things are clear: 1) the potential for conjunctive water management to contribute to a more secure water supply in California is too large to ignore, and 2) one of the factors that most inhibits the realization of this potential is the lack of definitive information on hydrogeologic suitability. Uncertainties in this regard engender fear of unintended consequences within those communities currently most reliant upon groundwater. Fear creates resistance among those who have most to gain from this water management technique—those landowners who control the aquifers and could manage them as a local public good and those public officials charged with managing our limited water supplies. If we wait for the optimal list of conjunctive use projects, developed from unimpeachable information, to appear, we may miss the opportunity to realize the enormous potential of conjunctive water management. Imperfect as it is, we hope that this document, along with others published by the investigation, will assist as we push toward the realization of actual conjunctive use projects.

2.0 Identification of Potential Groundwater Banking Sites

As stated in Section 1.0, differences in the hydrologic conditions encountered in the Sacramento and San Joaquin Valleys militate in favor of applying the Hydrogeologic Suitability Index separately to these two regions. In both regions a core index, based on geology, groundwater quality and soils considerations, can be applied. An extended index that takes into account hydrologic information can be applied in the San Joaquin Valley. Before applying either index, however, a list of potential groundwater banking sites in both regions of the Central Valley must be developed.

A number of inventories of potential groundwater banking sites have been assembled in recent years. Many of these were synthesized in the list of potential sites reported in *A Feasibility Study of a Maximal Scale Program of Groundwater Banking in California* published by the Natural Heritage Institute in 1999. A less inclusive list of the sites judged to be most feasible from a technical and political vantage point were evaluated for recharge and recovery capacity in the February 2000 *Conjunctive Use Site Assessment* prepared by the Integrated Storage Investigation of the CALFED Bay-Delta Program. In general, these inventories have adopted a broad perspective, leading to the identification of rather large areas as potential banking sites (e.g., Yuba County or the Tuolumne/Merced Basin). A slightly more refined optic was adopted during the development of the Hydrogeologic Suitability Index. Here an attempt was made to identify the actual regions where measured groundwater levels reveal the opportunity to store water within dewatered aquifer material, or areas where in spite of the current high water table conditions, geologic conditions would favor an increase in aquifer management through more ambitious pumping and recharge.

The following steps were taken in the process of identifying potential groundwater banking sites in the Central Valley. Data from the Department of Water Resources semi-annual survey of wells was downloaded for Fall 1992. Using a contouring program, a groundwater head surface was developed for the entire Central Valley. Data from areas that exhibited groundwater head levels lower than that found in the surrounding area were examined in greater detail. Based primarily on the geometry of the mapped depressions, a qualitative assessment was made as to whether the depressions represented water table declines or comparatively low piezometric surfaces in deep water-bearing horizons. In general, water table declines were deemed to exhibit continuity with levels observed in the majority of nearby wells while low piezometric surface readings were associated with “bulls eye” type depressions that exhibited little correlation with nearby wells. Once depressions that appeared to be related to declines in the regional water table were identified, the second step in site identification involved examining soils maps to identify promising sites for recharge basins. This examination, which also relied upon qualitative analysis of existing data, sought to identify four-square-mile blocks of land with the most “promising” assemblage of soils. This involved looking for blocks dominated by sandy soils with a minimum of clay. While this step did not involve statistical analysis of soil assemblages, it was generally possible to visually distinguish sites with generally coarse soil from those dominated by fine-grained material. The four-square-mile blocks of land located over what were considered to be water table depressions were selected as the potential groundwater banking sites.

Viewed through this lens, several potential sites emerge within the broad regions previously defined. Figures 2.0.1 and 2.0.2 depict the locations of the sites that were ultimately selected for consideration in the Sacramento and San Joaquin Valleys, respectively. Information on the sites depicted in Figures 2.0.1 and 2.0.2 includes a site name, identifies the groundwater basin where the site is located and provides a reference to the site location based on the California State Land Survey system. The California Department of Water Resources delineated the groundwater basins.

The site names that appear in Figures 2.0.1 and 2.0.2 require some clarification. Information relevant to the Hydrogeologic Suitability Index is available at a variety of scales. In general, however, information on the characteristics of soils overlying potential groundwater banking sites is available at the finest scale (as fine as 1:20,000 in many soils surveys prepared by the United States Soil Conservation Service). In attempting to define important parameters associated with the soil characteristics at potential groundwater banking projects, four-square-mile land sections with the most attractive soil assemblages were identified in the region overlying targeted storage sites. The site names associated with each location are derived from prominent geographic features located near the selected land units. While these names may be less recognizable than Yuba County or the Tuolumne/Merced Basin, all information needed to locate the banking site selected for analysis are included in Figures 2.0.1 and 2.0.2.

In selecting the sites depicted in Figures 2.0.1 and 2.0.2, we anticipate that many readers will find reasons to object to the inclusion of a particular site or the exclusion of another. We make no claim that the lists we developed are complete and comprehensive. We do feel, however, that we have created a sample that reasonably reflects the range of potential groundwater banking sites in the Central Valley. There are sites in the western Sacramento Valley that are associated with the flashy gravel-laden streams that emerge from the Coast Range Mountains. Sites on the east side of the Sacramento Valley are associated with large perennial streams that drain the granite-rich Sierra Nevada. In the San Joaquin Valley there are sites associated with rivers that issue to the Bay-Delta system and others that drain into the Tulare Lake Basin. The only region of the Central Valley not represented is the western San Joaquin Valley, a region plagued by poor groundwater quality that makes it less favorable to groundwater banking based on the use of recharge ponds.

In addition, if others feel that additional sites should be added to the list, it is easy to do so in the spreadsheet developed as part of this project. It is simply a matter of defining the required parameter values and adding the site to the database.

Figure 2.0.1: Potential Groundwater Banking Sites in the Sacramento Valley

3.0 Description of the Sub-Index Parameters

As mentioned in Section 1.0, conditions encountered in the Sacramento and San Joaquin Valleys are sufficiently distinct to warrant the application of different versions of the Hydrogeologic Suitability Index. One major difference is the degree to which aquifers in the two regions have been drawn down. While the San Joaquin Valley is characterized by substantial cones of depression, surface aquifers in the Sacramento Valley generally exhibit water tables that closely track the land surface profile. This makes it more difficult to speculate how these aquifers would respond to the more intensive management that would accompany groundwater banking. As such, a sub-index related to hydrologic conditions in the target aquifers has been applied only at sites in the San Joaquin Valley.

In both locations, however, a core set of data related to geology, groundwater quality and soils can be used to develop relevant sub-indices. This section describes the parameters included in the core index and a methodology for evaluating their impact on the overall hydrogeologic suitability of potential groundwater banking sites. One of the central challenges in developing these sub-indices was to assign values to their various components. In the geology sub-index, for example, we consider the permeability of water-bearing geologic formations below potential groundwater banking sites. In making this consideration we reviewed numerous reports describing the geology of the target basins. These reports often used terms such as the formation is “highly” or “moderately” permeable. In a few cases, ranges of permeability values were also given, many of which were quite broad.

We did not attempt to translate these observations into a rigorous geo-statistical representation of permeability across the Central Valley. Instead we sought to develop associations between what previous researchers called highly, moderately and non-permeable materials and the range of actual permeability values that were occasionally reported in the literature. While this qualitative approach did not allow us to distinguish between two formations that were deemed to be highly permeable to find the “most promising sites”, it did allow us to confidently sort the geologic formations into broad categories useful in defining the “most promising sites”. This level of refinement was in keeping with the fact that the hydrogeologic suitability of a potential site will be only one factor influencing its ultimate selection for a groundwater banking project. A similar qualitative approach was taken in defining values for certain components of other core sub-indices. While this approach may seem cursory to some, we feel it is in keeping with the intent of this effort, which is to provide insight useful in identifying a suite of potential sites that merit the type of closer consideration that will lead to more refined comparisons among potential groundwater banking project locations.

3.1 Geology Sub-Index

Perhaps the most important factor in evaluating the hydrogeologic suitability of potential groundwater banking sites is the nature of the underlying geologic formations. The characteristics of these formations will control the amount of water that can be stored within a given volume of aquifer material and the ease with which water can be recharged to and extracted from the water-bearing formations. Clearly, an unconsolidated, uncemented, coarse-grained alluvial formation would offer easier access to larger storage volumes than a consolidated, fine-grained, lacustrian formation.

3.1.1 Geology Sub-Index Parameters

Having reviewed some of the voluminous geologic literature available for the Central Valley (see the Geology portion of Section 7.0: References), we decided to employ three parameters to characterize the geologic suitability of formations underlying potential sites for groundwater banking: permeability, the presence of paleosols, and the presence of geologic structures that could enhance or detract from aquifer storage potential. While many other parameters could have been used, we limited our selection based on the availability of data across most of the sites under consideration and on our desire to use parameters that were likely to be independent of one another. For example, we originally considered using both the percent coarse-grained material and the degree of cementation and consolidation of the target aquifer as parameters in the geology sub-index. These were ultimately discarded because they are likely correlated with the permeability of the aquifer formation. Details on the final set of parameters are presented in the following paragraphs.

Permeability

Permeability describes the ease with which water can flow through geologic material. Measured in units of length per time, permeability affects the rate at which water can percolate into the geologic material for storage and also the rate at which it can be pumped out in recovery. In general, the higher the estimated permeability, the better the yield of wells installed in a formation. Increases in well yield would facilitate the recovery of water stored in a potential groundwater banking site, enhancing that site's suitability. Permeability was scored based on textual descriptions of formations from the references cited in Section 7.0. Formations were described as being impermeable, moderately permeable, or highly permeable.

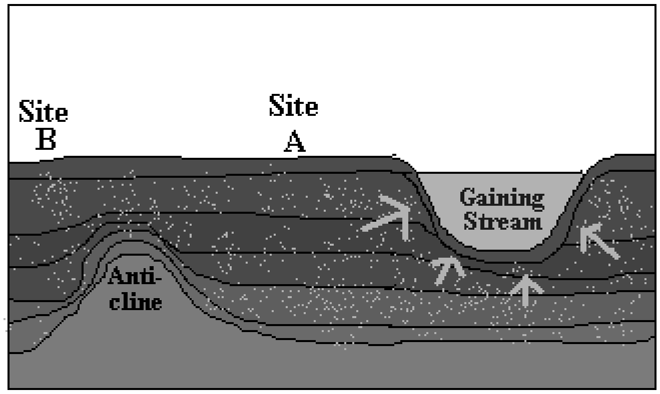
Paleosols

The deposition of sedimentary formations is not a continuous process. At certain periods the forces contributing to deposition are absent, resulting in long-term exposure of the material at the surface of the formation. During these periods, soil development can occur. Paleosols, or fossil soils, are old soil layers that are buried in a geologic formation when the forces contributing to deposition resume. As a high concentration of clay minerals and the potential for hardpan development exist in the paleosols, they can impede the vertical flow of water through a formation. Such an impediment could restrict the access to storage available in the geologic formations below the paleosol layer, thereby reducing the suitability of a potential groundwater banking site.

Geologic Structure

Tectonic forces acting on sedimentary deposits can create structures within a formation. Depending on their location and orientation, folds and faults can serve to isolate stored groundwater from the surrounding aquifer. Figure 3.1.1 depicts a situation where the presence of an anticline in folded sedimentary deposits could isolate stored groundwater from a gaining stream that conveys water away from aquifer storage. By separating Site B from the stream's influence, the anticline structure increases the suitability of that site relative to Site A.

Figure 3.1.1: Influence of Geologic Structure on Geologic Suitability



Groundwater banked at Site A, which is in proximity to a gaining stream, would be subject to higher losses than water banked at Site B, which is isolated from the stream by an anticline structure within the formation.

3.1.2 Geology Sub-Index Weighting Factors

Having described these parameters for each of the formations found below potential groundwater banking sites, we gave them a score on a scale from 0 to 10, with a score of 10 representing characteristics that would make a particular formation a suitable target for groundwater banking. Our scoring system is described in Table 3.1.1.

Having scored each of the parameters, a composite formation score was calculated based on Equation 3.1.

Table 3.1.1: Parameter Weighting Factors Used to Calculate the Geology Sub-Index

Component	0	5	10
Permeability	Impermeable	Moderately permeable	Highly permeable
Paleosols	Contains resistant paleosols	Contains some slightly resistant paleosols	No paleosols
Geologic Structure	Contains structural features that direct stored groundwater toward gaining streams	Contains no structural features	Contains structural features that isolate stored groundwater from gaining streams

$$\boxed{\text{Formation Score} = 2*(\text{Permeability}) + 0.5*(\text{Paleosols}) + (\text{Geological Structure})} \quad (3.1)$$

Given the relative importance of permeability in terms of evaluating the suitability of a formation for groundwater banking, it was assigned a weighting factor of 2. The existence of paleosols was assigned a weighting coefficient of 0.5 because, although they can act as barriers to the vertical movement of water, they tend to be described as thin and discontinuous in the Central Valley. The geology sub-index values are calculated as the sum of the scores for each of the formations underlying a particular groundwater banking site, weighted by the relative formation thickness within the top several hundred feet of the sub-surface (Equation 3.2). In the Sacramento Valley, several stratified formations were often encountered; in the San Joaquin Valley, undifferentiated alluvial deposits were the norm.

$$\boxed{\text{Geology Sub-Index} = \Sigma\,(\text{Formation Score}_A * \text{Formation Thickness}_A)} \quad (3.2)$$

The preceding equations point out the role that weighting factors play in the calculation of the Hydrogeologic Suitability Index. Scores for both the parameters and the formations rely upon somewhat arbitrary weighting factors. When a formation is ranked as highly permeable, it receives a score twice as high as a moderately permeable formation, and that difference in score is multiplied by 2 in calculating the formation score. It is here that another individual interested in groundwater banking could apply a different set of weighting factors in the spreadsheet developed for this project.

3.2 Water Quality Sub-Index

If water is stored at a potential groundwater banking site, it will commingle with the native groundwater. The quality of this native water will influence the ultimate quality of water stored in and recovered from the aquifer (the quality of stored water will also influence the quality of water available to existing groundwater users). This sub-index attempts to compare sites in terms of the quality of groundwater found at potential sites.

3.2.1 Water Quality Sub-Index Parameters

Four water quality components were selected based on their importance to both urban and agricultural water users and on the availability of data for the potential groundwater banking sites: arsenic, boron, lead and total dissolved solids. These parameters were defined using USGS National Water Information System (NWIS) data collected after 1/1/1970.

Arsenic (As)

Arsenic is a micronutrient for humans. However, long-term exposure to high concentrations of arsenic in drinking water can lead to many dangerous health problems including at least 8 different types of cancer (EPA website, 2001). Arsenic contained in groundwater generally comes from the natural weathering of the local geologic materials, although it can also result from anthropogenic sources such as industrial waste, arsenical pesticides and smelting operations (De Zuane, 1997). The maximum contaminant level for As enforced by the EPA is 50 ppb (or 50 mg/L), though this standard is currently under review and may be lowered to 10 ppb (or 10 mg/L) (EPA website, 2001).

Boron (B)

Boron is a micronutrient required in small amounts by both humans and plants. However, if the concentration of boron in groundwater is too high, it can be toxic for many commercially important crops in California. In general, water used for irrigation of boron-sensitive crops should contain less than 1.0 mg/L (or 1000 mg/L) to prevent toxicity.

Lead (Pb)

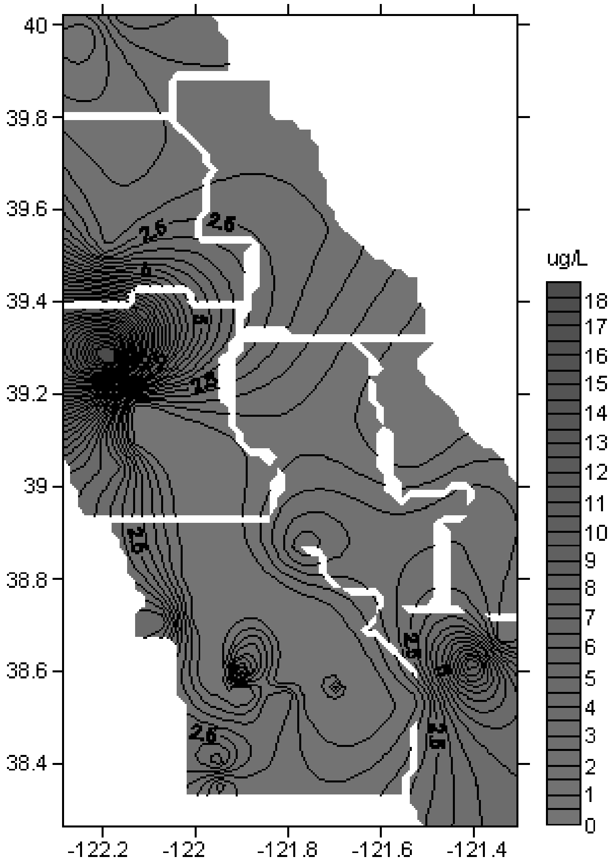
Lead is a metal that can be found in drinking water as a result of natural weathering of local ore deposits. Lead is extremely hazardous and can cause a multitude of health problems including stroke, kidney disease and cancer. It also disrupts normal physical and mental development in infants and children (EPA website, 2001). Due to these extreme effects, the EPA maximum contaminant level for lead is zero; however, the action level at which clean-up takes place is 15 ppb (or 15 mg/L) due to current technological and resource-oriented constraints (EPA website, 2001).

Total Dissolved Solids (TDS)

TDS is not a trace element like the other water quality parameters, but is a measure of the concentration of inorganic salts (primarily Ca, Mg, K, Na, bicarbonates, chlorides and sulfates) and organic material dissolved in water (WHO, 1993). Although there are no specific health problems or regulations associated with high TDS levels, the generally accepted limit for drinking water is 1000 mg/L (WHO, 1993). For TDS, the EPA sets the National Secondary Drinking Water Regulation, a non-enforceable guideline based on the cosmetic and aesthetic qualities of water, at 500 mg/l (EPA website, 2001).

Data gathered on each of these parameters (see the Water Quality portion of Section 7.0: References) reveal a fair amount of spatial variability across the Central Valley. As an example, measured lead concentrations in groundwater in the Sacramento Valley are shown in Figure 3.2.1. The most elevated levels were observed in Colusa and Sacramento Counties. Contour maps of the three other parameters reveal distinct patterns of spatial variability that could influence the selection of potential groundwater banking sites.

Figure 3.2.1: Lead Contour Map for the Sacramento Valley



3.2.2 Water Quality Sub-Index Weighting Factors

The raw water quality data for the four parameters above is listed in Appendix A. In order to convert these raw parameter values into a water quality sub-index, a method for assigning parameter scores between 1 and 10 was developed. As with the geology sub-index parameters, a score of 10 corresponds with conditions most favorable to groundwater banking. Table 3.2.1 describes the scores assigned to distinct ranges of raw parameter values. In each case, a score of 5 corresponds with the EPA-recommended level.

Table 3.2.1: Parameter Weighting Factors Used to Calculate the Water Quality Sub-Index

		Arsenic			Boron			Lead			TDS		
	Score	µg/L			µg/L			µg/L			mg/L		
Toxic	1	50.00	+		9000.00	+		15.00	+		1000.00	+	
	2	40.00	-	49.99	7000.00	-	8999.00	13.33	-	14.99	875.00	-	999.00
	3	30.00	-	39.99	5000.00	-	6999.00	11.67	-	13.32	750.00	-	874.00
	4	20.00	-	29.99	3000.00	-	4999.00	10.00	-	11.66	625.00	-	749.00
Recommended	5	10.00	-	19.99	1000.00	-	2999.00	8.33	-	9.99	500.00	-	624.00
	6	8.00	-	9.99	800.00	-	999.00	6.67	-	8.32	400.00	-	499.00
	7	6.00	-	7.99	600.00	-	799.00	5.00	-	6.66	300.00	-	399.00
	8	4.00	-	5.99	400.00	-	599.00	3.33	-	4.99	200.00	-	299.00
	9	2.00	-	3.99	200.00	-	399.00	1.67	-	3.32	100.00	-	199.00
	10	0.00	-	1.99	0.00	-	199.00	0.00	-	1.66	0.00	-	99.00

Scores for the individual parameters can be combined to calculate a composite water quality score, as in Equation 3.3. In this case no weighting factors have been employed, although someone interested in a particular parameter could weight that constituent accordingly in the spreadsheet developed as part of this effort.

$$\boxed{\text{Water Quality Score} = (\text{As Score}) + (\text{B Score}) + (\text{Pb Score}) + (\text{TDS Score})} \quad (3.3)$$

Below a particular groundwater banking site, two water quality scores may be of interest. The first corresponds with the water quality immediately below a potential groundwater banking site and reflects the short-term mixing between recharge water and native groundwater that occurs when they come into contact. Once a significant amount of recharge occurs and water is stored at a banking site for extended periods of time, the potential for longer-term mixing between stored water and the native groundwater extends over a much larger area. Over this time scale, it is the quality of the groundwater in the basin surrounding the potential banking site that is important. Using available data, basin groundwater quality scores were calculated by averaging all the data from the wells within the basin boundaries for a specific component. This same data was then used to create a contour map (similar to Figure 3.2.1) so the approximate water quality score at potential groundwater banking sites could be determined.

Our attempt to capture the full spectrum of potential mixing between banked water and native groundwater led us to define the two components of the water quality sub-index described in Equation 3.4.

$$\boxed{\text{Water Quality Sub-Index} = 1.5*(\text{Basin Score}) + (\text{Site Score})} \quad (3.4)$$

In this version of the water quality sub-index, the basin score was weighted more heavily than the site score. The heavier weighting on the basin score tends to stress the impact of long-term interactions between banked water and native groundwater. This is in keeping with the utility assigned to most banked groundwater in California—namely that it is to serve as a source of supplemental supply in the relatively infrequent dry and critical water years.

One final point that should be made regarding the water quality sub-index is that the data used to develop water quality contour maps come from wells screened at different depths. Ideally the vertical relationship between water quality observations should be considered along with their relative horizontal positions. We made an attempt to limit the vertical extent of water quality observations by excluding any samples that were noted as having been taken from below the Corcoran Clay in the San Joaquin Valley. As the screened interval in most sampled wells is neither known nor reported, it was difficult to introduce the vertical dimension into our water quality contour maps. Any attempt to screen the samples by depth would have proved much too expensive and time consuming to be undertaken in the current effort. This is another area where more specific analysis of potential sites will be required once the field of potential groundwater banking sites has been thinned.

3.3 Soils Sub-Index

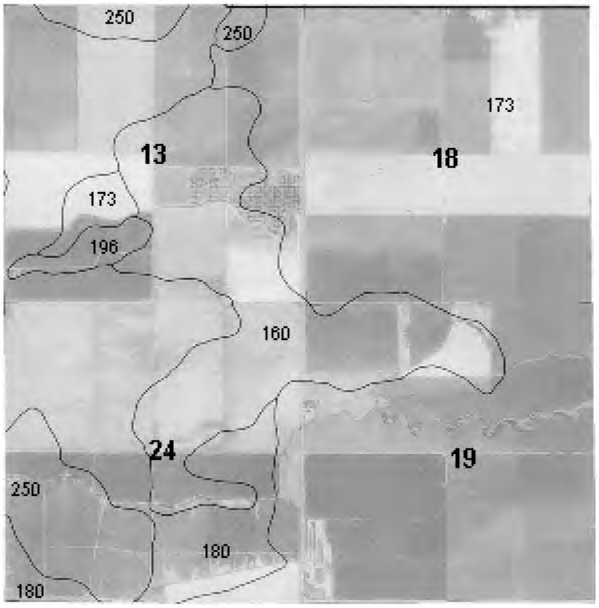
Soil characteristics exert a potentially important control on the overall hydrogeologic suitability of potential groundwater banking projects employing recharge ponds, since the physical properties of the soil profile may limit the percolation rate. Sites with low percolation rates will require larger basins in order to recharge a given volume of water, thereby increasing the overall cost of the project. If the soil chemistry at a site is poor, the quality of banked water might be degraded as it percolates from the recharge basin. In the extreme, problematic soils could be removed from a potential site prior to the construction of recharge basins. However, this would greatly increase the overall cost of the project, potentially making it less attractive with respect to other alternatives.

3.3.1 Soils Sub-Index Parameters

The main data source used to define parameters for this sub-index was the USDA soil survey series for California (see the Soils portion of Section 7.0: References). Each volume of the series covers an area of California (typically a single county) and is composed primarily of detailed maps showing aerial photographs overlain by the delineation of soils found in the area. An example (Figure 3.3.1) is an excerpt from the Soil Survey of San Joaquin County, California (McElhiney, 1992). The large font numbers that appear on the figure (13, 18, 24, 19) are the township and range sections associated with the California Public Lands Survey. The small number found within each soil polygon correlates to a soil type and a series of soil parameters. For example, 180 represents an area covered by Jackstone clay.

From the extensive list of parameters reported for each soil type, we selected four that we feel capture the impacts that the physical and chemical properties of a soil can exert on groundwater banking via recharge ponds: soil thickness, soil permeability, soil pH and the presence or absence of hardpans. These parameters were evaluated for each soil type encountered at potential groundwater banking sites according to the approach described in the following paragraphs.

Figure 3.3.1: Soil Survey Map of Mormon Slough (McElhiney, 1992)



Thickness

Each soil's thickness was recorded in inches and normalized relative to the maximum soil thickness encountered at the full suite of potential groundwater banking sites to generate a soil thickness score between 0 and 1. A thick soil will magnify any negative effects on percolation or water quality encountered as water flows through the soil column to the underlying aquifer. Similarly, a thick soil will magnify positive soil characteristics.

Permeability

Soil permeability is a measure of how easily and quickly water moves through a soil. The USDA soil surveys report permeability in a range in inches of water per hour. We took the average value of the range reported for each soil type encountered at the each of the potential groundwater banking sites and normalized it to arrive at a score between 0 and 1, where a value of 1 is desirable. In cases where no specific permeability value was provided, the permeability was estimated as a function of soil structure and clay content as per the National Soil Survey Handbook (USDA, 1999).

pH

Soil pH is a measure of the acidity of a soil. The USDA assigns categories to pH levels, and we assigned numerical values to the categories in order to include them in the soils sub-index, as shown below in Table 3.3.1. In this case, a neutral pH of 7 corresponds with component score of 1. Increasingly acidic and alkaline soils are awarded decreasing parameter scores. While not a perfect predictor for the types of chemical transformation water percolating from a recharge pond will undergo, pH is a good proxy for a number of potential water quality problems in the soil.

Table 3.3.1: pH Rating Scale

pH reading	USDA category	Suitability Index
3.5 - 4.4	Extremely acid	0
4.5 - 5.0	Very strongly acid	0.2
5.1 - 5.5	Strongly acid	0.4
5.6 - 6.0	Moderately acid	0.6
6.1 - 6.5	Slightly acid	0.8
6.6 - 7.3	Neutral	1.0
7.4 - 7.8	Slightly alkaline	0.8
7.9 - 8.4	Moderately alkaline	0.6
8.5 - 9.0	Strongly alkaline	0.4
9.1 - 11.0	Very strongly alkaline	0.2

Hardpan

Each soil description was checked to see if the presence of a hardpan was reported. A hardpan can impede the percolation of water below a recharge pond, limiting the suitability of a potential project site. If a hardpan was present, a parameter score of 0 was assigned. If there was no hardpan occurrence, then a value of 1 was assigned.

The raw soil data is available in Appendix B. As can be expected when gathering data from diverse sources, not all soil surveys reported the same soil parameters. When a particular piece of data, such as permeability, was not available for a soil type, we attempted to locate the value in a soil survey for an adjacent county before invoking any other approximation method. We will point out where we were forced to approximate a soil parameter in later sections dealing with specific potential groundwater banking sites.

3.3.2 Soils Sub-Index Weighting Factors

Once the parameter scores were developed for each of the soil types at the potential groundwater banking sites, a weighted average parameter score was calculated based on the area of each soil type overlying potential project sites. The area data is available in Appendix C. This produced a score for each site for each of the four soil parameters. The soils sub-index was calculated by applying the weighting factors shown in the following equation:

$$\boxed{\text{Soils Sub-Index} = (\text{Thickness})*\ (3*[\text{Permeability}] + [\text{pH}] - 2*[1 - \text{Hardpan}])} \tag{3.5}$$

In Equation 3.5, permeability was weighted by a factor of 3 and hardpan by a factor of 2 to stress the importance of these components on the ability of water to percolate below recharge basins. Since potentially constraining soil parameters are subtracted in Equation 3.5, it is possible to arrive at negative sub-index values. Once again, another individual interested in groundwater banking could apply a different set of weighting factors in the spreadsheet developed for this project.

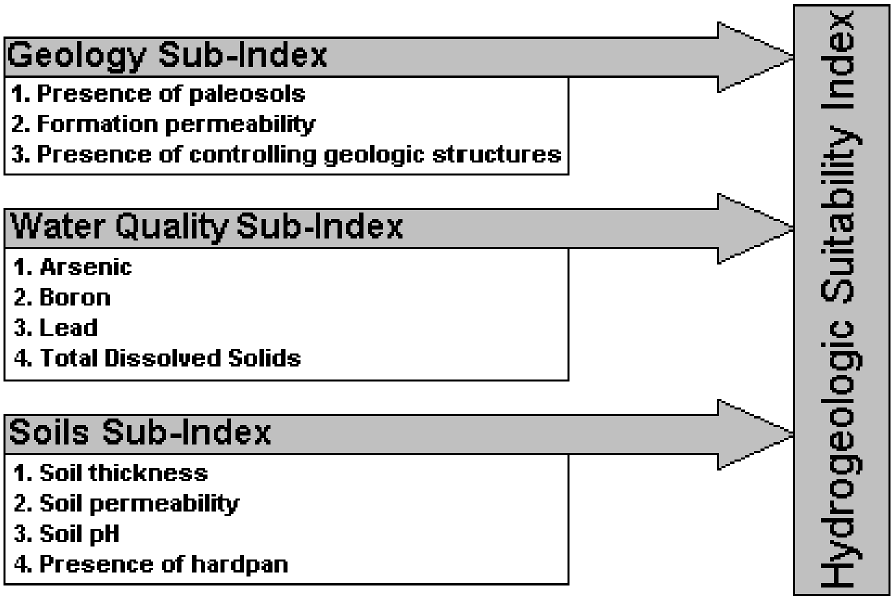
3.4 Application of the Core Hydrogeologic Suitability Index

The sub-indices presented in the previous sections constitute the core of the Hydrogeologic Suitability Index that will be applied to potential groundwater banking sites in both the Sacramento and San Joaquin Valleys. A separate sub-index based on the temporal evolution of the elevation of the water table is applied only in the San Joaquin Valley. Details of this sub-index are presented in Section 5.0 dealing with the application of the index in that region.

4.0 Application of the Hydrogeologic Suitability Index in the Sacramento Valley

As mentioned previously, differences in the hydrologic conditions between the Sacramento and San Joaquin Valleys prompted our decision to apply the Hydrogeologic Suitability Index separately in the two regions. In the Sacramento Valley, a core index that includes sub-indices related to geology, groundwater quality and soils has been applied. Figure 4.0.1 provides a summary flow chart of the information used to develop each of the sub-indices and the overall Hydrogeologic Suitability Index. Descriptions of each of the parameters presented in Figure 4.0.1 are given in Section 3.0, along with a proposed methodology for assigning parameter scores. The following sections present the data used to calculate the sub-indices for each of the potential Sacramento Valley groundwater banking sites shown in Figure 2.0.1.

Figure 4.0.1: Flow Chart of Parameters Analyzed in the Development of Relevant Sub-Indices and the Overall Hydrogeologic Suitability Index in the Sacramento Valley



4.1 Sacramento Valley Geology Sub-Index

In Section 3.1.1, the geology sub-index parameters were discussed. These parameters are permeability, the presence of paleosols, and the presence of any controlling geologic structures. The methodology used to create a weighted average of parameter scores based on the thickness of the formations encountered at a given site was also presented in Equation 3.2. The influence of formation thickness is a particularly important issue in the Sacramento Valley because although there is a tendency to think of Sacramento Valley groundwater in terms of a homogeneous underground reservoir that fluctuates gradually with wet and dry cycles, the reality is more complex. While much of the Sacramento Valley groundwater basin is interconnected, aquifer structure is far from uniform (DWR, 1998). Considering the properties of only the uppermost formation would miss many important controls that this complex geology could exert on the groundwater banking operations using recharge ponds. The vertical sequence of formations must be taken into consideration along with their horizontal extent.

Geology Sub-Index Equation Key

Eq. 3.1: Formation Score = 2*(Permeability) + 0.5*(Paleosols) + (Geological Structure)
Eq. 3.2: Geology Sub-Index = Σ (Formation Score $_A$*Formation Thickness $_A$)

4.1.1 Results of the Sacramento Valley Geology Sub-Index

Table 4.1.1 contains a list of the geologic formations encountered below the potential groundwater banking sites identified for the Sacramento Valley. The table also includes the parameter scores assigned to the formations in terms of permeability, paleosols and geologic structures. The formation scores, as calculated using Equation 3.1, are listed in the Rank column. These scores are then normalized between 0 and 1 according to their relative position between the formation with the highest (Stony Creek Fan with a score of 32) and lowest (Mehrten, Flood Basin Deposits and South Fork Gravels with scores of 14) ranks. The normalized ranks are found in the % column.

Table 4.1.1: Scores for Formations Found in the Sacramento Valley

Weighting Coefficient	0.5	2	1		
Formation	**Paleosols**	**Permeability**	**Geo. Strct.**	**Rank**	**%**
Stony Creek Fan	10	8.5	10	32	1.00
Putah Plain	10	6	10	27	0.72
Tuscan	0	10	5	25	0.61
Arbuckle Fan	10	7	5	24	0.56
Chico Fan	10	7	5	24	0.56
Laguna	10	5	5	20	0.33
Victor	0	6	5	17	0.17
Tehama	10	3	5	16	0.11
Fanglomerate	10	2.5	5	15	0.06
Mehrten	10	2	5	14	0.00
Flood Basin	10	2	5	14	0.00
South Fork Gravels	10	2	5	14	0.00

Having ranked the various formations encountered in the Sacramento Valley, we examined the vertical stratification of these units below each of the potential groundwater banking sites located in the Sacramento Valley (as shown in Figure 2.0.1). The formations encountered, which have been color coded according to their formation scores, are shown in Figure 4.1.1. If a program of groundwater banking is based on the use of recharge ponds, then the sequence of formations down from the ground surface at a potential site is critical. If a formation that is poorly suited to groundwater banking overlies one with attractive geologic properties, the opportunity for groundwater banking using recharge ponds is constrained by the poorly suited upper formation. In applying Equation 3.2, the formation sequence was taken into consideration.

Table 4.1.2 contains a list of the potential groundwater banking sites in the Sacramento Valley with the sequence of formations encountered down to a depth of 500 feet listed to the right, along with the formation score and local thickness. The geology sub-index is calculated by applying Equation 3.2 down to and including the first formation that overlies one with a higher score. For example, at the American Basin site, where the Victor Formation with a score of 0.17 overlies the Laguna Formation with a score of 0.33, only the properties and thickness of the overlying Victor Formation are considered in calculating the geology sub-index. This calculation has been carried out based on three assumed operational depths for the proposed groundwater banking projects: 100 ft., 300 ft. and 500 ft.

Figures 4.1.2 through 4.1.4 graphically present the rank associated with each potential site in terms of the geology sub-index under different assumptions regarding operational depth.

Figure 4.1.1: Vertical Stratification of Formations Encountered at Potential Groundwater Banking Sites in the Sacramento Valley

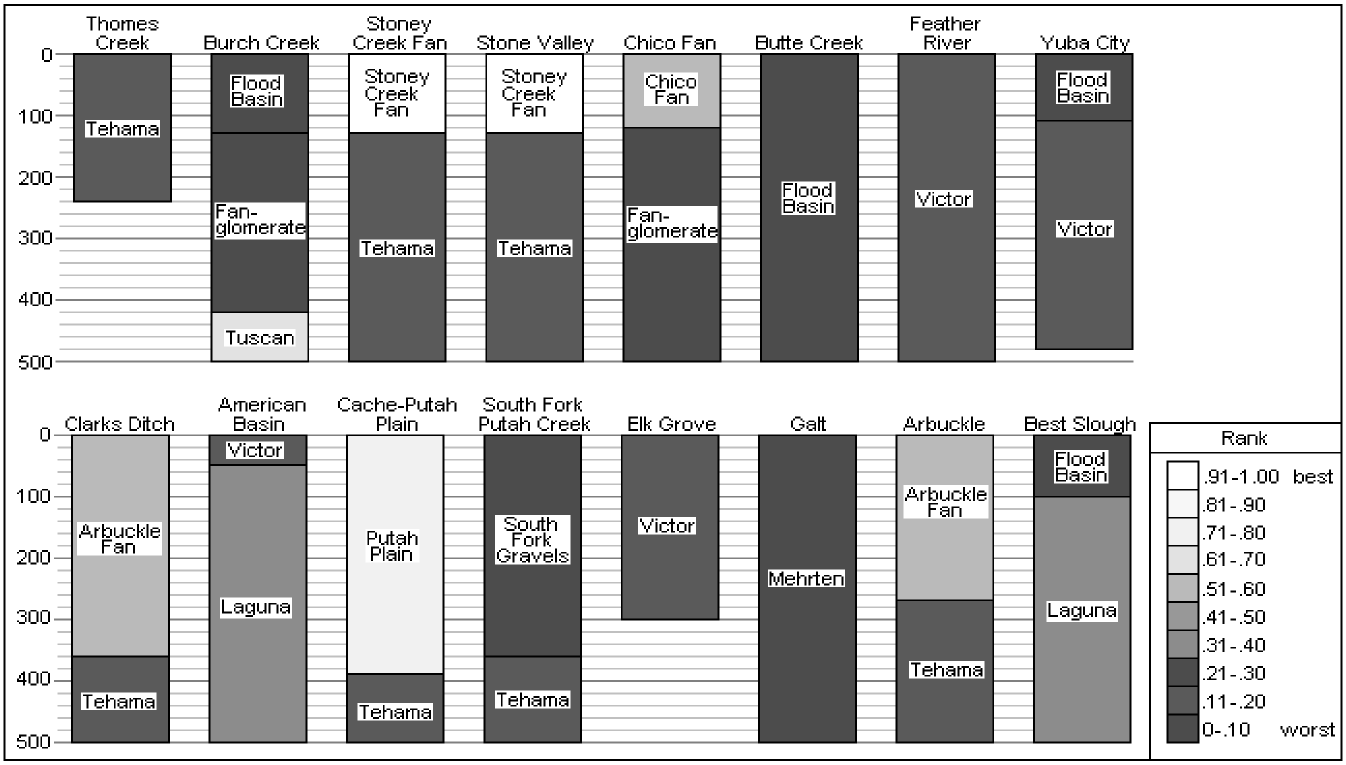


Table 4.1.2: Geology Sub-Index Values Calculated for Potential Groundwater Banking Sites in the Sacramento Valley

	Formation 1			Formation 2			Formation 1			Operational Depth					
										500 ft		300 ft		100 ft	
Site	Formation	Score	Thickness	Formation	Score	Thickness	Formation	Score	Thickness	Score	Normal	Score	Normal	Score	Normal
Cache-Putah Plain	Putah Plain	0.72	390	Tehama	0.11	110				293.9	1.00	216.7	1.00	72.2	0.72

Figure 4.1.2: Sacramento Valley Geology Sub-Index Values Assuming an Operational Depth of 500 Feet

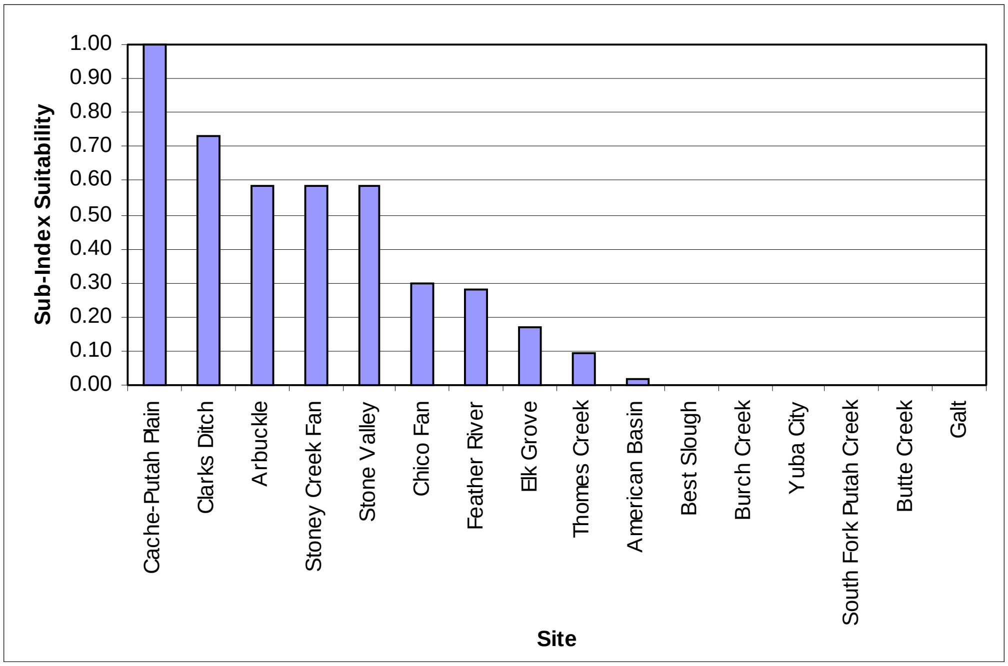

Figure 4.1.3: Sacramento Valley Geology Sub-Index Values Assuming an Operational Depth of 300 Feet

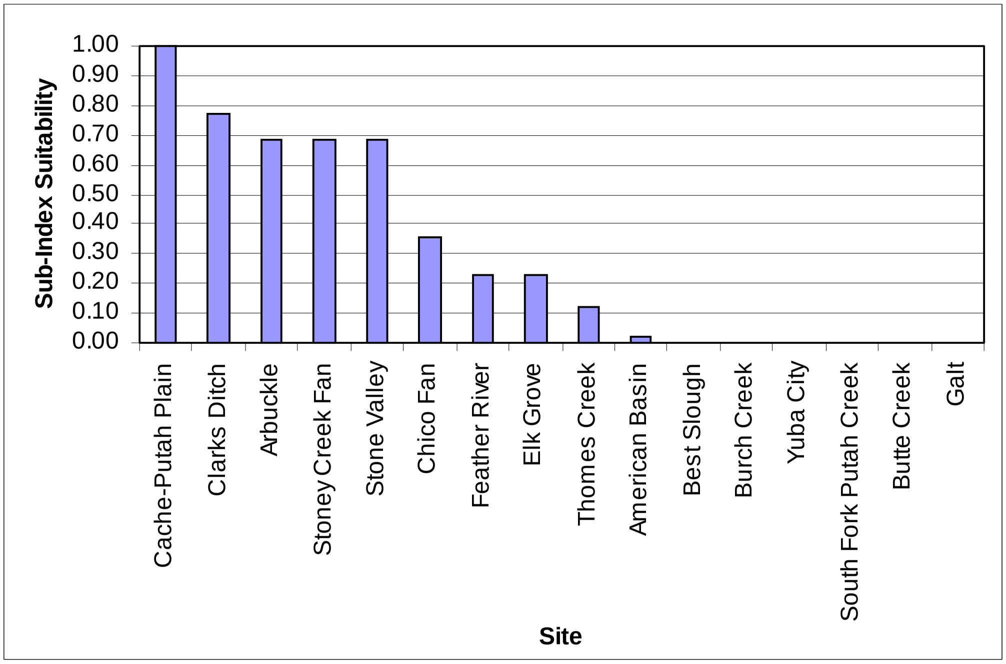

Figure 4.1.4: Sacramento Valley Geology Sub-Index Values Assuming an Operational Depth of 100 Feet

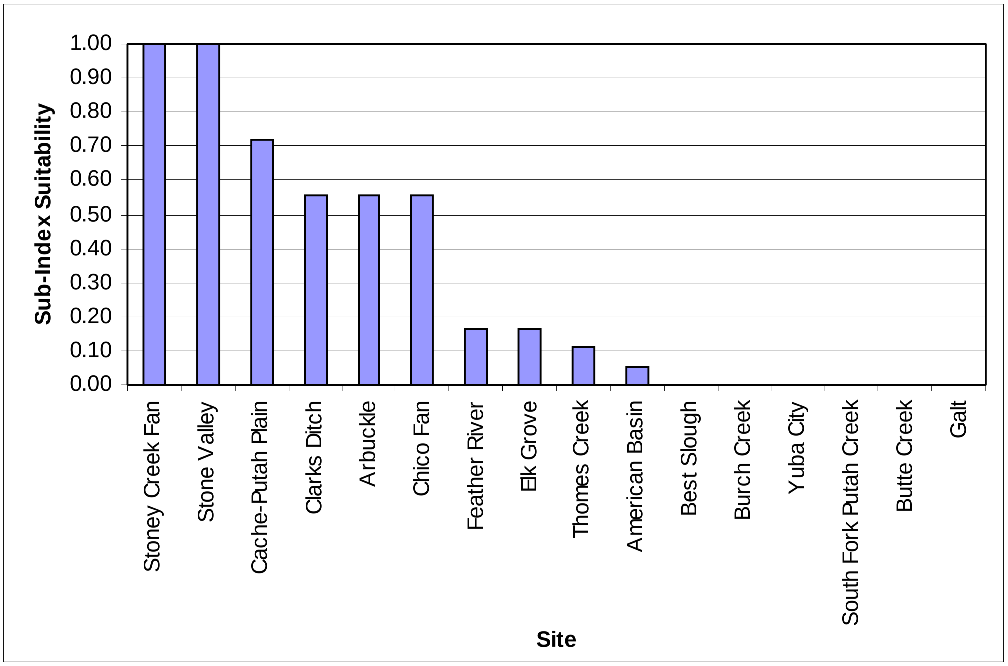
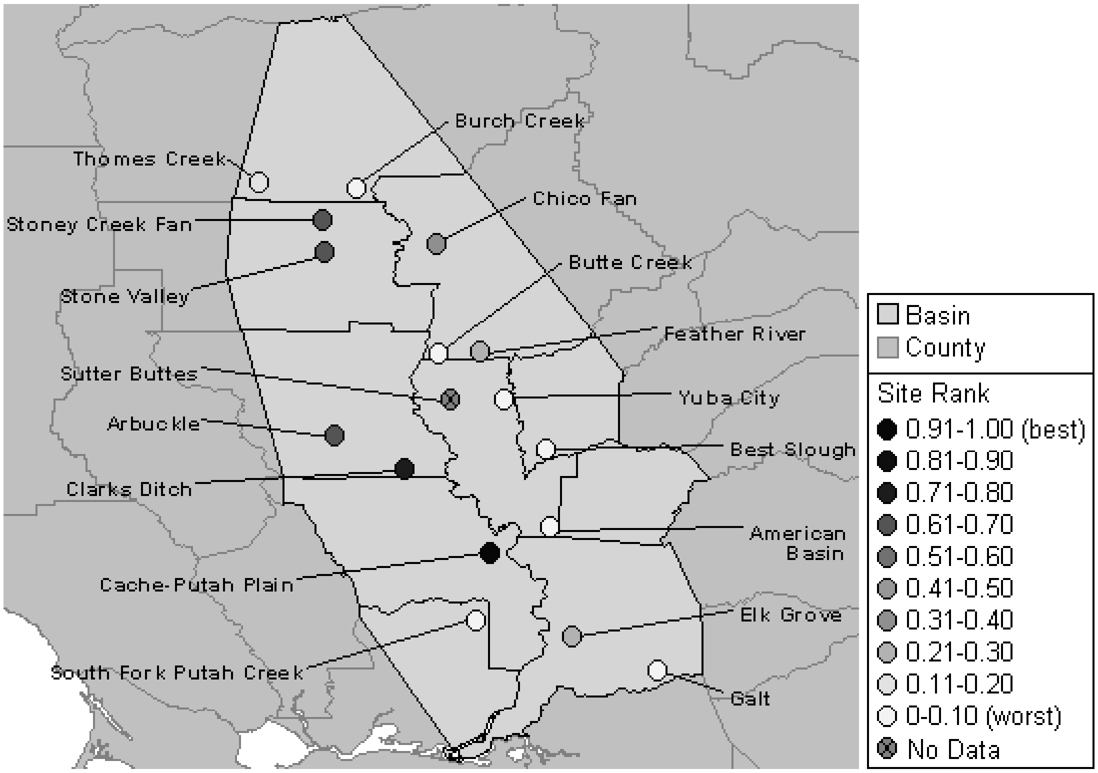


In calculating the overall Hydrogeologic Suitability Index for sites in the Sacramento Valley, geology sub-index values based on an assumed operational depth of 300 ft. are employed. Figure 4.1.5 displays the site comparison of the potential groundwater banking sites with respect to the 300 ft. depth rank.

Figure 4.1.5: Spatial Distribution of 300 Ft. Depth Geology Sub-Index Values Across Potential Groundwater Banking Sites in the Sacramento Valley



4.1.2 Comments on the Geology Sub-Index

Several interesting observations emerge from the results of the geology sub-index. First, sites in the western Sacramento Valley (e.g., Stony Creek Fan, Arbuckle Fan, Cache-Putah Plain) provide excellent geologic settings for groundwater banking. This is an important discovery because the aquifers underlying these sites are generally full. As such, groundwater banking would require some level of enhanced groundwater pumping in order to create the space required for storing banked groundwater—a management sequence that raises legitimate concerns on the part of overlying groundwater users. The relative superiority of these sites in terms of the geology, however, suggest that it may be worth the effort to design the legal and institutional arrangements needed to make these sorts of projects viable.

Sites located in the central and eastern portions of the Sacramento Valley generally fare less well in terms of the geology sub-index. This is due to the prevalence of flood basin deposits and the Victor Formation in the upper portion of the stratigraphic column below these sites. While more promising formations often lie below these units, access to them via recharge basins will be constrained by the less suitable overlying formations. These are areas where groundwater banking via injection wells or *in lieu* arrangements may be the preferred alternative.

4.2 Sacramento Valley Water Quality Sub-Index

As mentioned in Section 3.2, the water quality sub-index was based on the reported concentrations in groundwater of four parameters: arsenic, boron, lead and total dissolved solids.

Water Quality Sub-Index Equation Key

Eq. 3.3: Water Quality Score = [As Score] + [B Score] + [Pb Score] + [TDS Score]
Eq. 3.4: Water Quality Sub-Index = 1.5*[Basin Score] + [Site Score]

4.2.1 Results of the Sacramento Valley Water Quality Sub-Index

For each of the basins in the Sacramento Valley (see Figure 2.0.1), the average of all observations was used to assign a parameter score according to Table 3.2.1. The total water quality scores (in the Rank column), calculated using Equation 3.3, and normalized values between 0 and 1 (in the % column), are shown in Table 4.2.1.

Table 4.2.1: Water Quality Scores for Basins in the Sacramento Valley

Weighting Coefficient	1	1	1	1		
Basin Name	**As**	**B**	**Pb**	**TDS**	**Rank**	**%**
Tehama	10	9	10	8	37	1.00
Yuba	9	10	10	8	37	1.00
Butte	9	10	9	8	36	0.86
Placer	9	8	10	8	35	0.71
Glenn	8	10	9	7	34	0.57
Sutter	7	10	9	7	33	0.43
Colusa	9	9	8	6	32	0.29
Solano	9	8	10	5	32	0.29
Sacramento	7	10	8	8	31	0.14
Yolo	9	5	10	6	30	0.00

Based on contour maps developed from the available data in each basin, estimated concentrations, parameter scores and normalized values between 0 and 1 were developed for each of the potential Sacramento Valley groundwater banking sites (Table 4.2.2).

The information in both Tables 4.2.1 and 4.2.2 is displayed spatially in Figure 4.2.1.

Table 4.2.2: Water Quality Scores for Sites in the Sacramento Valley

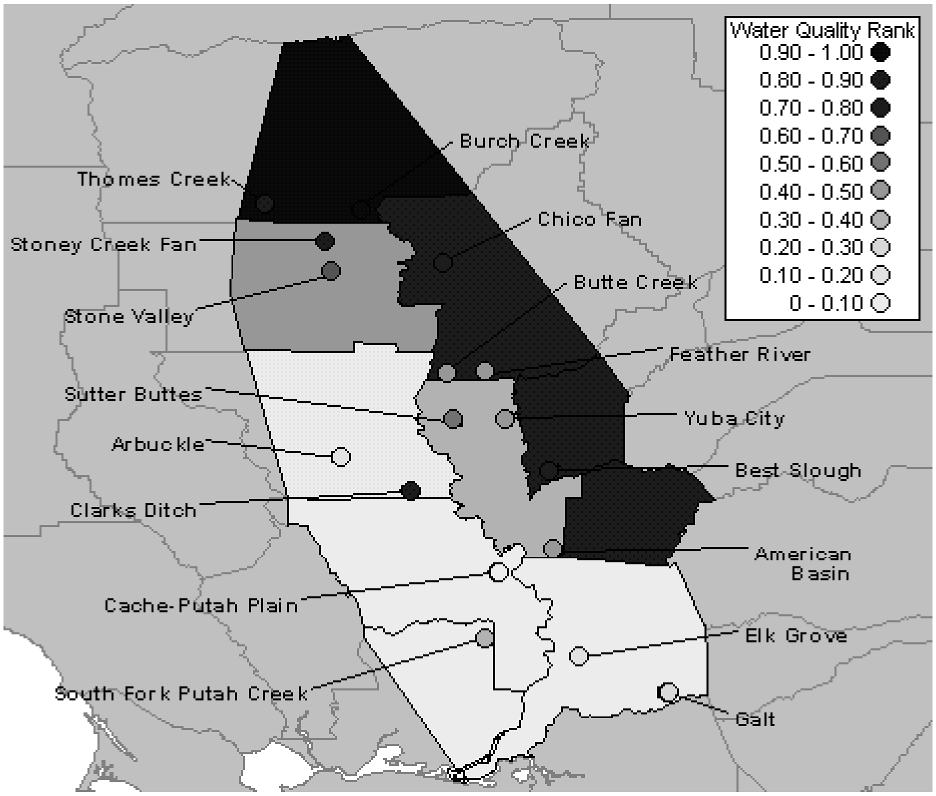
Cache-Putah Plain	8	5	10	7	30.00	0.00

Figure 4.2.1: Spatial Distribution of Basin and Site Water Quality Scores



Based on the water quality scores presented in Tables 4.2.1 and 4.2.2, the water quality sub-index for potential groundwater banking sites in the Sacramento Valley was calculated according to Equation 3.4. These scores were normalized between 0 (corresponding with the poorest groundwater quality at the Cache Putah Plain site) and 1 (corresponding with the best groundwater quality observed at the Burch Creek site). The results are shown in Table 4.2.3.

Table 4.2.3: Water Quality Sub-Index Values for Potential Groundwater Banking Sites in the Sacramento Valley

Weighting Coefficient		1.5	1

South Fork Putah Creek	Solano	0.29	0.33	0.76	0.30
Best Slough	Yuba	1.00	0.78	2.28	0.91

Figures 4.2.2 and 4.2.3 present the value of the water quality sub-index for potential banking sites in the Sacramento Valley derived from available data in terms of relative rank and spatial distribution, respectively.

4.2.2 Comments on the Water Quality Sub-Index

It is worth noting that the water quality of all sites in the Sacramento Valley is fairly good. However, boron does reach the recommended maximum level for boron-sensitive crops in the Cache-Putah Plain site and is also rather high in the Arbuckle region. There appears to be an area of increased arsenic levels in the northeast part of the valley, though these levels are still below the recommended levels and far below toxicity. Lead levels are very low in the Sacramento Valley, though anything over zero is considered too much by EPA standards. TDS is also very low, though levels seem to rise toward the south. While the Hydrogeologic Suitability Index is applied separately to sites in the Sacramento and San Joaquin Valleys, the relatively good quality of groundwater in the Sacramento Valley suggests that sites in this region are worthy of consideration despite the fact that little or no aquifer storage space currently exists in this region.

Figure 4.2.2: Water Quality Sub-Index Ranking for Potential Groundwater Banking Sites in the Sacramento Valley

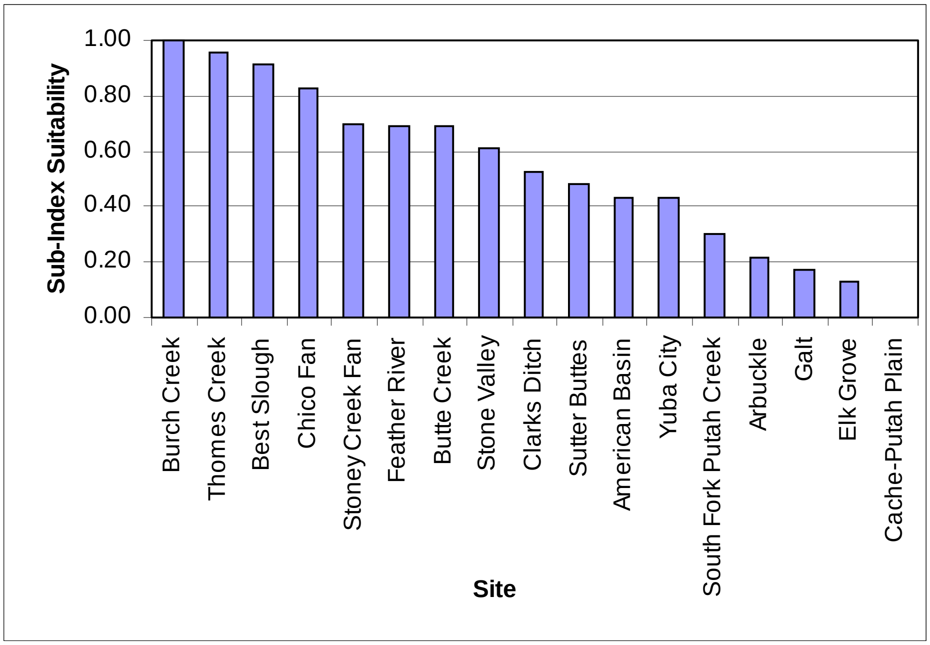

Figure 4.2.3: Spatial Distribution of Water Quality Sub-Index Values Across Potential Groundwater Banking Sites in the Sacramento Valley

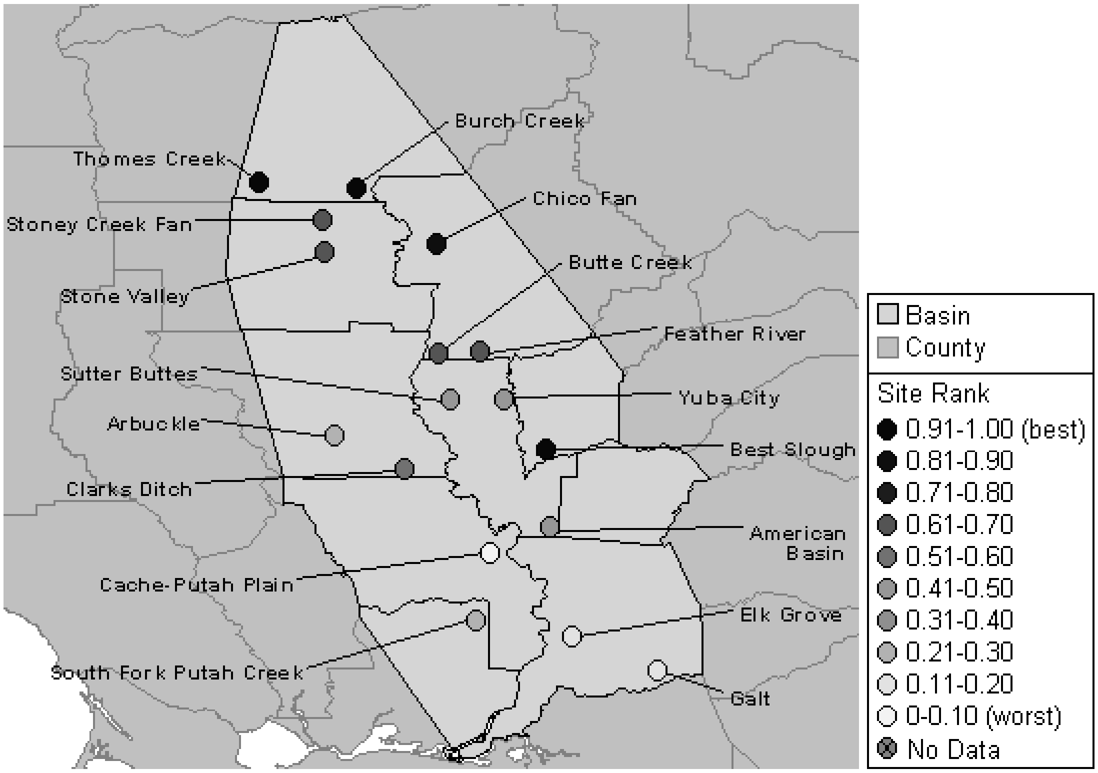

4.3 Sacramento Valley Soils Sub-Index

The soils sub-index was calculated as described in Section 3.3. The soil types under a site were identified, evaluated and scored based on the four soil parameters: thickness, pH, permeability and hardpan. The soils sub-index was not calculated directly for several of the sites in the Sacramento Valley owing to a lack of an available soil survey. These sites are listed in Table 4.3.1. For these sites, treatment of the soil sub-index in the calculation of the overall Hydrogeologic Suitability Index is discussed in Section 4.4.

Table 4.3.1: Soil Sites Lacking Available Soil Surveys

Site	Basin
Chico Fan	Butte
Butte Creek	Butte
Feather River	Butte
Arbuckle	Colusa
Clarks Ditch	Colusa

4.3.1 Results for the Sacramento Valley Soils Sub-Index

The soils sub-index values that were calculated using Equation 3.5 are shown in Table 4.3.2, in the column entitled "Rank." Normalized values between 1 (corresponding to the Sutter Buttes site) and 0 (corresponding with the Elk Grove site) are listed in the % column. These results are displayed graphically in terms of their rank and their spatial distribution in Figures 4.3.1 and 4.3.2, respectively.

Soil Sub-Index Equation Key

Eq. 3.5: Soils Sub-Index = (Thickness) [3(Permeability) + (pH)– 2(1 – Hardpan)]

Table 4.3.2: Soils Sub-Index Values for Potential Groundwater Banking Sites in the Sacramento Valley

Weighting Coefficient	1	3	2	1		
Site	**Thickness**	**Permeability**	**Hardpan**	**pH**	**Rank**	**%**
Thomes Creek	0.70	0.13	1.00	0.65	1.75	0.78
Stoney Creek Fan	0.75	0.14	0.86	0.71	1.58	0.71
Stone Valley	0.73	0.13	1.00	0.81	1.92	0.85
Sutter Buttes	0.41	0.33	1.00	0.90	2.32	1.00
Galt	0.78	0.08	0.95	0.51	1.41	0.64
Cache-Putah Plain	0.40	0.22	0.96	0.65	1.64	0.73
Yuba City	0.54	0.07	1.00	0.78	1.53	0.69
South Fork Putah Creek	0.66	0.01	1.00	0.65	1.34	0.62
American Basin	0.75	0.08	0.16	0.80	0.09	0.12
Best Slough	0.50	0.06	0.31	0.77	0.07	0.11
Elk Grove	0.75	0.08	0.00	0.79	-0.21	0.07
Burch Creek	0.60	0.11	0.77	0.65	1.11	0.52

To estimate the soils sub-index for the sites lacking the soil survey data needed for sub-index Equation 3.5, the agricultural crops grown on these sites were identified. Two types of crops were identified on the five sites in Table 4.3.1. The Butte Creek site cultivated rice, which requires clayey soils with extremely low permeabilities. These types of soils are not appropriate for groundwater banking, as discussed in Section 3.3.1, so Butte Creek was given a soils sub-index value of zero. The other four sites from Table 4.3.1 were mainly composed of orchards, which indicate a more average loamy soil with moderate permeability. The score for these sites was calculated by averaging the sub-index scores shown in Table 4.3.2, arriving at an estimated score of 0.56. Figure 4.3.1 shows these estimated values in relation to the values displayed in Table 4.3.2.

Figure 4.3.1: Soils Sub-Index Ranking for Potential Groundwater Banking Sites in the Sacramento Valley

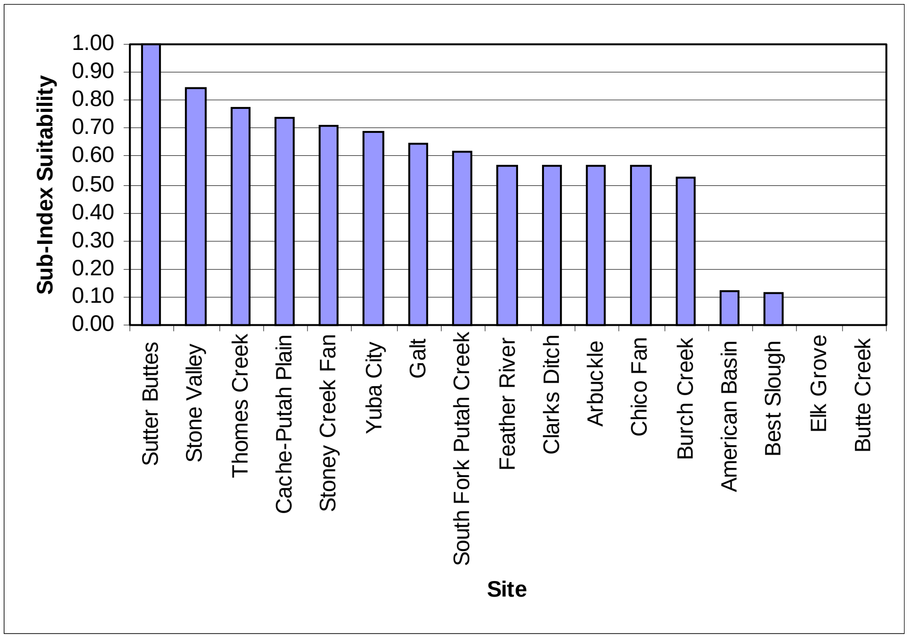

Figure 4.3.2: Spatial Distribution of Soils Sub-Index Values Across Potential Groundwater Banking Sites in the Sacramento Valley

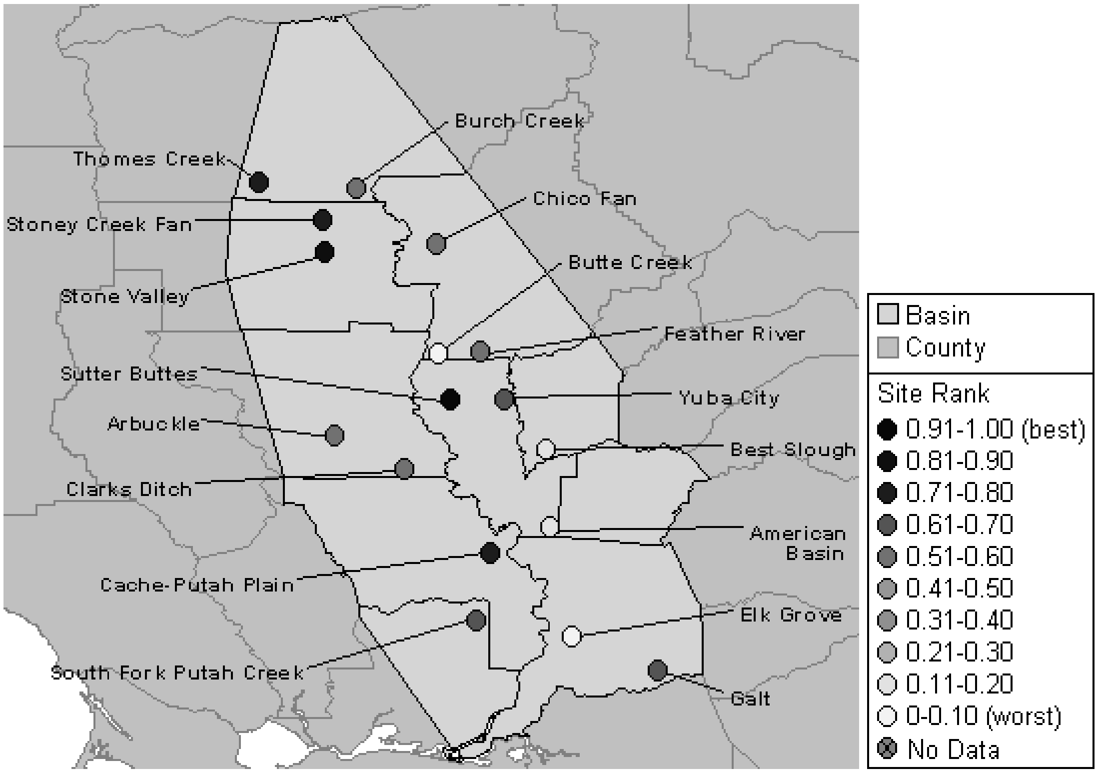

4.3.2 Comments on the Soils Sub-Index

Areas with highly desirable soil characteristics are found primarily in the northern and western regions of the valley. Unfortunately, actual data were not available for much of Butte and Colusa Counties and had to be estimated. The Excel project that accompanies this report would be an appropriate place to input more specific soil data for these sites, should this information become available.

4.4 Sacramento Valley Hydrogeologic Suitability Index

Having evaluated the sites in terms of three relevant sub-indices, we combined the sub-indices to derive the overall Hydrogeologic Suitability Index. The overall index of suitability in the Rank column in Table 4.4.1 was arrived at by applying Equation 4.1.

$$\boxed{\text{Hydrogeologic Suitability Index} = 2*(\text{Geology}) + 2*(\text{Water Quality}) + (\text{Soils})} \tag{4.1}$$

In this analysis, the geology and water quality sub-indices are weighted by 2 to stress their importance. The characteristics of the underlying formations determine whether water can be stored in an aquifer, and the water quality of the area is crucial if stored water is to be used for agriculture and urban uses. Soils are not weighted as high because problematic soils can be removed as part of project construction, although this would increase the overall cost of the project.

4.4.1 Results for the Sacramento Valley Hydrogeologic Suitability Index

Table 4.4.1 shows the overall Hydrogeologic Suitability Index. Values were normalized between 1 (corresponding to the most suitable site at Stoney Creek Fan) and 0 (corresponding with Elk Grove) in the % column.

The overall Hydrogeologic Suitability Index values for sites in the Sacramento Valley are displayed graphically in terms of their rank and their spatial distribution in Figures 4.4.1 and 4.4.2, respectively.

Table 4.4.1: Sacramento Valley Hydrogeologic Suitability Index

Weighting Coefficient	2	2	1		
Site	**Geology**	**Water Quality**	**Soils**	**Rank**	**%**
Stoney Creek Fan	0.69	0.70	0.71	3.48	1.00
Thomes Creek	0.12	0.96	0.78	2.93	0.80

Best Slough	0.00	0.91	0.11	1.94	0.44
Burch Creek	0.00	1.00	0.52	2.52	0.65

Figure 4.4.1: Hydrogeologic Suitability Index Ranking for Potential Groundwater Banking Sites in the Sacramento Valley

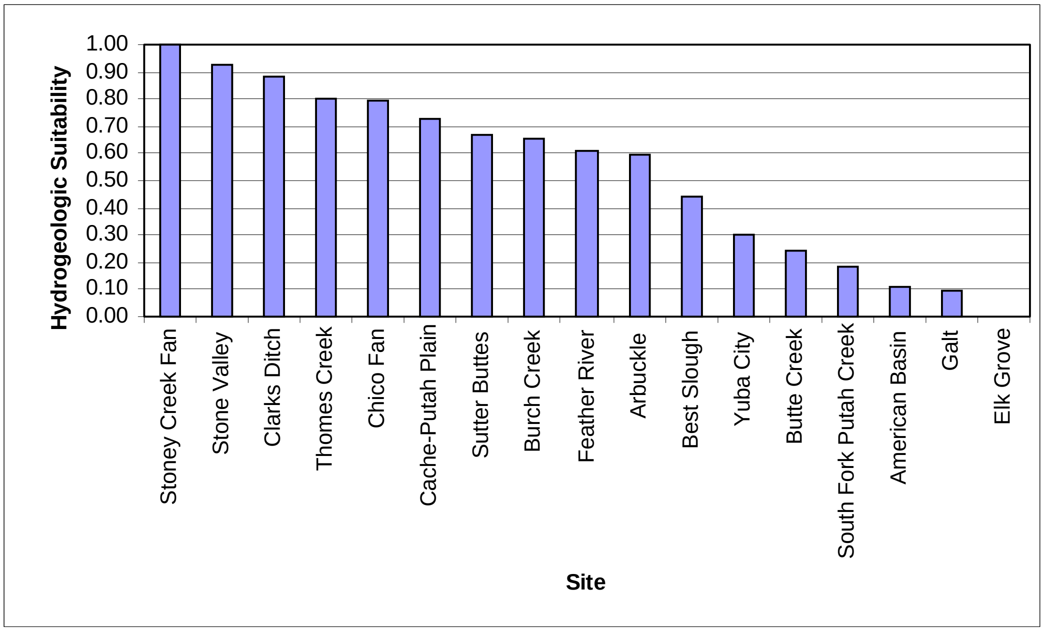

Figure 4.4.2: Spatial Distribution of the Hydrogeologic Suitability Index Values Across Potential Groundwater Banking Sites in the Sacramento Valley

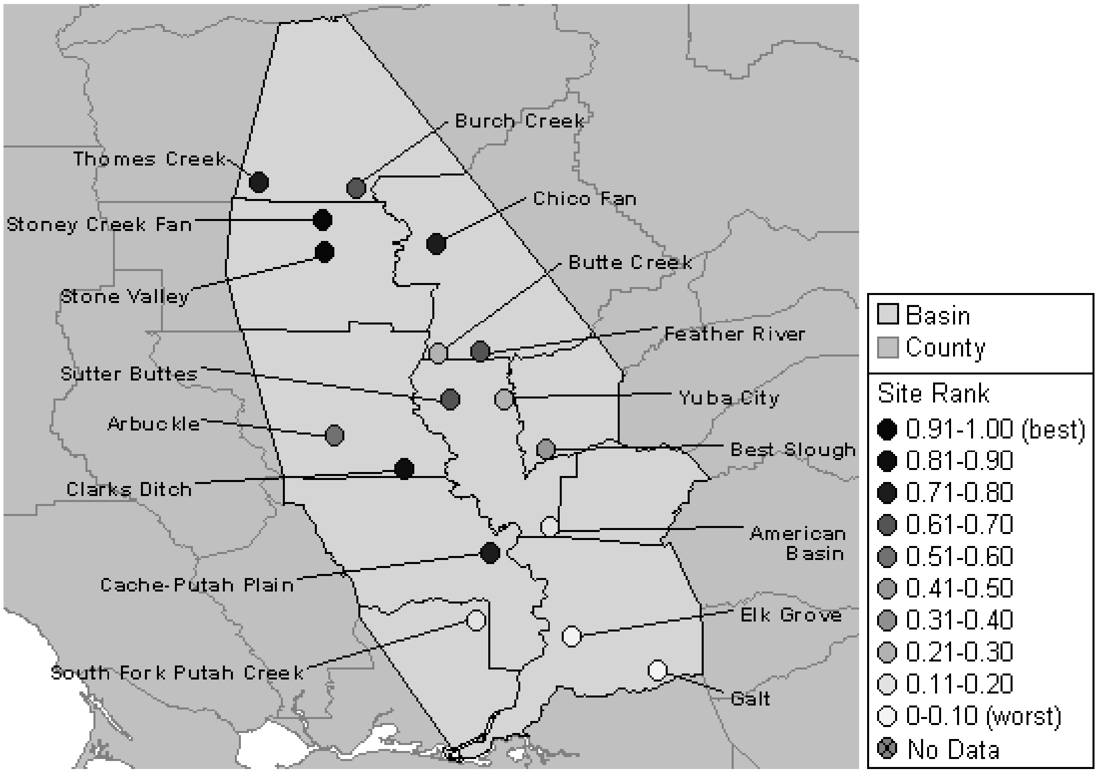


4.4.2 Comments on the Sacramento Valley Hydrogeologic Suitability Index

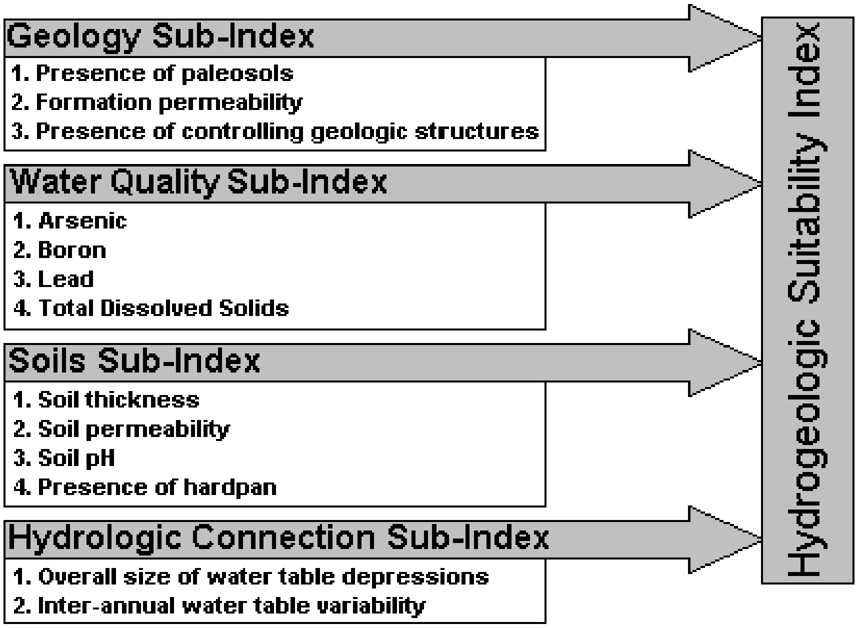
When all of the relevant sub-index values are taken into consideration, there appears to be a trend from the most suitable sites in the northern portion of the Sacramento Valley toward generally less suitable sites in the south. This has important implications in terms of integrating these sites into the state's surface water distribution network, as only Shasta Reservoir physically commands the most northern sites. While Shasta is a large facility, operational constraints associated with temperature control objectives may limit the ability to use Shasta as a direct source for groundwater banking. This suggests that a program of coordinated release from all of the Sacramento Valley reservoirs may be needed to "back" water up into Shasta Reservoir for eventual transfer to northern banking sites.

It should be pointed out that the ranking depicted in Figure 4.4.1 is purely a function of the numerical values assigned to each of the components and the weighting coefficients shown in Equation 4.1. It is possible that others interested in groundwater banking in the Central Valley would apply different component values and weighting coefficients. In order to allow for further exploration of geology, groundwater quality and soils on the suitability of potential groundwater banking sites in the Sacramento Valley, the information used to generate the ranking in Table 4.4.1 has been made available in the spreadsheet developed as part of this effort. In this spreadsheet, any of the values or weighting coefficients applied to the sub-indices may be changed and the new results can be viewed in tables and graphs similar to those in Table 4.4.1 and Figure 4.4.1.

5.0 Application of the Hydrogeologic Suitability Index in the San Joaquin Valley

The second application of the Hydrogeologic Suitability Report is in the San Joaquin Valley. Potential groundwater banking sites in this region are shown in Figure 2.0.2. As in the Sacramento Valley, each of the sites is evaluated in terms of the core index that covers relevant geology, groundwater quality and soils characteristics. In the case of the San Joaquin Valley, however, the index has been expanded to include a sub-index related to observed fluctuations in the water table below potential banking sites. As mentioned in Section 1.0, portions of the San Joaquin Valley have been exposed to prolonged periods of groundwater overdraft, resulting in the creation of significant and persistent cones of depression. These features will likely serve as the locus of groundwater storage in the San Joaquin Valley. The hydrologic connection sub-index is designed to assess the degree to which water deposited by groundwater banking at potential sites will remain available for eventual recovery. Details of this sub-index are presented in Section 5.4. Figure 5.0.1 provides a summary flow chart of the information used to develop and apply the Hydrogeologic Suitability Index in the San Joaquin Valley.

Figure 5.0.1: Flow Chart of Parameters Analyzed in the Development of Relevant Sub-Indices and the Overall Hydrogeologic Suitability Index in the San Joaquin Valley



5.1 San Joaquin Valley Geology Sub-Index

Deep, undifferentiated lacustrian and alluvial deposits characterize San Joaquin Valley geology. This contrasts with the Sacramento Valley, where various formations of differing thickness are encountered with depth below numerous sites. As such, in the San Joaquin Valley it is not generally possible to construct stratigraphic columns similar to those found in Figure 4.1.1. In fact, we assume that the formations encountered at each potential banking site are sufficiently thick to span the entire operational depth of a potential groundwater bank. In this case, the thickness of the single formation encountered at each potential banking site is treated as a parameter in the geology sub-index rather than as a weighting factor applied to the other geologic parameters (as in Equation 3.2). This thickness parameter is scaled as shown below (Table 5.1.1) in the adaptation to the Parameter Weighting Factors Table (Table 3.1.1).

Geology Sub-Index Equation Key

Eq. 3.2: Geology Sub-Index $= \Sigma$ (Formation Score $_A$ *Formation Thickness $_A$)

Table 5.1.1: Parameter Weighting Factors Used to Calculate the Geology Sub-Index, Adapted to Include Thickness as a Parameter for the San Joaquin Valley Hydrogeologic Suitability Index

Component	**0**	**5**	**10**
Permeability	Impermeable	Moderately permeable	Highly permeable
Paleosols	Contains resistant paleosols	Contains some slightly resistant paleosols	No paleosols
Geologic Structure	Contains structural features that direct stored groundwater towards gaining streams	Contains no structural features	Contains structural features that isolate stored groundwater from gaining streams
Thickness	Less than 20 ft. thick	6 = 50 to 80 ft. 3 = 20 to 50 ft.	Equal to or exceeds 100 ft.

5.1.1 Results of the San Joaquin Geology Sub-Index

Parameter scores associated with the formations encountered at potential banking sites in the San Joaquin Valley are shown in Table 5.1.2. As in the Sacramento Valley, a score of 10 is associated with the most favorable characteristics of a given parameter. The geology sub-index (Table 5.1.3) was calculated from parameter scores based on Equation 5.1.

$$\text{Formation Score} = 2*(\text{Permeability}) + 0.5*(\text{Paleosols}) + (\text{Geological Structure}) + (\text{Thickness}) \qquad (5.1)$$

In this equation, permeability was assigned a weighting coefficient of 2 due to its importance in the suitability of a formation for groundwater banking. The existence of paleosols was assigned a weighting coefficient of 0.5 because the extent to which paleosols are described varies between

Table 5.1.2: Scores for Formations Found in the San Joaquin Valley

Kern Water Bank	Kern	Tulare Formation	29	0.20
James Bypass	Kings	Alluvial Fan Deposits	28	0.00
White River	Tule	Alluvial Fan Deposits	28	0.00
Allensworth	Tule	Alluvial Fan Deposits	28	0.00

information sources, and when they are described they tend to be thin and discontinuous. The resulting score for each of the formations encountered at potential banking sites in the San Joaquin Valley is found in the Rank column in Table 5.1.2.

Having established the formation scores, an association was made between each potential groundwater banking site and the formation encountered at the target location. These associations are shown in Table 5.1.3, along with the normalized value of the geology sub-index site found in the % column. In this case a value of 1 corresponds with sites overlying the northwestern Kern fan deposits, as these were deemed to be most geologically suitable. A value of 0 is assigned to the alluvial fan deposits associated with the James Bypass, White River and Allensworth sites. The results of the geology sub-index are shown graphically for each of the potential banking sites in Figures 5.1.1 and 5.1.2. Respectively, these figures show the results in terms of the relative rank and the spatial distribution.

Figure 5.1.1: Geology Sub-Index Ranking for Potential Groundwater Banking Sites in the San Joaquin Valley

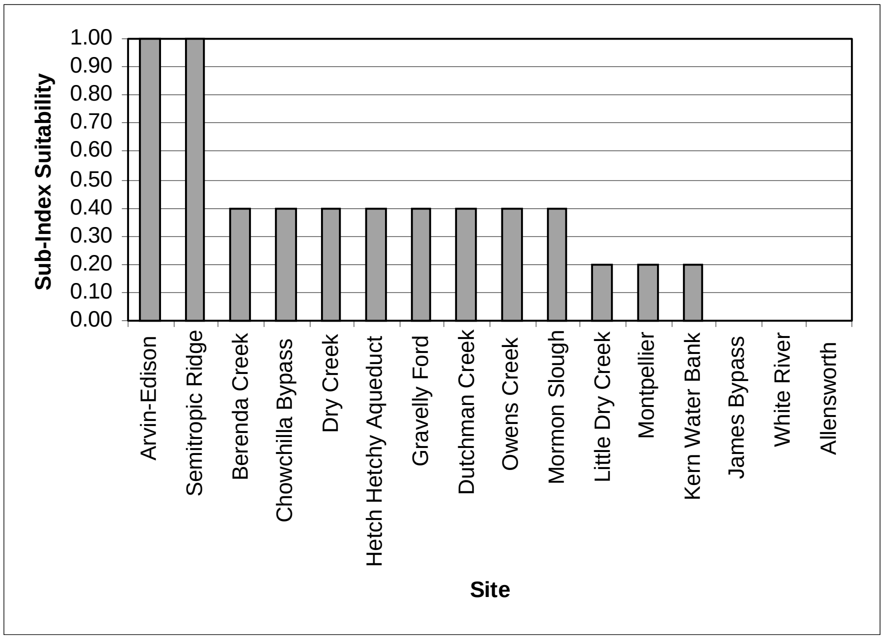

Figure 5.1.2: Spatial Distribution of Geology Sub-Index Values Across Potential Groundwater Banking Sites in the San Joaquin Valley

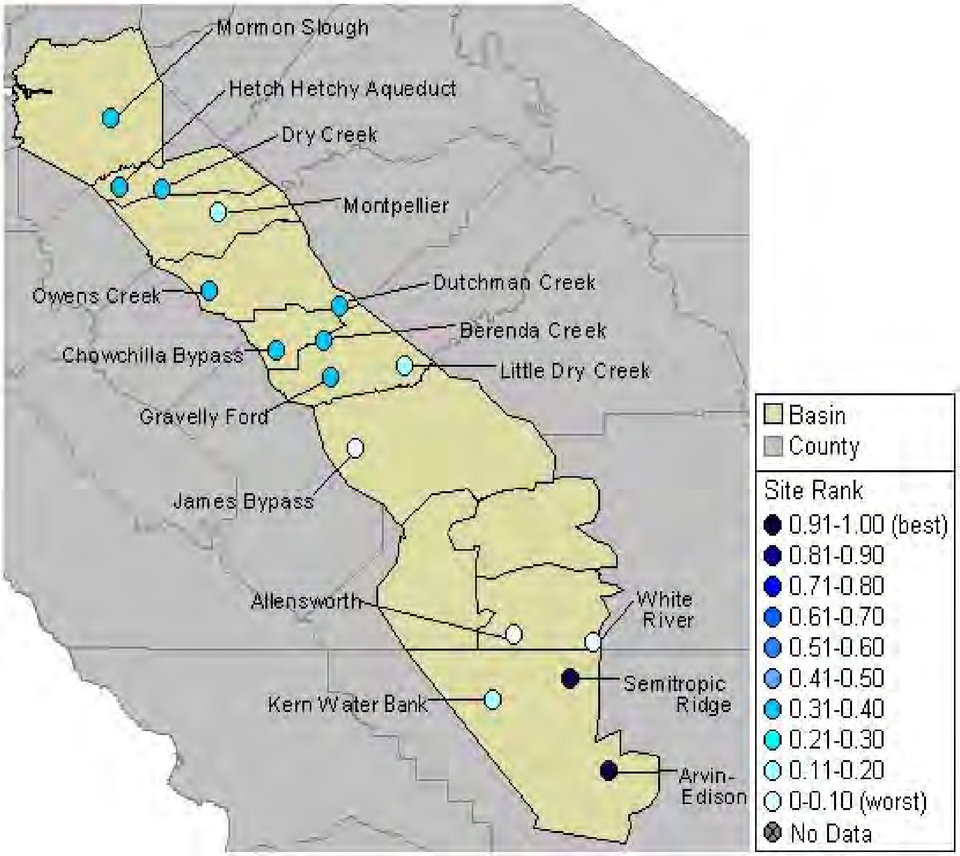

5.1.2 Comments on the San Joaquin Geology Sub-Index

The eastern Kern Basin sites (Arvin-Edison and Semitropic Ridge) emerge as well-suited for a groundwater banking project owing to the favorable geologic properties of the underlying northwestern Kern fan formation laid down by the Kern River. By comparison, sites on Tule and Kings River alluvial fans rank low. A large part of this discrepancy is due to a relative lack of information in the published literature on the specific alluvial fans associated with the sites. This lack of information forced us to set parameter scores based on fairly coarse descriptions found in regional mapping studies. Given the quality of the data, we erred on the side of caution in assigning the parameter scores. If these sites prove to be extremely suitable based on other components of the index, further research and testing of these alluvial deposits might be warranted.

In general, however, sites in the San Joaquin Valley demonstrate much less geologic variability than those identified in the Sacramento Valley. The influence of the geology sub-index on the overall index, then, should be viewed in comparative rather than absolute terms.

5.2 San Joaquin Valley Water Quality Sub-Index

As in the Sacramento Valley, the water quality sub-index in the San Joaquin Valley comprises four parameters: groundwater concentrations of arsenic, boron, lead and total dissolved solids. The methodology employed to assign scores to each of these parameters and to calculate the sub-index value is found in Section 3.2.

Water Quality Sub-Index Equation Key

Eq. 3.3: Water Quality Score = (As Score) + (B Score) + (Pb Score) + (TDS Score)
Eq. 3.4: Water Quality Sub-Index = 1.5*(Basin Score) + (Site Score)

5.2.1 Results of the San Joaquin Valley Water Quality Sub-Index

Groundwater quality parameter scores for both basins and sites in the San Joaquin Valley are given in Tables 5.2.1 and 5.2.2 respectively. Figure 5.2.1 illustrates these results spatially.

Table 5.2.1: San Joaquin Valley Basin Scores

Weighting Coefficient	1	1	1	1		
Basin Name	**As**	**B**	**Pb**	**TDS**	**Rank**	**%**

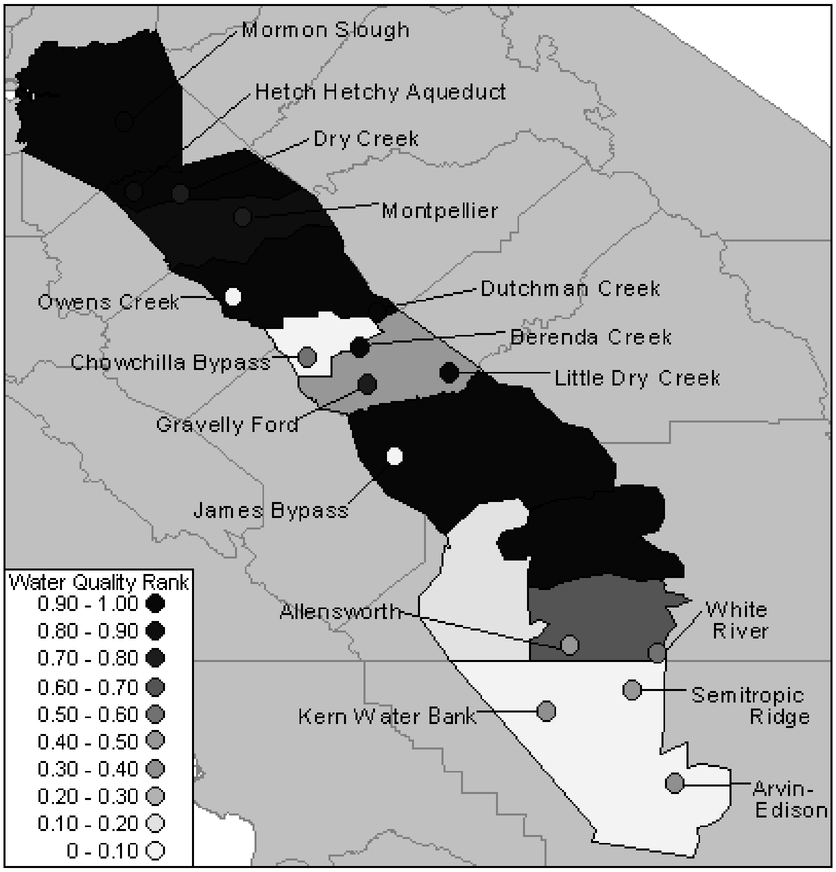
Figure 5.2.1: Spatial Distribution of Basin and Site Water Quality Scores



These scores were used to calculate the water quality sub-index based on Equation 3.4. The results for potential banking sites in the San Joaquin Valley are found in Table 5.2.3.

In preparation for inclusion in the overall Hydrogeologic Suitability Index for the San Joaquin Valley, water quality sub-index values have been normalized between 1 (corresponding with best groundwater quality at the Dutchman Creek site) and 0 (corresponding with the poorest observed groundwater quality at the Kern Water Bank and Arvin-Edison sites) in the % column. These results are shown with reference to the overall rank and the spatial distribution in Figures 5.2.2 and 5.2.3.

Table 5.2.3: Water Quality Sub-Index Values for Potential Banking Sites in the San Joaquin Valley

Weighting Coefficient		1.5	1		
Site Name	**Basin**	**Basin Wide**	**Site Specific**	**Rank**	**%**
Dutchman Creek	Merced	1.00	1.00	2.50	1.00
Mormon Slough	San Joaquin	1.00	0.93	2.43	0.96
Hetch Hetchy Aqueduct	Modesto	0.87	1.00	2.30	0.89
Dry Creek	Modesto	0.80	1.00	2.20	0.84
Montpellier	Turlock	0.73	0.89	1.99	0.73
Little Dry Creek	Madera	1.00	0.44	1.94	0.71
Gravelly Ford	Madera	0.80	0.44	1.64	0.55

Figure 5.2.2: Water Quality Sub-Index Ranking

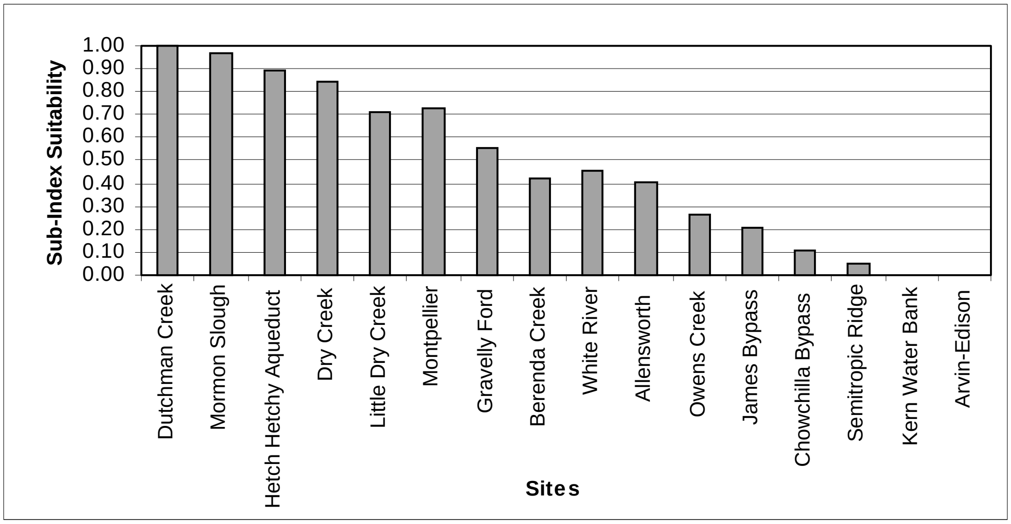

Figure 5.2.3: Spatial Distribution of Water Quality Sub-Index Values

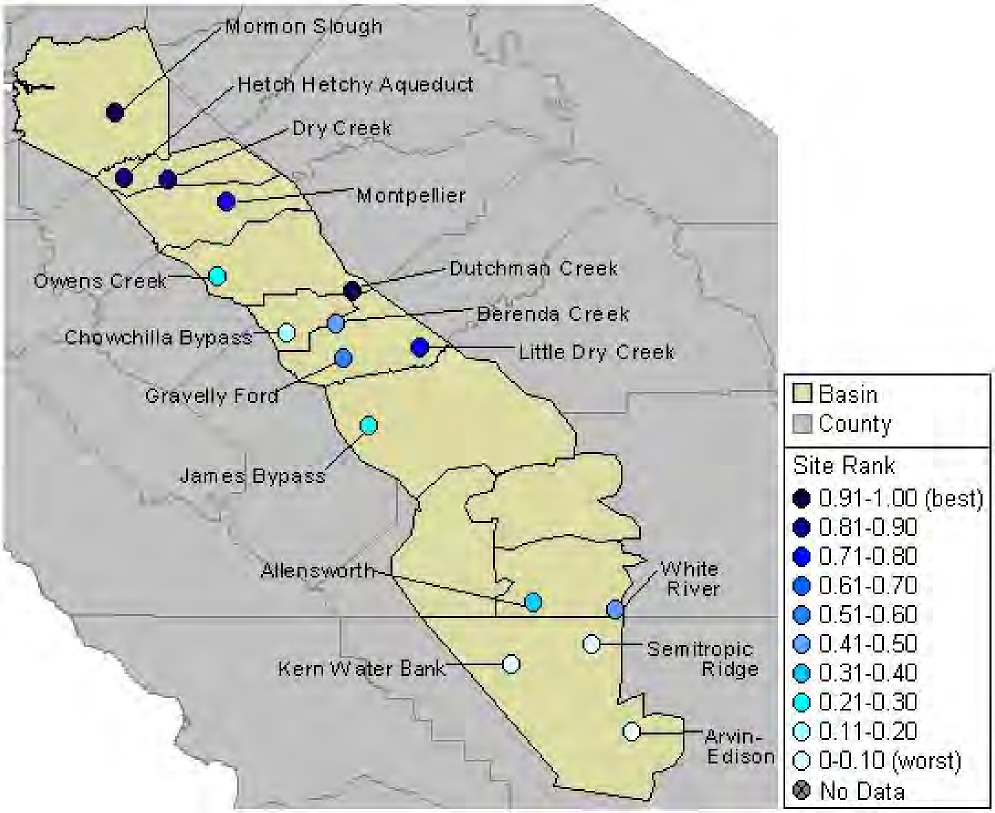

5.2.2 Comments on the Water Quality Sub-Index

Excluding the western San Joaquin Valley, where groundwater quality is generally poor across wide areas and where no potential banking sites have been identified, groundwater in the San Joaquin Valley is characterized by the presence of spots of poor quality. Arsenic levels are particularly high in the southern part of the valley in Kern and Tulare Lake Basins. Boron levels peak in parts of Merced, Kings and Tulare Lake basins, a pattern that is mimicked by the distribution of elevated TDS measurements. Lead concentrations are fairly low throughout the valley.

This spatial pattern of groundwater quality points out the utility of the spreadsheet developed as part of this effort. In general, boron is of greatest concern to agricultural water users while arsenic is particularly problematic for municipal water providers. In calculating the water quality sub-index, equal weighting was given to each of these parameters. Someone interested in evaluating the implications of groundwater banking on either of these user communities may wish to weight the sub-index in favor of one of these parameters over the others.

5.3 San Joaquin Valley Soils Sub-Index

Parameters used to calculate the soils sub-index are described in Section 3.0.

Soils Sub-Index Equation Key

Eq. 3.5: Soils Sub-Index = (Thickness) [3(Permeability) + (pH)– 2(1 – Hardpan)]

5.3.1 Results for the San Joaquin Valley Soils Sub-Index

Parameter scores and the soils sub-index values for selected sites in the San Joaquin Valley are shown below in Table 5.3.1.

Table 5.3.1: Soils Sub-Index

Weighting Coefficient	1	3	2	1		
Site	**Thickness**	**Permeability**	**Hardpan**	**pH**	**Rank**	**%**
Hetch Hetchy Aqueduct	0.80	0.60	1.00	0.83	2.10	1.00
Dry Creek	0.75	0.31	0.96	0.79	1.25	0.71
Montpellier	0.48	0.75	0.85	0.74	1.28	0.72
Semitropic Ridge	0.78	0.20	1.00	0.70	1.01	0.63
Gravelly Ford	0.77	0.24	0.87	0.54	0.77	0.55
Little Dry Creek	0.66	0.40	0.55	0.80	0.73	0.54
Arvin-Edison	0.86	0.03	1.00	0.74	0.71	0.53
Kern Water Bank	0.76	0.01	1.00	0.69	0.55	0.48
Owens Creek	0.75	0.02	1.00	0.41	0.36	0.42
White River	0.52	0.06	0.85	0.80	0.35	0.41
Chowchilla Bypass	0.67	0.13	0.51	0.50	-0.05	0.28
Berenda Creek	0.75	0.23	0.11	0.85	-0.17	0.24
James Bypass	0.77	0.20	0.19	0.51	-0.40	0.16
Dutchman Creek	0.64	0.14	0.23	0.68	-0.27	0.20
Mormon Slough	0.75	0.02	0.00	0.76	-0.88	0.00

The resulting values are normalized between 1 (corresponding with the most favorable soils at the Hetch Hetchy Aqueduct site) and 0 (corresponding with the Mormon Slough site) in the % column. These are presented graphically in Figures 5.3.1 and 5.3.2, which show the relative rank and spatial distribution of the results.

Figure 5.3.1: Soils Sub-Index Rank

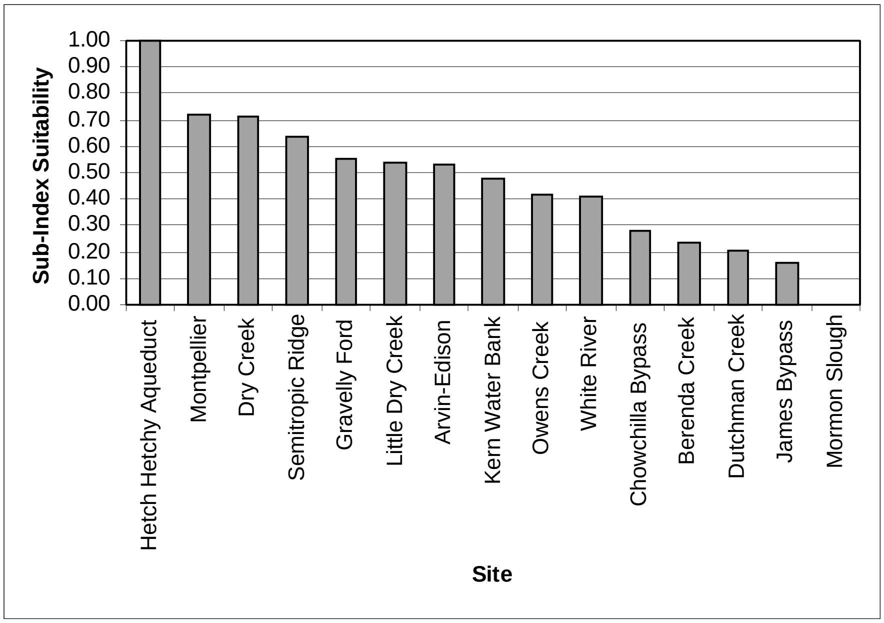

Figure 5.3.2: Spatial Distribution of Soils Sub-Index Values

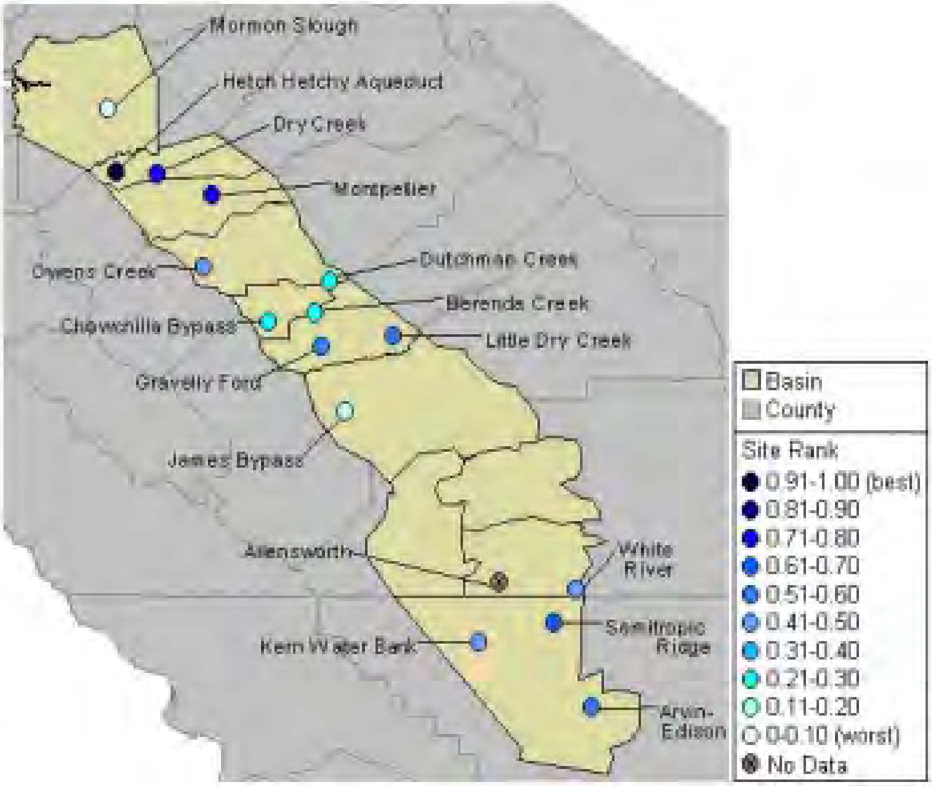


5.3.2 Comments on the Soils Sub-Index

Based on the selected parameters, the Turlock and Merced basins appear to possess the most suitable soils in the San Joaquin Valley. Soils in this region are derived from material of Sierran origin deposited by the high-energy Tuolumne and Merced Rivers. The result is a generally more coarse assemblage of soils as compared with material deposited by lower-energy streams to the north and south.

While more complete soil data was available for the San Joaquin Valley than in the Sacramento Valley, one site, Allensworth, lacked published soils information. Owing to a lack of data, in calculating the overall Hydrogeologic Suitability Index this site will be assigned a zero in terms of the soils sub-index.

5.4 San Joaquin Valley Hydrologic Connection Sub-Index

In the San Joaquin Valley, an additional sub-index has been added to the core Hydrogeology Suitability Index dealing with the hydrologic connection between potential storage space located within existing cones of depression and the surrounding hydrologic system. Groundwater basins are not surface reservoirs. While exposed to losses due to evaporation and seepage, water stored behind a dam is largely under the direct control of reservoir operators. When water is required, it need only be released from the storage pool. Storage in a groundwater bank does not benefit from the same level of control. Aquifers are open systems within which the existing level of use and conditions in surrounding groundwater basins and overlying surface water bodies influence flow patterns. In such a system, there is no guarantee that water recharged to a groundwater bank will remain within the pore space of the aquifer material immediately below the banking site. In assessing the hydrogeologic suitability of potential sites in the San Joaquin Valley, it is important to understand the way in which banked water would interact with the surrounding hydrologic system.

The most rigorous way to understand these potential interactions is through the use of groundwater models that describe flow patterns within an aquifer under various conditions. While the development of project-specific groundwater models will certainly occur once promising groundwater banking sites are identified and project design begins, it was beyond the scope of the current effort to develop such a tool for all of the potential sites in the San Joaquin Valley. In order to assess the potential for interaction between banked water and the surrounding aquifer, a simple method based on measured water level data was developed.

This methodology begins with the supposition that water banked in the San Joaquin Valley will ideally be stored within large, well-defined, stable drawdown features within an aquifer. This statement is based on two assumptions. First, it is assumed that where such features occur, the existing patterns of groundwater use and aquifer recharge leave a significant portion of the aquifer material perpetually unsaturated and available for long-term storage. Second, it is assumed that once recharge water joins the water table within such a large, well-defined, stable feature, it would be contained within the cone of depression and would not flow away from the recharge site. The methodology used to assess the degree of hydrologic connection between banked water and the surrounding aquifer relies upon analysis of the size and stability of target drawdown features.

5.4.1 San Joaquin Valley Hydrologic Connection Sub-Index Parameters

The components used in the hydrologic connection sub-index were all derived from data included in the semi-annual well survey conducted by the California Department of Water Resources. An example of the type of data contained in the survey is shown in Table 5.4.1.

Table 5.4.1: Water Contour Data for Turlock Basin, 6/1/77 to 12/31/77

UTM East	UTM North	WSE	GSWS	SWN	Meas. Date	UTM Zone
707008	4167178	118.0	82.0	03S12E33L01M	11/04/1977	10
672518	4159172	49.7	12.3	04S08E25D01M	11/01/1977	10
672572	4157724	48.6	9.4	04S08E25N01M	11/01/1977	10
670810	4158643	34.0	16.0	04S08E27H01M	11/01/1977	10
670808	4157564	44.4	8.6	04S08E34A01M	11/01/1977	10
669361	4157504	39.4	10.6	04S08E34D01M	11/01/1977	10
679642	4165707	33.4	24.6	04S09E03B01M	10/18/1977	10
677098	4165374	29.0	39.0	04S09E05H01M	10/14/1977	10

In the table, "UTM East", "UTM North" and "UTM Zone" are used to specify the physical location of wells included in the survey. The column heading SWN denotes the state well number, which makes reference to the California Public Lands Survey. The date of the semi-annual measurement at a well is provided under the heading "Meas. Date". We excluded from our analysis any data for which problems were encountered during measurement (as recorded during data collection). Hydrologic data related to the water surface elevation and the difference between the ground surface elevation and the water surface elevation are found under the "WSE" and "GSWS" headings, respectively (the sum of WSE and GSWS should yield the land surface elevation at the measurement site).

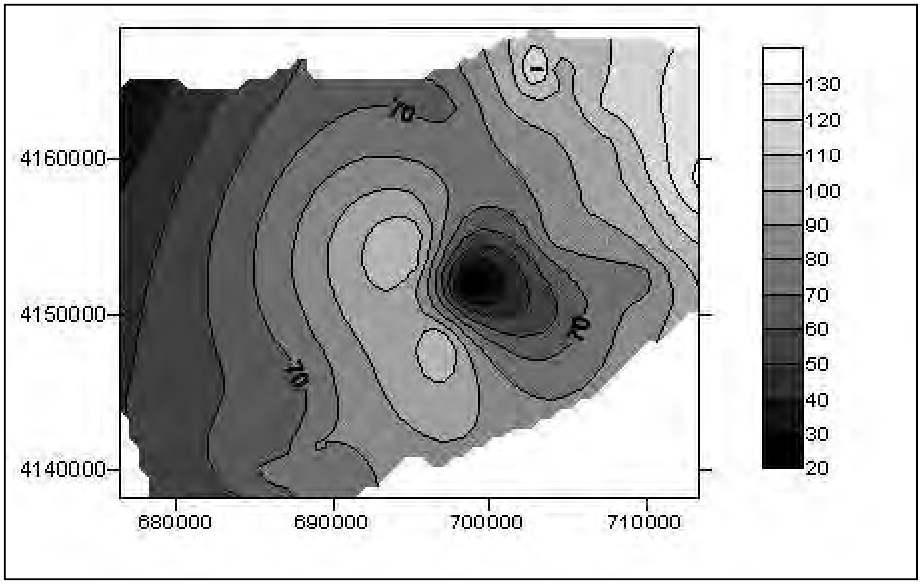
Data highlighted in Table 5.4.1 were used to define the parameters for the hydrologic connection sub-index. Water surface elevation data for the entire San Joaquin Valley were collected from Fall 1977 (selected to represent dry year conditions) and Fall 1997 (a wet water year) surveys. These data were used to develop approximate water table contour maps for each of the basins in the San Joaquin Valley. Figure 5.4.1 is an example of a map developed for the Turlock Basin based on the Fall 1977 survey. The large closed depression in the figure is located beneath the Montpellier site identified in Figure 2.0.2.

These maps should be considered approximate in that the wells included in the semi-annual survey were not specifically designed to track the position of the water table. Most are private wells that are screened across several hundred feet of aquifer material. As such, the water level observed in the well is an integrated sample of heads encountered both at the water table and at depth below the water table. In cases where significant flow-restricting horizons exist in the interval spanned by the well screen, these deeper heads may be quite different than the actual elevation of the water table surface. While an attempt was made to screen out problematic wells, some of the heads used to develop the contour maps most certainly did not reflect the true water table elevation at a given location.

Nonetheless, the contour maps developed as part of this analysis, found in Appendix E, capture the general location and scale of major cones of depression known to exist in the San Joaquin Valley. Lacking the resource to develop more accurate local water table maps, we used our

Figure 5.4.1: Turlock Basin Fall 1977 WSE Contours

(Elevation in feet above MSL)



basin scale maps to estimate the storage volume located within a cone of depression using a standard specific yield estimate of 0.2. In the case of the depression below the Montpellier site, a horizontal plane set at 75 ft. capped approximately 208 TAF of available storage during Fall 1977. Based on the estimated basin scale water table contour maps developed during the fall surveys of 1977 and 1997, two parameters were defined for use in the hydrologic connection sub-index.

Maximum Overall Size of Water Table Depressions

The larger of the estimated available storage volumes calculated based on data from the Fall 1977 and Fall 1997 surveys was selected to represent the maximum overall size of water table depressions parameter. We anticipated the available storage volume would be larger during 1977 owing to the extremely dry conditions encountered at that time. We discovered, however, that some locations manifested larger available storage volumes during the wet 1997 water year. This is presumably due to the fact that groundwater overdraft during the 20 intervening years masked any water table recovery associated with higher levels of aquifer recharge.

Inter-Annual Water Table Change

Nonetheless, changing levels of aquifer recharge do contribute to fluctuations in the water table surface that can be observed between dry and wet periods. Groundwater basins that experience significant changes in water levels, and hence available storage volumes, generally benefit from a high degree of natural recharge during wet periods. If the storage of banked water would limit the ability to capture a portion of this natural recharge, then the project could create conflicts with historic groundwater users. Any such fluctuations can be described in the following equation used to define the inter-annual water table change parameter of the hydrologic connection sub-index.

$$\text{Inter-Annual Change} = (V_{77F} - V_{97F}) / \text{Max. Volume} \tag{5.2}$$

where V_{77F} = volume of a basin in Fall 1977
and V_{97F} = volume of a basin in Fall 1997

Because the effects of long-term overdraft can mask water table recovery associated with enhanced recharge during wet years, Equation 5.2 occasionally produces negative numbers. A site in overdraft provides a unique opportunity for a groundwater banking project because, not only would the site have a large depression available for storage, but the storage of water there could be used to provide benefits to overlying groundwater pumpers if some portion of the banked water could be used to slow down or reverse incipient water table declines.

5.4.2 San Joaquin Valley Hydrologic Connection Sub-Index Weighting Factors

As in the case of the sub-indices included in the core index, calculation of the hydrologic connection sub-index can be influenced by the assignment of appropriate weighting factors. As the size of the cone of depression is the most important feature in determining what scale of a project could be pursued at a potential groundwater banking site, this parameter was weighted by a factor of two. In addition, the inter-annual change parameter should be subtracted from one so that a basin that experiences a small rise in the water table between wet and dry years (suggesting a small amount of hydrologic connection with the surrounding hydrology) would score higher than a basin where large fluctuations occur, presumably in response to significant interaction between the aquifer and the surrounding hydrologic features. In addition, for sites in overdraft (the inter-annual change parameter is negative), where banking could contribute to water table recovery, this subtraction would enhance the suitability of the site. Each of these assumptions is contained in the following equation used to calculate the hydrologic connection sub-index.

$$\text{Hydrologic Connection Sub-Index} = 2*\text{Max. Volume} + (1 - \text{Inter-Annual Change}) \tag{5.3}$$

5.4.3 Results for the San Joaquin Valley Hydrologic Connection Sub-Index

Applying Equation 5.3 to the estimated water table elevation data derived from the available data produces the hydrologic connection sub-index values shown in Table 5.4.2. These values have been normalized between 1 (corresponding with the Kern Water Bank site) and 0 (corresponding with the Dry Creek site) in the % column. Normalized results are shown in terms of relative rank in Figure 5.4.2 and spatial distribution in Figure 5.4.3.

Table 5.4.2: Hydrologic Connectivity Sub-Index Table

Site	Max. Vol.	Annual	Rank	%
Kern Water Bank	21.61	-0.40	44.62	1.00
Allensworth	7.77	-0.83	17.37	0.39
James Bypass	6.13	0.18	13.08	0.29

Figure 5.4.2: Hydrologic Connection Sub-Index Rank

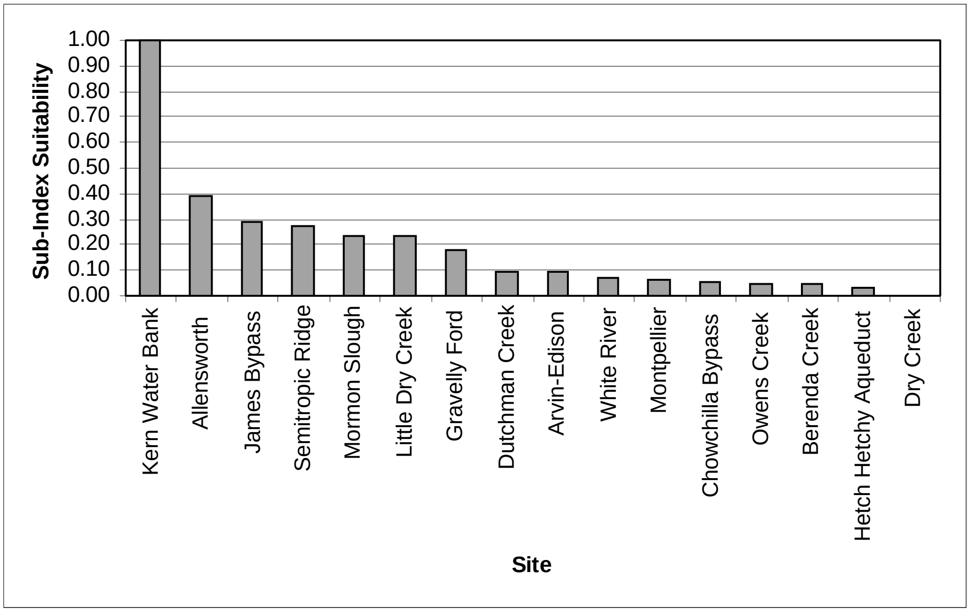

Figure 5.4.3: Spatial Distribution of Hydrologic Connection Sub-Index Values

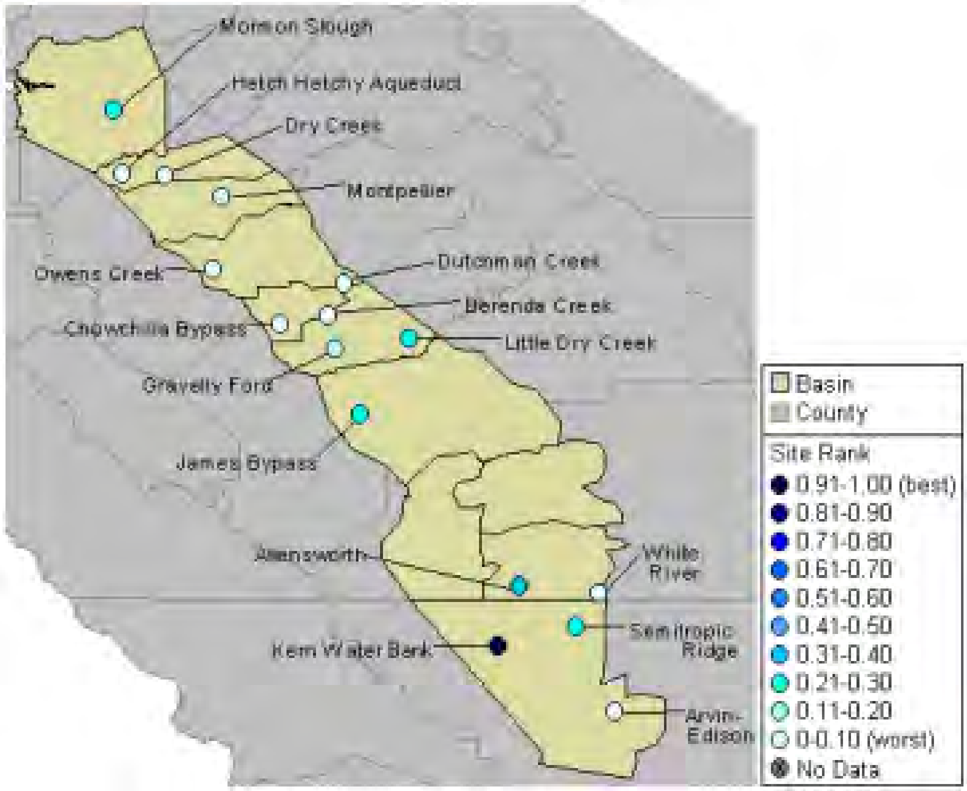


5.4.4 Comments on the Hydrogeologic Connectivity Index

The Kern Water Bank dwarfs the rest of the potential groundwater banking sites in the San Joaquin Valley with respect to the hydrologic connection sub-index. This site overlies what was a large depression in 1977 and has been the locus of an active groundwater banking project for the past decade. While it no longer merits the label of a potential site, it was included in the analysis for comparative value.

Another cluster of relatively promising sites lies in the vicinity of the San Joaquin River. The Little Dry Creek, Gravelly Ford and James Bypass sites all score relatively high. The opportunity to manage these sites in conjunction with reoperation of Friant Dam on the San Joaquin likely merits additional evaluation.

5.5 San Joaquin Valley Hydrogeologic Suitability Index

Having developed the four relevant sub-indices, the overall Hydrogeologic Suitability Index for potential groundwater banking sites in the San Joaquin Valley was calculated based on the following equation.

$$\boxed{\text{Hydrogeologic Suitability Index} = (\text{Geology}) + 2*(\text{Water Quality}) + (\text{Soils}) + 0.5*(\text{Hydrologic Connection})} \tag{5.4}$$

The results of this analysis are shown in Table 5.5.1 with the normalized values between 1 (corresponding with the Hetch Hetchy Aqueduct) and 0 (corresponding with James Bypass) shown in the % column. These results are shown graphically in Figures 5.5.1 and 5.5.2, which present the relative rank and spatial distribution, respectively.

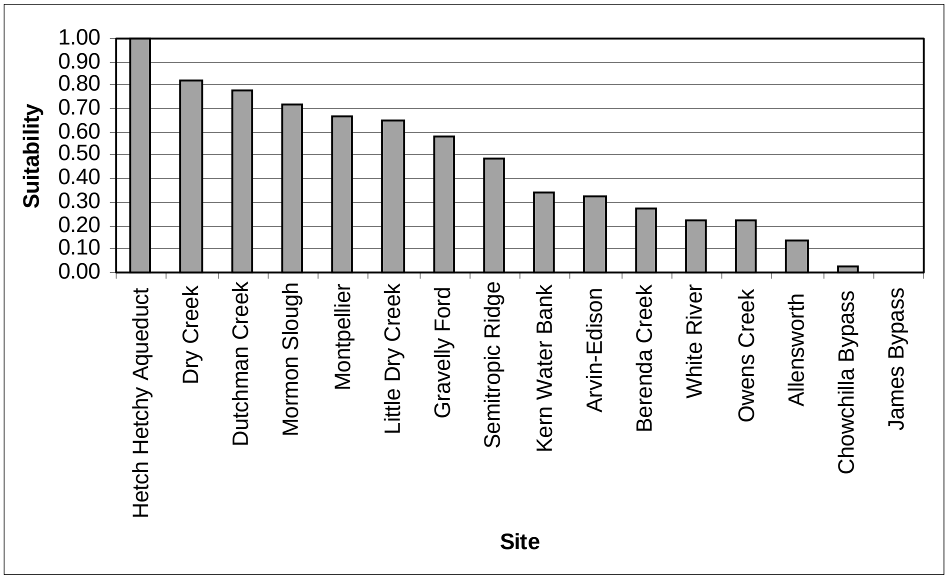
Table 5.5.1: San Joaquin Valley Hydrogeologic Suitability Index

Weighting Coefficient	1	2	1	0.5		
Site	**Geology**	**Water Quality**	**Soils**	**Hydrologic Connectivity**	**Rank**	**%**
Hetch Hetchy Aqueduct	0.40	0.89	1.00	0.03	3.22	1.00
Dry Creek	0.40	0.84	0.71	0.00	2.80	0.82
Dutchman Creek	0.40	1.00	0.20	0.10	2.70	0.78
Mormon Slough	0.40	0.96	0.00	0.24	2.57	0.72
Montpellier	0.20	0.73	0.72	0.06	2.45	0.67
Little Dry Creek	0.20	0.71	0.54	0.24	2.39	0.65
Gravelly Ford	0.40	0.55	0.55	0.18	2.23	0.58
Semitropic Ridge	1.00	0.05	0.63	0.27	2.01	0.48
Kern Water Bank	0.20	0.00	0.48	1.00	1.68	0.34
Arvin-Edison	1.00	0.00	0.53	0.10	1.63	0.32
Berenda Creek	0.40	0.42	0.24	0.04	1.52	0.28
White River	0.00	0.46	0.41	0.07	1.39	0.22
Owens Creek	0.40	0.26	0.42	0.05	1.39	0.22
Allensworth	0.00	0.40	0.00*	0.39	1.19	0.14
Chowchilla Bypass	0.40	0.11	0.28	0.05	0.94	0.03
James Bypass	0.00	0.21	0.16	0.29	0.87	0.00

* In cases where values were missing, the value zero was used.

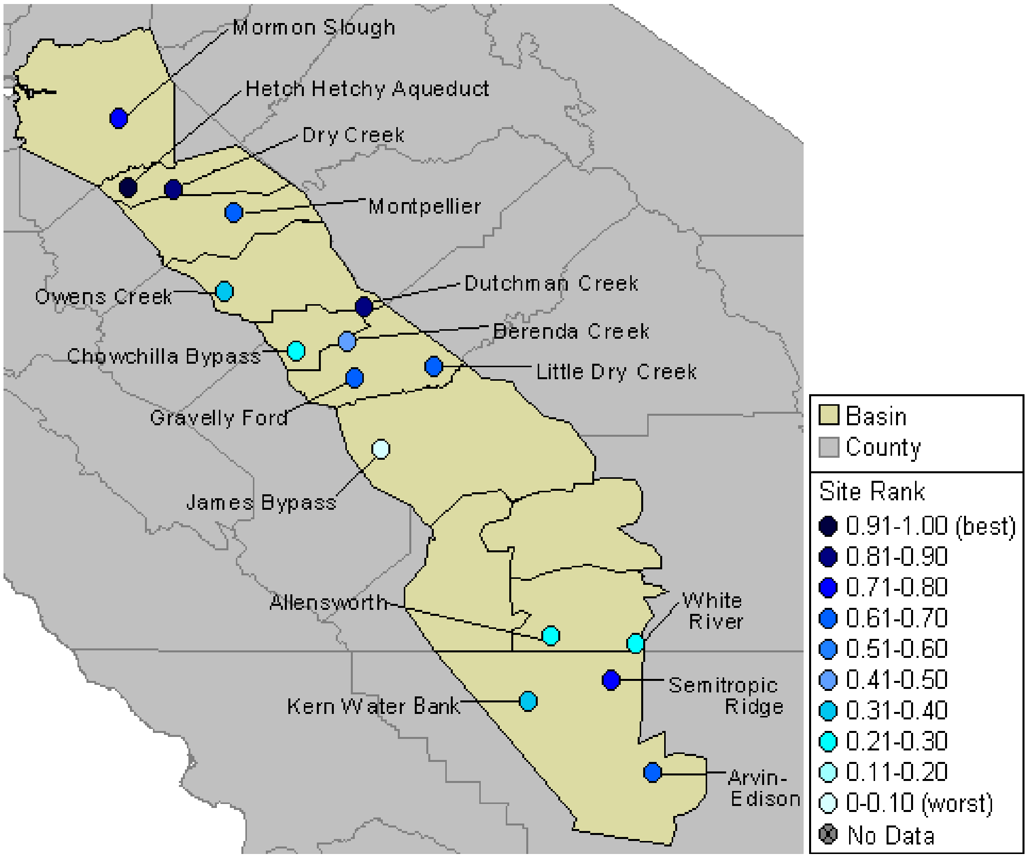
In this analysis, the water quality sub-index was weighted by 2 to stress its importance to the ultimate users of banked groundwater. In the San Joaquin Valley, the geology sub-index only receives a weighting factor of 1 (as opposed to 2 in the Sacramento Valley) in order to reflect the fact that the data do not suggest as clear a differentiation between sites in terms of this important characteristic. Soils receive a weight of 1 to reflect the fact that while they can exert important controls on the operation of recharge basins, problematic soils can be removed as part of project construction, although this would increase the overall cost of the project. The hydrologic connection sub-index receives a weight of 1 because, while the information on the water table depression size and stability is extremely important, the approach taken here is based on the hydrologic response of the system under existing management conditions. The initiation of storage and recovery operations at a potential site would substantially alter these conditions. As previously mentioned, the best way to evaluate this possibility is through the application of groundwater models—an exercise that was beyond the scope of the current investigation. In the event that modeling results become available, it would be possible to increase the weighting on this sub-index.

Figure 5.5.1: San Joaquin Valley Hydrogeologic Suitability Index Rank



It should be pointed out that the ranking depicted in Figure 5.5.1 is purely a function of the numerical values assigned to each of the components and the weighting coefficients shown in Equation 5.4. It is possible that others interested in groundwater banking in the San Joaquin Valley would apply different component values and weighting coefficients. In order to allow for further exploration of geology, groundwater quality, soils and the degree of hydrologic connection on the suitability of potential groundwater banking sites in the San Joaquin Valley, the information used to generate the ranking in Table 5.5.1 has been made available in the spreadsheet developed as part of this effort. In this spreadsheet, any of the values or weighting coefficients applied to the sub-indices may be changed and the new results can be viewed in tables and graphs similar to those in Table 5.5.1 and Figure 5.5.1.

Figure 5.5.2: Spatial Distribution of Hydrogeologic Suitability Index Values



6.0 Conclusions

A recent review of an attempt to develop an Environmental Sustainability Index (ESI) that could be applied to nations across the world (found in the 01/25/01 edition of *The Economist*) seized upon two major problems inherent to the development of comparative indices. First, "a tricky challenge…is to decide how to weigh each indicator". Second, "another challenge remains the paucity of good data. By forging ahead anyway, the report risks lending a quantitative gravitas to conclusions that are based on still-sketchy data".

The first critique stems from the fact that the ESI gives equal weight to all its 22 indicators. The authors of the ESI accepted this criticism, but explained that their database will soon be available on CD-ROM. Critics will then be able to use whatever weightings they prefer. The authors of the ESI responded to the second critique by arguing that they have created a framework that exposes the data deficiencies, and so spurs others to remedy them. Future versions of the report, they point out, can only get better. In fact, the authors conclude "the chief virtue of this index is that it begins the process of shifting environmental debates on to firmer foundations, underpinned by data and a greater degree of analytic rigor".

While our development of a Hydrogeologic Suitability Index for potential groundwater banking sites in the Central Valley is a much less weighty endeavor than the development of the ESI, we anticipate that similar criticisms will be directed at this effort. Rather than weight each of our sub-indices equally, however, we made an attempt to highlight what we perceive to be the relative importance of the geologic setting and water quality sub-indices. By making the aforementioned Excel workbook available on the web, we encourage all those interested in groundwater banking in California to use whatever weightings they prefer. While the data used in this effort are likely better than those available to the authors of the ESI, we have pointed out that several compromises were made in order to assemble the minimum suite of data used to develop the Hydrogeologic Suitability Index. We encourage those with access to better information to improve upon our effort by bringing this information to bear on the on-line database. This process of refinement will only improve the quality of our effort.

As a starting point, however, we feel that the Hydrogeologic Suitability Index reveals several interesting findings in terms of potential projects that should be considered for more refined analysis. Notably, we found that the groundwater basins in the Sacramento Valley are generally more favorable in terms of their hydrogeologic suitability for groundwater banking. As has been mentioned on several occasions in this report, this finding raises a number of complicated legal and institutional issues related to the fact that these basins are not currently endowed with substantial volumes of unsaturated aquifer material ready to be used for storage. While these issues will by no means be simple to resolve, the quality of these basins from a purely hydrogeologic perspective suggests strongly that the effort should be made to resolve them.

In the Sacramento Valley, the best opportunities for groundwater banking seem to cluster near the northern end of the valley, with Stone Valley and Stoney Creek Fan leading the pack. The geology in particular under these sites is well-suited for a banking project.

In the San Joaquin Valley, there is no clear geographic gradient of favorable to poor sites. Clusters of favorable sites exist in Modesto, Madera and Kern basins. Both soils and hydrologic connection vary greatly in the San Joaquin Valley, which could account for the discontinuous distribution.

In concluding their review of the Environmental Sustainability Index, the commentators concluded that it "is a thoughtful step in the right direction". While much work remains to be done in translating the promise of groundwater banking to actual yield-enhancing projects, we hope that the Hydrogeologic Suitability Index described in this report will ultimately be viewed in a similar light.

Appendix B: Raw Soil Data

Soil Name	Thickness (in.)	Permeability	pH (rank from Table 5.2)	Hardpan (rank as described in Section 5.1)
Marvin silty clay	60	0.50	80	1.00
Zamora silty clay loam	60	0.50	80	1.00
Clear Lake clay	60	0.12	90	1.00
Altamont clay	35	0.12	100	1.00
Cortina gravelly fine sandy loam	72	10.00	45	1.00
Maywood loam	62	1.64	80	1.00
Perkins gravelly loam	60	1.64	70	1.00
Alamo-Fiddyment complex	37	0.12	75	0.00
Cometa-Fiddyment complex	60	1.02	70	1.00
Cometa-Ramona sandy loams	73	1.02	80	1.00
San Joaquin-Cometa sandy loams	60	1.02	70	0.00
Corning complex	62	1.02	50	1.00
Redding loam	66	1.02	60	0.00
Redding gravelly loam	66	1.02	60	0.00
Bruella sandy loam	61	3.00	90	0.00
Galt-urban land complex	60	0.12	75	0.00
Galt clay	60	0.12	75	0.00
Madera-Galt complex	60	0.12	75	0.00
San Joaquin silt loam	60	1.02	80	0.00
San Joaquin-Galt complex	60	1.02	75	0.00
San Joaquin-urban land complex	60	1.02	80	0.00
San Joaquin-Xerarents complex	60	1.02	80	1.00
Live oak sandy clay loam	60	3.29	75	1.00
Exeter sandy loam	60	1.10	80	1.00
Marcum clay loam	60	0.33	80	1.00
San Joaquin sandy loam	60	1.02	80	0.00
San Joaquin-Arents-Durochrepts complex	60	1.02	80	0.00
Madera fine sandy loam	60	3.02	85	0.00
Madera loam	60	1.02	85	0.00
Madera-Alamo complex	60	3.02	85	0.00
Alamo clay	60	0.12	75	0.00
Atwater loamy sand	60	6.25	90	1.00
Greenfield sandy loam	72	3.75	90	1.00
Lewis loam	60	1.02	60	0.00
Ramona sandy loam	60	2.59	90	1.00
Ramona sandy loam w/H	60	2.59	90	0.00
Atwater loamy sand w/H	60	6.25	90	0.00
Chino clay loam	64	3.46	90	1.00
Calhi loamy sand w/H	60	7.50	40	0.00
Calhi loamy sand	60	7.50	40	1.00
Fresno and El Peco loams	60	1.27	30	0.00
Artois loam	60	1.27	90	1.00
Artois gravelly loam	60	1.27	90	1.00
Cortina gravelly loam	60	10.00	80	1.00
Hillgate clay loam	54	1.27	80	1.00
Myers clay	60	0.12	100	1.00
Pleasanton gravelly loam	54	0.50	70	1.00
Pleasanton very gravelly sandy loam	54	0.50	70	1.00
Delano sandy loam	63	3.09	70	1.00
Zerker loam	62	1.10	70	1.00
Chanac clay loam	60	1.10	70	1.00
Wasco sandy loam	60	4.00	80	1.00
Borden loam	60	1.35	85	1.00
Grangeville sandy loam	60	3.75	70	1.00
Greenfield coarse sandy loam	60	3.75	100	1.00
Dinuba-El Peco fine sandy loams	60	2.52	55	1.00

Feasibility Study of a Maximal Program of Groundwater Banking

December, 1998

Acknowledgements

This report would not have been possible without the sustained support of the Ford Foundation. Recognizing the enormous contribution which groundwater banking could make towards diffusing water allocation conflict in California, indeed around the world, Ford was willing to underwrite several years of foundational research. By necessity, this research focused on framing the broad structural considerations and the general legal and institutional tenets of a maximal program of groundwater banking. Thanks to their generous financial assistance, however, we have also succeeded in adding form to the frame. The exciting payoff from the Ford Foundation's investment are the explorations of site-specific details of groundwater banking opportunities which are recounted in this report. Extending this analysis to the full suite of opportunities is now possible.

Our explorations have been facilitated by the availability of the Water Evaluation and Planning system (WEAP). This innovative river basin planning software, developed by the Tellus Institute in Boston, Massachusetts, underwent a major upgrade thanks to the financial support of the CalFed Bay-Delta Program, the U.S. Fish and Wildlife Service, the U.S. Bureau of Reclamation, and the Metropolitan Water District of Southern California. We sincerely appreciate the contribution of each of these valued partners and look forward to additional collaboration in the area of groundwater banking.

Finally, we would like to acknowledge you, the reader, for your willingness to read this document. We cannot promise that it will always make for gripping reading, although we are confident that it is an important contribution to the ongoing discussion of groundwater banking. Whatever your position in the California Water Community, it is in this context that we thank you. Only an open exchange of ideas will transform groundwater banking into a water management reality and we look forward to continued dialogue in the months and years to come.

Preface

Periodically since 1957, the California Department of Water Resources has published *The California Water Plan*. A review of these documents reveals that what began as an inventory of existing water supply and demand patterns, and projected future changes, has evolved into planning document which recommends options for balancing water demand and supply in the future. Bulletin 160-93, the 1993 version of *The California Water Plan Update*, was particularly noteworthy in terms of its recognition of the need to integrated the management of the state's surface water and groundwater resources (conjunctive use). According to *The Plan* (DWR 1994):

> In the future, carefully planned conjunctive use will increase and become more comprehensive because of the need for more water and the generally higher cost of new surface water facilities. Conjunctive use programs generally promise to be less costly than new traditional surface water projects because they increase the efficiency of water supply systems and cause fewer negative environmental impacts than new surface water reservoirs (page 103).

This statement is full of promise and expectation, positive tones which have sustained a conceptual discourse on conjunctive use and groundwater banking in California for many years. The end result of this promise and expectation is that groundwater banking has become an element of the standard litany of water management strategies for California, and is often held up as a win-win alternative for the state's disparate stakeholders.

When an attempt is made, however, to translate the conceptual model into actual yield enhancing projects, promise and expectation often give way to concern and uncertainty. Focusing attention on the conjunctive management of specific rivers and groundwater basins consistently raises "red flags" for those whose livelihoods depend on these resources. NHI does not seek to discredit these reactions. Given the level of investment in the current water management system and the hydrologic and economic uncertainly associated with conjunctive use, most are legitimate. Nonetheless, this report adopts the perspective that these concerns should catalyze analysis and dialogue, not extinguish them. The research we have conducted to date flows from this perspective and responds to many of the regularly waved red flags. In the interest of catalyzing increasingly site-specific analysis, the pages of this document report that:

- Re-operation of the terminal reservoirs on each of the major rivers between the Lake Shasta and Millerton Lake as part of a maximal groundwater banking program, in coordination with reservoirs located upstream, could generate approximately 1 MAF of average annual yield and increase the overall performance of the surface water infrastructure.
- Under existing law, there is no proscription against importing surface water for storage in a groundwater basin and eventual recovery for use off site.
- An inventory of potential aquifer storage sites discovered over 10 MAF of available storage a various places around the Central Valley, much of which could be accessed by re-operating and/or modifying conveyance infrastructure.
- Modification of conveyance infrastructure in a portion of the Sacramento Valley could enhance the yield of Shasta Dam by up to 40 TAF during dry years, while assisting water managers in Yolo County forestall future groundwater overdrafts.
- By increasing yield on the San Joaquin River, aquifer storage at Gravelly Ford could allow for downstream releases of approximately 144 TAF to restore the anadramous fishery while largely preserving the important agricultural economy in the southern San Joaquin Valley which currently diverts nearly the entire flow of the river.
- The proximity of a significant aquifer storage resource to the east of the Delta in San Joaquin County could increase the reliability of water supply south of the Delta, relieve chronic groundwater overdraft conditions and allow for enhanced Delta outflow when integrated with enhanced Delta conveyance infrastructure.
- At a cost which is generally less than $300 per acre-foot, groundwater banking projects similar to the examples cited above are must more affordable that surface water development projects which can cost up to $3000 per acre-foot.

These findings are an exciting step in the translation of a conceptual model of groundwater banking into actual programs which produce new water for both water supply and environmental restoration. We are optimistic that they are sufficiently compelling to allow some red flags to be lowered, if not furled. In keeping with this optimism, NHI anticipates that the analysis presented in this report will launch a useful dialogue about fulfilling the promise of groundwater banking. This analysis employs several innovative analytical tools which we expect will assist in developing a consensus around this management strategy. These including:

- The Conjunctive Use Potential model, or CUP, which can be used to assess the yield potential of the Central Valley reservoirs under a variety of assumptions regarding reservoir operating rules, conveyance capacities, and aquifer storage space.
- A legal matrix which weighs the relative strength of claims to various types of water stored in groundwater banking sites.
- A matrix of criteria which can be used to rank the suitability of specific groundwater banking sites.
- The Water Evaluation and Planning system, or WEAP, a monthly time-step water allocation model which allows for operational simulations which place specific groundwater banking sites in the context of surface water infrastructure and distributed water demand.
- An extensive database of existing groundwater banking activity in California which can be mined for important insights about avoiding potential pitfalls in the path towards groundwater banking.

We recognize that the task of fulfilling the promise of actual groundwater banking opportunities will only come from site-specific analysis which sufficiently resolves local details to allay the concerns of local actors and regional water managers alike. Our next phase of analysis will involve extending preliminary operational analysis similar to that conducted in Yolo and San Joaquin Counties and along the San Joaquin River to the other potential sites depicted on the cover of this report (also Figure 8). In all cases further refinement of site specific analysis will include:

- Facilitating stakeholder consultations;
- Defining operational changes required to practice groundwater banking;
- Assessing the suitability of groundwater banking in light of competing land uses;
- Evaluating potential environmental complications;
- Addressing local socio-economic and political realities;
- Optimizing the economic value of the site; and
- Resolving legal and institutional barriers.

The end result of this effort will be a suite of the most compelling groundwater banking opportunities ready for presentation to policy makers. The importance of this step cannot be underestimated. The policy making community must have this analysis in hand before making any final decisions about groundwater banking. Absent a well articulated strategy for capitalizing on this storage modality, it is unlikely that any storage enhancement program can be advanced. NHI offers ours analysis as an important contribution to this articulation.

I. Introduction

California's Central Valley watershed, made up of the San Francisco Bay-Delta Estuary and its upstream tributaries, is an extraordinary environmental resource for fish and wildlife. At the same time, the watershed provides much of the water that fuels California's enormous economy. Experience gained during the 1987-1992 drought indicates that operating the installed hydraulic infrastructure in the Central Valley under existing rules and proposed regulations will increasing bring economic and environmental water management objectives into conflict. The hard reality is that under rigid adherence to antiquated management arrangements, the Central Valley watershed cannot shoulder the enormous burden of simultaneously satisfying environmental and economic needs. Both the economy and the environment will ultimately suffer if this incompatibility remains unresolved.

One path towards resolution is increased water use efficiency and demand management. Environmentally benign water development which capitalizes on the storage capacity available in California’s chronically dewatered aquifers is another. While in no way discounting the potential benefit of the first approach, this paper reports the findings of a feasibility study which rigorously explored the second path, specifically the potential for increasing both environmental and economic water supplies through an aggressive, maximal scale program of groundwater banking in the Central Valley water system. The results are very promising. Based on hydrologic considerations alone groundwater banking has the potential to provide approximately 1 MAF of additional annual yield, with the greatest benefit coming in new opportunities to supply consumptive demands and to enhance stream flows.

NHI's specific mission is to seek out and define opportunities for the conservation of natural resources. In responding to this objective, we cannot ignore the environmental benefit which an annual 1 MAF augmentation of water supplies in California would create. Cognizant of the pressing need to rededicate water back to the rivers and estuaries whence it has been diverted over the past century and a half, we have viewed this potential yield increase largely through the optic of environmental restoration. NHI, however, is also very pragmatic. Recognizing that powerful interests will naturally seek to defend the economic developments made possible through historic water diversion, ***we sought to demonstrate that groundwater banking can become one of the elusive win-win alternatives long desired by the California water community***. To make this case we adopted a very systematic approach towards analyzing and surmounting the physical, legal and institutional barriers which could stymie full realization of the yield potential associated with groundwater banking. The intent of this reductionist approach is to preemptively respond to the visceral reactions which are sure to greet a call to strengthen the ties between the management of California’s surface water and groundwater resources. By addressing, and hopefully dispelling, some of these concerns in advance, this report lays the groundwork for to the full realization of the wide-spread benefit made possible through groundwater banking.

Funding from the Ford Foundation enabled NHI to produce this feasibility study. Although the work is the most comprehensive collection of analysis on the various aspects of groundwater banking in California produced to date, much work remains if we are to witness on the ground changes which capture the potential benefits of 1 MAF of new annual yield. NHI will use this feasibility study as a vehicle to actively solicit supplemental support from foundations, as well as from interested agencies and private sector beneficiaries, so that implementation of groundwater banking can help reduce the burden on the Central Valley water system.

I.1 The Problem: Imbalance Between Existing Stocks and Anticipated Flows

In the parlance of systems analysis, system reliability is a function of stock and flow characteristics. Systems where the desired flows are a large fraction of available stocks are vulnerable to disruption. This general axiom is true whether the system in question is a warehouse which furnishes goods in satisfaction of retail demand or a system of reservoirs which furnish water to cities and farms. Just as the warehouse which barely keeps up with retail demand in June will not satisfy the December rush, so a system of reservoirs which just covers demand under average hydrologic conditions will have difficulty providing adequate water supplies during times of drought. Municipal supply organizations have long understood the importance of system reliability. A survey conducted for the California Urban Water Agencies estimated the statewide value of water supply reliability to urban consumers at more than one billion dollars annually (Barakat & Chamberlin 1994). The Metropolitan Water District of Southern California began its recent Integrated Resource Planning process with the establishment of water supply reliability goals (MWD 1995). Only having set these goals did MWD begin to evaluate the anticipated levels of water supply and demand.

In California, the anticipation is that municipal demand will increase in response to population growth. The important agricultural industry in California would like to preserve historic production levels while at the same time emerging environmental standards respond to the critical need for additional water to enhance stream flow, particularly during dry years. Once again in the parlance of systems analysis, the desired flows in the California water system are likely to increase. Historically, the response to increased demand has been to increase stocks by constructing massive surface reservoirs. This approach, however, has fallen out of favor due to its high economic and environmental costs and it is unlikely to prove useful in the future without exhaustive consideration of alternatives. However, when the existing stocks fail to capture the excess wet year supplies needed to satisfy higher anticipated system flows, both economic and environmental values will be threatened. To reduce future disruptions, the desired system flows should be regulated via demand management. In addition, however, opportunities for increasing stocks, to the mutual benefit of economic and environmental interests, should be explored. This report focuses on one particularly compelling strategy for enlarging the stock, groundwater banking.

I.2 A Solution: Groundwater Banking to Increase Future Stocks

Relative to the construction of surface water reservoirs, enlarging the stock via groundwater banking, the storage of excess wet year supplies in subsurface aquifers, is a less controversial, lower cost, more environmental benign approach. Groundwater banking has numerous economic and environmental advantages compared to surface water storage: it reduces losses from evaporation, thus allowing for long-term storage; it allows for greater regulation of natural inflows, without the construction of a huge new network of reservoirs;[1] and it is generally less expensive than surface storage. As with all water storage systems, however, the main purpose of groundwater banking is to convert a fluctuating input of water from precipitation and snowmelt, into a steady supply stream which responds to a water demand pattern which differs from the input stream. Also in keeping with other forms of storage, groundwater banking occurs when water is plentiful, and produces stocks to tap when water is scarce.

Based on this operational definition, the natural hydrologic system is the preeminent practitioner of groundwater banking. During wet years, excess precipitation and elevated stream flows result in high levels of infiltration. As a result, aquifer recharge exceeds pumping, which has been suppressed by well endowed surface water supplies, and there is a net inflow into the aquifer. Groundwater has been banked. When dry hydrologic conditions return, suppressing both infiltration and surface water supplies, pumping by those overlying the aquifer will exceed recharge and the bank will be tapped. Natural groundwater banking, which cycles volumes of water which are orders of magnitude larger than those contemplated here, is not the focus of the maximal program of groundwater banking. Nor will the program rely on shaving the peaks off of the relatively infrequent and limited duration large flow events which already occur below California’s surface water reservoirs during wet years.

In order to increase the available stock, the maximal program of groundwater banking will start by intentionally transferring water from surface water storage to a groundwater bank during the late spring and summer. As this is the period of time when storage in California’s reservoirs is generally highest, the transfers can be aggressive and sustained. They can be accomplished either directly, through percolation at spreading basins, or through "in lieu" surface water deliveries in areas which rely heavily on groundwater pumping . The result of several months of intentional transfer will be an increment of additional storage in an aquifer and the equal increment of potential storage space in the surface water reservoir. Final

---

[1] New facilities would be required but the unacceptable environmental and economic costs associated with primary dependence on surface storage could be reduced.

augmentation of the available stock in the system will be accomplished during subsequent winter storms and early spring runoff when the extra available reservoir space enable flood control operations which capture an increased volume of the reservoir inflow. Should a reservoir emerge from the wet season full, then the increment of water in the groundwater bank represents yield which would have otherwise gone unrealized. With these additional supplies in place, when the next dry year inevitably comes, economic demand for water may be satisfied from the groundwater bank, leaving the available surface water to be used to respond to the critical environmental need for enhanced stream flow.

1.3 Building a Case

This type of groundwater banking, which can help satisfy both economic and environmental water supply needs, has not developed on a significant scale in the Central Valley. The workplan which was implemented in carrying out this feasibility study was conceived to systematically address the barriers which have prevented aggressive groundwater banking from occurring. First among these is the perception that surface water reservoirs must be operated to serve only a narrow set of project beneficiaries. This parochial attitude towards the State's hydraulic infrastructure has discouraged the type of hydrologic analysis needed to determine the full water supply potential of a maximal program of groundwater banking. In a similar manner, the dependence of anadramous fish in the Central Valley on cold water releases from the major foothill reservoirs has forestalled consideration of aggressive reservoir re-operation.

Workplan Step 1: Hydrologic Potential Analysis
Assuming perfectly efficient storage and recovery potential, investigate the magnitude, frequency, and location of water that, absent reservoir re-operation as part of a maximal program of groundwater banking, would be released for flood control purposes and would otherwise be unavailable for environmental or consumptive purposes. Constrain the analysis only by the need to maintain suitable temperatures for fisheries downstream of the major foothill reservoirs.

The fear that this re-operation could further imperil Central Valley fisheries is not without merit. In one case where intentional transfers of surface water to aquifer storage have been accomplished, the environmental effects have been extreme. Because of the relatively small size of its central reservoir, the beneficiaries of the Friant-Kern unit of the Central Valley Project aggressively maximize pre-delivery from Millerton Reservoir on the San Joaquin River to the aquifers below their service area, to the point that a stretch of the San Joaquin below Friant Dam is frequently dry. The Friant-Kern example illustrates both of the potential for groundwater banking to enhance stocks, and the risk posed when the sole beneficiaries of the enhance groundwater storage are the local consumptive uses. This scenario is possible because water in groundwater storage in the Central Valley is viewed differently than surface storage. Whereas surface storage is endowed with specific user rights, even for distant beneficiaries, groundwater it is generally perceived of as a local resource, available only to overlying landowners. As a result, the use of groundwater storage to provide economic and environmental benefits for areas remote from the aquifer storage site is relatively rare in the Central Valley.

Workplan Step 2: Legal and Institutional Analysis
Investigate the legal support for the perception that the benefit of all water stored in a aquifer is the sole possession of overlying land owners and describe institutional arrangements, including voluntary contractual arrangements, that would be necessary to get overlying landowners and water districts to cooperate in a program of groundwater banking with broad economic and environmental benefit.

And yet, in the San Joaquin Valley the potential for maximal groundwater banking is massive. Past dependence on groundwater has produced areas where the water table is depressed, creating opportunities for storage. Moreover, heavy groundwater development has catalyzed a number of detailed hydrogeologic studies and information on aquifer characteristics is widely available. In the Sacramento Valley there are fewer areas of long term overdraft as there exists a high degree of interaction between rivers and groundwater. Thus, groundwater elevations tend to recover relatively quickly during wet period following dry years when heavy pumping occurs. While this natural interaction between river and groundwater is useful for local water users, it complicates

Workplan Step 3: Site Analysis
Identify groundwater basins which are well suited for direct recharge and retrieval and/or in lieu recharge and retrieval based on the physical characteristics of groundwater basin as well as land use patterns, ownership, water district jurisdiction and water supply systems. Display sites on a map.

efforts to use Sacramento Valley aquifers as a storage medium for non-local beneficiaries. While areas do exist within the Sacramento Valley where groundwater levels have been permanently depressed by pumping, there is less local incentive to pursue intentional groundwater storage north of the Delta. As a result the hydrogeology of the Sacramento basin remains poorly documented and accounting for the water stored can be a significant problem. In both the Sacramento and San Joaquin Valleys, however, detailed inventories of potential groundwater banking sites need to be elaborated and presented. Of particular interest should be the degree to which integration of a particular groundwater basin into the Central Valley water system facilitates the efforts of overlying water managers as compared with strictly local water management initiatives.

Even with this inventory in hand, however, developing an operational strategy to capitalized on specific groundwater banking opportunities will remain problematic. Surplus surface water for groundwater banking is most commonly available in the Sacramento Valley. The Mokelumne River, and the San Joaquin tributaries, while endowed with excess surface waters, have less substantial hydrologic potential. Hydrogeologically, however, many of the most promising storage sites lie in the San Joaquin Valley. Moving excess Sacramento Valley surface water to these sites may involve transit through the Delta, from which exports are increasingly constrained. Overcoming this potential barrier will turn upon the ability to investigate the operational details of linking reservoir operations to groundwater storage and recovery. This type of investigation requires a simulation tool which is both flexible and robust so that the scope of potential operating regimes can be defined.

Workplan Step 4: <u>Operational Analysis</u>
Investigate if changes in the current operating regime in the Central Valley can overcome constraints on moving water from re-operated reservoirs to groundwater banking sites, and from there to points of economic and environmental use. These changes may be both physical (e.g., the capacity and availability of conveyance facilities) and regulatory (e.g., Delta pumping standards) in nature.

In addition to operational considerations, economic obstacles to the realization of a maximal program of groundwater banking must be identified and overcome. As both the physical and institutional arrangements for aquifer storage differ from surface storage, so to must the financial considerations. In terms of planning and construction costs, aquifer storage and recovery is significantly less expensive then dam construction. However, some of the ancillary benefits of surface storage, such as hydroelectric power generation, flood control and recreation, which have been used to offset these costs are not associated with groundwater banking. In fact, reservoir re-operation as part of the program may either enhance or detract from these uses of California's reservoirs. In order to build a case for the program, these issues must be studied.

Workplan Step 5: <u>Economic Analysis</u>
Investigate the costs of groundwater banking programs relative to surface water development and define the potential benefits. Comment on unique economic aspects of capturing the available surface water supply, conveyance to a groundwater banking site, and storage and recovery for a prescribed end-use.

NHI began this groundwater banking feasibility study with the hypothesis that: (1) It is physically possible to generate substantial amounts of new water for the environment and the economy using groundwater storage; (2) The environmental and economic benefits of such a program outweigh the costs; and (3) any institutional barriers to the use of groundwater for this purpose can be overcome. By implementing of the five broad programmatic workplan steps described above, NHI sought to test whether this hypothesis is true and under what conditions. NHI recognizes that local concerns over the possible local impacts of groundwater banking **<u>must be</u>** overcome before a maximal scale program can become a reality. Prior to engaging in the difficult negotiations needed to address local concerns, however, some sense of the ultimate payoff is needed. By describing the outcome of the five program steps, this report provides that sense. It is intended to be eminently practical, not theoretical in its approach; it is not an academic exercise, but is intended to lead to action. Our premise is that this convincing portrayal of the potential of a maximal program of groundwater banking will generate an action plan which is useful to the governmental entities and stakeholder groups empowered to craft and implement such an ambitious, yet promising program.

II. The Context

Prior to presenting the conclusions of the five workplan steps, a description of the physical setting for a maximal program of groundwater banking is required. The following sections provide a context and a rationale for elaborating the link between the management of California's installed surface water hydraulic infrastructure and potential groundwater banking sites.

II.1 Surface Water Supply

On average, California is not short of water. Annual runoff averages roughly 71 MAF (78 MAF when out of state supplies are included). In 1990, a relatively dry year, environmental uses such as instream flow standards and wild and scenic river designations accounted for 24 MAF, irrigated agriculture for 24 MAF, urban use for 6 MAF, and "other uses" for 1 MAF. Roughly 30 MAF of the 1990 total was accounted for as "other outflow" -- e.g. not allocated to any specific use (DWR 1994).[2] These long-term averages, however, mask the variability which characterizes California hydrology. Consider that:

- Extended droughts are common. Over the six year periods from 1929-34 and 1987-92, cumulative runoff in the Sacramento and San Joaquin Rivers was slightly above half the long-term average. Runoff in 1976-77 was only 33% of the long-term average for the two rivers.
- Much year to year variability exists. In the period between 1906 and 1993, 27 years were dry to critical while 34 were wet.
- Runoff in California is highly seasonal. Much of the flow occurs during a few months when snow melt and rainfall coincide.
- Surface water supplies are spatially non-uniform. Roughly 75% of the natural runoff is north of Sacramento while 75% of the demand is south (DWR 1994).

The existing storage and conveyance infrastructure is designed to "even out" this variability in surface water supply. However, given the location and intensity of current and anticipated water demand, DWR projects a supply shortfall of between 2.1 and 5.2 MAF by the year 2020 if the capacity of the system remains static.[3]

II.2 Groundwater Supplies

Under current working assumptions one method of covering the anticipated shortfall will be an increased reliance on groundwater. Already, during dry years such as 1990, increased pumping results in a statewide groundwater overdraft of roughly 1.3 MAF. Future increases in demand would suggest that these overdrafts will continue at high levels indefinitely unless major changes in water management occur, particularly in the San Joaquin Valley (DWR 1994). Plans to cope with these changes must be tempered by hydrogeologic realities.

Table 1: Estimated Central Valley Groundwater Storage

Aquifer	Estimated Storage (MAF)
Sacramento Valley	170
Delta	130
San Joaquin Valley	160
Tulare Basin	370
Total Central Valley	830

Structurally, the deposits which form the aquifer system in the Central Valley range from a few tens to a few thousands of feet in depth. Total estimated fresh water within the upper 1,000 feet of these sediments is 830 MAF (Table 2). Traditionally the Sacramento Valley has been thought to consist of

---

[2] It is important to recognize that this "other outflow" probably generates environmental benefits and should not be viewed entirely as surplus. The outflow is simply excess to minimum environmental flow standards that have been established for various streams and wetlands

[3] In reality, such shortages would not occur. Rather, water demand would be brought into balance with supply by some means -- water conservation, water recycling, water transfers, or desalinization. However, the economic and social costs and the political consequences of such a large reduction in demand make it highly likely that other means would be found to meet demands, such as additional diversions from the environment. The point of groundwater banking is to find ways to meet growing economic and environmental needs in ways that are acceptable to each side.

a single unconfined aquifer while the San Joaquin Valley was conceived of as an upper unconfined system and a lower confined system below the dense Corcoran Clay member of the Tulare formation. More recent studies conclude, however, that the Central Valley ground water reservoir is more accurately portrayed as a single heterogeneous aquifer, characterized by water bearing sediments interspersed with clay lenses.

Largely according to the nature of local interactions between surface water and groundwater, this vast water bearing reservoir has been divided into four hydrographic subregions: Sacramento Valley, Delta, San Joaquin Valley, and Tulare Basin. In each of the sub-region, all significant streams emerge from the Sierra Nevada or Cascade Mountains to the east. The sole exception is the Sacramento Valley where Stony Creek, Cache Creek, and Putah Creek flow into the valley from the Coast Range Mountains to the west. The mean annual runoff into the Central Valley from the surrounding mountains is about 32 million acre feet. Under historic conditions, the Central Valley rivers recharged the aquifers below the valley floor during periods of high flow and the groundwater sustained the low flow stage in rivers. By comparison, recharge via direct precipitation on the valley floor was a relatively minor component of the historic water balance (± 1.5 MAF/year according to Williamson et al 1989).

The regulation of high flows in the rivers of the Central Valley, combined with extensive groundwater pumping, substantially altered this annual cycle. In many parts of the Central Valley, groundwater no longer contributes to low stage stream flow, which is now comprised primarily of agricultural return flows. Across the region, current groundwater flow patterns are linked to the confounding alterations of the natural system which have accompanied decades of groundwater extraction and the hydraulic manipulation of surface water. In the western San Joaquin Valley, for example, the arrival of imported surface water from the Sacramento Valley raised the water table by as much as 170 feet. Further south in the Tulare Basin, where groundwater remains the primary source of irrigation water, the free surface has fallen as much as 400 feet. In the Sacramento Valley, where the interaction between rivers and the underlying aquifer remains closer to the natural regime, groundwater levels are generally stable. Even this general observation is violated, however, in the rapidly urbanizing regions around Sacramento and in numerous locations along the relatively dry west side of the valley.

The overall impression one gains is that the condition of the Central Valley aquifer has evolved through time and is at present extremely variable across the landscape. Williamson and other (1989) documented the steps leading to this dynamic situation:

- The total flow through the aquifer system increased from about 2 million acre-ft/yr prior to hydraulic development to nearly 12 million acre-ft/yr at the current time.
- Increased groundwater pumping prior to the 1960's, to nearly 11.5 million acre-ft/yr, drove the increase in groundwater flow.
- The groundwater pumping prior to the 1960's depleted total groundwater storage by some 20 MAF and was accompanied by increased pumping costs and dramatic land subsidence.
- Increased importation of surface water to some areas of the Central Valley, beginning in the 1960’s, prompted local declines in groundwater pumping.
- During the early 1980's, groundwater pumping decreased to a level approximately equal to the estimated rate of aquifer recharge.
- Since the arrival of surface water, groundwater levels have risen in most areas benefiting from imported surface water, and elsewhere further decreases in ground-water storage have been arrested.
- From a valley-wide perspective the system has achieve a state of quasi equilibrium where persistent zones of dewatered aquifer are largely in balance with adjacent zones of net aquifer recharge from overlying streams and imported surface water. In this context, any additional increment of groundwater pumping will eventually reduce surface flows.

This is not a system which can sustain the practice of satisfying increases in demand in the coming decades with a steadily increasing reliance on groundwater pumping. Such a strategy would likely return the system to the period of rapidly falling water tables, increased pumping cost, and land subsidence which plagued the first epoch of groundwater dis-equilibrium. There must be some consideration given to the need to increase storage in order to avoid a potentially destabilizing increase in groundwater pumping.

II.3 Storage Opportunities

Table 2: New/Enlarged Surface Storage

New Facilities	Storage (MAF)	Cost ($/acre-ft)
Cottonwood	1.6	480
Auburn	2.3	420
Marysville	1.05	1240
Los Banos Grande	1.73	660
Facility Enlargement		
Shasta	14.3	430
Folsom	1.34	1080
Friant	1.4	2920
Pardee	0.36	1640
Farmington	0.16	300
Berryessa	13.0	610
Total	30.56	

The ability to store additional water and further "even out" natural variability would ease the predicted water availability shortfalls. Although California has a network of some 1400 major reservoirs, total storage in these reservoirs is approximately 42 MAF – only 60% of the average annual runoff (DWR 1994). The creation of sufficient additional surface storage to substantially even out variability is unrealistic. For example, proposals to build Auburn dam, a facility capable of storing 2.3 MAF, have been so controversial that funding has been blocked since Congress initially authorized the project in 1965. Even if Auburn dam were constructed, it would only increase the total system storage from 60 to 62.5% of annual runoff. Construction of all the new proposed surface storage facilities identified in Table 2 would increase the total capture of the system to 71% of annual runoff – and at an unacceptably high financial and environmental cost. Enlargement of the existing facilities in Table 2 would increase the system capture to just above the average annual runoff. As with new facilities, however, the financial and environmental costs of facility enlargement would be high.

That underground aquifer storage is the primary supply-side alternative to the construction of new surface water reservoirs is widely recognized. As stated by the Department of Water Resources: "In the future, carefully planned conjunctive use will increase and become more comprehensive because of the need for more water and the generally higher cost of new surface water facilities." (DWR 1994). Groundwater banking was also recognized as one of the least cost sources in a review of yield enhancement opportunities undertaken under the Central Valley Project Improvement Act (USDOI, USBR et al., 1995) with cost estimates ranging from $60/acre-ft to $120/acre-ft of yield at source – greatly below the $300-$2920 unit cost of new surface storage.

This then is the hydrologic context for a maximal program of groundwater banking. Adequate surface water supplies exist in California if they can be further "even out" in space and time. Absent an effort to accomplish this management change, future anticipated growth in the State's water demand will likely lead to an increased reliance on groundwater pumping, disrupting the quasi-equilibrium currently in place and re-initiating problems with rapidly falling water tables and land subsidence. As the will to accept the high financial and environmental costs of additional surface water development has dissipated, the most viable alternative is to capitalize on the existence of regions of aquifer dewatering which developing prior to the 1970's, and which continue to plague overlying landowners. This is a scenario which can produce widespread benefit across the spectrum of water interests and which is the focus of the programmatic analysis which follows.

III. Workplan Step 1: Hydrologic Potential Analysis

A maximal program of groundwater banking seeks to divert surplus surface water to storage in suitable groundwater basins. This diversion would permit immediate storage and eventual recovery of water which would otherwise flow out to sea. The image most frequently conjured up by the aforementioned description is one of massive pumps and diversion canals, installed and ready to capture water during peak winter and spring flow events. Direct diversion during peak flows is depicted in the hypothetical example in Figure 1. In this case when the average daily flow in the Tuolumne River at Modesto exceeds 4000 cfs, 300 cfs of the large flow event is diverted to groundwater banking. Over the course of the 1994 and 1995 water years this approach generates approximately 80 TAF of storage. The important thing to note about this approach is that it involves manipulation of the hydrograph in the lower Tuolumne River while the storage in New Don Pedro Reservoir upstream remains unaltered.

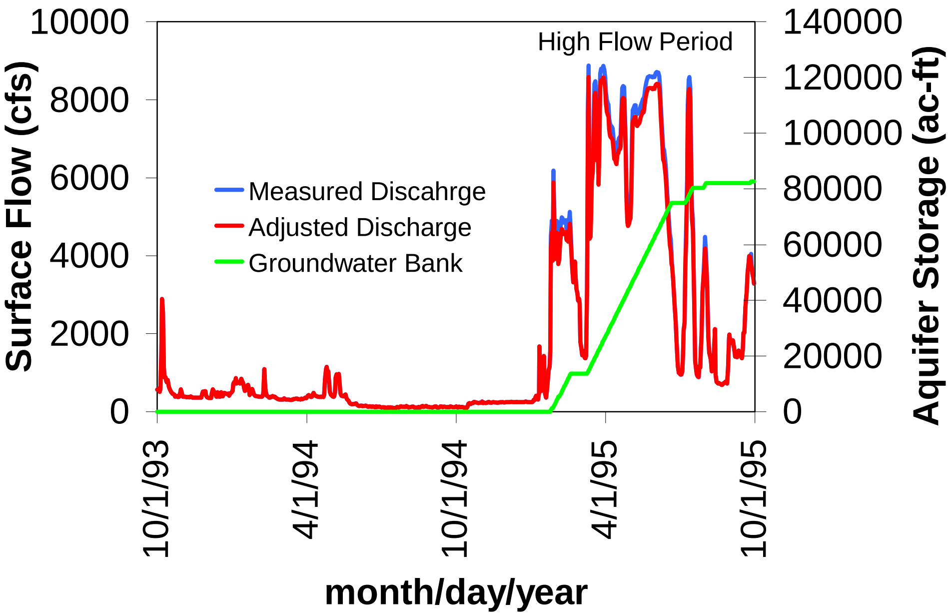

Figure 1: Banking Groundwater by Diverting Peak Flows from the Tuolumne River near Modesto

An alternate, and potentially complementary, strategy for groundwater banking involves the pre-delivery of water from surface water reservoirs to groundwater banking sites. Under this arrangement, water would be released from storage in California's major foothill reservoirs for transfer to aquifer storage during the summer and fall. This transfer could be accomplished directly through percolation at spreading basins or indirectly through *in lieu* deliveries to farms which would otherwise rely on groundwater for irrigation. Instead of directly altering downstream hydrographs during peak flow events, pre-delivery results in a decline in upstream reservoir storage levels. In the hypothetical example in Figure 2, each day between March and September, 1994 a supplemental release of 300 cfs is pre-delivered to groundwater banking from New Don Pedro Reservoir on the Tuolumne River. This re-operation causes a decline in reservoir storage relative to the historic trace which is balanced by a 130 TAF increase in aquifer storage. This aquifer storage becomes "new" water when, during the 1995 water year, measured reservoir releases in excess of 4000 cfs are cutback by 300 cfs. In effect, the excess available flood control capacity in New Don Pedro Reservoir allows for the eventual recovery of surface storage back to the historic trace.

Once storage in New Don Pedro recovers back to historic levels, the water stored in the groundwater bank becomes yield which would have otherwise been released during the peak flow events. It should be pointed out that a 300 cfs pre-delivery is relatively conservative as *in lieu* deliveries to farms could far exceed this level if a suitable distribution network were in place. The subsequent cutback of reservoir releases could also have been more aggressive than assumed in this example. Finally, the re-operation of surface reservoirs is a much more intentional and approach to groundwater banking than the periodic capture of peak flows as it does not require the installation of large diversion capacity which will only be used during short time windows. By "evening-out" the transfer of surface water to aquifer storage, pre-delivery allows for continual benefit to be derived from the physical and operational changes associated with groundwater banking.

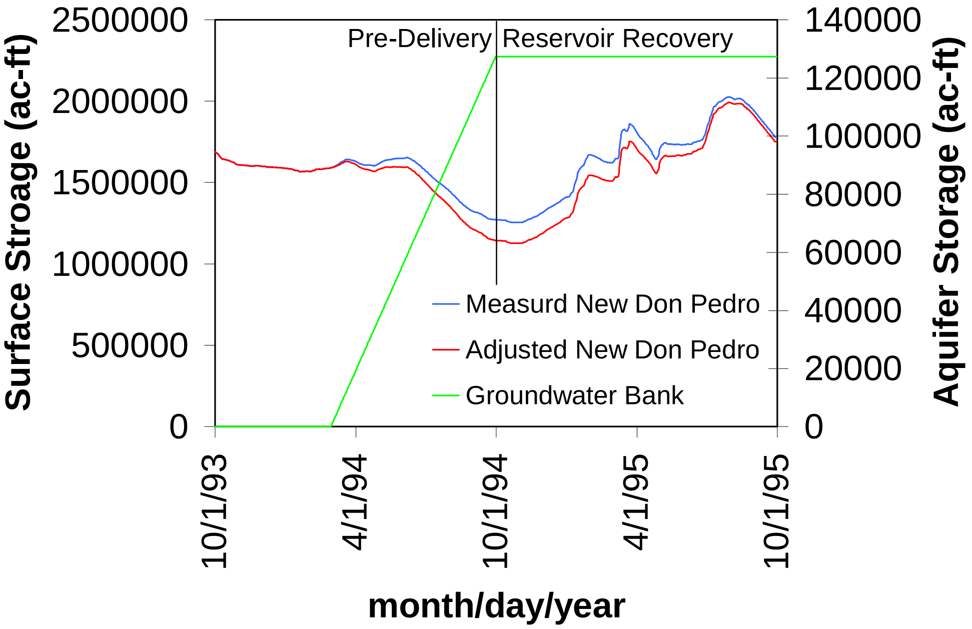

Figure 2: Banking Groundwater by Re-Operating New Don Pedro Reservoir on the Tuolumne River

III.1 Conjunctive Use Potential (CUP)

To estimate the hydrologic potential of the pre-delivery of surface water to groundwater banking in the Central Valley watershed, NHI developed the Conjunctive Use Potential model, or CUP (see the model methodology in the sidebar, parameters in bold italics must be provided by the user). CUP, which was developed for each of the river systems described in Table 3, is based on liberal assumptions about: (1) the existence of infrastructure; (2) a limited scale investment in the direct diversion of high flows to aquifer storage (as in Figure 1); and (3) the availability of suitable groundwater banking sites. On the other hand, CUP adopts a very conservative posture towards the need to preserve adequate cold water in the major foothill reservoirs. This cold water resource is needed to maintain suitable temperatures in the spawning and rearing reaches downstream of the reservoirs in Table 3. The conservative posture should help allay concerns over impacts to hydropower production targets or lake recreation opportunities, although these uses of surface

CUP Model Methodology

1. Compare ***historic daily reservoir releases*** to minimum ***required economic and environmental flows***. Historic releases in excess of required flows are considered "surplus", while smaller historic releases create a "deficit". Accumulate daily differences over the entire year to determine whether the year is wet or dry.
2. When environmental requirements create a deficit, adjust September 30 reservoir storage levels by this increment. Should the adjusted storage falls below a ***minimum carryover storage target*** set to preserve adequate cold water for anadramous fish below the dam, a shortage equal to the amount needed to meet the minimum carryover is applied to economic uses.
3. When a net surplus exists, the adjusted storage from Step 2 is compared to the ***target carryover storage***. If adjusted storage exceeds this parameter, water is pre-delivered to aquifer storage at a rate dictated by user defined ***transfer and storage constraints***. Surface storage is reduced by the same amount. Pre-delivered water is initially "provisional" storage as it can be recalled if needed.
4. Subsequent surplus flows will be held in surface storage until the Step 2 storage trace has been regained, transforming a similar amount of "provisional" storage to banked groundwater. If sufficient surpluses exist to transform all "provisional" storage to banked groundwater, additional surpluses can be transferred into the provisional groundwater account, provided that space is available in the bank.
5. Subsequent deficits which result in adjusted storage below target carryover initiate a search for replacement water and, if necessary, the recall of "provisional" storage at a rate dictated by ***user defined recovery constraints***. A shortage is declared when reservoir storage remains below the minimum target.

reservoirs are not specifically considered in the CUP analysis. The most important lesson to derive from Table 3 is that in six of the ten important rivers in the Central Valley, annual flows exceed the available storage and the improved flood control flexibility made possible through pre-delivery can help capture "new" water without imperiling anadramous fish below the dam.

Table 3: Details of the Major Foothill Reservoirs in the Central Valley

River	Reservoir/Dam	Operator	Storage (TAF)[4]	Mean 1921–1983 Unimpaired Flow[5]
American	Folsom	USBR/CVP	974	2,660
Calaveras	New Hogan	USBR	317	163
Feather	Oroville	DWR/SWP	3,538	4,441
Merced	New Exchequer	MeID	1,025	967
Mokelumne	Camanche	EBMUD	417	730
Sacramento	Shasta	USBR/CVP	4,552	8,303
San Joaquin	Millerton Lake	USBR/CVP	520	1,740
Stanislaus	New Melones	USBR/CVP	2,420	1,131
Tuolumne	New Don Pedro	MoID/TIDD	2,030	1,841
Yuba	New Bullards Bar	YCWA	966	2,333

III.1.1 Protecting Anadramous Fish

Prior to the development of the major foothill reservoirs, listed in Table 3, anadramous fish generally spawned in California's mountain streams. Construction of the dams which impound these reservoirs blocked passage to these sites, forcing fish to spawn in foothill and valley reaches which were historically warm during the summer and early-autumn. Figure 3 compares the water temperature in the Sacramento River downstream of the current Shasta Dam site. Before dam construction the summer water temperature was in excess of 70 °F and remained around 60 °F well into the autumn. Temperature moderation following dam construction resulted from the release of cold water found on the bottom of the reservoir. Similar temperature changes have been observed downstream of the other major Central Valley reservoirs.

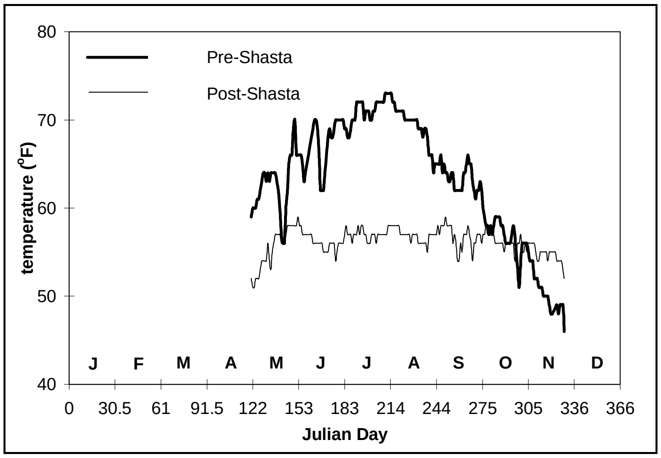

Figure 3: Sacramento River Water Temperature Downstream of Shasta Dam Site
(heavy line: Anderson-Cottonwood Diversion Dam; light line: Balls Ferry)

[4] Draft of the California Water Plan Update, Department of Water Resources, California Water Commission, November 1993.
[5] California Central Valley Unimpaired Flow Data, 2nd Edition, California Department of Water Resources, Division of Planning, February 1987

The Central Valley Project Improvement Act (CVPIA) enacted in 1992 sought to elevate fish and wildlife protection, and restoration to a level of parity with the other project purposes (U.S. Fish and Wildlife Service 1995). The act also called for a "program which makes all reasonable effort to ensure that, by the year 2002, natural production of anadromous fish in Central Valley rivers and streams will be sustainable, on a long-term basis, at levels not less than twice the average levels attained during the period of 1967-1991" (CVPIA 1992). For the rivers evaluated using CUP, a variety of temperature related actions were proposed as part of the U.S. Fish and Wildlife Service's Anadramous Fish Recovery Plan (AFRP). Some of these were specific prescriptions, others vague recommendations (see the adjacent sidebar). Table 4 describes specific reservoir carryover targets included in the AFRP.

Relevant USFWS Temperature Prescriptions

In order to maintain water temperatures below 56^{o}F in the **Sacramento River**, Shasta Reservoir should be operated to attain a minimum October 1 carry over storage of 1.9 MAF under all runoff conditions except the driest 10% of water years.

In the **Feather River** pulse releases from Lake Oroville are needed to reduce the temperature difference between the low flow channel and the reach immediately downstream of the Thermalito outlet.

In the **Yuba River**, colder temperatures for chinook salmon could possibly be maintained by drawing Englebright Reservoir down in August and refilling with cold water from New Bullards Bar. Reservoir

In the **American River**, by re-operating the reservoir release shutters to provide greater flexibility, downstream releases during October would be 1-9^{o}F colder than the temperature attained under current protocols and shutter configurations.

In the **Mokelumne River**, a minimum pool in Camanche Reservoir of 190 feet from April through September and a minimum pool of 170 feet from October through March, should be maintained to protect anadramous fish.

In the **Calaveras River**, temperatures could be kept cool enough for chinook salmon production with a minimum New Hogan Reservoir pool size of 85,000 ac-ft.

Water temperature in the **Stanislaus River** should be maintained below 56^{o}F between October 15 and February 15 and below 65^{o}F between April 1 and June 30 in order to enhance salmonid productivity below Goodwin Reservoir.

Water temperature in the **Tuolumne River** should be maintained below 56^{o}F between October 15 and February 15 and below 65^{o}F between April 1 and June 30 in order to enhance salmonid productivity below LaGrange Dam.

In the **Merced River** the same river temperature standards as for the Stanislaus and Tuolumne Rivers are suggested in order to enhance salmonid productivity below the Crocker-Huffman Diversion.

Table 4: AFRP Reservoir Carryover Targets in the Rivers Evaluated Using CUP

River	Specific Carryover Targets	No Clear Carryover Targets
Sacramento	1.9 MAF	
Feather		**X**
Yuba		**X**
American		**X**
Mokelumne	~108 TAF	
Calaveras	85 TAF	
Stanislaus		**X**
Tuolumne		**X**
Merced		**X**

In CUP, constraining the pre-delivery of water from reservoir storage to a groundwater bank based on the need to preserve the cold water pool requires the definition of both minimum and target carryover parameters. These parameters should be defined based on analysis of the physical juxtaposition of warm water in the Central Valley reservoirs with the release works on the face of the impounding dams, and on the thermal requirements of downstream fisheries. The carryover storage levels contained in Table 4 can be used as targets values in CUP. The remaining target parameters and all minimum carryover parameters must be set by the user.

III.1.2 Setting Carryover Targets

The derivation of these carryover parameters rests on physical principles, particularly a solid understanding of the tendency of reservoirs to stratify into warm and cold water pools during the summer and early autumn, and the potential for wind driven oscillation or *seiches* in stratified reservoirs. The limnological basis for this analysis is presented in Appendix I.

III.1.2.1 Required Data

The data required to carry out the required limnological analysis for the major foothill reservoirs in the Central Valley include:

- Historic EOM storage levels;
- Late summer vertical temperature profiles collected when the reservoirs were in a drawn down state;
- Late summer wind speed data from the vicinity of these reservoirs; and
- Information of the physical configuration of each reservoir and the impounding dam's release works.

Table 5 presents a matrix describing the data availability for each of the systems under investigation. In general, data for the Central Valley and State Water Project facilities was more easily acquired than in the case of projects managed by local-agencies. Gaps in the data availability were overcome by substituting the most appropriate data set available.

Table 5: Data Availability Matrix for Analysis of Minimum Carryover Storage Values of the Major Foothill Reservoirs

Reservoir	Operator	EOM Storage	Temperature	Wind Speed	Configuration
Shasta	USBR	✓	✓	✓	✓
Oroville	DWR	✓	✓	✓	✓
New Bullard Bar	YCWA	✓	✓	✓	✓
Folsom	USBR	✓	✓	✓	✓
Camanche	EBMUD	✓	✓	✓	✓
New Hogan	USACE	✓	✓	✓	✓
New Melones	USBR	✓	✓	***Use New Hogan***	✓
Don Pedro	TID	✓	***Use New Melones***	✓	✓
McClure	MID	✓	***Use New Melones***	✓	✓

III.1.2.1.1 Reservoir Storage

Figures 4A (Sacramento Valley) and 4B (San Joaquin Valley) depict the yearly October 1st reservoir storage values, for each of the major foothill reservoirs in Table 3, ranked in ascending order. The five lowest storage values are labeled, excluding the first five years of operation when filling could have influenced the storage levels as much as hydrologic conditions. The severity of the 1976-1977 drought is revealed in the fact that October, 1977 represents the lowest recorded level in eight of the nine reservoirs. The impact of the 1987-1992 drought is also revealed as many of these years also figure among the lowest measured storage levels. By examining the disposition of the cold water resource under these drawn down conditions appropriate carryover parameters can be established.

III.1.2.1.2 Vertical Temperature Profiles

Unlike reservoir storage data, data on the water temperature as a function of depth in the major foothill reservoirs is not collected and reported in a regular fashion. Every attempt was made to acquire temperature data corresponding to the lowest measure reservoir storage (see Figures 4A and 4B). Given the irregular character of this data, however, such a correspondence was not universally achieved. Table 6 summarizes the quality of the vertical temperature profile data collected for this analysis.

Table 6: Availability of Vertical Temperature Data for the Major Foothill Reservoirs Under Drawn Down Conditions

Reservoir	Measurement Date	Storage Rank	% Above Minimum
Shasta	Sept, 1976	3	8.9
Oroville	Sept, 1992	3	8.9
New Bullards Bar	Oct, 1992	>5	112.7
Folsom	Oct, 1977	1	0
Camanche	Oct, 1990	>5	28.0
New Hogan	Aug, 1990	3	1.6
New Melones	Sept, 1992	1	0
Don Pedro	N/A	N/A	N/A
McClure	N/A	N/A	N/A

Figure 4A: Ranked Historic October 1st Storage in the Major Sacramento Valley Foothill Reservoirs with Values of the First Operational Year (bold) and the Five Lowest Years Identified

(A: Shasta; B: Oroville; C: New Bullards Bar; D: Folsom)

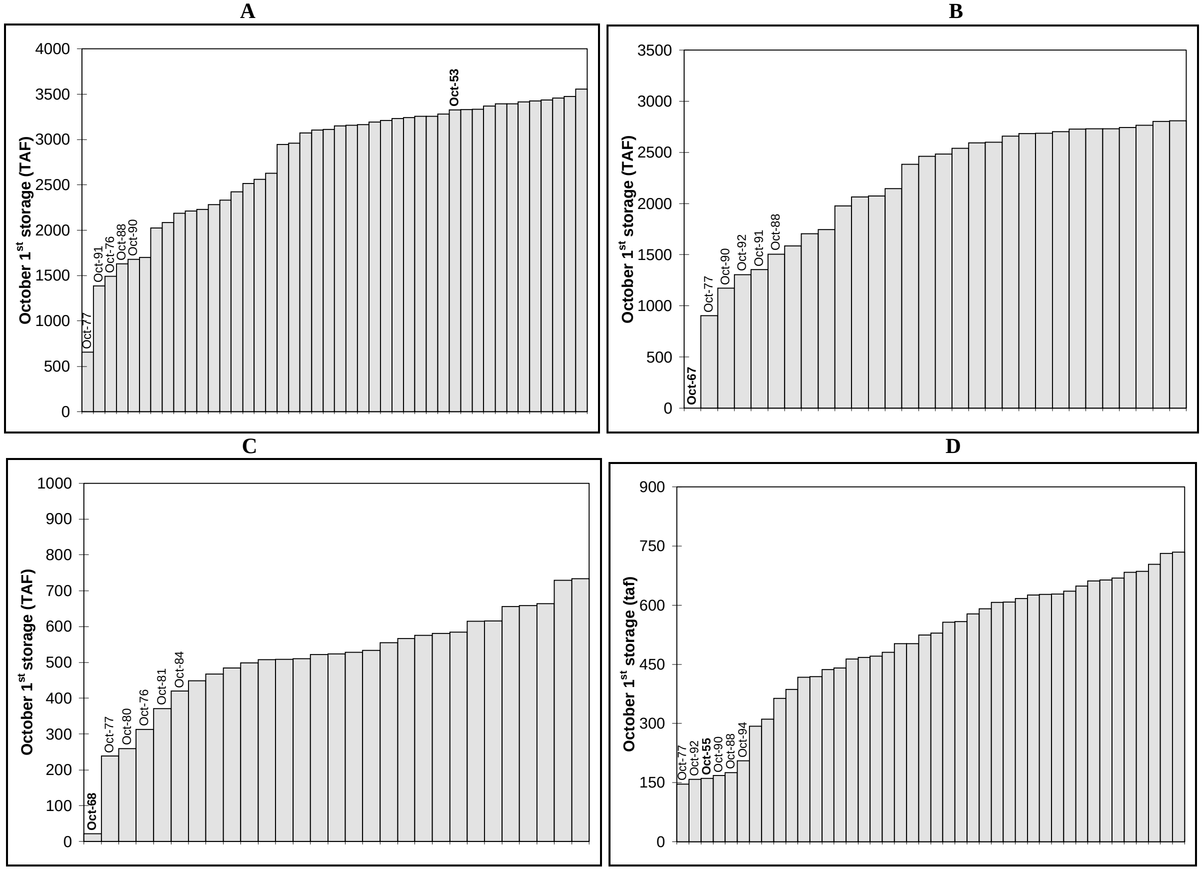

Figure 4B: Ranked Historic October 1st Storage in the Major San Joaquin Valley Foothill Reservoirs with Values for the First Operational Year (bold) and the Five Lowest Years Identified

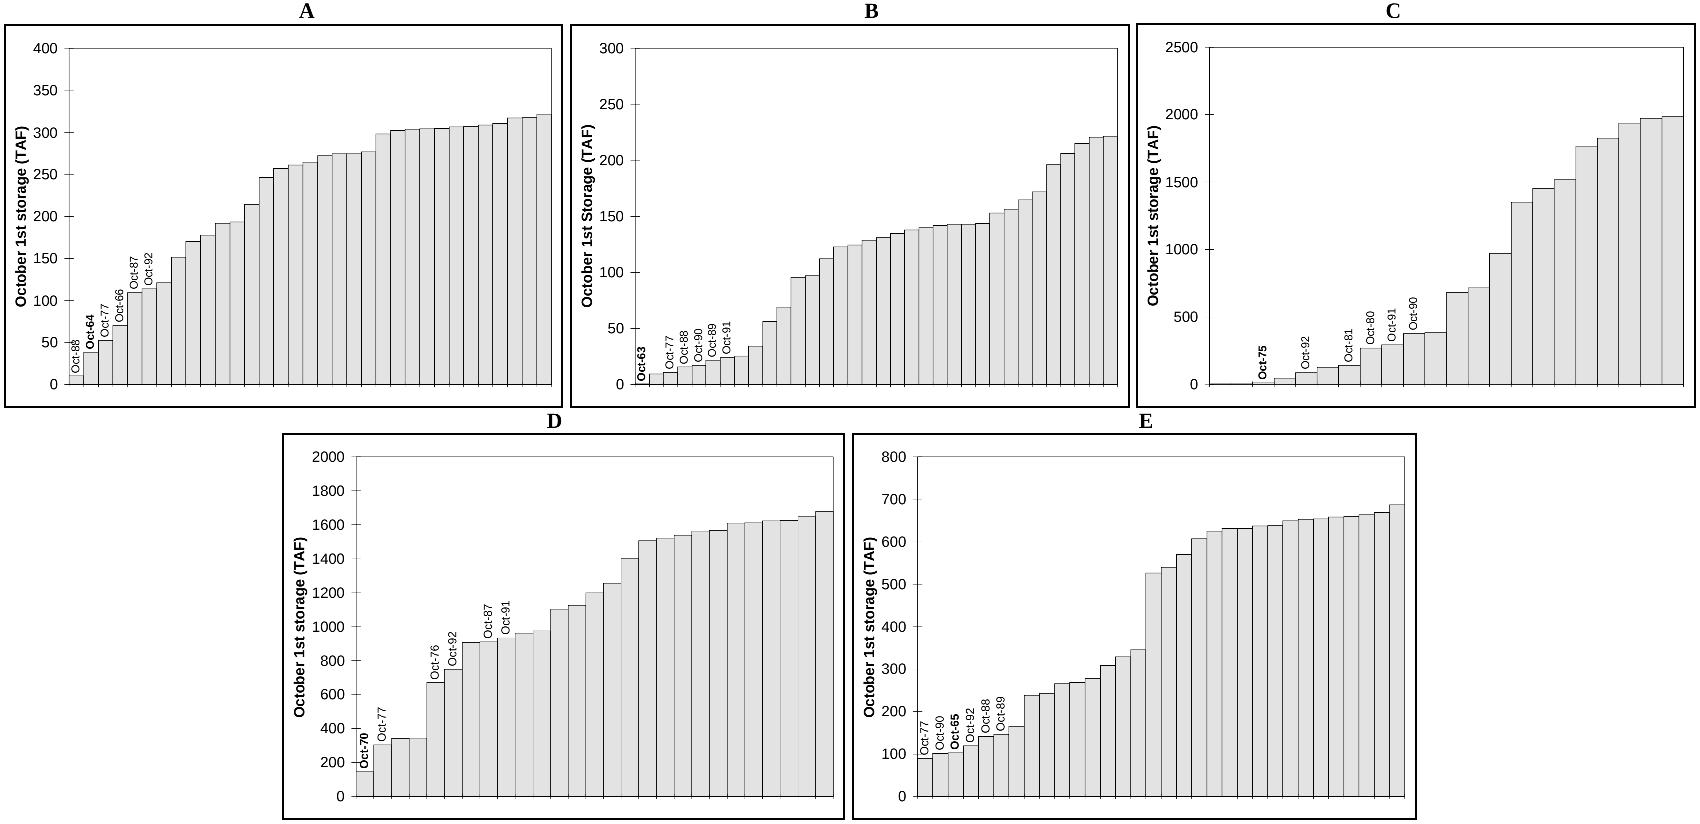
(A: Camanche; B: New Hogan; C: New Melones; D: Don Pedro; E: McClure/Exchequer)



Using these data to establish acceptable carryover levels relies on the implicit assumption that the interaction between the incoming solar radiation, the prevailing wind, and the volume of the body of water behind the dam remains essentially constant across the range of drawn down conditions. Given the fairly uniform climatic patterns which characterize Central Valley summers, applying this assumption to the two climatic factors seems reasonable. The last column of Table 5 contains the percent increase in reservoir storage at the time of the temperature sounding, relative to the minimum observed October 1st storage reported in Figure 4. With the exception of New Bullards Bar and Camanche Reservoirs, the storage levels at the time of the temperature sounding were not substantially above the minimum observed storage level. Figure 5 contains the vertical temperature profiles plotted as a function of the depth below the lake surface for each of the reservoirs where data was available. The soundings reveal the well developed nature of temperature stratification in these reservoirs during the late summer/early autumn. Any appropriate carryover parameters used in CUP must consider the disposition of the cold water pool in the hypolimnion relative to the physical works controlling downstream releases.

III.1.2.1.3 Wind Speed

The disposition of the cold water resource in the major foothill reservoirs cannot be considered static. Shear stress generated by wind passing over the lake surface performs work on the water body which can disrupt the patterns of thermal stratification observed in Figure 5. In order to assess the potential for disruption, or mixing, the wind speed in the vicinity of the major foothill reservoirs must be characterized. The major foothill reservoirs generally lie somewhere between the elevations of two common wind speed databases containing data collected in the Central Valley (CIMIS) or at higher elevations in the Sierra (CDEC). In order to minimize the potential error associated with the use of this data, the maximum available measured daily average wind speed for each reservoir was used to assess the potential for wind driven mixing. These are shown in bold in Table 7.

Table 7: Wind Speed Measurement Stations Associated with the Major Foothill Reservoirs
(stations with maximum daily average wind speed in bold)

Reservoir	Station	CDEC	CIMIS	Reservoir	Station	CDEC	CIMIS
Shasta	McCloud	✓		Camanche	Beaver	✓	
	Thomes Creek	✓			Mt. Zion	✓	
	Whitmore	✓			**Lodi**		✓
	Gerber		✓	New Hogan	Esparanza	✓	
Oroville	**Butte Meadows**	✓			**Manteca**		✓
	Chester	✓		Don Pedro	**Green Springs**	✓	
	Quincy Road	✓			Tuolumne Meadows	✓	
	Westwood	✓			Modesto		✓
	Durham		✓	McClure	**Crane Flat Lookout**	✓	
New Bullards Bar	Bangor	✓			Mariposa Grove	✓	
	Dorris Ranch	✓			Mariposa Ranger Station	✓	
	Browns Valley		✓		Merced River	✓	
Folsom	**Buffalo Creek**	✓			Modesto		✓
	Camino		✓				
	Linclon	✓					

From the maximum data set, the highest single daily average wind speed was extracted. The assumption implicit in the use of the peak value is that energy imparted to the system by a steady wind blowing for a single day will be sufficient to fully induce wind-driven water movement in the reservoir. The time series of wind speed data from these most windy sites are shown in Figure 6.

Figure 5: Late Summer/Early Autumn Vertical Temperature Profiles for the Major Foothill Reservoirs

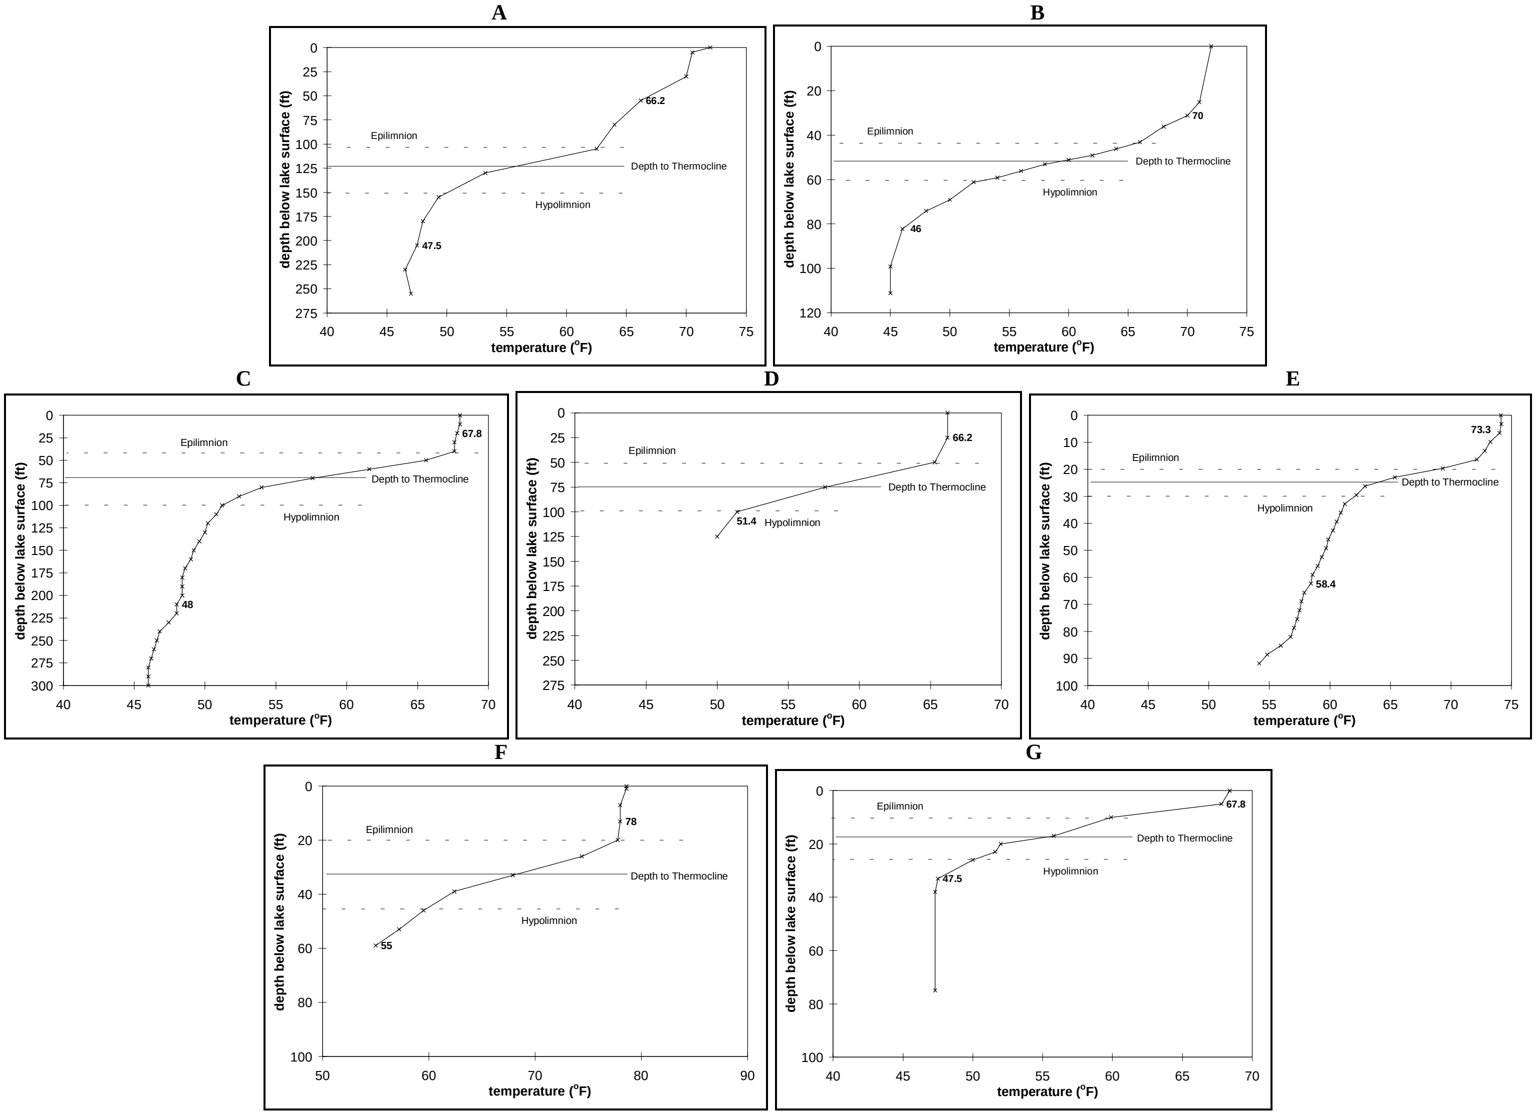

Figure 6: Recent Maximum Late Summer/Early Autumn Daily Average Wind Speed Date for the Major Foothill Reservoirs

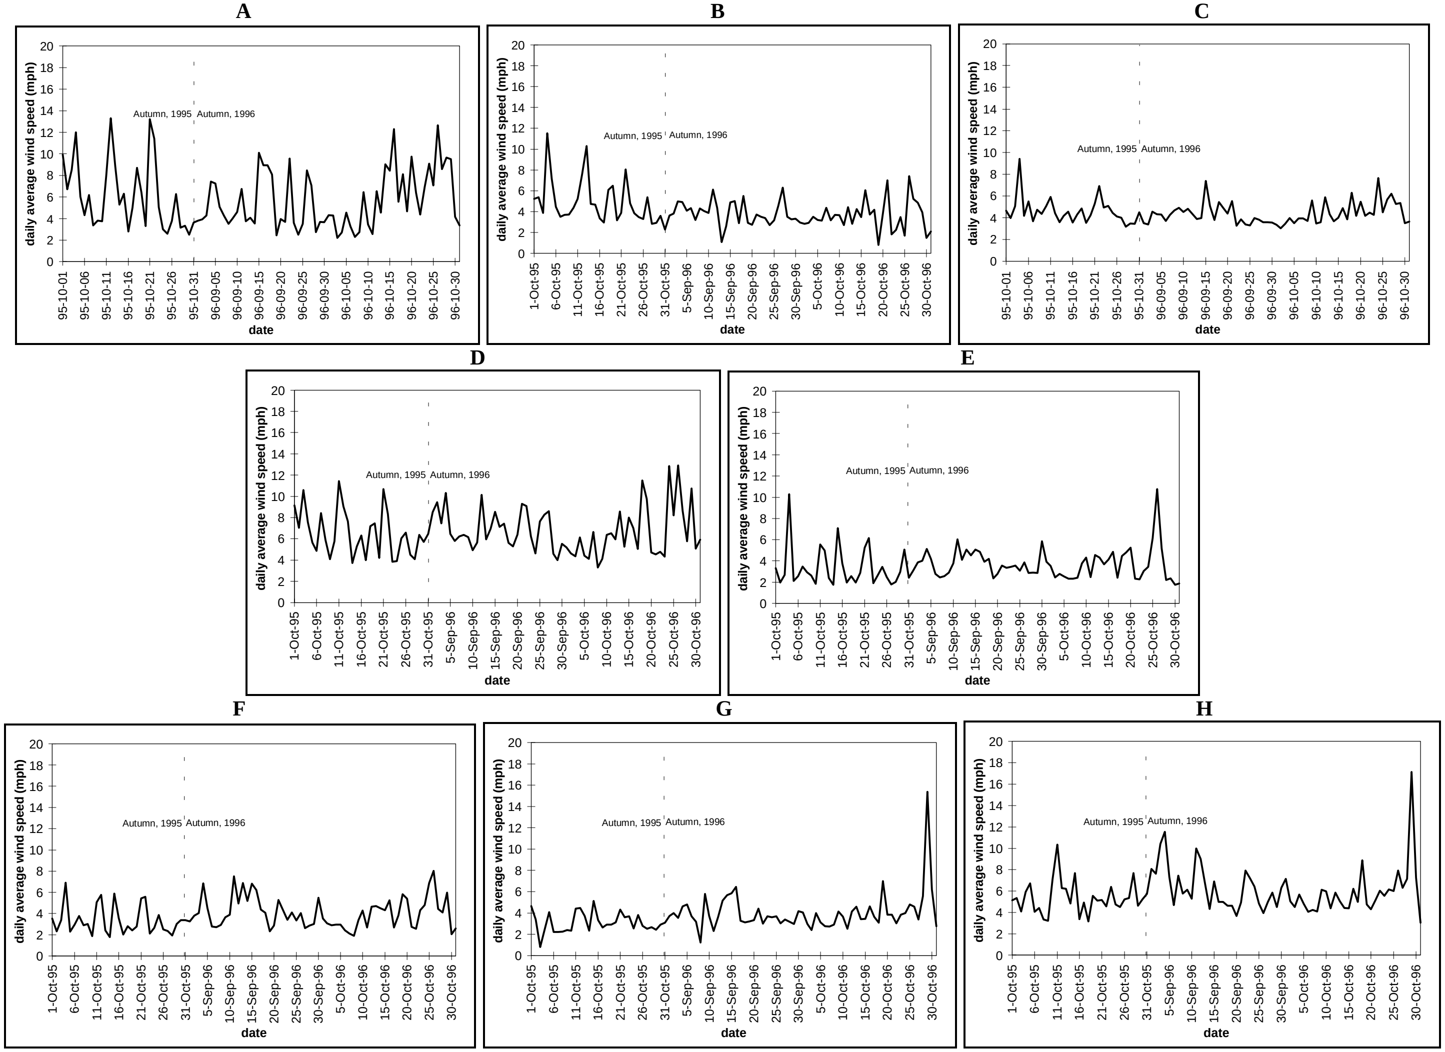
(A: Shasta; B: Oroville; C: New Bullards Bar; D: Folsom; E: Camanche; F:New Hogan; G: Don Pedro; H: McClure)



III.1.2.1.4 Physical Configuration

In order to evaluate the disposition of the cold water resource with respect to the release works of a given dam, data describing the physical configuration of the reservoir system is required. This data set includes information on the length of the lake, the elevation of the foot of the dam and the elevation of the release works used to discharge water downstream. Two complications influence the compilation of this data set. First, the major foothill reservoirs are not uniformly long and narrow, which makes it difficult to define the length of the lake corresponding to the fetch of open water above the dam. For this analysis the length was defined as the longest unobstructed distance over water which can be traced at high water from the dam itself. Second, stating the elevation of the release works was complicated by the fact that many of the major foothill reservoirs include installed hydroelectric generating capacity. The elevation from which water is released to the powerhouse is usually higher then the low level release works used for flood control. In order to minimize the potential impact on hydroelectric power production, in this analysis the elevation at which water is released to the powerhouse served as the reference for a comparison with the disposition of the cold water pool. Table 8 summarizes the requiired information for the reservoirs of interest.

Table 8: Physical Configuration Data for the Major Foothill Reservoirs

Reservoir	Length (mi)	Elevation Foot (ft)	Elevation Release (ft)
Shasta	5.9	576	725
Oroville	4.7	180	640
New Bullards Bar	2.3	1400	1622
Folsom	7.8	200	218
Camanche	6.8	100	104
New Hogan	2.0	525	534
New Melones	3.3	500	760
Don Pedro	4.1	290	600
McClure	3.1	400	477

III.1.2.2 Computational Steps

In this analysis, the evaluation of the ability to release cold water downstream from a stratified lake relies upon three sequential calculations carried out for an assumed reservoir storage level and vertical temperature profile. These are

- Determine the set-up of the lake caused by the passage of wind over the lake surface;
- Determine the displacement of the warm water pool, in response to the set-up; and
- Determine the juxtaposition of the warm water relative to the reservoir release works.

Appendix II examines these three computational steps in greater detail, focusing on the physical rationale behind each step.

III.1.2.3 Defining the Minimum and Target Carryover Parameters

Table 4 contains carryover storage targets for Shasta, Camanche, and New Hogan Reservoirs as defined in the Anadramous Fish Recovery Plan (USFWS 1995). These will be used as target carryover parameters in CUP. Appropriate carryover targets for the remaining facilities, as well as the minimum carryover levels for all of the reservoirs, remain unresolved. These values are set according to the following criteria:

$$CS_{target} = \left| \begin{matrix} CS_{AFRP} \\ CS \text{ where } HT \approx 50\text{ft} \end{matrix} \right. \text{ or if none} \tag{1}$$

$$CS_{minimum} = CS \text{ where } HT \approx 20\text{ft} \tag{2}$$

where CS is the carryover storage and HT is the minimum thickness of the cold water pool lying above the release works during wind driven oscillations. In those cases where no carryover standards are available, storage levels were adjusted in a trial and error fashion until conditions yielding HT values of 20 ft and 50 ft were identified. Table 9 presents the final CUP carryover parameter values for each of the nine simulated rivers (The San Joaquin was omitted from this analysis as extensive pre-delivery of surface water already takes place in the Friant Unit). These parameters were not based on political considerations, the sole consideration was the difference between the maximum downward displacement of warm water under *seiche* oscillations and the release works of a given facility. Obviously dams where the power plant intake is located well down the dam face are found to have much lower carryover requirements.

Table 9: CUP Carryover Parameters Developed According to Analysis of the Juxtapostion of Warm Water Relative to Reservoir Release Works (in ac-ft)

River	Carryover Target	Minimum Carryover
Sacramento	1,900,000	910,000
Feather	1,705,00	1,507,000
Yuba	210,000	190,000
American	190,000	100,000
Mokelumne	108,000	70,000
Calaveras	85,000	17,000
Stanislaus	382,000	268,000
Tuolumne	750,000	570,000
Merced	50,000	30,000

III.1.3 Tapping Upstream Storage

In CUP, when the re-operated storage falls below the minimum carryover parameter the model seeks to redress the deficit. The first place where CUP looks for replacement water is upstream towards storage in Sierra Nevada reservoirs. A time series of combined upstream storage for each river has been input into CUP and the user can specify the percentage of the upstream storage which can be tapped to make up any deficit. In CUP, water is returned to the surface reservoir from "provisional" storage only when the available upstream storage is insufficient to fill the gap. Figure 7 presents the time series of available upstream storage volumes.

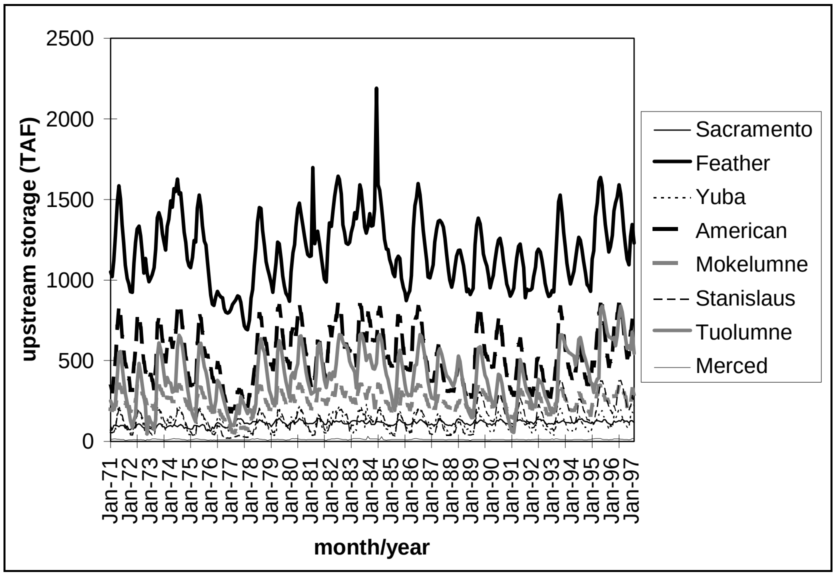


Figure 7: Time Series of Total Storage Upstream of the Major Foothill Reservoirs

III.1.4 CUP Simulations

Four different scenarios were simulated using CUP. These are summarized in the matrix shown in Table 10. The base case represents the case where instream flow standards are set to the highest possible level, carryover standards set in the AFRP are used where available to define the carryover target parameter, and 20% of the upstream storage can be tapped to make up any deficit relative to the minimum carryover. The other three simulations are departures from this base case. Scenarios 2 through 4 are designed to evaluate the sensitivity of the estimated average annual yield to various management strategies. Scenario 2 in particular merits some explanation. In this simulation the AFRP prescribed carryover targets are set aside in favor of the more aggressive targets derived from the application of the equations (1) and (2) to Shasta, New Hogan, and Camanche Reservoirs. Under each of these scenarios, a small simulated capacity to capture flow during peak winter and spring flow events was included (as depicted in Figure 1). It is important to keep in mind, however, that this approach is considered secondary to reservoir re-operation in CUP.

Table 10: Simulation Matrix for Revised CUP Model

Scenario	Carryover Target	Instream Standard	% Upstream Available
1. Base Case	AFRP if available, otherwise HT =50 ft	HIGH	20%
2. Set Aside AFRP	HT =50 ft everywhere	HIGH	20%
3. Relax Standards	AFRP if available, otherwise HT =50 ft	MEDIUM	20%
4. Full Upstream	AFRP if available, otherwise HT =50 ft	HIGH	100%

III.1.5 Results

The estimated average annual yield in the base case simulation is 894.4 TAF, a significant quantity of water which could contribute mightily to the quest for consensus in California's water sector. In addition, the alternative management strategies described in scenarios 2 through 4 improve the performance of the groundwater banking program. Table 11 summarizes the results for each simulated river under each of the management scenarios.

Table 11: Average Annual Yield Estimates from Revised CUP Model (in TAF)
(CU: conjunctive use re-operation; HP: capture of hydrograph peak)

	Base Case			**Set Aside AFRP**			**Relax Standards**			**Full Upstream**		
River	CU	HP	Total	CU	HP	Total	CU	HP	Total	CU	HP	Total
American	64.8	15.6	80.4	64.8	15.6	80.4	72.9	17.4	90.3	137.1	15.2	152.3
Calaveras	12.8	12.6	25.4	15.9	11.5	27.4	14.7	13.2	27.9	12.7	12.6	25.3
Feather	107.3	19.6	126.9	107.3	19.6	126.9	122.8	21.7	144.5	117.1	19.6	136.7
Merced	92.9	15.2	108.1	92.9	15.2	108.1	134.7	22.4	157.1	93.0	15.2	108.2
Mokelumne	53.7	15.7	69.4	51.6	15.7	67.3	77.6	23.3	100.9	59.6	15.0	74.6
Sacramento	170.8	26.0	196.8	184.5	26.0	210.5	195.3	31.2	226.5	170.8	26.0	196.8
Stanislaus	51.6	13.4	65.0	51.6	13.4	65.0	79.5	26.4	105.9	58.3	13.4	71.7
Tuolumne	65.3	12.6	77.9	65.3	12.6	77.9	116.4	24.8	141.2	72.1	12.4	84.5
Yuba	117.5	27.0	144.5	117.5	27.0	144.5	157.8	31.3	189.1	122.6	27.1	149.7
Total			894.4			908.0			1183.4			999.8

Relative to the base case, the most dramatic improvements come from reducing the simulated instream flow standards from high to medium. Even without relaxing the instream flow standards, however, the performance of the system can be improved by taking full advantage of the opportunity to release water from storage in upstream reservoirs when it is needed to re-establish the minimum carryover level on October 1st. Table 12 details the pattern of reliance on upstream storage which emerges from this simulation. Although the use of this water affords extra benefit to the ground water banking program, any advantage gained must certainly be weighed against power generation potential which might be lost in the process. This analysis suggest, however, that the notion of integrating storage upstream of the major foothill reservoirs into the maximal statewide groundwater banking program is certainly worth pursuing. This type of integration, however, would involved a wide array of actors running from the electric utilities which operate the upstream reservoirs, the water agencies which operate the major foothill reservoirs and their customers, and the land owners overlying the potential aquifer storage sites. The complexity of negotiating arrangements acceptable to all these parties will require a keen eye towards the legal and institutional nuances governing groundwater in California. Given the enormous potential payoff, however, there should be ample incentive to address any potential problems.

Table 12: Simulated Transfers from Upstream Storage to the Major Foothill Reservoirs under the Full Upstream Scenario (transfers in ac-ft)

River	No. of Transfers	Average Transfer
American	10	182,649
Calaveras	0	0
Feather	7	182,764
Merced	5	9195
Mokelumne	9	55,427
Sacramento	6	106,904
Stanislaus	3	87,343
Tuolumne	8	131,810
Yuba	3	53,935

IV. Workplan Step 2: Legal and Institutional Analysis

The infusion of approximately 1 MAF of new water into the California water system on an annual basis would undoubtedly help water managers in the state to meet water supply and environmental objectives. Realizing this hydrologic potential, however, requires that legal and institutional barriers be identified and surmounted.

IV.1 Basic Premise

Basically, the incentives for a maximal program of groundwater banking would be as follows, landowners overlying the storage site would agree to store the water as part of the program in exchange for a portion of the “new” water, or for a cash payment. Water will be regarded as “new” water if it would otherwise have been released for flood control purposes and flowed out to sea. Well monitoring may be necessary in selected areas to prevent increased pumping by overlying and adjacent landowners in storage areas, who could be tempted to irrigate new lands, avoid higher surface water costs, and/or to compensate for unrelated market transfers of surface water rights. Opportunities may exist to incorporate storage entities as a part of AB 3030 groundwater management plans for districts throughout the state, indeed in the case of *in lieu* storage this may be the preferred approach. Potential beneficiaries of the groundwater banking program would be invited to participate in the arrangement under agreements that would give them access to purchase a specified amount of the banked groundwater. The funds collected from the beneficiaries would be used to defray the costs of the program, which are expected to include the construction of new infrastructure and electricity for pumping the stored water.

IV.2 Basic Approach

A preliminary analysis of California groundwater law has been conducted to explore how a groundwater banking program could be set up so that the rights to the program water stored in groundwater basins could be protected against claimants which are not participating in the program. In pursuing this legal research two program designs were considered: (1) groundwater banking through active recharge and (2) groundwater banking through *in lieu* arrangements. Both designs would tap flood control releases that otherwise escape beneficial use. Thereafter the program designs diverge somewhat as they are predicated on different legal entitlements to extract and use the stored groundwater. The details of this legal research are included in an August, 1994 NHI document entitled *Analysis of Preferences in Rights to Groundwater Under California Law & Implications for Design of Conjunctive Water Use Programs*.

In this analysis NHI defined a number of distinct “types” of groundwater. While from a hydrologic perspective, a molecule of groundwater in a basin is not physically distinguishable from any other molecule, our analysis suggests that from a strictly legal perspective there are multiple groundwater types in the State. Our conception of a maximal scale groundwater banking program will focus on Groundwater Type 5, where the organizer of a groundwater banking program would seek to obtain rights to groundwater that is *percolating, used off-tract, imported to the watershed of use, and required for reasonable beneficial use, where area of origin statutes are inapplicable*. In more practical terms, this is groundwater which was imported from outside the groundwater basin, which has not become the underflow of a surface stream nor an underground stream, and which will be put to beneficial use at a location physically removed from the land overlying the basin. This type of groundwater offers several important protection to the organizers of a groundwater banking program. The most salient details of the legal analysis on the active and *in lieu* program designs are framed as responses to pertinent questions.

IV.3 Legal and Institution Questions

The questions posed below go right to the heart of perceptions that the benefit of water stored in an aquifer is the sole possession of overlying landowners. The responses assert that for groundwater of Type 5, at least, this perception is not universally valid. Having established this conclusion, questions related to how to best capitalize on potential storage opportunities can be posed.

IV.3.1 Could parties with potential claims on Groundwater Type 5 hamper the eventual recovery of stored groundwater?

IV.3.1.1 In the Case of Active Recharge

The universe of parties with potential claims to Groundwater Type 5 includes: the people of California through the public trust, as well as importers, prescribers and appropriators--both private and public.

The public trust is omnipresent. No disadvantage is incurred by using water of this type, since no type of water escapes the reach of the trust.

Prescribers, overlying users, and other importers are not of concern, if water of this type is used. If the organizer of the groundwater banking program is a public entity, as described below, prescribers are eliminated from competition for water imported by the organizer. The only colorable claim of overlying groundwater users to water of Type 5 would result if the importer abandoned the imported water once it was in the ground. Spreading does not constitute such abandonment.[6] Other importers can claim only rights to a quantity of water attributable to their own imports--a situation that does not threaten the operation of a groundwater banking program. Thus, a public importer of water of this type need only be concerned about being displaced by appropriators.

Appropriators have a superior claim to water of this type only if the importer fails to require the water for reasonable beneficial use--that is, if the water is considered “surplus.” The burden of proof would be on the would-be appropriator to show that such water was, in fact, surplus.[7] Storage of groundwater for domestic, irrigation, and municipal purposes is typically considered a reasonable beneficial use.[8] Storage of groundwater is a beneficial use if the water is later applied to the beneficial purposes for which the water was first appropriated on the surface.[9] Thus, it is important that, in addition to manifesting an intent to recapture imported waters stored in the ground, the organizer of the groundwater banking program demonstrate that such waters are being stored for later application to reasonable beneficial uses. In this way, the storage itself will be considered beneficial.

Thus, if the organizer of the groundwater banking program holds rights to groundwater of Type 5, the program should be able to deposit water in the ground and, by right, withdraw it again.

IV.3.1.2 In the Case of *In Lieu* Arrangements

Under an in lieu system, the program would enter into arrangements with overlying landowners who already have access to groundwater. During periods when the program desires to recharge groundwater, the landowners would forego pumping and accept a substitute surface delivery from the program instead. In the case where the landowner has access to surface water, when the program desires to withdraw groundwater, the landowner would curtail its surface water use and substitute groundwater pumping. When the landowner has no independent claim to surface water, recovery by the program would rely on the physical extraction of stored groundwater.

The basic problem with such an arrangement is that the program will not be withdrawing groundwater that it has physically put into the aquifer through an active recharge program. Instead, it will require groundwater rights holders to forego pumping water that they are otherwise legally entitled to

[9] CAL. WATER CODE § 1242 (West 1971).

extract in some years and to offset that forbearance by drawing more heavily on the aquifer in other years. The problem is that the contracting landowners have no better right to the underlying groundwater than do all of the other landowners overlying that same aquifer. The rights are "correlative", that is, of equal stature and limited by the principle of mutual avoidance of harm. Thus, in years of forbearance, the other pumpers would be entitled to extract the water that the program intended to store. In years of extraction, the contracting landowner's rates of withdrawal may impair the rights of the correlative pumpers.

Recognizing in the organizer a superior right to groundwater stored when surface water is used in lieu, could involve upsetting an established set of property rights and investment-backed expectations, something courts are typically loathe to do. Fortunately the only colorable claim of overlying groundwater users to water of Type 5 would result if the importer abandoned the imported water once it was in the ground. Delivery for surface use does not constitute such abandonment.[10] The important point when imported water is used is that the mass balance in the groundwater basin will be the same whether the water is actively recharged or delivered *in lieu* of groundwater pumping. In both cases during years or storage, more water is contained within the basin than would have been stored absent the program.

Of course, the problem associated with *in lieu* recharge may be avoided where groundwater basins have been adjudicated such that the particular extraction rights have been quantified. This is the situation with a number of groundwater basins in Southern California. A potential shortcoming of adjudication, other than the time and cost associated with the process, is that the final judgements in Southern California often proscribe out of basin transfers of groundwater. This may hinder the ability to recover groundwater of Type 5.

The technique of in lieu storage can be also used outside adjudicated groundwater basins, but special arrangements will be necessary. There are several potential approaches:

- The correlative rights problem can be avoided by bringing all of the correlative rights holders into the contractual arrangement, or mitigated by bringing most of them into it. The ability of any one rights holder to upset the program by withholding consent remains, however. This is were incorporation of storage entities as part of AB 3030 management plans could prove particularly beneficial.

- The program could be operated in a manner that would presumptively avoid injury to correlative rights holders by foregoing pumping for a period sufficient to assure that when accelerated pumping occurred, it would not disadvantage the correlative rights holders compared to the status quo. That might mean designing the program so that the number of sequential years of accelerated pumping was limited.

- Special legislation might be enacted to preclude suits against the program by non-contracting landowners where the groundwater that the program causes to be extracted in any one year was limited to amounts that could have been extracted in any previous year but for the forbearance imposed by the program. This would be a legislative interpretation of the "no harm" rule as applied in the narrow context of an in lieu groundwater banking program. While a general groundwater management regime may be beyond reasonable legislative expectations, a modest enactment of this sort may be realistic.

IV.3.2 What sort of entity should operate the program?

The organizer of the groundwater banking program will enjoy the best legal position to recover the groundwater that it has stored if it is a public agency managing groundwater of Type 5. Under these circumstances, the right to extract the stored groundwater enjoys a high priority. Such a right prevails over all rights except in the following circumstances:

> (1) It is inferior to the state-held public trust interest of the people of California, as are all usufructory rights;

---

[10] City of Los Angeles v. City of Glendale, 142 P.2d 289, ___, 23 Cal.2d at 76-78 (Cal. 1943).

> (2) It is of equal priority with pueblo rights, but, since pueblo rights apply only to native water, disputes between the two result in apportionment to the importer of the quantity of groundwater attributable to imports;[11]
>
> (3) It is of equal priority with other public and private importers in the watershed of destination and use, but disputes between these parties are also resolved by apportioning to each importer "the amounts attributable to the import deliveries of each."[12]

An importer's right to recapture imported recharge water is established by manifesting such intent prior to importation.[13] A groundwater banking program is predicated upon such an intent.

The advantage of the program organizer being a public entity is that that status precludes the potential for adverse rights attaching to the program's stored groundwater through prescription. While CAL. CIVIL CODE § 1007 (West 1982) literally protects "any public entity" from prescription, the courts have been reluctant to afford the statute its broadest application[14] and may try to limit the definition of "public entity" to exclude some marginal parties. Therefore, care should be exercised in choosing or establishing the program organizer. Further research is needed regarding the outer bounds of the "public entity" definition. For instance, it would be useful to know whether a groundwater banking program organizer that was the creature of a memorandum of understanding between the state and federal government might qualify.

IV.3.3 Where should the program store the imported water?

In the most general sense, in order to simplify the legal situation, the target groundwater storage basin should be composed of percolating strata and be isolated from surface waters, such as streams or the underflow of streams. This would minimize the interplay of various legal doctrines, avoid factual disputes, and make the legal outcomes more predictable. As a result, the participants in the program will feel more secure about their rights and about the investments required to implement active recharge.

Under the groundwater banking arrangements explored here, however, water might be introduced into a groundwater basin at one location and extracted at another some distance away. This raises the question of the hydrologic interconnections that must be maintained between the imported recharge water and the extracted water in order to preserve the importer's preference right. "Imported water" is "foreign water imported from a different watershed."[15] The advantage of obtaining the rights of an importer is that California law gives high priority to these rights in order "to credit the importer with the fruits of his expenditures and endeavors in bringing into the basin water that would not otherwise be there."[16] Under this rationale, it would appear that the area of recharge must be hydrologically connected to the area of discharge such that the program is pumping groundwater that "would not otherwise be there" but for the recharge. In other words, the two areas much be sufficiently proximate and interconnected so that the recharge water would be expected to replenish the area of discharge within the timeframe of the two events.[17]

Establishing proximity and interconnectedness is very important. Many California cases determining groundwater rights turn on geohydrologic characteristics of the groundwater aquifers. In

[12] City of Los Angeles v. City of San Fernando, 537 P.2d 1250, ____, 14 Cal.3d at 260-62 (Cal. 1975).

[13] City of Los Angeles v. City of Glendale, 142 P.2d 289, ___, 23 Cal.2d at 78 (Cal. 1943); City of Los Angeles v. City of San Fernando, 537 P.2d 1250, ____, 14 Cal.3d at 257-58 (Cal.1975).

[14] *See* City of Los Angeles v. City of San Fernando, 537 P.2d 1250, ____, 14 Cal.3d at 272, 274, 276 (Cal. 1975).

[15] City of Los Angeles v. City of San Fernando, 537 P.2d 1250, ____, 14 Cal.3d at 261 n.55 (Cal. 1975).

[16] City of Los Angeles v. City of San Fernando, 537 P.2d 1250, ____, 14 Cal.3d at 261 (Cal. 1975).

[17] One of the cases holds that it is possible to establish a right to imported water by making deliveries and withdrawals within one's own reservoir and alleging in a complaint that one intended to capture return flow from waters imported into the basin. City of Los Angeles v. City of Glendale, 142 P.2d 289, ___, 23 Cal.2d at 78 (Cal. 1943); City of Los Angeles v. City of San Fernando, 537 P.2d 1250, ____, 14 Cal.3d at 257-58 (Cal.1975). The issue, then, is whether the conjunctive use program would be viewed as delivering and withdrawing water from within the same underground reservoir.

addition to locating a storage site that is factually simple, it would be useful to locate one that is scientifically well-studied; ideally, one where the pertinent scientific facts have been determined in prior judgements. Such prior judicial fact finding may not be binding on parties to any future suit but would at least serve as an advance indicator of what the program might expect from future litigation.

IV.3.4 From what source(s) should the program obtain surface water for storage?

One consideration in selecting a source of program water is the fixed capital requirements of the program. If the program requires appreciable new physical infrastructure, as will likely be the case for a maximal program of groundwater banking, the costs of those capital investments will presumably have to amortized by the project itself over a period of time. In that circumstance, the program will require a reliable source of water over that same time horizon. If, by contrast, the program requires only limited capital investment, the program water can be intermittent or less reliable. Therefore, an early question to be resolved is whether the program can be based on an interruptible source of water, or does it require a durable source? The hydrologic distinction between capturing peak floods (intermittent) and re-operating reservoirs (reliable) will certainly bear on the appropriate response to this question.

IV.3.5 What parties should be involved?

The program organizer should seek contractual arrangements with parties owning land overlying groundwater since they may possess both spreading grounds and a right to extract groundwater. Their participation and cooperation may be secured by sharing the benefits of the program with them, either in terms of new water or monetary compensation. The presumption in this case is that the sharing of benefits made available to the overlying landowners will be sufficient to surpass the water management opportunities afforded by strictly local opportunities.

V. Workplan Step 3: Site Analysis

The hydrologic potential analysis described in Section III relied upon making assumptions about the ability to convey surface water and to store it in a suitable groundwater banking site. The assumed conveyance and groundwater storage capacities input for the simulated foothill reservoirs in CUP are presented in Table 13. By virtue of is large flows and significant existing surface water storage capacity, the Sacramento-Shasta system was accorded the largest portion of the assumed 2 MAF storage capacity. The relatively small Caleveras-New Hogan system lies at the other end of the conveyance/storage spectrum.

Table 13: Partition of System Capacity Among the Nine Simulated Rivers in CUP

River	Conveyance Capacity (cfs)	Provisional Storage (TAF)
Sacramento	648	370
Feather	518	296
Yuba	387	222
American	387	222
Mokelumne	260	148
Calaveras	130	74
Stanislaus	387	222
Tuolumne	387	222
Merced	387	222

At first glance, the values in this table may seem to indicate that conveyance infrastructure and potential storage sites are located in close physical association with each surface water system. Any such impression is an artifact of the way CUP operates as it simulates each river as an independent system. Given the highly engineered character of the Central Valley water system, it is more likely that surface waters from various rivers diverted as part of the groundwater banking program will co-mingle during the aquifer storage process. This section deals with identifying the sites which can provide the required aquifer storage resource.

Much work in this area has already been carried out by the CalFed Bay-Delta Program. as part of its Storage and Conveyance Component, the ongoing water planning forum produced and inventory of 17 potential groundwater storage sites. These were described in a matrix which included a number of attributes, including: the active storage capacity; the extent to which groundwater banking will alter groundwater elevations; required infrastructure; long-term regional groundwater conditions; and environmental concerns. Details of the active storage attribute, which total over 10 MAF are shown in Table 14.

Table 14: CALFED Estimates of Active Groundwater Storage Capacity

North of Delta Storage	Potential Storage	South of Delta Storage	Potential Storage
Butte Basin	470 TAF	Folsom S. Canal (east S.J. County)	860 TAF
Cache Creek Fan (Cache-Putah)	450 TAF	Kern River Fan	930 TAF
Colusa County	320 TAF	Gavelly Ford/Madera Ranch	350 TAF
Eastern Sutter County	470 TAF	Medota Pool (Westside)	900 TAF
Sacramento County	260 TAF	Mojave River	200 TAF
Stony Creek Fan	640 TAF	Semitropic WSD	1000 TAF
Sutter County	1180 TAF	Tuolumne/Merced Basin	1250 TAF
Thomes Creek Fan	220 TAF		
Yuba County	540 TAF		
Total North of Delta	**4,550 TAF**	**Total South of Delta**	**5,490 TAF**

The spatial distribution of these sites, along with other potential storage targets located in Southern California, is depicted in Figure 8. When compared with the hydrologic potential of the rivers considered in CUP (Table 11), the first observation one makes is that while most of the yield associated with reservoir re-operation will be generated in the Sacramento Valley, much of the potential storage is located south of the Delta. This raises the issue of how best to convey water across that keystone of the California water system. It should not be assumed that the ability to realize the full potential of groundwater banking in the Central Valley is neutral with regards to the three Delta conveyance opportunities under consideration by CalFed. What is required is operational analysis of specific groundwater banking opportunities which can explore the full implications of various assumption about the existence and operation of conveyance infrastructure. This sort of operational analysis which is presented in the Section VI.

By virtue of their inclusion in the CalFed inventory, the storage sites listed in Table 14 likely comprise a likely constellation of potential groundwater banking sites. NHI has neither the resources nor the desire to redevelop the CalFed list. From our vantage point, however, there are issues other than the active storage capacity which go to the relative merits of a particular groundwater banking site. In fact, prior to the release of the CalFed inventory NHI had already completed a first assessment of promising groundwater banking sites. Based on consultation with experts,[18] and on a literature review,[19] we chose several criteria for selecting candidate sites for new or enhanced artificial or *in lieu* recharge of ground water:

1. Aquifer storage capacity available for groundwater banking
2. Opportunities to solve collateral problems
3. Impact on habitat and species of fish and wildlife
4. Infiltration characteristics of soils and water courses
5. Hydraulic properties of aquifers
6. Extent of well development and yields of wells
7. The magnitude of surface water/groundwater interaction
8. Water quality effects of recharge
9. Land use effects of recharge

Figure 8: Spatial Distribution of Potential Groundwater Storage Sites in California

This listing has been selected to cover the broad range of conditions occurring in California with respect to groundwater banking. Appendix III contains the results of a survey conducted by NHI which sought out examples of where the convergence of these criteria have already generated interest or activity in groundwater banking. It is important to keep in mind that each site listed in the inventory could

potentially become more productive with an infusion of new yield derived from reservoir re-operation. The nature and importance of these criteria are explored in greater detail in the following comments.

The volume of water which can be stored in the subsurface is dependent on the **aquifer storage capacity**. At an given moment, however, most of the water in storage will be the result of basin scale hydrologic processes. An intentional program of groundwater banking seeks to capitalize on the increment of storage capacity which could be integrated with the yield estimated in Section III. The challenge is defining the increment of storage capacity available to the groundwater banking program.

In areas of severe groundwater depletion that increment of storage clearly exists in the form of a persistent cone of depression. The presence of a cone of depression on the water table surface, a fairly common phenomenon in the Central Valley south of the Mokelumne River drainage, indicates that local pumping historically exceeded the natural recharge to the aquifer. If the cone is stable, then a water balance has likely been re-established via enhanced seepage from overlying rivers and streams in response to the increased hydraulic gradients associated with the drawdown feature. Defining the increment of groundwater storage in this case involves a fairly straight forward computation of filling the basin with known quantities of water and discounting the reduction in the induced seepage from overlying rivers and streams. This increment of enhanced stream flow would be a direct environmental benefit of the program. In addition, the net rise in the water table during periods of aquifer storage would have direct and quantifiable local benefit relative to the persistent cone of depression currently plaguing local groundwater users. The primary disadvantage of utilizing this increment of storage are the pumping costs associated with recovery from a deep cone of depression and the need to carry out a period of storage before any recovery can be achieved.

A second increment of storage available for groundwater banking should be viewed in more speculative terms. In locations where there has been no sustained, long-term imbalance between basin scale hydrologic process, as is commonly the case in the Sacramento Valley, the water table is generally more stable and closer to the surface than in zones of persistent dewatering. In order to create the increment of storage required for groundwater banking, recovery, either through increased local reliance on groundwater pumping or though the export of groundwater, must precede storage. This is somewhat akin to the situation in the drought water bank of the early 1990’s when Sacramento Valley farmers sent groundwater to water strapped communities in Southern California in exchange for monetary compensation. Achieving this increment of storage essentially involves treating the aquifer as a direct extension of the reservoir. As in a reservoir where the lake surface fluctuates from month to month, the end result of this integration would be a water table which fluctuates within a prescribed management range. While a case can be made that the optimal overall system yield will emerge from this integration it is more difficult to demonstrate the local benefit of this type of storage and recovery.

For that reason we initially focused our attention in this feasibility study on zones where groundwater overdraft has already created a cone of depression. This focus should not be understood as completely discounting the potential role of the more integrated form of groundwater banking. In fact, given the imbalance in hydrologic potential towards the Sacramento Valley (Table 11) and the potential complexity of conveying water across the Delta, it may ultimately be necessary to explore the full range of Sacramento Valley alternatives. The premise of the program, however, should remain the same whether storage takes place in persistently de-watered or stable hydrologic regimes. Namely the use of any available aquifer storage resource must provide sufficient local benefit to inspire substantial local enthusiasm.

The best way to motivate local enthusiasm for groundwater banking is to demonstrate that implementation of the program might help **solve collateral water problems**. Our starting premise for this assertion is that even in relatively stable hydrogeologic provinces, water managers face challenges which call for action. These challenges often involve water quality consideration, the desire to resolve emerging conflicts between municipal and agricultural water use sectors, or the need to redress the degradation of aquatic habitat. In all such cases, controlling the rate and place of ground water recharge and pumping may create opportunities to accomplish local water management goals which would go unrealized save for the introduction of new yield into the system. Examples of the types of collateral problems which could be resolved in this manner include land subsidence and ground water quality degradation in Yolo County and increasing pumping lifts in eastern San Joaquin County.

Attention must also be paid to the **impacts, both positive and negative, which groundwater banking can have on fish and wildlife**. Appendix IV includes our assessment of some potentially negative impacts of groundwater banking which must be resolved. Commonly, groundwater recharge sites are viewed as wetlands conducive to enhanced wildlife management opportunities. Wildlife experts[20] remind us that to be beneficial to wildlife, water must be provided to an environment, in the right amount, at the right time, in suitable quality; and, the supply must be reliable. It would seem that specific benefits to wildlife could be built-in to many recharge projects, to create and maintain wetlands, where needed, or to increase the base flow of small streams through raising ground water levels. Another, perhaps more far reaching, environmental benefit of groundwater banking goes beyond the local impact of a flooded recharge basin. This benefit goes to the aquatic eco-system restoration opportunities which would have otherwise been missed without the added water management flexibility associated with the potential yield increase from groundwater banking. An examples of this type of benefit include the potential to enhance Delta outflow by storing groundwater in San Joaquin County and to restore the anadramous fishery in the San Joaquin River by banking groundwater near the Gravelly Ford reach of the river.

Aquifer recharge, the first of two central operations in a groundwater bank, occurs primarily by spreading water on land and in stream beds, or, or by filling percolation ponds. In all cases, **the infiltration characteristics of soils and sediments** determine the rate at which surface water becomes ground water. Clayey soils and sediments tend to inhibit infiltration. Generally, suitable soils must overlie permeable sediments in order to provide the physical environment essential to recharge the water table. Soil surveys developed by the U.S. Natural Resources Conservation Service provide information adequate to evaluate the recharge potential of soils, but, information on underlying sediments usually does not extend beyond the description of parent material.[21] Work conducted by the USGS in the Tulare Lake Basin, for example, identified large areas in which shallow clays underlying surface soils[22], precluding the development of any effective program for recharging ground water reservoirs, even though surface soils accept water readily. Other USGS studies in eastern San Joaquin County and along the Gravelly Ford reach of the San Joaquin River reveled conditions conducive to groundwater banking. When aquifer recharge is accomplished via *in lieu* substitution the pre-existence of extensive groundwater pumping is required. By substituting surface water for this pumping, ground water storage can be increased. In order to estimate the potential for *in lieu* groundwater recharge, information must be developed on the amount of pumping which is likely to occur during years of normal or above normal precipitation. An inventory of agricultural pumping in Yolo County is an example of information required in this case[23].

The rate at which aquifers can be discharged by pumping wells, the second of the two central operations of a groundwater bank, is dependent on **the hydraulic properties of the aquifers**, the spatial extent of these aquifers, and on the hydraulic head created by pumping.[24] Although specific investigations are required to quantify these properties, a history of groundwater use in target areas is a good indication that under natural hydrologic conditions these conditions favor aquifer storage and recovery. In selecting a site, the presence of groundwater wells should be the minimum threshold for consideration. **The extent of well development and the long term yield** of large volumes of ground water to wells suggests a favorable physical environment for recovery.

The magnitude of surface water/groundwater interaction at any given site may influence groundwater banking opportunities. In the San Joaquin Valley, where past overdrafts have dropped

groundwater levels far below ground level, the degree to which adding groundwater storage may impact streamflow levels is relatively small. However, in many locations within the Sacramento Valley, groundwater storage may lead to increases in surface flows. Conversely, groundwater withdrawals could lead to reductions in surface flows. These kinds of interactions reduce the benefits of groundwater banking and increase the complexity of storage accounting. What is required is a thorough understanding of basin hydrogeology. Within California, there is a wide range in the certainty of knowledge of the hydraulic properties of specific aquifers.[25] Some water user organizations, such as the Turlock and Modesto Irrigation Districts, are well-armed with information to plan and operate an artificial recharge program, as part of a conjunctive use strategy. Others, like the Butte Basin Water Users Association, are in the process of developing the quantitative models and monitoring devices useful for participation in such programs. This information is lacking in regions such as Tehama County.[26] Wherever groundwater banking ultimately occurs, detailed hydrogeologic analysis will be required.

A review of the history of irrigation and ground water recharge in California,[27] shows the importance of considering **the water quality effects of recharge**--whether that recharge is coincidental or planned. Positive or negative effects can be produced in soil water or in underlying ground water reservoirs through the introduction of surface water of a certain quality. For example, some of the soils of the eastside San Joaquin Valley (Fresno area) are too sodic to be recharged effectively with Sierra water, without the addition of gypsum to the soils.[28] Looking for a "win-win" situation, the San Joaquin Valley Drainage Program, [29] analyzed the feasibility of exporting gypsiferous drainage water to irrigate these lands and recharge ground water. The concept was feasible, technically, but could not overcome political objections.

Most information on **land use effects of ground water recharge** is anecdotal, obtained from discussions with various water experts. In San Bernadino County, artificial recharge was halted in one locale, when rising ground water levels caused clays to swell and threaten the structural integrity of piers in a highway overpass.[30] In highly urbanized Santa Clara County there have been chronic complaints, and lawsuits, from residents adjacent to percolation ponds.[31] Nearby residents have alleged the creation of mosquito problems, marshy soils, and dangerous nuisances from open water bodies. Because of these and associated cost factors, ground water recharge in urban areas is most effectively conducted in natural or modified stream courses.

In light of resource limitations, NHI did not conduct detailed analysis of each of these attributes at all of the twenty potential sites in Figure 8. Our reconnaissance of the landscape, however, lead us to three locations where a convergence of groundwater banking attributes seems to exist. While by no means claiming that these are the sites which must ultimately store yield generated through pre-delivery[32], these are striking examples of the ability of groundwater banking to help meet: 1.) water management objectives; 2.) eco-system restoration objectives; and 3.) a combination of both these objectives.

<u>Cache-Putah Basin</u>. Cache and Putah Creeks are significant westside tributaries of the Sacramento River. Historically, flows in these creeks recharged groundwater below Yolo County through instream hydraulic connection with the aquifers which provide much of the county’s municipal and agricultural water supply. Recently the intensity of local reliance on groundwater has combined with the out-of-basin export of water from Putah Creek and the mining out of the instream gravel in Cache Creek to create nagging problems

with groundwater overdraft, land subsidence, and deteriorating ground water quality.[33] Despite the high cost and political uncertainty, these challenges have prompted both agricultural and municipal water providers to initiate planning to secure a Sacramento River water right. Such a claim would certainly be facilitated by increasing the available yield through reservoir re-operation. This could be accomplished by developing new off-stream percolation ponds or negotiating *in lieu* arrangements with local farmers which would be supplied through an extension of the Tehama-Colusa Canal. In exchange for this introduction of water, the Yolo water users could continue to allow the Yolo County ground water reservoir to be used as part of the drought water bank which performed well during the heart of the 1987-92 drought. To garner local support for such a scenario, however, this approach needs to be compared with purely local opportunities to meet water management objectives.

Gavelly Ford/Madera Ranch. As mentioned in Section II, operation of the Friant Unit on the San Joaquin River has lead to the virtual de-watering of the river below Friant Dam. Other then during occasional flood flows which spill from Millerton Lake, nearly all of the water in the San Joaquin in diverted to provide water for irrigation. Obviously this severe alteration of the hydrograph in the San Joaquin River has had a dramatic impact on fish. In particular, runs of anadramous fish were decimated. Enter the Anadramous Fish Recovery Act spawned by the CVPIA and its call for a doubling of the number of anadramous fish in the Central Valley, and restoration of the San Joaquin emerges as a promising management alternative. The challenge is to achieve this eco-system objective in a manner which minimizes negative impacts on existing water users. Groundwater banking opportunities in an expansive cone of depression below the Gravelly Ford reach of the San Joaquin and the adjacent Madera Ranch site could assist in removing political opposition to an environmental goal.

East San Joaquin County. Two associated ground water basins in this area are overdrafted and the northernmost basin, which is used directly for water supply by the city of Stockton, is experiencing intrusion of brackish water from the Sacramento-San Joaquin Delta. There is an overall shortage of both ground water and surface water, particularly surface water for environmental releases to the Stanislaus River Basin. Plans to extend the Folsom South Canal in order to use imported Ameircan River surface water for aquifer recharge have been discussed for many years although a consulting firm hire by local water districts[34] found that the structural modifications needed to facilitate large-scale groundwater banking would be formidable. Nevertheless, the strategic location of the ground water basins with respect to the Delta, make this a viable candidate area because water stored in this location would be well placed to help improve the export and environmental water management objectives in the Delta which may be compounded by certain Delta conveyance options under consideration by CalFed.

It is our hope that detailed operational analysis of the Cache-Putah, east San Joaquin, and Gravelly Ford/Madera Ranch groundwater banking sites, which is found in Section VII, will motivate additional support to bring the remaining sites under similar scrutiny.

VI. Workplan Step 4: Operational Analysis

In order to analyze both how any specific groundwater banking interventions might function and how they might interact with other features of the Central Valley water system, a simulation model is required. One of the key elements of an intentional program of groundwater banking will certainly be specific distribution and conveyance arrangements of both a structural and an institutional nature. An exploration of the ramifications of these arrangements is needed. In California, the type of exploration envisioned for this operational analysis has traditionally relied on the use of DWRSim, a simulation model of the State Water Project which has evolved into the standard reference for modeling the Central Valley water system.

In the current planning context, where the California water community is being encourage to pursue "fresh thinking rather than entrenched ideologies"[35] DWRSim is somewhat constrained by its attention to the details and nuances of the current system. It is not easy to reprogram DWRSim to model radical departures from the current system such as reservoir re-operation and the integration of the groundwater banking site in Table 14 into the Central Valley water system. To accomplish this exploratory analysis NHI initiated a collaborative program with several California water partners to identify an appropriate screening level river basin simulation model. The goal of the effort was to develop a tool which could help identify water management arrangements which show promise and which merit further attention. The premise behind this search was that identifying a sub-set of promising arrangements could provide a sharper focus for subsequent refinement of the more cumbersome DWRSim model.

To develop this screening tool NHI joined with the CalFed Bay-Delta Program, the US Bureau of Reclamation, the US Fish and Wildlife Service, and the Metropolitan Water District of Southern California to form the Joint Technical Unit (JTU). This grouped selected and guided the enhancement of the Water Evaluation and Planning system, or WEAP, developed by Tellus Institute. WEAP is a flexible water balance modeling tool conducive to the initial evaluation of management options at a system level. Unlike most river basin models, it effectively integrates supply, operation and demand. It is also highly flexible in that it can be easily reconfigured to screen emerging management options and to flesh-out those which appear promising.

In order to make WEAP more appropriate for the Central Valley, the JTU funded two phases of model enhancement. Phase I included the development of a conjunctive use node to simulate the intentional transfer of water from the surface water system to a target groundwater banking site. The magnitude of the simulated transfer is the minimum of the excess surface supply during a given month, the available storage capacity in the aquifer, and the transmission capacity available to effectuate the transfer. A second Phase I modification involved the development of an active diversion feature. This feature mimics the operation of a single canal which services multiple points of demand; a common feature in the water management landscape of California. A second phase of modifications funded by the JTU fell into three categories: graphical output enhancements, water year type controls, and refinement of the conjunctive use node. The enhanced version of WEAP was delivered to the JTU in April, 1998.

Since receiving the enhance software, NHI has carried out operational analysis on the three specific groundwater banking opportunities identified as the end of Section V: 1.) the Cache-Putah Basin; 2.) the Gravelly Ford/Madera Ranch reach of the San Joaquin; and 3.) east San Joaquin County. Respectively, these were selected as particularly strong examples of how groundwater banking can help meet: 1.) local and regional water management objectives; 2.) eco-system restoration objectives; and 3.) a combination of both these objectives. It must be reiterated that NHI chose these examples only to demonstrate the far-reaching benefit which can be realized through the implementation of a maximal scale program of groundwater banking. The analysis presented in this section should not be interpreted as an endorsement of these particulate sites over the other contained in Table 14. In fact, NHI hopes that the following demonstration of WEAP's ability to screen potential groundwater banking sites will motivate the additional resources required to complete operational analysis on all potential storage sites.

---

[35] Deep Water Thinking, Sacramento Bee Editorial, November 18, 1998.

VI.1 Meeting Water Management Objectives: The Cache-Putah Basin

Located in the southwestern Sacramento Valley between Cache and Putah Creeks, the Cache-Putah Basin (Figure 9) serves as an important source of water for both the agricultural and urban communities of Yolo County. Under current operating arrangements, surface water from Cache Creek, regulated by dams at the outlet of Clear Lake and on Indian Valley Reservoir and diverted at Capay, provides irrigation water for farms west of Davis and Woodland. The water in Putah Creek has been developed for use in Solano County and much of the flow is exported from the basin towards the south at a point east of Winters. In the extreme north of Yolo County, surface water is also available from the Tehama-Colusa Canal, and the Colusa Drain which convey Sacramento River water from points of diversion located in the Sacramento Valley to the north of the county. In the eastern portion of the Yolo County, water is taken directly from the Sacramento River for both irrigation and the municipal supply for the City of West Sacramento.

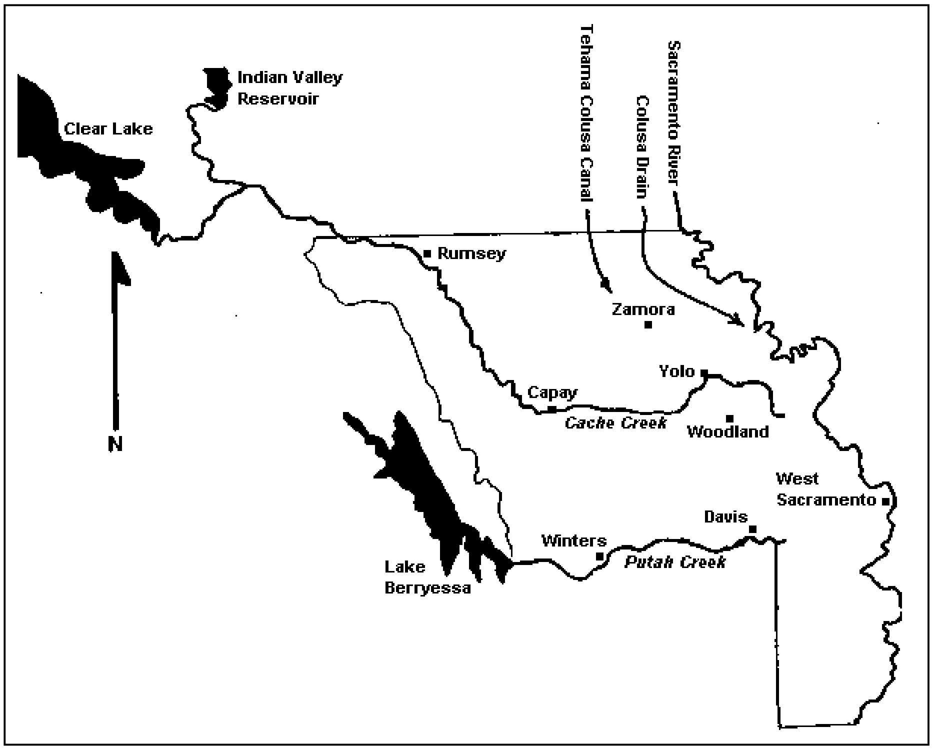

Figure 9: The Cache-Putah Basin

In spite of the availability of surface water from Cache Creek and the Sacramento River, there remain regions of Yolo County which rely exclusively on groundwater for supply. Overlying a map of the areas in which surface water is available with a map of the primary groundwater sub-basin of the Cache-Putah aquifer (Figure 10) reveals that a substantial portion of the land overlying the Lower Cache-Putah Sub-Basin has no access to surface water. This region includes Yolo County's principle cities, Davis and Woodland, as well as some of the most productive agricultural land in the Central Valley.

The result of this heavy reliance on pumped groundwater has been the development of a cone of depression in the water table of the Lower Cache-Putah Sub-Basin. The dimensions of this feature following the wet winter of 1993 are shown in Figure 11. Water table elevation data suggest that depending on hydrologic conditions this cone of depression will vary in size and depth, although it remains persistent. This feature is a remnant of the much more extensive depression which plagued the county prior to the construction of Indian Valley Reservoir on the North Fork of Cache Creek in the 1975. The enhancement of surface supplies afforded by the reservoir has allowed for a reduction in groundwater pumping, improving the water balance in the county. Nonetheless, the nagging persistence of this overdraft feature continues to create concern over land subsidence, the initiation of groundwater flow patterns which threaten water quality, and increasing pumping costs.

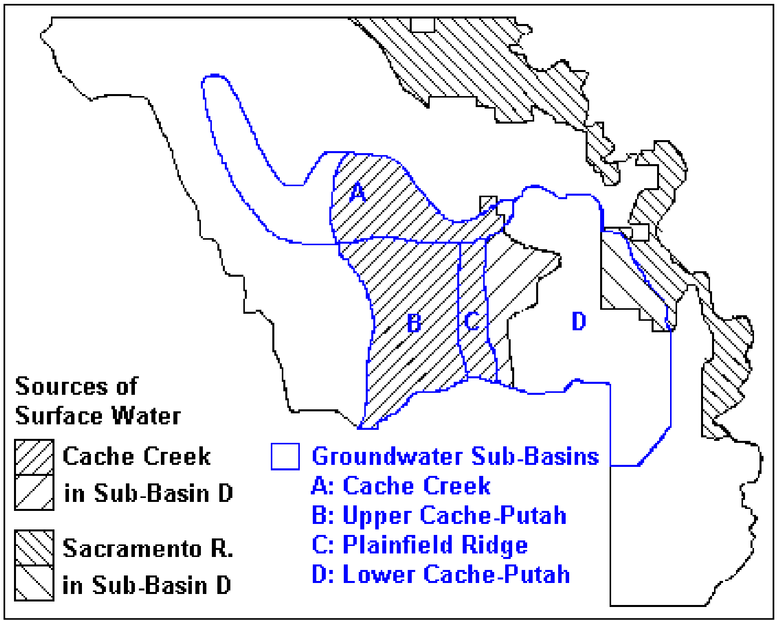

Figure 10: Composite Map of Groundwater Basins and Surface Water Service Areas

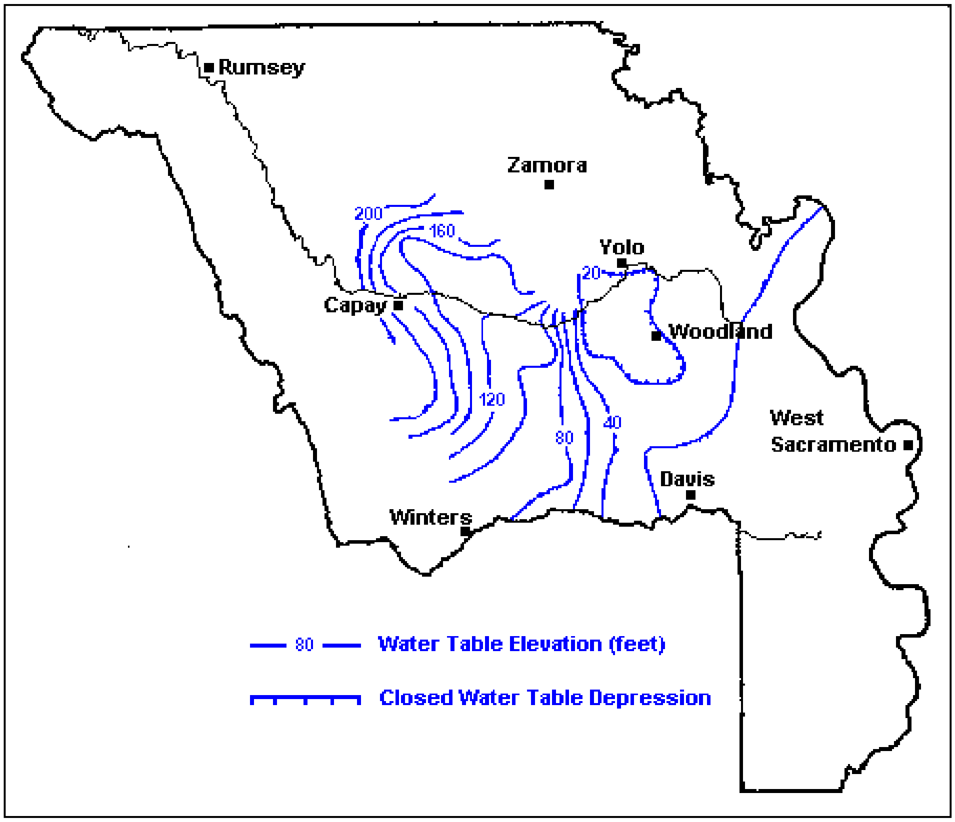

Figure 11: 1993 Cone of Depression in the Lower Cache-Putah Sub-Basin

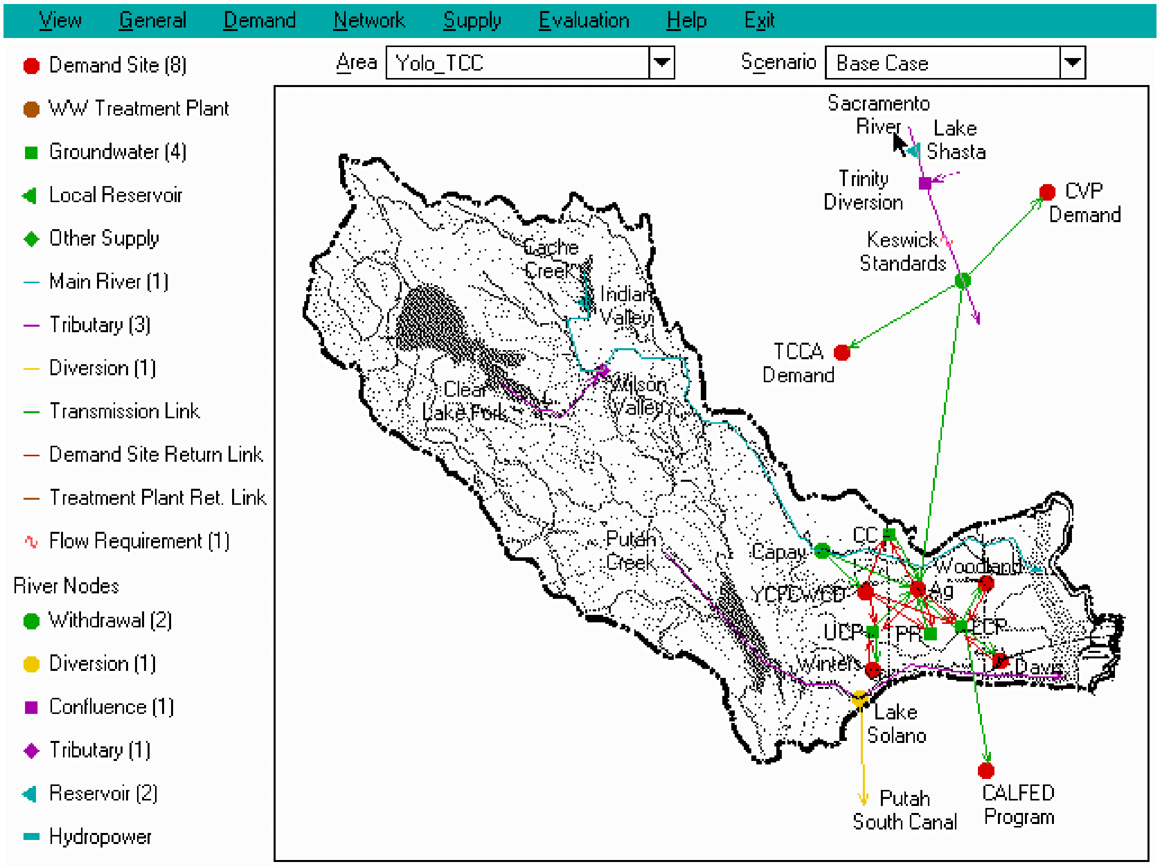
In response to these threats, local water managers have proposed many alternatives. One is expand the area receiving surface water from Cache Creek as part of a local *in lieu* substitution program.

An alternative to this purely local response might be integration of the aquifer storage resource in the Lower Cache-Putah Sub-Basin into the broader Central Valley water system. Such integration could potentially assist in capturing some of the yield which could be generated through re-operation of Shasta Dam. It could be accomplished by implementing the long discussed extension of the Tehama-Colusa Canal into central Yolo County. With the connection in place, imported surface water could be used to implement *in lieu* transfers with farms overlying the dewatered portion of the Lower Cache-Putah Sub-Basin. Operational analysis using WEAP was conducted to explore the relative advantages and dis-advantages of these two water management strategies.

This was accomplished by configuring WEAP to represent the major features of the hydrologic system. Within the Cache-Putah Basin the essential features include the major sources of water supply, the principle points of demand, and existing and proposed hydraulic infrastructure. These are depicted in the WEAP Network Configuration shown in Figure 12. The data used to define these nodes was gathered primarily from the pages of the detailed inventory of Yolo County water developed by Jenkins (1992)



Area Yolo_TCC

Scenario Base Case

Figure 12: WEAP Cache-Putah Basin Network Configuration

The network configuration in Figure 12 includes all of the elements required to simulate three scenarios: the current base case; *in lieu* groundwater banking using surface water from Cache Creek; and *in lieu* groundwater banking using surface water from the Sacramento River. In the base case the transmission links joining the Capay and T-C Canal withdraw nodes with the Ag demand node in Yolo County are inactive. For the Cache Creek *in lieu* scenario the Capay link is activated and Indian Valley Reservoir is re-operated to pre-deliver water to the Ag node when surface water is available. In this scenario, the operation of Clear Lake Dam does not change as the YCFCWCD annually takes as much water as it can from that resource. By activating the transmission link between the T-C Canal and the Yolo County Ag demand node, Central Valley scale integration can be simulated. In this case Lake Shasta is re-operated to transfer available surface water to Yolo County for *in lieu* substitution. Broad water supply benefit can be achieved by activating the transmission link between the Lower Cache-Putah Sub-Basin and the CALFED Program demand node which calls for supplemental supplies during dry and critical water years.

Realization of either scenario will require the support of Yolo County water managers, stakeholders and politicians. From this perspective there are two essential question in evaluating the relative merits of the various approaches. Does a the water management intervention reduce the threats posed by the existence of a persistent aquifer draw down feature? How do existing stakeholders fare under the modified arrangements? Responds to both questions relies upon the establishment of a base reference.

Figure 13 is a simulated forecast of storage in the Lower Cache-Putah Sub-Basin under existing management arrangements and projected demand, assuming that the hydrologic record from 1972-1992 recurs between 1990 and 2010. The implication is that absent management intervention there will be a continued depletion of the groundwater resource in Yolo County. This change would likely strength the water quality and land subsidence threats faced by the county.

.

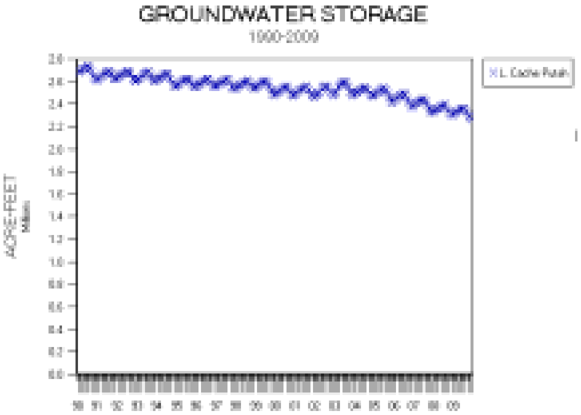


Figure 13: Simulated Groundwater Storage in the Lower Cache-Putah Sub-Basin Under Existing Arrangements

Recognizing this likely trend, local water managers have proposed the Cache Creek *in lieu* substitution scenario as a potentially beneficial strategy. In terms of the first essential question, by reducing groundwater pumping at the Ag demand node through the delivery of surface water the simulated decline in aquifer storage substantially reduced (Figure 14). In this case, rather than demonstrating a steadily decreasing trend, aquifer storage appears to fluctuate within an acceptable management range. The decline in storage at the end of the simulation corresponds to the recurrence of the 1987-1992 drought.

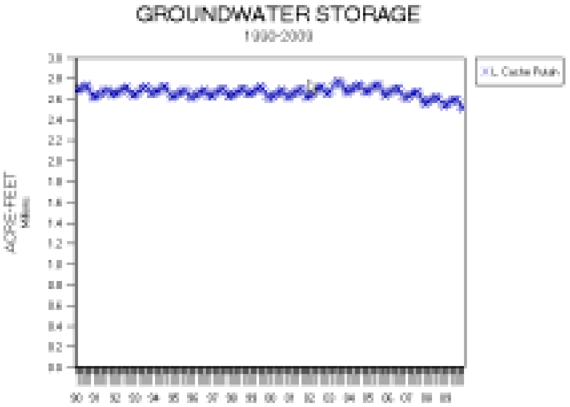

Figure 14: Simulated Groundwater Storage in the Lower Cache-Putah Sub-Basin Under Local *In Lieu* Arrangements

Increasing the area which receives water from Cache Creek, however, will presumably place a heavier burden on the surface water infrastructure on Clear Lake and Indian Valley Reservoir. In terms of the second essential question, this could make it more difficult to supply water to existing YCFCWCD customers. Figure 15 compares the difference in supply requirement coverage, or the extent to which demand is satisfied, under the proposed local *in lieu* substitution program as compared with the current arrangements. Relative to the base case, the heavier draw on the local surface water system would apparently cause the existing YCFCWCD customers to experience a decline in service relative to the level they would have received absent the program. Building a case for local *in lieu* substitution could be hampered by the decline in service experienced by an important group of stakeholders.

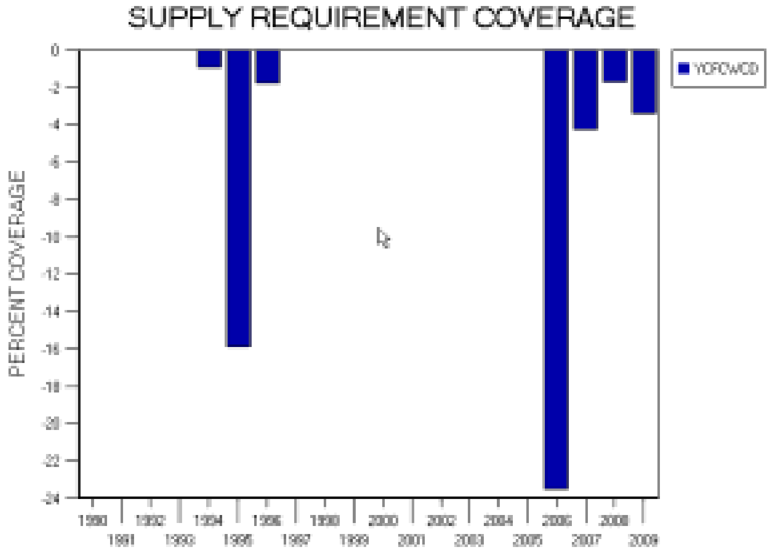

Figure 15: The Difference Between the Percent of the Supply Requirement (Demand) Coverage in the Base Case and the Local *In Lieu* Program Using Surface Water from Cache Creek

Carrying out *in lieu* arrangements with agricultural interests overlying the Lower Cache-Putah Sub-Basin using surface water made available through re-operation of Shasta Dam also mitigates the steady decline in aquifer storage predicted under the base case (Figure 16). The wider fluctuations in storage experienced under this arrangement relative to the local approach are the result of the more aggressive storage and recovery program carried out under integration into the Central Valley water system.

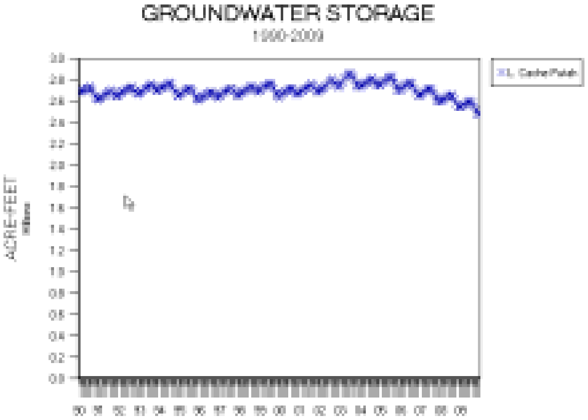

Figure 16: Simulated Groundwater Storage in the Lower Cache-Putah Sub-Basin Under Central Valley *In Lieu* Arrangements

Under this integration, no re-operation of the Cache Creek surface water system occurs and therefore existing YCFCWCD customers would experience no decline in service relative to the base case. Under this scenario, however, statewide water stakeholders would anticipate gaining some water supply advantage. In the simulation this is achieved by activating a 100 cfs transmission link between the Lower Cache Putah aquifer and the CALFED Program demand node. This node calls for 20 TAF of water during dry water years and 100 TAF during critical years. Under these arrangements the pattern of water supply enhancement which could be generated is shown in Figure 17.

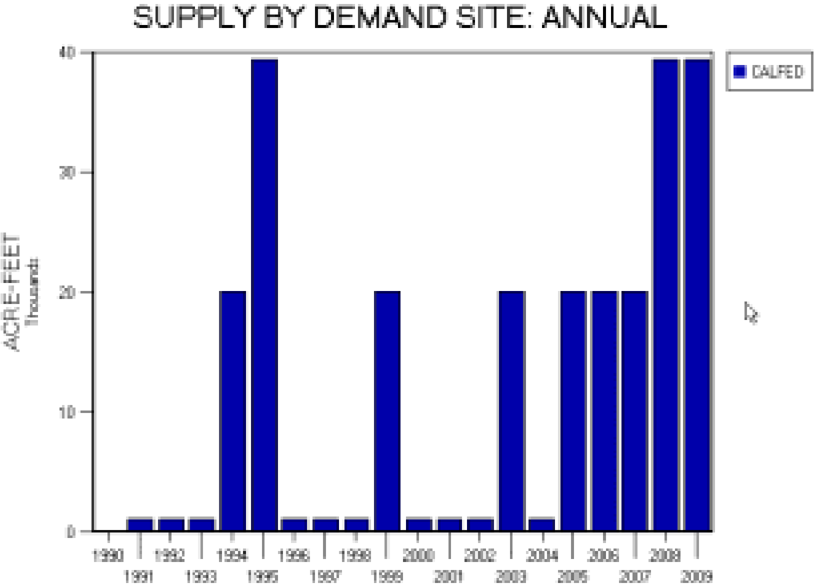

Figure 17: Simulated Water Supplies Enhancement for the CALFED Program Under a Central Valley *In Lieu* Substitution Program in the Lower Cache-Putah Sub-Basin

Increasing the capacity of the transmission link between the aquifer storage and the CALFED demand node could enable more complete coverage of the dry year demand, although potentially at the expense of stabilizing groundwater storage in the Lower Cache Putah Sub-Basin. As it is, there is a net transfer of water from the CVP storage system into the Yolo County groundwater system. Achieving a more balanced distribution could be achieved by fine tuning the capacities of important transmission links. The important implication of these simulations, however, is that without some sort of intervention groundwater levels in Yolo County will likely continue to decline and that the opportunity to negotiate storage and recovery arrangements with the managers of the Central Valley water system could provide water supply benefits both locally and a broader scale.

VI.2 Meeting Environmental Objectives: Gravelly-Ford/ Madera Ranch

In addition to facilitating the achievement of water supply objectives, groundwater banking can also assist in achieving important eco-system restoration objectives. One particularly exciting opportunity would be the restoration of the anadramous fishery in the San Joaquin River below Friant Dam. This fishery was completely decimated when the U.S. Bureau of Reclamation impounded the San Joaquin River and diverted it for use outside the basin. The hydrologic impact of this manipulation is depicted in Figure 18 which presents measured flows at the USGS *San Joaquin R Bl Friant Ca* gauge. Once the Friant Unit of the Central Valley Project went on-line, base flows in the San Joaquin were drastically reduced, with only peak event spills from Millerton Lake passing downstream. This flow regime proved incapable of supporting spawning and rearing salmon and steelhead. Reversing the loss of this fishery could provide substantial momentum towards meeting the AFRP anadramous fish doubling narrative standard. NHI believes this could be achieved by integrating the substantial groundwater banking opportunity at the Gravelly Ford/Madera Ranch into the surface water system in the San Joaquin Valley.

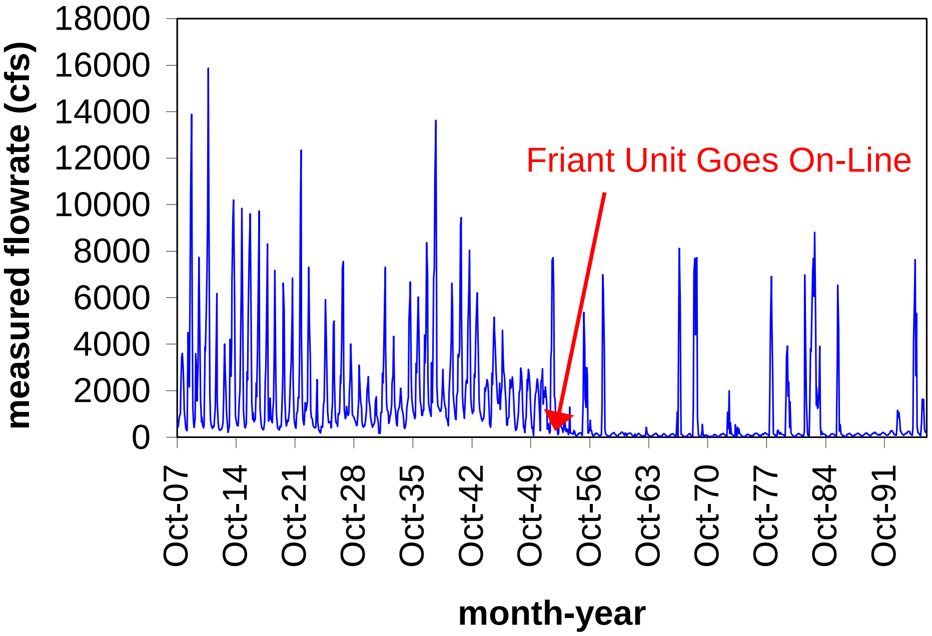

Figure 18: Measured Flows at the USGS *San Joaquin R Bl Friant Ca* Gauge Before and After the Construction of the Friant Unit of the Central Valley Project.

This system, depicted in Figure 19, includes the Delta-Mendota Canal which was constructed at the same time as the Friant Unit to provide roughly 800 TAF of replacement Delta water to exchange contractors holding water rights on the de-watered San Joaquin River. Later, the California Aqueduct system, including the Delta pumps at Clifton Court, the regulating facility San Luis Reservoir, and various pumping plants, was constructed by the State of California to convey water to the southern San Joaquin Valley and then over the Tehachapi Mountains to Southern California. The Cross Valley Canal, financed by Kern County interests, was constructed to capitalize on the water management flexibility which could be achieved through exchanges between the Delta and San Joaquin River systems.

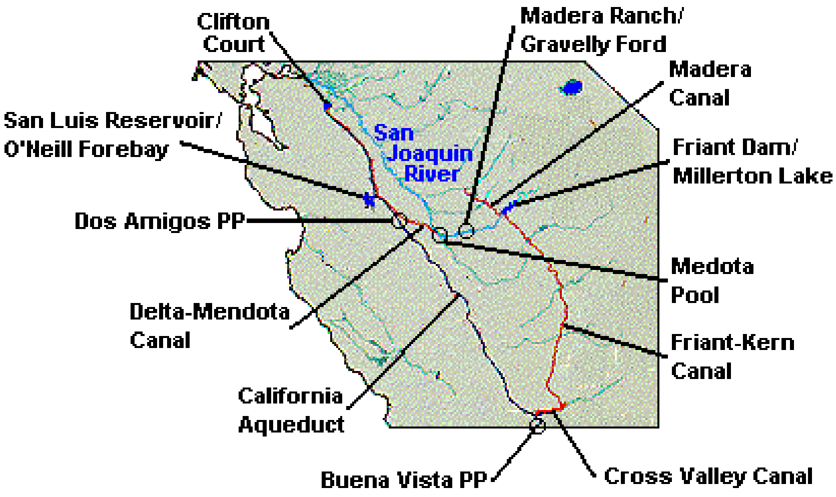

Figure 19: Important Elements of the San Joaquin Valley Water System

It is this type of flexibility which NHI would like to expand upon into order to profit from the substantial groundwater storage potential located below the de-watered Gravelly Ford reach of the San Joaquin. Figure 20 depicts the evolutions of the water table below the Central Valley over the first half of the 20th century based on simulations conducted by the USGS (Willamson et al. 1989). Where once groundwater flowed smoothly towards the valley outlet through the Carquinez Strait, by 1960 this surface was interrupted by numerous depressions related to the long-term imbalance between aquifer recharge and discharge. One of the most substantial depressions, located underneath the San Joaquin River downstream of metropolitan Fresno, developed in response to the elimination of seepage from the overlying San Joaquin River and the steady increase in groundwater pumping in this region. The decline was particularly acute given that the historically high seepage rate afforded by the coarse bed material in the Gravelly Ford reach was virtually eliminated by the closure of Friant Dam.

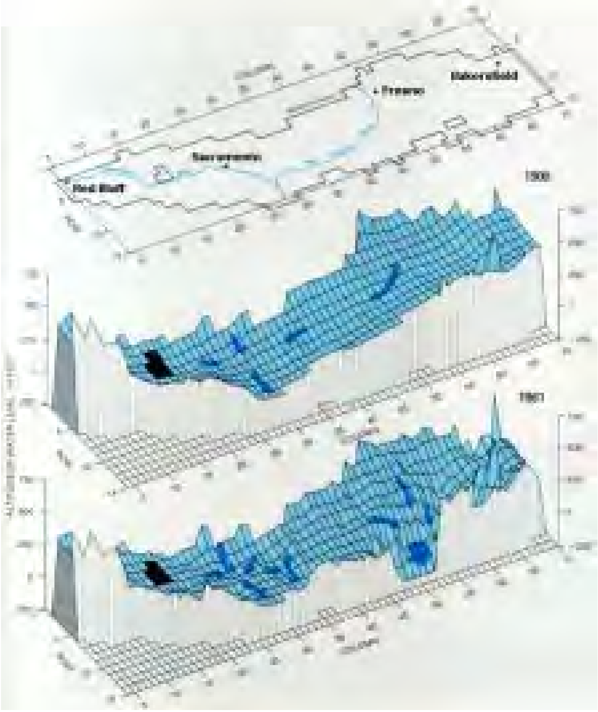

Figure 20: Water Table Evolution Below the Central Valley

There are those who discount any thought of restoring salmon to the San Joaquin precisely because of the heavy seepage losses at Gravelly Ford. They argue that the flows require to overcome these losses and to reconnect the Upper San Joaquin with the tributaries between Mendota Pool and the Delta would cripple the important agricultural economy in the southern San Joaquin Valley which rely the Friant Unit for irrigation water. Viewing the drawdown feature below Gravelly Ford as a groundwater banking site instead of as a hydrologic sink, however, provides the flexibility to restore the San Jaoquin with a minimum of disruption to the agricultural economy. This would be accomplish by re-routing water as depicted in Figure 21.

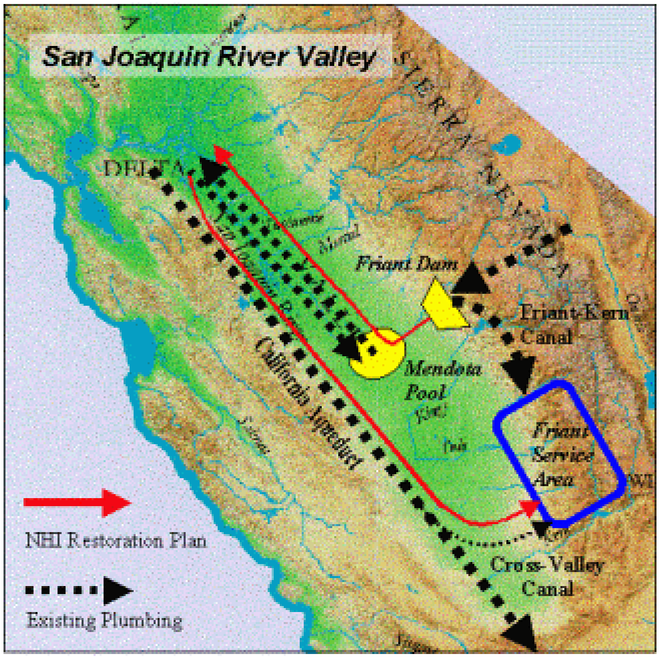

Figure 21: Proposed Arrangement for Restoring a Flow Regime in the San Joaquin River Suitable for Anadramous Fish

The basic premise of the arrangement involves wheeling Delta water currently delivered to the exchange contractors through the Delta-Mendota Canal to the southern Friant Unit via the California Aqueduct and an appropriate cross valley link. Relieving some of the demand for San Joaquin water would allow the exchange contractors to compensate for lost Delta water with releases from Millerton Reservoir. During passage over the Gravelly Ford reach, a portion of these releases would seep through the river bed and become stored in the groundwater banking site. This storage could be reclaimed by the exchange contractors should the surface water system fail to meet their demand.

In order to avoid disrupting the use of the California Aqueduct facilities by its current beneficiaries, an analysis was conducted to determine what excess capacity was available in the system between 1975 and 1996. Using monthly reports of operation for the State Water Project, the minimum capacity available to move historical deliveries from the Delta-Mendota Canal to the California Aqueduct through the O'Neill Pumping Plant and to convey these transfers through the Dos Amigos Pumping Plant was calculated. Figure 22 depicts the time series of the wheeling through the California Aqueduct which could have been accomplished using available capacity alone. This is a conservative trace as future restrictions on Delta exports may limit pumping into the California Aqueduct at Clifton Court while the exchange contractors, by virtue of their superior export right, will likely continue to have access to their 800 TAF annual allotment of Delta water delivered though the Delta-Mendota Canal.

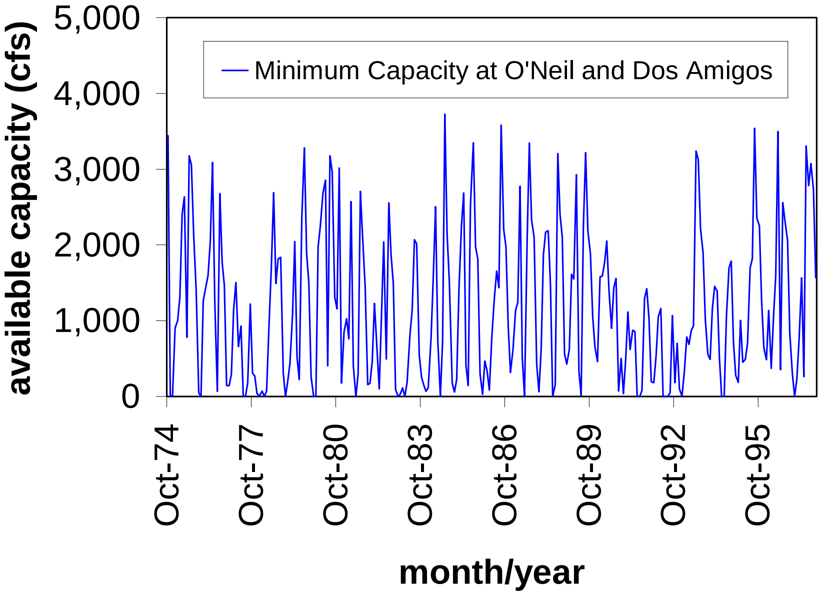

Figure 22: Historical Available Wheeling Capacity in the California Aqueduct System to a Point Below the Dos Amigos Pumping Plant.

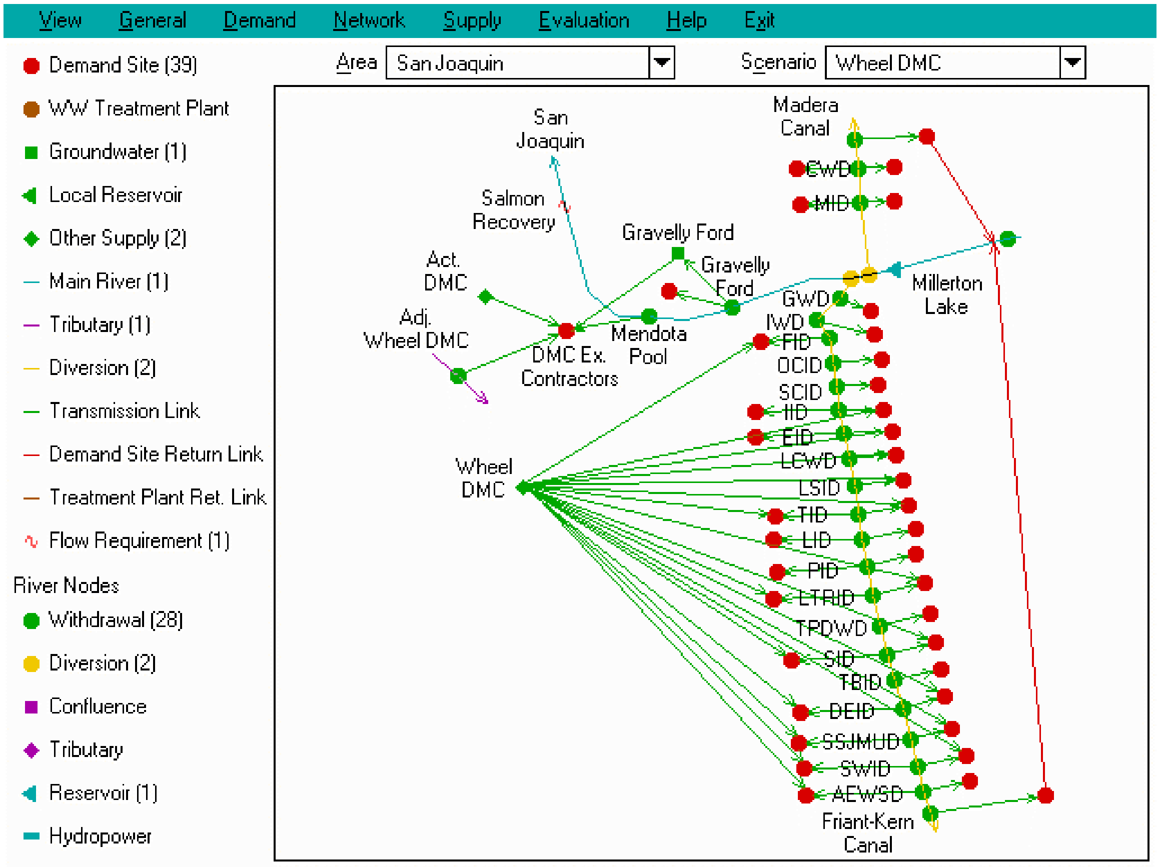
Transfer of this Delta water into the Friant Unit could be accomplished through a variety of means. These could included the expansion of the Cross Valley Canal, the construction of some form of a Mid-Valley Canal, or institutional arrangements which would offer the wheeled water to agricultural interest in the Tulare Basin in exchange for the right to divert some of their Kings River water to the southern Friant Unit. In the context of this feasibility study, how the wheeling would be completed is of less interest then the opportunity which it would create to profit from the groundwater banking opportunity at Gravelly Ford.

The WEAP network configuration for this opportunity is presented in Figure 23. Three scenarios are simulated in this analysis. In a base case, which mimics the current arrangements, the exchange contractors receive water from the Act. DMC supply node while all other transmission links to the node are inactive. Transmission links emanating from the Wheel DMC supply node are also inactive under this scenario, as are those associated with Mendota Pool node and the Gravelly Ford groundwater banking site. In essences the exchange contractors receive their water from the Delta while the irrigation districts serviced by the Friant Unit receive water from Millerton Lake on the San Joaquin. Under a salmon recovery scenario a set of instream flows are imposed below the Mendota Pool. These standards, which were developed based on analysis by Cain (1997), are in keeping with the screening scope of this analysis.

As the analysis of this groundwater banking opportunity evolves these standards will be submitted to prominent fish biologists for review. Anticipating that the imposition of these standards will adversely impact the important agricultural interests in the Friant Unit, a final scenario integrates the Gravelly Ford groundwater banking site into the surface water system. Under these arrangements those transmission links which were inactive during the base case become active, the exchange contractors receive a smaller supply of Delta water though the Adj. Wheel DMC tributary, with the wheeled water being sent into the southern Friant Unit trough the Wheel DMC node. Groundwater is stored in the groundwater banking site both by simulated seepage in the river reach between Gravelly Ford and Mendota Pool and through intentional transfers of water from Millerton Lake to the Gravelly Ford groundwater node through the Gravelly Ford withdraw node.



Area: San Joaquin

Scenario: Wheel DMC

Figure 23: WEAP Gravelly Ford/Madera Ranch Network Configuration

In these simulations, an active salmon recovery standard is met prior to any San Joaquin River water being diverted for consumptive use. The implication of this logic is that the desired eco-system objectives will be achieved under both the salmon recovery and wheeling scenarios. What is most relevant to this analysis is the degree to which groundwater banking can mitigate any impact which existing water users would experience by virtue of losing access to the San Joaquin River water released downstream to meet the standard. Figure 24 depicts the supply requirement coverage for the Class 1 contracts of two representative water districts in the Friant Unit, the Ivanhoe Irrigation District on the Friant-Kern Canal and the Chowchilla Water District on the Madera Canal. The negative economic impacts of imposing standards would apparently be most severe during drought periods. In 1977 for example, the degree to which demand was satisfied under the base case would have been reduced by nearly 14 % because of the reduction in Millerton storage associated with downstream releases. In this simulation however, the Delta-Mendota Canal exchange contractors would have experienced no decline in their level of service as deliveries from the Delta do not change. Under wheeling arrangements on the other hand, Friant Unit districts experience less severe reductions in service relative to the base case, even with the imposition of the salmon recovery instream standard. The exchange contractors also fare well under these arrangements. In the simulation, the critically dry 1977 was difficult for both the exchange contractors, which suffered reduced Delta deliveries without being able to tap into a fully recharged groundwater bank, and the Chowchilla WD which did not have access to the wheeled DMC supply. With access to this Delta water, the Ivanhoe Irrigation District actually benefited from improved service.

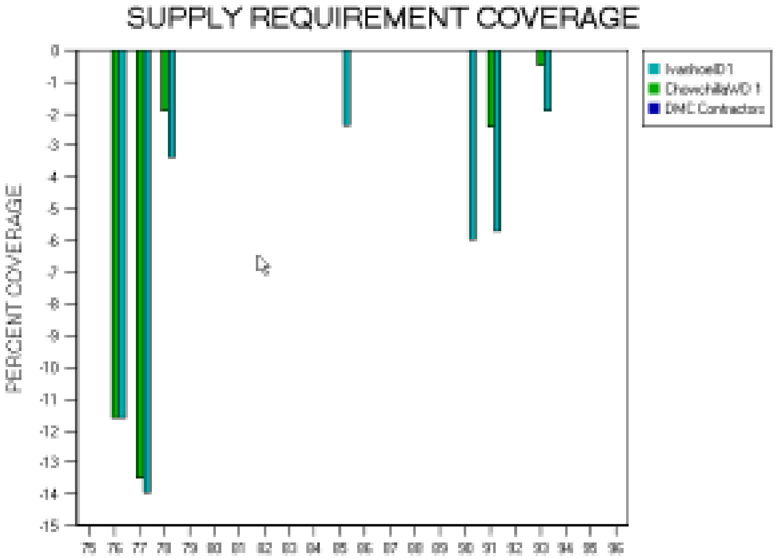


Figure 24: Change in Supply Requirement Coverage Between the Base Case and the Salmon Recovery Scenarios

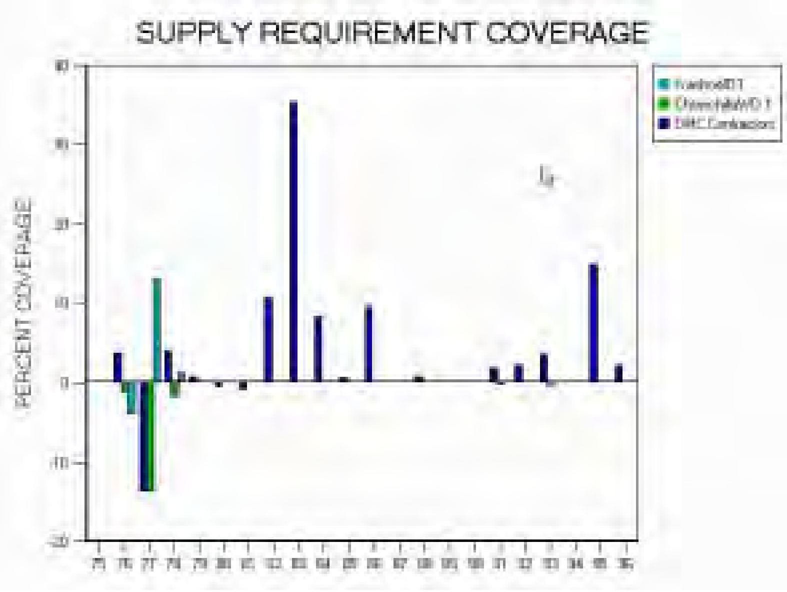

Figure 25: Change in Supply Requirement Coverage Between the Base Case and the Wheeling Scenarios

Figure 25 is a compelling example of how groundwater banking can transform potentially contentious environmental goals such as the restoration of the San Joaquin River into achievable objectives. Although water quality considerations, which could potentially prove problematic, have not been explicitly considered in this analysis, from a purely water supply perspective it appears that the salmon restoration releases can be made without overly taxing existing interests. This can occur because of the extra storage available in Gravelly Ford Groundwater Bank allows for greater flexibility in flood control operations at Millerton Lake which reduce the magnitude of the peak spill events in the San Joaquin River (Figure 26).

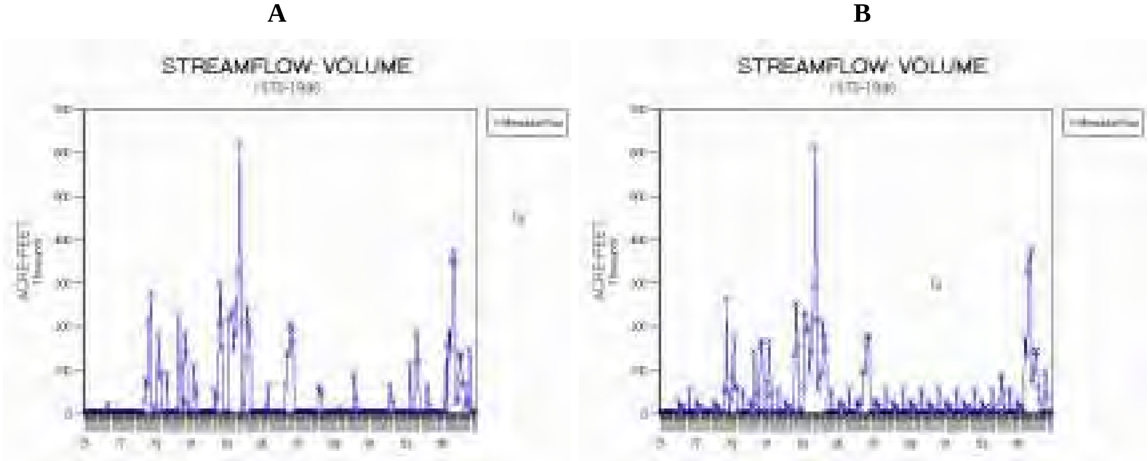

Figure 26: Simulated Streamflow Volumes in the San Joaquin River Below Mendota Pool Under the Base Case and Wheel DMC Sceanrios

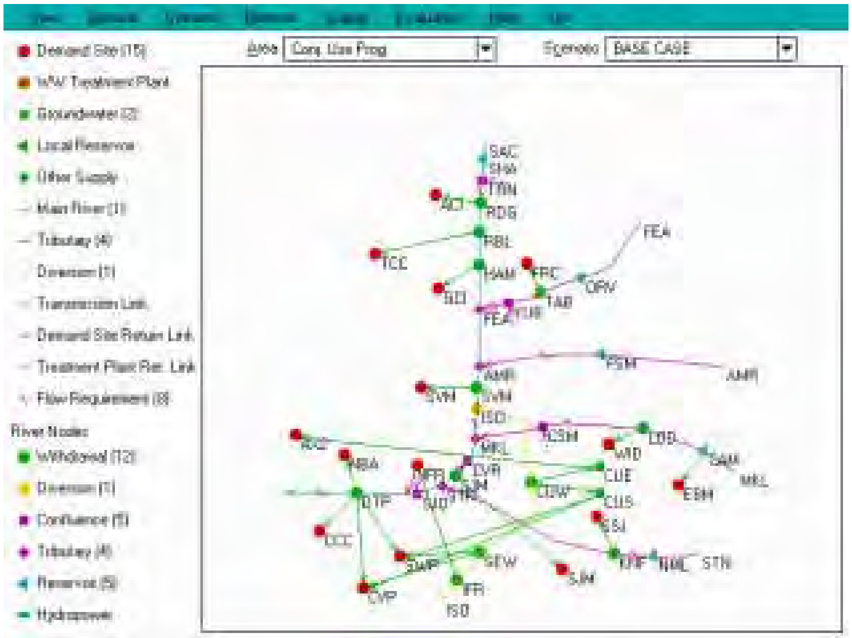
The groundwater banking opportunity in Yolo County was framed as an approach for increasing both local and regional water management opportunities, while the Gravelly Ford opportunity was explored for its environmental restoration potential. By virtue of its strategic location relative to the Delta, the next suite of operational analysis highlights the real opportunity which maximal scale groundwater banking creates to achieve the full range of water supply and environmental benefits.

VI.3 Achieving Broad Benefits: East San Joaquin County

A WEAP network configuration which integrates the east San Joaquin County aquifer into the Central Valley water system is shown in Figure 27. A full a description of each of the features in the network is contained in Table 17.



Area: Conj. Use Prog
Scenario: BASE CASE

	Contra Costa Canal	CCC
	Central Valley Project	CVP
	State Water Project	SWP
Fictitious Demand Node[2]	Isolated Facility Return Flow	IFR
	Additional X2 Water	AX2

Notes

1. An actual demand node refers to one meant to represent an actual off-stream demand site for which data on water consumption has been collected and evaluated
2. A fictitious demand site refers to a feature which has been added to “trick” the program into carrying out a water transfer not explicitly included in the allocation algorithm.

This configuration represents a large-scale view of the northern portion of the Central Valley which encapsulates two management scenarios: a base case and an enhanced Delta conveyance/ groundwater banking alternative. When the 8500 cfs ISO active diversion feature and the groundwater banking nodes are active, unallocated surface water in the Sacramento Valley is pre-delivered to a severely overdrafted groundwater banking site in eastern San Joaquin County. This water can be used to raise the level of the groundwater system during times of abundant water supply and to supplement local and south of Delta demand or enhance Delta outflow during times of shortage. When no unallocated water is available or when the groundwater banking site is full, the active diversion feature can be used to meet south of Delta demand. By shutting off the active diversion labeled ISO, all of the features which branch from the enhanced conveyance system, including the groundwater banking site and the links to the southern export demand sites are deactivated, leaving the system in roughly its current form.

The hydraulic infrastructure currently in place in California developed progressively over the course of the 20th century. By the 1970s, however, the current hydraulic infrastructure in California was largely built out. Therefore the actual flow measurements made at various points around the State during this period already reflect the modifying influence of the fully developed water system. By limiting the simulated time horizon to the period between 1970 and 1992, historical hydrologic data can be used to drive the simulation. The proposed simulated time horizon contains some of the wettest years in the historical record, the 1974 water year for example, and the strongest, 1976-1997, and longest, 1987-1992, recorded droughts in the region. The placement of the protracted drought at the end of the simulated time horizon allows for direct comparison between the current arrangements and the proposed scenario.

The California Water Plan Update (DWR, 1994) estimated that 6.0 MAF of aquifer storage capacity exists in San Joaquin County. Rather than except this extremely optimistic assessment, whose derivation is not fully explained, our analysis adopted a very conservative view on the actual storage potential present in the field. A realistic available capacity of 600 TAF was derived following close evaluation of the drawdown feature shown in Figure 28, and was allocated equally to water supply and environmental restoration storage.

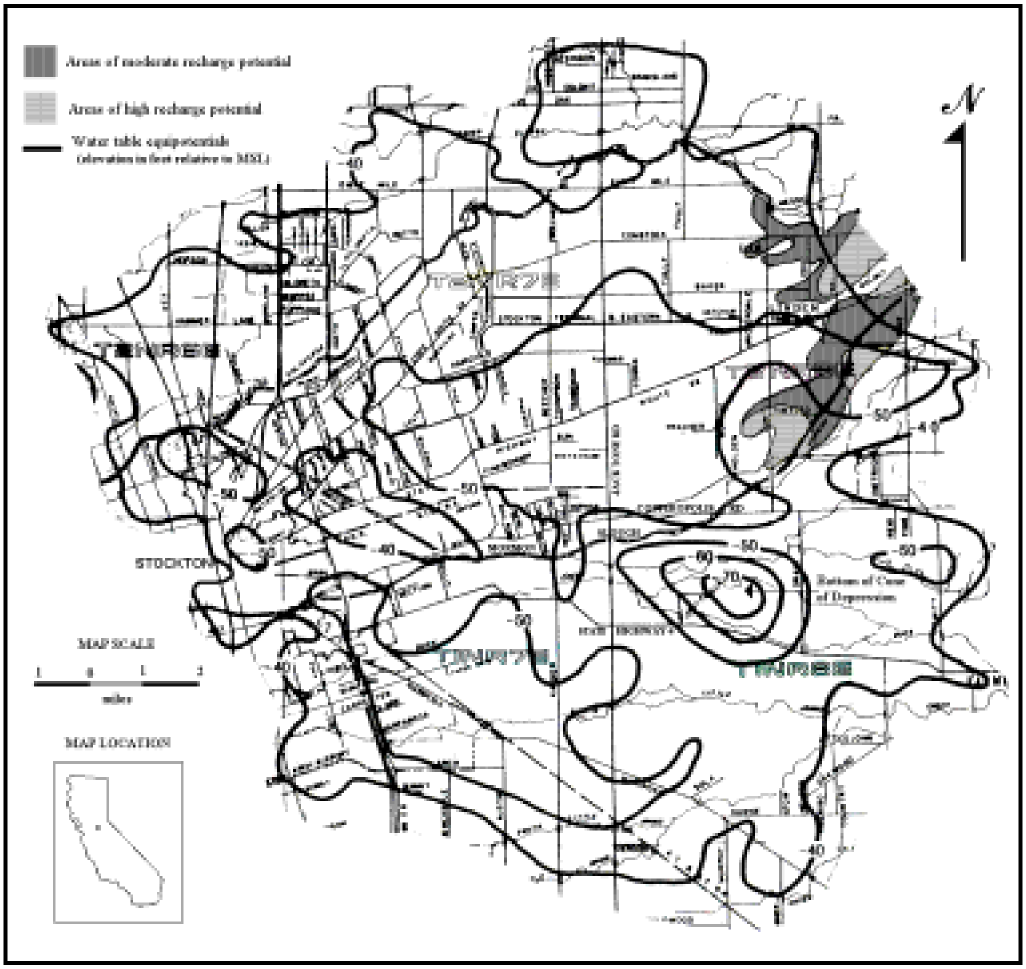

Figure 28: Spring 1995 Water Table Elevation Map East of Stockton, California

One basic result of the simulation has to do with the degree to which the enhanced Delta conveyance/ groundwater banking alternative improves the ability to deliver water to points of demand which can be supplemented by tapping storage in the groundwater bank. These include the SWP and CVP actual demand sites which access water supply storage and the Additional X2 demand which accesses environmental storage. The water supply benefit is seen clearly in Figures 29 and 30 which depict the temporal pattern of deliveries to the SWP and CVP nodes respectively. Under the proposed alternative, during 1977, surface water deliveries through the Delta pumps under the Base Case are largely replace by surface deliveries through the Isolated Facility with supplemental water being drawn from aquifer storage to help make up the simulated shortfall (Figures 29B and 30B). During 1988, the decrease in surface storage means that little or not deliveries of surface water take place under the proposed alternative, either through the Delta pumps of the Isolated Facility. In the extreme case, July 1988, the only water going to meet supply is from aquifer storage (Figures 29C and 30C). It seems likely that the generally poorer performance of the CVP relative to the SWP is related to the smaller amount of transmission capacity dedicated to the Federal project in the Isolated Facility and in the links issuing from the aquifer storage site. The results would have been different had the percent participation of the State and Federal projects been reversed. Adjusting the distribution of capacity is the type of screening exercise to which WEAP is ideally suited.

Figure 31A depicts the total Delta outflow in the Base Case and under the enhanced Delta conveyance/ groundwater banking alternative. Under the proposed alternative Delta outflow is the sum of the simulated flow at the bottom of the river system and the transfer from aquifer storage to the Additional X2 node. The curves reveal that in extremely wet years, outflow in is higher in the Base Case, presumably because some of the excess water is being transferred to aquifer storage. In the driest years, on the other hand, the proposed alternative offers a small supplement over and above the minimum standards which have been imposed. This is a logical result. It also seems reasonable that the Export:Import regime in the Delta improved under the proposed scenario (Figure 31B). In dry years water is delivered for southern export primarily through the Isolated Facility prior to entering the Delta. In this case the ratio of southern export to Delta inflows drops to nearly zero.

On balance, the results of this simulation reinforce the notion that the proposed alternative could improve the performance of the Central Valley water system. What is particularly attractive about this specific opportunity is how it could help both local and regional water managers to respond to both water supply and environmental challenges. Located as it is at the nexus of the Central Valley water system, the east San Joaquin County groundwater banking site offers flexibility which may be unparalleled in California. The staggering effects of the dewatered local aquifer also provide enormous potential for collateral local benefit in terms of reducing energy expenditures for pumping and protecting the water quality of one of the States important metropolitan centers. All of the actors, both locally and regionally, should be assembled to further investigate how this potential benefit of this site could be realized.

VI.4 Concluding Thoughts

The three preceding examples of operational analysis clearly demonstrate the array of issues which must be addressed in working out the operational details of a specific groundwater banking opportunity, and the enormous benefit which can be gained in so doing. These examples also demonstrate the utility of the WEAP model for exploring the site specific nuances of these opportunities. Developing WEAP network configurations for the other potential sites will be a major focus of future work on this project. These models will allow for an exploration, in concert with all interested actors, of the implications of site specific management decisions. NHI is convinced that this dialogue will allow the most promising sites to emerge from the pack, so to speak, so that further requisite analysis using DRWSim and other suitable tools can proceed apace.

VII. Workplan Step 5: Economic Analysis

The economics of groundwater banking are often difficult to estimate and highly dependent on the specific characteristics of a given project. Recharge and extraction costs vary depending on aquifer characteristics and the nature of existing facilities. Greater uncertainties arise from the potential for unanticipated costs due to third party or environmental impacts. These can arise both in the source and recharge areas. Benefits are also variable. They range from the easily quantified savings associated with lower pumping lifts to the less easily quantified benefits associated with the insurance value of secure supplies. As with costs, many of these benefits depend on site characteristics.

VII.1 Direct Costs

Recharge and extraction costs in current projects range from a low roughly $20 to over $300 per acre-foot (Appendix V). Typical cost ranges for new projects estimated in the context of the CVPIA are $90-120/acre-foot at the source (USDOI, USBR et al. 1995). These costs do not, however, include any charges for the water being supplied. Districts in MWD's service area would, for example, need to pay its charges for replenishment water on top of their actual costs for recharge and extraction. Where in-lieu methods of recharge are possible using existing facilities, recharge costs can be extremely low. On the Conway ranch in Yolo County and in parts of Kern county they can be as little as $5/acre-foot.[36]

The direct costs indicated above and in Appendix V may, however, be misleading for conjunctive management activities in the future. As MWD notes in its recent IRP document: "A significant problem with groundwater conjunctive use storage is getting the water into the basin." (MWD 1996). This constraint is noted as a significant justification for their major Eastside Reservoir Project which could be used to temporarily store water during periods when existing recharge facilities are operating at capacity. The cost of this facility is estimated to be $1.9 billion.

VII.2 Benefits

Previous analyses of groundwater banking economics have focused primarily on the value of groundwater management activities within a limited agricultural area (e.g. Knapp and Olson 1995). Groundwater banking is modeled not as a way of creating "new" water supplies that would be available for any use, but more as a way of changing the cost structure of supplying a given amount of water to existing -- generally agricultural -- uses. As a result, the benefits are determined primarily by changes in the pumping costs versus management investments to supply that water. In contrast, this paper views the economics of groundwater banking from the perspective of storage creation. Groundwater banking use is a way of increasing the reliability of existing supplies and capturing new supplies that would otherwise be unavailable to the system as a whole through the creation of groundwater reservoir storage facilities. The economics of groundwater banking must therefore be analyzed in the same manner as surface storage reservoirs or other mechanisms for generating new or more reliable yield within an existing system.

While a full economic analysis of the benefits from groundwater banking is beyond the scope of this paper, it is important to note that the benefits associated with groundwater banking are not fully captured by analysis of new yield options on a least-cost of average annual supply basis. Three factors seem particularly important to note: (1) the stabilizing role of groundwater supplies; (2) the insurance value associated with ability to pre-deliver supplies; and (3) relative insensitivity of groundwater banking projects to changes in key economic assumptions.

In any situation where surface water supplies are variable, the presence of groundwater resources that can be tapped "as needed" for municipal, agricultural or other uses carries a stabilization value beyond that associated with increases in water supply alone. In an analysis of wheat cropping in the Negev desert,

---

[36] DWR, 1994, SWP Conjunctive Use--Eastern Yolo County; Kern County CA. April 1995. 1995 KFE Property Recharge Program.

Tsur estimated the stabilization value of groundwater development as "more than twice the benefit due to the increase in water supply."(Tsur 1990). In Southern California where surface water supplies are less variable than the Negev, the stabilization value in agriculture is, in some cases, as much as 50% of the total value of groundwater (Tsur 1993). Crop yield responses are often dependent on the timing of water application as well as the volumes delivered. Since water stored in a groundwater banking site and dedicated for agricultural use will often be close to the point of end-use (e.g. on overlying lands), users will be far more able to fine tune extraction to meet their needs than they would be if they depended primarily on supplies stored in distant reservoirs. Groundwater banking operations will, thus, enhance the ability of groundwater resources to play a stabilization role. Furthermore, developing groundwater banking operations in areas currently dependent primarily on surface water would give those areas direct access to new "stabilization" benefits. In an analysis of groundwater banking in the South Platte system in Colorado, Bredehoeft and Young found that *installing sufficient groundwater pumping capacity to provide water to all areas irrigated by surface supplies made economic sense*. Doing this maximized expected net benefits and minimize annual income variation (Bredehoeft and Young 1983). As Tsur notes, ignoring the stabilization value of groundwater in economic comparisons with surface supplies, can seriously bias policy making based on cost-benefit considerations (Tsur 1993).

Municipal users also place a premium on supply stability. A recent contingent valuation survey found that: "on average California residents are willing to pay $12 to $17 more per month per household on their water bills to avoid the kinds of water shortages which they or their regional neighbors have incurred in recent memory. The statewide magnitude of such additional consumer payments would be well over $1 billion per year." (Barakat & Chamberlin 1994). The lower figure represents a 20% shortage every 30 years while the higher applies to a 50% shortage every 20 years. Residents are also willing to pay between $11.67/month and $12.14/month to avoid shortages of 10% occurring with a frequency of 10 and 3 years respectively.

Insurance values associated with groundwater banking are closely related to stabilization. The distinction between stabilizing natural fluctuations in water availability and insurance against major disruptions is important. Elements of California's surface water supply system are highly vulnerable to earthquakes. Other sudden events -- for example, major pollution spills -- could also disrupt water supplies over short to medium term periods. The economic costs of these disruptions could be major for any of the industrial, agricultural, municipal or environmental users. Groundwater banking operations, by pre-delivering water to locations nearer to points of end-use and storing it in underground reservoirs that are relatively invulnerable to sudden disruption, will provide major insurance benefits.

Another economic benefit of conjunctive use in comparison to most water supply projects is relative insensitivity to discount rate and other development cost assumptions. Unlike surface supply, most conjunctive use projects can be completed rapidly or brought on-line sequentially as components are completed. They often do not have the long gestation periods and high up-front capital costs associated, for example, with the construction of a new reservoir. Furthermore, the benefits associated with individual components, such as spreading basins, can be realized even if a system is only partially completed. They do not depend on completion of an entire system. As a result, the economic viability of conjunctive use does not depend to the same degree as large surface projects on accurate projections of economic and other parameters (such as population growth) into the future. This benefit will, of course, only be true to the extent that groundwater banking projects are not dependent on the construction of major new surface facilities.

The stabilization and insurance values of water stored underground and the relative insensitivity to economic assumptions of conjunctive use projects are not captured in least-cost comparisons of yield generated. Estimating these and incorporating them into the economic evaluation will be important to evaluate the true costs and benefits of conjunctive use.

Appendix I: Limnological Context for Reservoir Stratification

In a barotropic water body, the fluid density remains invariant with depth. This is somewhat of a hypothetical state which would be difficult to establish and maintain in a natural system. Many factors leading to the establishment of vertical density gradients, so called baroclinic conditions, act upon lakes in nature. In the context of a maximal groundwater banking program, the most important is the input of solar radiation at the water surface. Workplan Step I describes how reservoir re-operation would increase yield in the Central Valley water system via the transfer of surface water to aquifer storage in advance of winter storms. In the event of a wet winter, the excess reservoir capacity would be used to retain runoff normally released as part of flood control operations. A dry winter, on the other hand, might leave the reservoirs drawn down to a point where the input of solar radiation might subsequently make it difficult to maintain downstream temperature regimes suitable for aquatic resources, primarily anadromous fish.

As solar radiation penetrates into a lake or reservoir, it is absorbed at an exponential rate. Figure AI.1 shows how far into a body of distilled water two different wavelengths of visible light penetrate.

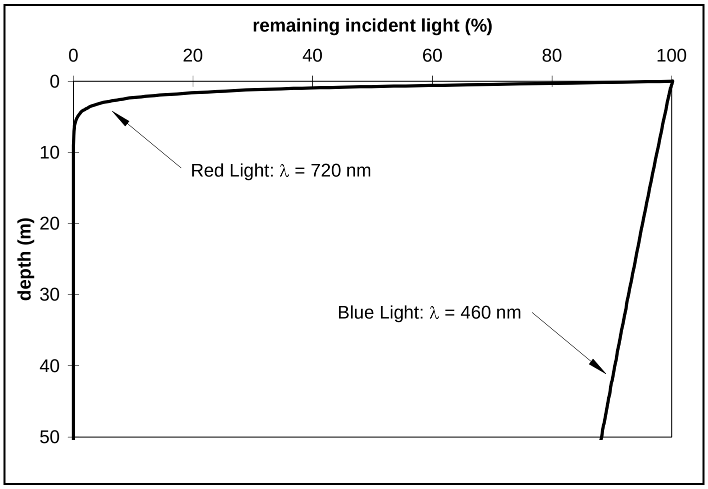

Figure AI.1: Light Penetration into Distilled Water for Red and Blue Regions of the Visible Light Spectrum
(source: Cole 1983)

According to these curves, by a depth of 5m, all but 1% percent of the incident red light (λ=720 nm) has is absorbed by the water and converted to thermal energy. A similar pattern exists for infrared radiation which lies just outside of the visible portion of the spectrum. Shorter wavelength blue light (λ=460 nm), on the other hand, remains relatively unabsorbed even at depth of 50 m. Since it is the red/infrared wavelengths which convert much of their energy to heat when absorbed, the most intense warming takes place in top several meters of the water column.

If the input of solar radiation occurred in an initially isothermal lake, the resulting temperature profile would resemble the red/infrared penetration profile (Figure AI.2A). Under these conditions additional inputs of radiation would generate downward heat flow driven by temperature gradients. In addition to this driving force, however, the lake is exposed to winds passing over its surface. This wind serves to mix the water near the surface of the lake distributing the heat more evenly within the zone of mixing (Figure AI.2B). The end result is a layer of warmer, less dense water which overlies colder heavier water below. Additional inputs of solar energy and further wind-driven mixing will continue to warm the surface layer making it increasing less dense relative to the cold layer below. The lake has become *stratified*, a common occurrence during the summer months in deep lakes located in temperate regions.

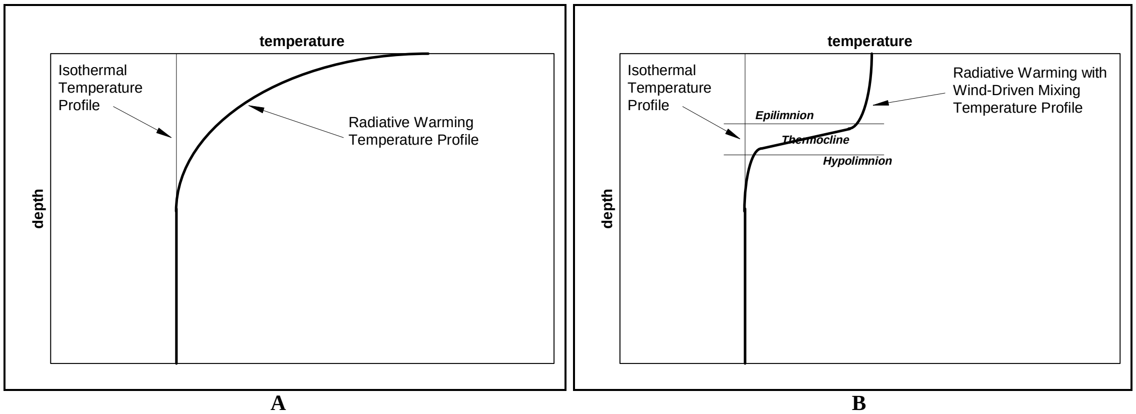

Figure AI.2: Hypothetical Vertical Temperature Profiles Assuming A: Simple Radiative Warming; and B: Combined Radiative Warming and Wind-Driven Mixing
(source: Laska 1981)

The thickness of the upper layer, or the *epilimnion*, is a function of the physio-chemical properties of the water in the lake and the dynamic interaction between the temporal pattern of incoming solar radiation and the local wind regime. It should be pointed out that the same amount of thermal energy can lead to the conditions shown in Figures AI.2A and AI.2B. If so, the integral of temperature with depth must be the same for both profiles. As the uniformly cold regions of each curve, referred to as the *hypolimnion* of the lake, are identical, the only way to preserve this equality is for a region of rapid temperature drop, or a *thermocline*, to become established between the two layers. The sharp temperature, and hence density, contrast means that in a *stratified* lake the epilimnion and the hypolimnion essentially act as separate bodies of fluid until sufficient work can be done on the system to remix them.

Actual temperature profiles taken at Lake Shasta during the month of September, Figure AI.3, reveal that stratified conditions do develop in the reservoir. Stratification seems to be most pronounced in years where the lake stage was relatively low in the late summer, as in 1961, 1964, and 1968. Data also suggest that the thermocline deteriorates with the advancing autumn. Figures AI.4A and AI.4B depict the evolution of the 1968 temperature profile in Shasta and Whiskeytown Lakes between September and November. Presumably the acceleration of radiative cooling and the inflow of cooler water with the onset of winter storms are responsible for the general cooling down of these lakes late in the fall.

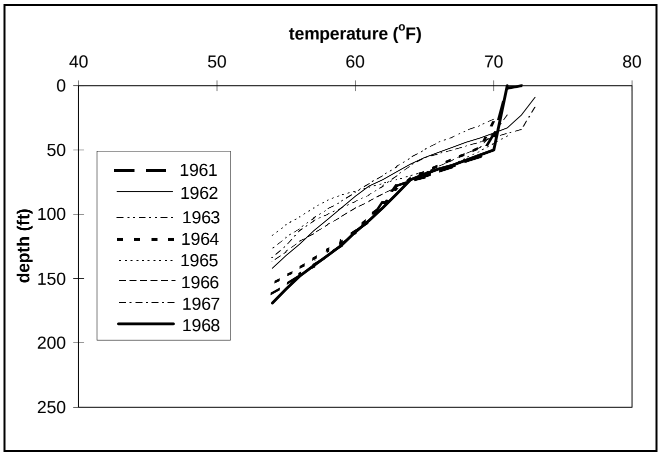

Figure AI.3: September Temperature Profiles in Lake Shasta
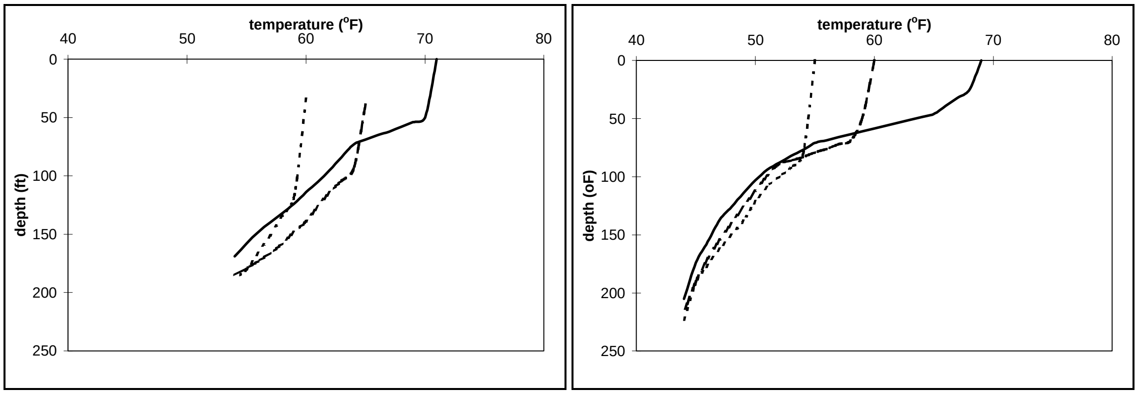
(bold curves represent years of low reservoir stage)
(source: Weidlein 1971)



A **B**

Figure AI.4: Evolution of Autumn, 1968 Water Temperature Profiles in A; Lake Shasta; and B: Wiskeytown Lake
(September: solid line; October: long dashed line; November: short dashed line)
(source: Weidlein 1971)

One conclusion which can be drawn from Figures AI.3 and AI.4 is that water temperatures in the epilimnion of these reservoirs are substantially higher than the 56^{o}F recommended in the AFRP for the protection and restoration of anadromous fish in the Sacramento River, particularly in September. This has profound implication for the operation of reservoirs as part of the proposed groundwater banking program. To insure that only cold water from the hypolimnion will flow into the river downstream, reservoir releases must be made from depths below the thermocline. Unfortunately, under the worst case scenario of a critically dry winter following the ambitious pre-delivery of water to aquifer storage, the thermocline may be dangerously close to the level of the reservoir release works. In this case the flow hydraulics in the vicinity of the intake may lead to the release of warm water from the epilimnion. Of particular concern in this context are internal waves in the body of the reservoir, or *seiches*, which can cause the thermocline to oscillate and may, under drawn down conditions, result in periods of time when cold water is completely absent from the vicinity of the reservoir release works. The equations governing this phenomenon are presented in the following Appendix.

Appendix II: The Initiation and Magnitude of *Seiche* Oscillations

AII.1 Wind Driven Set-Up

As the wind passes over a reach of open water it imposes a shear stress proportional to the square of the wind speed and the density of the atmosphere. This relationship is defined as:

$$\tau_S = C\rho_a W^2 \qquad \text{(AII.1)}$$

where τ_S is the shear stress; ρ_a is the density of the atmosphere immediately above the lake surface; W is the wind speed and C is an empirical parameter known as the drag coefficient. The imposition of this shear stress acts to pile up the lake surface at the offshore end thereby generating a head gradient along a line parallel to the wind direction. Theory holds that at steady state this head gradient is balanced by the opposing shear stresses acting on the lake surface and along the lake bottom.

$$\tau_S - \tau_B = \rho g i H \qquad \text{(AII.2)}$$

where τ_B is the shear stress acting along the bottom of the lake; g is gravitational acceleration; i is the angle of denivelation of the lake surface; and H is the static depth of the lake. When lake currents are turbulent, the shear stress at the surface is generally considered to be significantly larger than those acting on the lake bottom so that the ϑ_B parameter can be ignored.

Making this assumption, one can equate equations AII.1 and AII.2 and solve for the angle of denivelation under a given wind regime:

$$i = C\frac{\rho_a}{\rho}\frac{W^2}{gH} \qquad \text{(AII.3)}$$

When combined with a parameter describing the length of the lake, equation AII.3 can be used to determine the magnitude of the wind driven set-up:

$$\zeta' = \frac{iL}{2} \qquad \text{(AII.4)}$$

where ζ' is the set-up, or lake surface displacement, at the off-shore end; and L is the length of the lake. During this investigation, to solve equation AII.4, the drag coefficient was set equal to $2.3\text{x}10^{-3}$ and the density of the atmosphere to $1.25\text{x}10^{-3}$ gm/cm^3.

AII.2 *Seiche* Oscillation

Stratified lakes are not static features in which a warm layer rest motionless upon a static pool of cold water. It has long been recognized that the interface between the two bodies of water in stratified lakes, the thermocline, oscillates (Wedderburn, 1909). This oscillation is often uninodal around some central point in the lake with the end effect being that when the thermocline is elevated relative to it static level at one end of the lake, it is depressed at the other.

When a dry rainy season follows pre-delivery to aquifer storage, there is an increased risk that these oscillations, or *seiches*, will periodically place warm water in close proximity to the reservoir release works thereby displacing the cold water which would have been present under static conditions. This displacement could compromise the ability to maintain suitable temperature regimes downstream. Obviously *seiches* are complex hydrodynamic features whose properties depend on multiple variables. Nonetheless, by making some simple assumptions about the system, it is possible to develop some rules of thumb about the amplitude of these oscillations which might guide the establishment of suitable reservoir carryover storage parameters for the Central Valley reservoirs.

Consider a lake of length L and width W, where L>>W. Assume the lake is stratified into an upper warm layer of thickness h' and density ρ' and a lower cold layer of thickness h and density ρ. Once oscillation is initiated, the divergence of the lake surface and the thermocline from their static levels are represented by ζ' (the wind driven set-up in equation AII.4) and ζ respectively. As the lake is much longer than it is wide, one can assume that the oscillation is largely confined to the long, or x axis, of the lake. Manipulation of the equations of continuity and momentum for this simplified system lead to the following definition of the amplitude of the internal oscillation:

$$\zeta = -\zeta' \frac{\rho}{\rho - \rho'}\left(1 + \frac{h'}{h}\right) \qquad \text{(AII.5)}$$

Equation AII.5 suggests the following interactions between the displacement of the water surface and the displacement of the thermocline at depth:

- For a given water surface displacement, ζ', and for a given set of static eplimnoin and hypolimnion thickness values, h' and h, the internal displacement of the thermocline is inversely proportional to the density contrast between the warm and cold water pools; and
- For a given water surface displacement, ζ', and for a given density contrast between the warm and cold water pools, the internal displacement of the thermocline is proportional to the relative thickness of the epilimnion.

The combined effect of these interactions is that in stratified lakes a set-up on the order of centimeters can generate *seiche* displacements on the order of meters.

AII.3 Juxtaposition of Warm Water and Reservoir Release Works

Using the data presented in the previous sections, it is possible to approximate the magnitude of the wind driven set-up in each of the major foothill reservoirs (equation A.II.4) and the maximum displacement of warm water in the epilimnion below the static thermocline elevation during seiche-like oscillations (equation A.II.5). Having estimated the potential magnitude of displacement, the difference between the minimum elevation of the warm water in the reservoir and the elevation of the intake to the reservoir release works can be established for a given reservoir storage condition according to:

$$HT = \left(E_{surf} - D_{thermo} - \zeta\right) - E_{releases} \qquad \text{(AII.6)}$$

where: HT is the minimum hypolimnion thickness lying above the release works; E_{surf} is the lake surface elevation associate with the assumed reservoir storage level; D_{thermo} is the observed depth of the thermocline below the lake surface; and $E_{release}$ is the elevation of the release works.

Appendix III: Survey of District Recharge Activities

District	Storage Potentially Available	Current annual operating potential	Average current recharge volume
Arcade WD[37]			17,960 AF
Yuba Co. WA[38]	1,710,000		
DWR - M&T Chico Ranch[39]			12,000 AF
Western Canal Water District[40]	4,000,000 AF - total groundwater basin storage		
DWR - American Basin[41]			
DWR - Eastern Yolo County[42]			19,000 AF[43]
Alameda County WD[44]	20-32,000 AF		28,900 AF
Alameda Co. Flood Control District #7[45]	250,000 AF		10,000 AF
East Bay MUD[46]	600,000-700,000 AF	200,000 AF[47]	feasibility stage
Santa Clara Valley WD[48]		400,000 AF[49]	150,000 - 210,000 AF max Average year 100,000
Stockton-East WD[50]			5,800 AF
Chowchilla WD[51]	75,000 AF		30,000 AF

---

[37] CH2MHILL prepared for Arcade Water District. November 1993. Groundwater Recharge Project Feasibility Report. Arcade WD is in the process of implementing a combination injection and in-lieu recharge program. Figures were calculated using Arcade's recommended project which injects 9896 AF/yr and purchases 7.2 mgd of surface water from the City of Sacramento and delivered as in-lieu recharge. 7.2 mgd * 365 = 2,628 g/year. 2,628 g/year = 8,064 AF/yr in-lieu (1 AF = 325,900 g). 9,896 injection + 8,064 in-lieu = 17,960 AF/yr. This program, however, has not yet been implemented.

[38] Yuba County WA. September 1992. Ground Water Resources and Management in Yuba County. Figure is total storage capacity, it would not be feasible to include this amount of water in a conjunctive use program. Calaculated within the Yuba Co. groundwater study area which includes 49,800 acres in Yuba-North subarea and 88,700 acres in Yuba-South subarea to a depth of 200 feet.

Appendix IV: Environmental Risks

AVI.1 Risks in Changing Surface Operations

One approach to increasing system yield analyzed in this paper involves transferring water from surface storage to underground storage in advance of periods when precipitation can be anticipated. This mode of operation may lead to two kinds of negative impacts. First, since the surface reservoirs will, in general have greater empty space going into the winter, pulse flows that would normally pass through the reservoir will now be captured. This may have negative consequences downstream. Second, if reservoir levels are lowered before the winter the winter is dry, it may be more difficult to maintain instream flows and temperature control below the dam .

The environmental benefits of pulse flows is a high priority topic for additional work. Benefits may be derived from the effect of the water in transporting organisms downstream. Perhaps more important, occasional high flows are important for maintaining the natural morphology in downstream streambeds. Central Valley rivers are already highly regulated, though very high flow peaks still cannot be captured by storage. The use of groundwater storage to enhance yield would continue the historical reduction in pulse flows. The working hypothesis is that the benefits of enhanced environmental flows during critical seasons and dry years outweighs this negative effect, but more work is needed to determine whether this assumption is warranted.

As previously noted, many in-stream environmental uses depend on water temperature. Anadromous fish migration and spawning is affected by stream temperatures. Major streams such as the Sacramento and Mokelumne have temperature standards. Supplying water at these temperatures depends on maintaining thermal stratification in water supply reservoirs. Temperatures in upper levels increase during the summer but water at lower levels maintains stable temperatures and can be used to meet instream flow needs. If buffer storage levels are drawn down too far, water in the reservoirs will turn over and thermal stratification will be lost.

Risks of losing thermal stratification may increase with groundwater banking operations. Since conjunctive management necessitates partial evacuation of reservoirs in advance of precipitation, storage will inevitably be lower if the anticipated precipitation does not occur. As previously noted, California has historically faced drought periods extending for six or more years. The adequacy of groundwater banking to maintain sufficient surface storage will be most critical when this happens. Anadromous fish species have a migration cycle that spans a number of years. If spawning and other conditions are sub-optimal for individual years, overall population impacts may be minor. If sub-optimal conditions extend over consecutive years, net impacts will be substantially greater.

With groundwater banking, reservoir storage levels going into droughts will be lower than they would be under current operating procedures. Risks to in-stream flows and temperatures during this type of event depend critically on how rapidly the likelihood of a long-term deficit can be identified and how completely non-environmental users can be shifted to banked groundwater. If non-environmental demands on surface supplies can be reduced greatly before surface storage reaches critical levels, conjunctive management may increase the ability to maintain temperature stratification and surface supplies for in-stream uses. On the other hand, if operating mechanisms do not allow adequate shifts of high priority non-environmental demands from surface storage, if warning systems are insufficient to identify the probability of long-term deficits or if aggressive operating procedures result in inadequate surface reserves, temperature and in-stream flow impacts could be substantial. Current instream flow standards are often set just below dams. It is likely to be physically impossible (or at least economically impossible) to shift water from aquifer storage sites to these locations if buffer supplies prove inadequate. If buffer storage is too low, additional supplies could, potentially, be purchased from utility or district reservoirs upstream. How this might work, what it would cost and the availability of water for purchase during long-term droughts have yet to be investigated.

Beyond the environmental costs associated with conjunctive management, it is important to note that realizing many of the environmental benefits depends very heavily on operations procedures and hydraulic system configuration. The ability to shift non-environmental users onto groundwater during drought years depends on their location in relation to groundwater basins having appropriate storage characteristics. Banked water often cannot be directly applied to meet in-stream environmental needs. Aquifers are often located substantially downstream from critical environmental needs – such as spawning sites. In addition, groundwater is often warmer than water in surface streams. Since many habitat characteristics are temperature dependent, this can greatly affect the usability of banked groundwater for environmental purposes. As a result, generation of environmental benefits may depend critically on the degree to which banked water can be used to displace non-environmental demands on surface water supplies, particularly during intense drought periods. Similarly, the ability to create wetland habitat benefits depends on the match between the timing of water availability for recharge in relation to waterfowl wetland needs.[109] Overall, the environmental benefits of conjunctive management could be major – but the devil lies in specific details.

AIV.2 Recharge and Extraction Associated Risks

There is an array of potential environmental risks associated with the extraction and recharge component of any conjunctive management operation. In a broad sense these can be divided into two categories: (1) those associated with basin hydrology such as the potential for subsidence or interaction with surface stream flows; and (2) those related to water quality and pollution considerations. The first class of risks heavily depends on the degree to which the regional hydrology is accurately understood and the magnitude of flows related to storage and extraction in comparison to other flows. The second class may depend more on recharge and extraction mechanisms and agricultural chemical use patterns.

AIV.2.1 Hydrologic Uncertainty

The degree to which basin hydrologic characteristics are understood is a major factor influencing the risk of unanticipated environmental impacts. In addition, the accuracy with which the regional hydrology is understood greatly influences the degree of assurance the program has regarding ability to store and extract water in the amounts anticipated – and, thus, the overall benefits of conjunctive management.

Information on basin hydrology in the Sacramento-San Joaquin systems varies greatly depending on location. In general, the hydrology of the adjudicated basins in southern California has been quantified to a much greater degree than basins further north. This reflects the much longer history of water shortage and attempts to address it in the south compared to the north.

Characterization of the aquifer system underlying the Sacramento-San Joaquin has changed significantly over time. Early reports viewed the Sacramento basin essentially as a single unconfined aquifer and the San Joaquin essentially a two or multi-layered system in which confined and unconfined aquifers were separated by the dense and regionally extensive Corcoran Clay, or e-clay, member of the Tulare formation (Bertoldi, Johnston et al. 1991). More recently, the intensive Regional Aquifer System Analysis (RASA) study undertaken by the USGS has changed that image fundamentally. This detailed modeling effort characterized both the Sacramento and San Joaquin systems as essentially a single aquifer with multiple, discontinuous layers of low permeability clays creating semi-confined conditions in many locations (Bertoldi, Johnston et al. 1991). Study authors viewed flow within the system as linked throughout with substantial changes due to development. In some areas, vertical permeability of confining layers such as the Corcoran Clay has been reduced by 1.5 to 6 times (Bertoldi, Johnston et al. 1991, p. A26). Overall vertical flow has, however, increased by roughly an order of magnitude from conditions prior to development up to the 1970s. This was caused by leakage through wells with long perforated

---

[109]. It would, for example, be important to evacuate reservoirs in the fall in advance of major precipitation periods in order to increase capture. Much of the recharge might, for this reason, need to be done in the late fall and early winter. Wetland habitat needs may, however, be particularly important in the spring and early summer.

sections (Bertoldi, Johnston et al. 1991). Most recently, work by the California DWR suggests that much of the Sacramento Valley might best be conceived as a two layer aquifer system in which extraction from or recharge to lower layers is essentially isolated from river flows.[110]

The above uncertainties have potentially great implications for conjunctive use activities. First, in parts of the Central Valley, the hydrologic system is not well enough understood at present to predict potential recharge and extraction effects on stream flows, wetlands and other associated environmental resources. This is particularly true in the Sacramento basin. Second, the same uncertainty limits the assurance a program could have regarding how much of the water it recharges will actually be available for extraction when needed and what liabilities the program might incur due to impacts on third parties. Vertical flow rates might be particularly important to this. In the Sacramento valley, for example, much would depend on whether or not recharge to deeper aquifer levels could be tapped during drought years without affecting levels in the upper unconfined aquifer or surface streams.

The above uncertainties are unlikely to represent as much of a concern in parts of the Central Valley (such as much of the San Joaquin and other groundwater basins in Southern California) where hydrological conditions are better known and where aquifers have been historically drawn down substantially or major pumping depressions currently exist. In these areas, surface-groundwater interactions are often minimal because streams are not in direct hydraulic connection with aquifers. Subsidence, while a concern, has often already occurred and, if fluctuations are kept within historical ranges, is unlikely to increase. Furthermore, because of overdraft, subsidence and other concerns, these areas have often been subject to extensive study. There is, therefore, a much larger body of information on aquifer characteristics and probable responses to the types of operations involved in a conjunctive management program. This substantially increases the degree of assurance a program would face with regard to environmental and third party impacts and the probability of stored water being available when needed.

AIV.2.2 Water Quality

A groundwater banking project of the type envisioned here should not encounter major water quality related problems in the short run. Longer term impacts are, however, much more difficult to predict. During the initial phases of a state-level conjunctive use program, water quality related problems are likely to be limited primarily to monitoring residues from agricultural operations (fertilizers and pesticides) and potential micro-element concerns in source water.[111] If direct percolation of water conveyed without intervening uses in dedicated recharge facilities is the primary recharge mechanism, source water quality should be high and problems relatively straightforward to monitor and control. Contamination is a point of concern primarily with spreading. It is also a concern if extraction causes major changes in hydraulic gradients and results in the mobilization of polluted or otherwise low quality water. This could emerge as a particular concern during long duration droughts when irrigators would be depending on groundwater as their primary source of supply over extended periods. There are two points it is important to make in this context:

1) Substantial contaminant loads including pesticides, fertilizers, salts and micro-elements such as selenium are currently isolated in the soil column. Increased flushing of the soil column due to intentional recharge (spreading) could mobilize large amounts of these contaminants. This would add to the contaminants picked up from current agricultural operations. Flushing from increased recharge could, on the other hand, have the opposite effect. Some suggest that the increased flow through aquifers resulting from conjunctive use operations could be used as a technique to reduce existing nitrate and other contamination.[112]

---

[110]. Discussion with Glen Pearson, DWR on 8/17/95. In rice growing areas of the Sacramento Valley, shallow wells are observed to maintain steady water levels (lots of recharge) but deeper wells fluctuate substantially as pumping levels change. This suggests at least partial isolation of lower aquifers from upper levels.

[111]. Many conjunctive use projects envision recharge of reclaimed water. In this situation, treatment prior to injection is a major source of cost.

[112]. Personal communication, Walter Swain, U.S. Geological Survey

2) Changes in hydraulic gradients associated with extraction of stored groundwater is a major potential cause of contamination. In many locations, fresh water aquifers are in hydrologic contact with low quality water. Pumping fresh aquifers can cause intrusion of the low quality water essentially ruining them as a source or storage location. This is a common problem in coastal areas but is also of potentially great concern in many inland locations as well. On the western side of the Sacramento valley there are large areas of shallow saline groundwater that could be mobilized if hydraulic gradients change due to pumping associated with a conjunctive use program. Similar issues are present where high levels of Boron exist in groundwater making it unusable for many agricultural operations.[113]

Groundwater banking will inherently increase fluctuations in aquifer levels. This will increase both lateral and vertical flow within the groundwater system. This will, in turn, have a tendency to mobilize pollutants and naturally occurring contaminants. The net effects are, on a broad scale, difficult to predict. In some areas, increased flushing could cause net water quality improvements. In others, mobilization could have the opposite impact.

The degree to which water quality concerns are likely to emerge if conjunctive use operations are implemented is unknown. Clearly, care would be needed to avoid regions where quality problems already exist that could be exacerbated by program operations. Program exposure to potential quality problems is likely, however, to be greatest with spreading methods. These techniques are otherwise often the least costly. This suggests that direct recharge using percolation or injection techniques may, over the long term, prove less expensive because it is possible to avoid non-point sources of contamination to a much greater extent. Overall, monitoring of groundwater quality trends is particularly essential in any conjunctive management program using spreading for recharge or one that causes significant water table fluctuations to ensure that contamination from agricultural residues or other sources does not occur.

Appendix V: Groundwater Banking Cost in California

Site	Cost per Acre-Foot (1994-95)	Method
Eastern Yolo County [1]	54	In lieu of irrigation
Natomas Central Mutual Water Company [2]	150	In lieu of irrigation
Pleasant Grove-Verona Mutual Water Company [2]	71	In lieu of irrigation
South Sutter Water District [2]	83	In lieu of irrigation
WID [3]	110-208	In-lieu and off season irrigation, price range depends on scale, small scale=low price. Most of difference related to additional wells and reconfiguring existing surface storage for recharge.
Antelope Valley-East Kern WA [4]	90	In lieu deliveries
Water Replenishment District of Southern California [5]	112	In lieu deliveries
Yuba County Water Agency [6]	30-35	In lieu deliveries
Leach Canyon in Riverside County [7]	141	Spreading Basins
McVicker Canyon in Riverside County [7]	176	Spreading Basins
Kern-Tulare WD and Rag Gulch WD [8]	30	Spreading Basins outside of district
Rosedale-Rio Bravo WSD [9]	10-12	Spreading Basins using excess river flow
Water Replenishment District of Southern California[10]	20	Spreading Basins using imported water. Cost/AF of imported water, depending on source can be $263, $480, or $501 11
Water Replenishment District of Southern California[10]	20	Spreading Basins using recycled water. Cost/AF of recycled water can be $15 or $380 11
Rosedale-Rio Bravo WSD [9]	50-62	Spreading Basins using SWP water
San Bernadino Valley MWD [12]	60-120	Spreading Basins
Mojave WA [13]	200	Spreading basins using SWP water
Kern County WA [14]	5-35	Spreading Basins, depending on source of water, cost for recharge alone.
Joint Management Board - Terra Bella ID, Lower Tule River ID, Saucelito ID, Pixley ID, and Porterville ID[15]	25	Spreading Basins
Average for various sites in Central Valley 16	90-120	Active percolation
Orange County WD [17]	20	Active percolation
WID & SJCID [3]	110-337	Active percolation combined with in-lieu and off-season irrigation. Price range depends on scale. Most of difference related to conveyance facilities for withdrawal.
Alameda Co. WD [18]	189	Active percolation in recharge pits and along creek bed
Raymond Basin Management Board[19]	10	Active percolation of natural run-off

Chino Basin Watermaster[20]	249	Active percolation with MWDSC SSP water
Chino Basin WCD[21]	102	Active percolation recharge
Dudley Ridge WD[22]	65-110	Active percolation recharge outside of district
Wetlands east of Lake Elsinore in Riverside County[7]	186	Injection
MWDSC with Calleguas WD in Las Posas Basin[23]	130	Injection and extraction
Raymond Basin Management Board[19]	50	Injection using discounted water from MWDSC
Arcade WD[24]	80	Combination of injection and in-lieu deliveries

RESEARCH BRIEF
Public Policy Institute *of* California
JULY 2005
ISSUE #102

Does California Have the Water to Support Population Growth?

California's population grew by over 10 million between 1980 and 2000, and it is expected to increase by another 14 million by 2030, reaching a total of 48 million. One of the most serious concerns of policymakers is whether the state will be able to supply the water needed to sustain this growth. Much of the state's population lives in areas that rely on "imported" water—water brought in from distant north-state rivers, Sierra Nevada watersheds, or even beyond California's borders. It is clear that the old way of doing business—simply damming up rivers and building aqueducts to move captured surface water—is no longer a viable strategy for accommodating this tremendous increase in population.

Policymakers and water planners have begun considering several alternative ways to bring supply and demand into balance over the years ahead. Options include expansion of nontraditional sources of supply (for example, underground storage, recycling, and desalination), reallocation through water marketing, and conservation incentives and regulations.

Although many large water projects in the past were undertaken with state and federal leadership, most current options are local or regional in scope. The California Department of Water Resources (CDWR) produces a statewide water plan every five years or so, but the frontline agencies responsible for water supply are the hundreds of municipal utilities serving the state's residential and commercial customers.

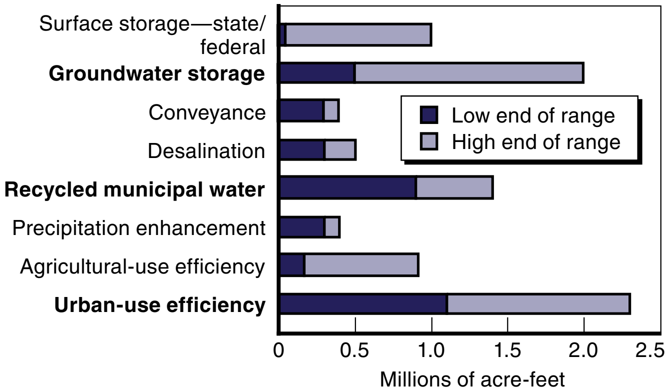
Key considerations of water demand growth are also in local hands: City and county governments are responsible for making land-use decisions—relating to general and specific plans, zoning, and subdivision maps—that affect not only the quantity but also the footprint of local development. The footprint is important because landscaping frequently accounts for more than half of all municipal water use.

In *Water for Growth: California's New Frontier*, Ellen Hanak examines how well California is faring in meeting the water supply challenges of growth. Her report examines the performance of water utilities throughout the state and draws on her original survey of local governments to see how they are integrating water supply concerns into their land-use planning.

She finds that if per capita urban water use remains at its 2000 levels of 232 gallons per person per day, California will face an expansion of water demand by 40 percent, or 3.6 million acre-feet, by 2030. Yet her review of supply options suggests that the situation may not necessarily prove dire. Ample opportunities are available over the coming decades to meet the state's needs through a diverse portfolio of conservation, groundwater banking, recycling, and water transfers that can help supplement surface storage.

Figure 1 illustrates CDWR estimates of how much water could be generated from various sources between 2000 and 2030. These estimates, which draw on assorted studies, indicate a scope for expansion well above the range of expected growth in urban and environmental demand.

Figure 1—Annual Production Potential from New Water Supply Sources and Conservation, 2000–2030



SOURCE: Department of Water Resources, "California Water Plan Update," Bulletin 160-05, Public Review Draft, Sacramento, California, April 2005.

California's water supply could be greatly increased through groundwater storage, municipal wastewater recycling, and greater efficiency in urban water use.

However, there are shortcomings with local agencies' water planning efforts. The Urban Water Management Planning Act introduced in 1983 requires that all large municipal utilities prepare a comprehensive water supply and demand planning document every five years. Yet in 2000, one-sixth of required municipal agencies submitted no water plans whatsoever, and a significant portion of submitted plans lacked detailed projections of supply and demand. Many utilities seem to be banking on "paper water" that is already being used by someone else within the state's water system. It does appear that water planning is more comprehensive and complete when water districts coordinate with other public agencies and seek information from the public on their intentions for future water use. And in terms of supply planning, there appears to be a positive movement toward recycling. But on the negative side, there seems to be limited focus on conservation and a threat of overexpansion of groundwater use in unmanaged basins.

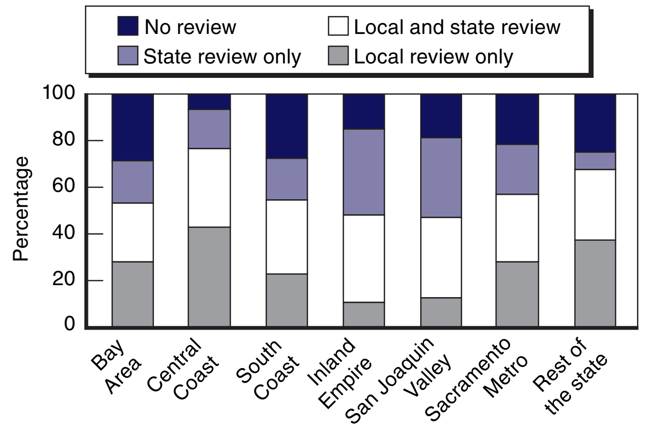
Integrating Water and Land Use

Hanak's survey of city and county land-use planners suggests that the "disconnect" between utilities and local governments is not as large as many might have imagined or feared. Six out of 10 land-use agencies participate in the planning activities of at least some of their local utilities, and nearly as many are active in water policy groups concerned with regional resource management.

A central concern has been that the local government-utility disconnect will lead to the approval of new development without adequate water supplies, putting existing and new residents at risk of shortages. However, the survey showed that over half of all cities and most counties—housing over half of the state's residents—have some form of local oversight policy to guard against this possibility (Figure 2). In addition, the passage in 2001 of Senate Bills 610 and 221—the "show me the water" bills—requires the demonstration of adequate long-term water supply before approval of large development projects. These new laws have already made their mark. Developers are being sent back to the drawing board to come up with more secure supply options, and many projects are being designed to incorporate recycling and conservation.

Appellate court rulings have also put developers, land-use authorities, and utilities on notice that project water supply assessments can be successfully challenged if they do not adequately analyze long-term supply reliability.

Figure 2—Regional Patterns of Water Adequacy Review Activity



SOURCE: PPIC land-use planner survey.

New state laws are filling a gap where local oversight policies were lacking.

Meeting the Water Supply Challenge

The author notes that although success is not guaranteed, California is well positioned to tackle the challenges of finding and managing water for growth. She points out that if communities reject growth rather than finding water supply solutions compatible with it, the state faces the prospect of more critical housing shortages. To avoid either scenario—a water shortage or a housing shortage—she argues that California's utilities and local governments must focus on four key challenges: (1) strengthening long-term water planning; (2) streamlining water adequacy screening for new development, so that local planners look carefully at the situation without unreasonably slowing housing growth; (3) realizing the potential of water conservation (especially in the fast-growing inland areas where tiered rates could do the most to moderate use); and (4) consolidating progress in groundwater management.

How Can the State Help?

To date, the state's main role has been to facilitate better local water and land-use planning through certain pieces of legislation, financial incentives, and technical support. However, water management laws have relied on citizen enforcement rather than direct state oversight. Billions of dollars in state water bond funds have enabled the state to reward local entities for taking positive actions. Yet, the author suggests, there is more room for regulatory actions—in particular, withholding new water-rights permits, as a way to encourage local entities to manage water resources responsibly.

This research brief summarizes a report by Ellen Hanak, Water for Growth: California's New Frontier *(2005, 196 pp., $15.00, ISBN 1-58213-108-2). mrusso@water.ca.gov

Overview

Sacramento Valley has a history of floods and management of floods that goes back as long as people have populated the region. Prior to flood management, the valley floor would be blanketed by seasonal runoff nearly every year; the Sacramento Valley was once nicknamed the "inland sea." This tendency to flood results from the geography of the region as well as the weather. The occasionally large amounts of rain that fall in the surrounding Coastal ranges and the relatively steep Sierra Nevada mountain ranges produce rapid surface water runoff to the Sacramento River. The amount of this surface water runoff can be quite large, depending on the amount of rainfall, snow melt, and soil moisture of the watershed. Fast water flowing from the mountains is blunted by the relatively shallow grade of the Sacramento River south of the city of Red Bluff, and would often overtop the river banks. In addition, The Sacramento River would begin depositing sediment in the more shallow grades that would often alter its direction of flow. In order to control these storm flows that would otherwise flood farmland and cities, the Sacramento River Flood Control Project (the Project) was created.

The Project was designed with the understanding that runoff from many of the storm events experienced in the Sacramento River watershed cannot be contained within the banks of the river. Nor could this flow be fully contained within a levee system without periodically flooding adjacent property. Thus, the Project was designed to occasionally spill through a system of weirs and flood relief structures into adjacent basins. These basins are designed to contain flood waters and channel them downstream, to eventually be conveyed back into the Sacramento River near Knights Landing and Rio Vista. Dry weather flows are contained within levees near the river banks and land within the flood basins is then used for agricultural purposes.

There are ten overflow structures in the Project (six weirs, three flood relief structures, and an emergency overflow roadway) that serve a similar function as pressure relief valves in a water supply system. Weirs are lowered sections of levees that allow flood flows in excess of the downstream channel capacity to escape into a bypass channel or basin.

All six weirs of the Project (Moulton, Colusa, Tisdale, Fremont, Sacramento, and Cache Creek) consist of the following: (1) a fixed-level, concrete overflow section; followed by (2) a concrete, energy-dissipating stilling basin; with (3) a rock and/or concrete erosion blanket across the channel beyond the stilling basin; and (4) a pair of training levees that define the weir-flow escape channel.

All overflow structures except the Sacramento Weir pass floodwaters by gravity once the river reaches the overflow water surface elevation. The Sacramento Weir has gates on top of the overflow section that hold back floodwaters until opened manually by the Department of Water Resources' Division of Flood Management.

Four other relief structures are concentrated along 18 river miles between Big Chico Creek (River Mile 194) and the upstream end of the left (east) bank levee of the Sacramento River Flood Control Project (near River Mile 176). These structures function like weirs but are not called weirs because they do not have all four structural characteristics previously described. All of these relief structures convey water into the Butte Basin (a natural trough east of the river) upstream of the levee system designed to guide the flood waters.

Three of the structures are designated as flood relief structures (M&T, 3B's, and Goose Lake). If these three fail as designed a raised 6,000-foot roadway near the south end of Parrott Ranch allows excess floodwaters to escape the Sacramento River to the Butte Basin before being confined by the downstream project levees.

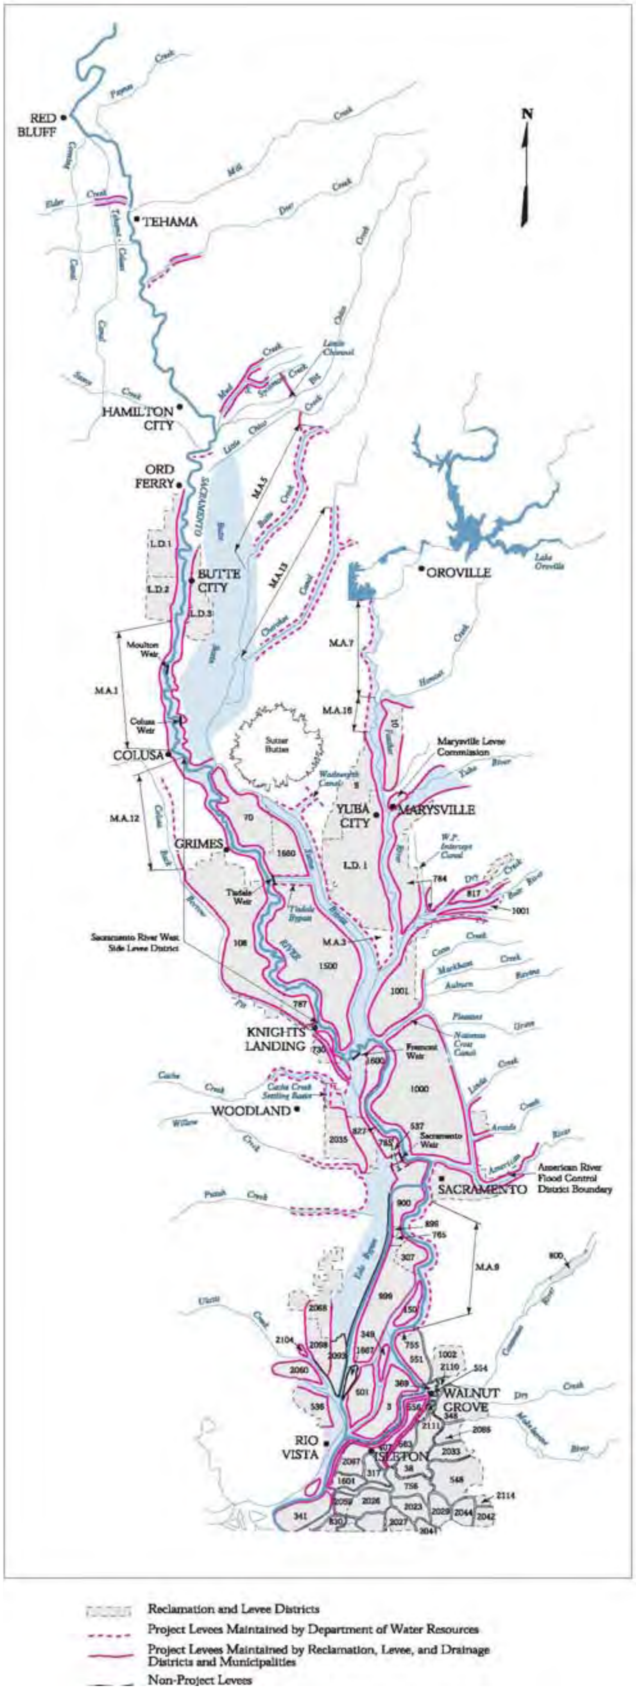

Figure 1 (above), Location Map for Weirs and Relief Structures in the Sacramento River Flood Control Project

Figure 2 (right), Sacramento River Flood Control Project Overview, showing project levees and basins

Moulton Weir

Moulton Weir was completed in 1932. It is located along the easterly side (left bank looking downstream) of the Sacramento River approximately eight miles north of the town of Colusa and about 100 miles north of Sacramento. Its primary function is to release overflow waters of the Sacramento River into the Butte Basin at such times when floods exceed the safe carrying capacity of the main channel of the Sacramento River downstream from the weir. The fixed crest reinforced concrete weir is 500 feet long with concrete abutments at each end. The outlet channel is flanked by training levees and is approximately 3,000 feet long. The crest elevation is 76.75 feet and the project design capacity of the weir is 25,000 cubic feet per second (cfs). The Moulton Weir is typically the last of the non-gated weirs to overtop, and spills for the shortest duration.

Figure 3, Moulton Weir, January 1997

Colusa Weir and Bypass

Colusa Weir was completed in 1933. It is located along the left bank of the Sacramento River one mile north of the town of Colusa. Its primary function is to release overflow waters of the Sacramento River into the Butte Basin. The fixed crest reinforced concrete weir is 1,650 feet long and is flanked by training levees that connect the river to the basin. The crest elevation is 61.80 feet and the project design capacity of the weir is 70,000 cfs. Normally, the Colusa Weir does not overtop until the Tisdale Weir is also spilling, except for flood events that are characterized by rapid rise in Sacramento River stage.

Figure 4, Colusa Weir, January 1997

Tisdale Weir and Bypass

Tisdale weir was completed in 1932. It is located along the left bank of the Sacramento River about ten miles southeast of the town of Meridian and about 56 miles north of Sacramento. Its primary purpose is to release overflow waters of the Sacramento River into the Sutter Bypass via the Tisdale Bypass. The fixed crest reinforced concrete weir is 1,150 long. The four-mile leveed bypass channel (Tisdale Bypass) connects the river to the Sutter Bypass. The crest elevation is 45.45 feet and the project design capacity of the weir is 38,000 cfs. Typically, the Tisdale Weir is the first of the five weirs in the Sacramento River Flood Control System to overtop, and continues to spill for the longest duration.

Figure 5, Tisdale Weir and Tisdale Bypass (Sutter Bypass in background, January 1997

Fremont Weir

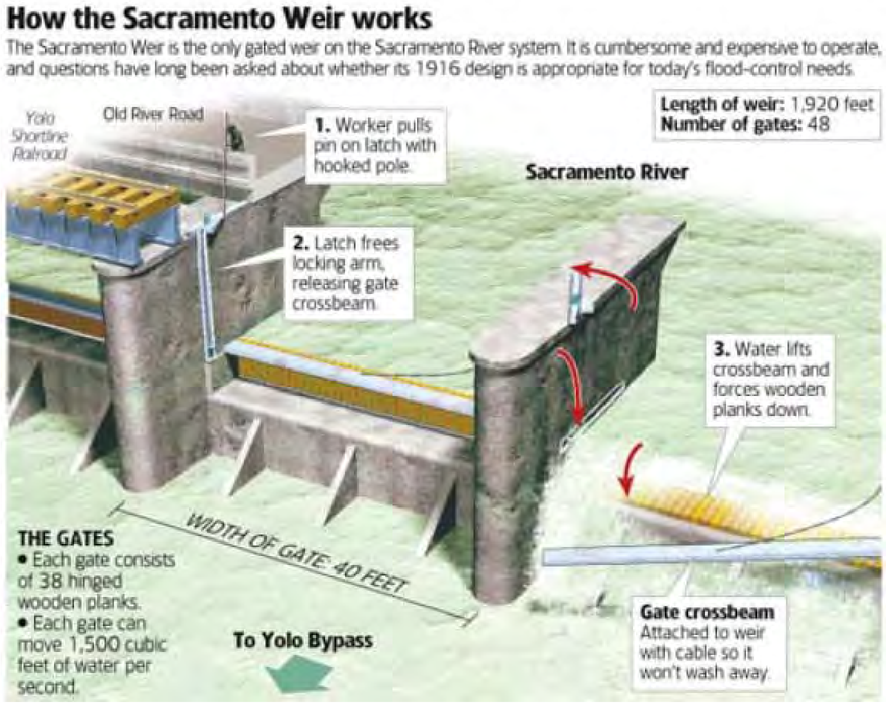
Fremont Weir was completed in 1924. It is the first overflow structure on the river's right bank and its two-mile overall length marks the beginning of the Yolo Bypass. It is located about 15 miles northwest of Sacramento and eight miles northeast of Woodland. South of this latitude the Yolo Bypass conveys 80 percent of the system’s floodwaters through Yolo and Solano Counties until it connects to the Sacramento River a few miles upstream of Rio Vista. The weir’s primary purpose is to release overflow waters of the Sacramento River, Sutter Bypass, and the Feather River into the Yolo Bypass. The crest elevation is 33.50 feet and the project design capacity of the weir is 343,000 cfs.

Figure 6, Fremont Weir (Sutter Bypass on left, and Yolo Bypass on right)

Sacramento Weir and Bypass

The Sacramento Weir was completed in 1916. It is the only weir that is manually operated – all others overflow by gravity on their own. It is located along the right bank of the Sacramento River approximately 4 miles upstream of the Tower Bridge, and about 2 miles upstream from the mouth of the American River. Its primary purpose is to protect the City of Sacramento from excessive flood stages in the Sacramento River channel downstream of the American River. The weir limits flood stages (water surface elevations) in the Sacramento River to project design levels through the Sacramento/West Sacramento area. The project design capacity of the weir is 112,000 cfs.

It is 1,920 feet long and consists of 48 gates that divert Sacramento and American River floodwaters to the west down the mile-long Sacramento Bypass to the Yolo Bypass. Each gate has 38 vertical wooden plank "needles" (4 inches thick by 1 foot wide by 6 feet long), hinged at the bottom and retained at the top by a hollow metal beam. The beam is manually released using a latch. Flood forecasters provide the necessary predictive information to weir operators who manage the number of opened gates in order to control the river's water surface elevation. Closing the hinged gates is a more laborious process than opening them. While opening a gate takes only a matter of minutes, closing it can take up to an hour. Long, hooked poles are used to raise each gate from its free open position to the vertical upright position. The hollow metal beam is then replaced, and the gate is released and allowed to rest against it.



How the Sacramento Weir works

The Sacramento Weir is the only gated weir on the Sacramento River system. It is cumbersome and expensive to operate, and questions have long been asked about whether its 1916 design is appropriate for today's flood-control needs.

Figure 7. Diagram Depicting the Opening of the Sacramento Weir.
Appeared in the Sacramento Bee on January 5, 2006.

The Department of Water Resources operates the weir according to regulations established by the U.S. Army Corps of Engineers. The opening and closing criteria have been optimized to balance two goals: (1) minimize sediment deposition due to decreased flow velocities downstream from the weir to the mouth of American River; and (2) limit the flooding of agricultural lands in the Yolo Bypass until after they have been inundated by floodwaters over Fremont Weir.

Though the weir crest elevation is 24.75 feet, the weir gates are not opened until the river reaches 27.5 feet at the I Street gage with a forecast to continue rising. This gage is about 1,000 feet upstream from the I Street Bridge and about 3,500 feet downstream from the mouth of the American River. The number of gates to be opened is determined by the NWS/DWR river forecasting team to meet either of two criteria: (1) to prevent the stage at the I Street gage from exceeding 29 feet, or (2) to hold the stage at the downstream end of the weir to 27.5 feet. Once all 48 gates are open, Sacramento River stages from Verona to Freeport may continue to rise during a major flood event. Project design stages are 41.3 feet at Verona, 31.5 feet at the south end of the Sacramento Weir, and 31 feet at the I Street gage.

Figure 8, Sacramento Weir with Yolo Bypass in foreground, January 1997

Figure 9, Sacramento Weir with American River in background, March 1995 (30,000 cfs)

During a major flood, opening the weir gates at river stages below 27.5 feet does not reduce ultimate peak flood stages in the Sacramento River from Verona to Freeport. Diversion of the majority of upstream floodwaters to the Yolo Bypass from Fremont Weir controls Sacramento River flood stages at Verona.

Downstream of the Sacramento Weir, the design flood capacity of the American River is 5,000 cfs higher than that of the Sacramento River. Flows from the American River channel during a major flood event often exceed the capacity of the Sacramento River downstream of the confluence. When this occurs, floodwaters flow upstream from the mouth of the American River to the Sacramento Weir.

The weir gates are closed as rapidly as practicable once the stage at the weir drops below 25 feet. This provides "flushing" flows to re-suspend sediment deposited in the Sacramento River between the Sacramento Weir and the American River during the low flow periods when the weir is open during the peak of the flood event.

A rating table has been developed to estimate flow over the Sacramento Weir into the Yolo Bypass (Table 1). This table can be used to calculate both the approximate discharge per open gate and, for higher stages, the approximate discharge over closed gates as well. All stages are listed with respect to USGS mean sea level datum.

Cache Creek Settling Basin and Weir

The Cache Creek Settling Basin and Weir were originally completed between the late 1930's through the early 1950's. The basin was expanded and the new weir was completed in 1991. It is located in Yolo County about two miles east of the City of Woodland. Its primary purpose is to preserve the floodway capacity of the Yolo Bypass by entrapping the heavy sediment load carried by Cache Creek before its waters pour into the bypass. The basin is bound by levees on all sides and covers approximately 3,600 acres. The roller compacted concrete weir is 1,740 feet long along the east levee of the basin and controls discharge to the bypass. The project design capacity of the weir is 30,000 cfs, which is also the maximum capacity of the upstream Cache Creek channel system.

Figure 10, Cache Creek Settling Basin Weir, March 1995

Overflow records for Moulton, Colusa, Tisdale, Fremont, and Sacramento Weirs from 1934 through 2007 are found on the following pages. Subsequent years will be added as the charts are updated.

Sacramento Valley Flood Control Historical Timeline

(Based on *Battling the Inland Sea*, by Robert Kelley)

1849	U.S. Congress passes Swamp Land Act of 1849
1850	Swamp Land Act of 1850
January 7, 1850	City of Sacramento floods
March, 1850	Another storm hits Sacramento. Hardin Bigelow organizes flood fighting party and successfully dams most low points along American and Sacramento Rivers (Bigelow soon becomes Mayor of Sacramento)
1851	First levees built in Sacramento (3-feet high)
December, 1852	First levees built in Sacramento failed
March, 1853	Second flood of season (larger than first) inundates Sacramento
May 31, 1861	AB 54 (State Reclamation Act) passed – Swamplands Commission created, tasked with statewide flood control program development
1861	Andrew Humphreys of the U.S. Army Corps of Engineers (USACE) submits Mississippi River flood study to U.S. Congress – Advocates levees only, main channel flood control approach (All storm flow to remain within levees, and assumption that river will scour out material from the bed to accommodate additional flow)
1862	City of Sacramento Levee District created
March 22, 1866	AB 591 passes – State-wide Swampland Commission dissolved (Reclamation authority delegated to county boards of supervisors)
1867 – 1880	Reclamation districts upstream and downstream of Colusa race each other to construct levees on each bank of Sacramento River
April 13, 1868	Sacramento Valley Levee District 1 (Sutter County) created
May 30, 1868	Green Act (named for *Colusa Sun* editor William S. Green, who authored the bill) passes – Greatly reduces County authority to block reclamation projects. William Green is also the earliest known figure to call for a system of flood overflow basins for the Sacramento River
December 6, 1871	Colusa-area swampland owner, William Parks completes construction of earthen dam across Butte Slough, the effect of which will inundate the property of others upstream

December 27, 1871	Parks Dam is cut by parties unknown; releasing pooled floodwaters downstream – Dam is rebuilt in following year
January 19, 1874	Parks Dam fails
December 28, 1874	L.F. Moulton proxy and Parks Dam flood victim, Justin Laux v. William Parks: Suit is dismissed when Parks purchases Laux's farm
January, 1875	Marysville inundated by water and mining sediment via Yuba River – Mining sediment from hydraulic mining operations had for several years been polluting rivers and settling in river beds, thus raising the bed elevation, and causing more frequent flooding and more extensive damage to adjacent properties
January 25, 1875	Parks Dam fails again
May 7, 1875	William Parks petitions for creation of swampland district
June 3, 1875	County Supervisors deny Parks' request to rebuild dam
June 16, 1875	William Parks' Swampland District (SLD) 226 created – Construction of dam recommences
January 5, 1876	Floodwaters impounded by Parks Dam breach Reclamation District (RD) 70 levee; flooding farm properties downstream
January 8, 1876	Thirty to Forty armed men from RD 70 form naval party to successfully destroy Parks Dam
March 4, 1876	Judge Phil. Keyser issues injunction against Parks' and SLD 226 dam constuction
March, 1878	Drainage Bill enacted – Independent public commission would establish drainage districts; State Engineer would plan projects (based on levees only); Districts would raise and expend taxes, construct and operate projects
March, 1879	Judge Phil. Keyser issues injunction against Bear River mining operations, citing Equity Clause
November, 1879	State Supreme Court overturns Keyser's injunction
January 21, 1880	California's first State Engineer, William Hammond Hall, submits Irrigation/Flood Control Report to State Legislature – A damning report on the mining operations' environmental destruction that advocated State control of drainage
September 26, 1881	Drainage Act declared unconstitutional – Act was not created by State Legislature

January, 1884	Edwards Woodruff v. North Bloomfield Gravel Mining Company-- Prohibited the discharge of mining waste in surface waters
February, 1891	USACE's Biggs Commission Report asserts mining operations may continue, with mining companies construction of debris dams, and Federal restoration of natural river channels downstream
March, 1893	Caminetti Bill (based on Biggs Commission Report findings) signed by President Benjamin Harrison – Establishes California Debris Commission
December, 1894	Marsden Manson & C.E. Grunsky, (consulting engineers working foe State Commissioner of Public Works, A.H. Rose,) issue *Marsden & Grunsky Report for Sacramento Valley Flood Control*, and present it to California Governor – First comprehensive report that advocated bypass channels (William Green had asserted this need three decades earlier)
January, 1896	Flood of '96 – Many mining debris dams (products of Biggs Commission recommendations) fail, sending waste downstream
March, 1896	Rivers and Harbors Act enacted in Congress -- $250K appropriated (none of which was for mining assistance)
May, 1902	River Improvement and Drainage Association of California created
May 11, 1904	San Francisco Chronicle editor and Commonwealth Club founder, Edward Adams' public presentation on statewide flood control and reclamation – A retelling of California reclamation history to date, and a call for State and Federal governments to assert control of future planning
1904	U.S. Army Corps of Engineers' Dabney Commission issues report that rejects the Manson & Grunsky Report's findings of the need for bypass channels and a design flood of 300,000 cfs. Advocates levees only main channel approach and a design flood of 250,000 cfs
March 19, 1907	Flood of '07 – First flood event to occur with USGS staff gages in place to measure river levels – Observed flow calculated to be 600,000 cfs (more than *double* the Dabney design flood) Feather River dumps into Butte Sink, Yuba City & Shanghai Bend Sacramento River jumps banks both north and south of Colusa
1907	USACE's California Debris Commission expands navigation assurance role to include flood control
1909	Flood of '09 – Nearly as large as the Flood of '07
1910	Thomas H. Jackson of the USACE produces the "Jackson Report"; the foundational plan for the Sacramento Flood Control Project – employing the Manson & Grunsky Report's bypass channels, only with a design flood of 600,000 cfs
1911	State Flood Control Act enacted

1913	State Reclamation Board given greater authority
1913	Dredging of the mouth of the Sacramento River begins – Continues through the 1920s
1917	Congress enacts Flood Control Act – Includes funding for the Sacramento Flood Control Project, but largely limited to navigation related tasks
1928	Flood Control Act of ’28 – Enacted as a response to the Mississippi Flood of ’27, and adds flood control to USACE directives
1936	Flood Control Act of ’36 – Promotion of multi-purpose water resource projects for USACE purview
February 11, 1986	Flood of ’86 – 600,000 cfs (maximum design flow) pours into Sacramento-San Joaquin Delta via Sacramento River and Yolo Bypass. Only upstream flood control reservoirs prevent approximately *one million cfs* from severely testing the Sacramento Flood Control Project. As a result, the system largely works as designed
January 3, 1997	Flood of ’97 – nearly 600,000 cfs again pours into Sacramento-San Joaquin Delta via Sacramento River and Yolo Bypass. Only upstream reservoirs prevent approximately one million cfs from inundating the Sacramento Flood Control Project.

Executive Summary

Introduction

In 2006, the Glenn Colusa Irrigation District (GCID) and the Natural Heritage Institute (NHI) jointly embarked on this investigation to explore how the largest water storage reservoir in the Federal Central Valley Project (CVP), Shasta, and the only such reservoir in the State Water Project (SWP), Oroville, could be re-operated in conjunction with northern Sacramento Valley groundwater aquifers to increase water supplies for both environmental and economic uses. GCID is the Sacramento Valley's largest agricultural water supplier with annual water entitlements of 825,000 acre-feet in most years, based on pre-1914 Sacramento River and other water rights. The Natural Heritage Institute (NHI) is a non-governmental, non-profit organization that works at the global scale to preserve and restore the natural functions of river systems and the services they provide to sustain and enrich human life. The investigation was enabled by a combination of state and federal grant funding, including Proposition 50 funding administered by the Department of Water Resources (DWR) and federal funds channeled through the Bureau of Reclamation's (Reclamation) Mid-Pacific Region.

Two other agricultural water suppliers, Western Canal Water District (WCWD) and Richvale Irrigation District (RID), participated in the investigation to the extent of providing technical information and by expressing their interest and potential willingness to support a conjunctive water management project, subject to their review of the investigation's findings. Both districts have water entitlements to Feather River water supplies delivered through the SWP.

Public outreach was conducted in a variety of forums to guide the investigation and to inform interested parties regarding findings and progress. Outreach activities included seven publicly noticed meetings held in the Sacramento Valley, three executive briefings for Reclamation and DWR management staff and four workshops designed primarily to facilitate collaboration with DWR and Reclamation staff involved with operating the CVP and SWP, respectively. Additionally, the project technical team met many times with Reclamation and DWR staff to advance and coordinate the technical work.

At its inception, the investigation focused on the Sacramento Valley's deep aquifers, particularly the Lower Tuscan Formation, which underlies much of the northern portion of the Sacramento Valley. However, as the investigation progressed the study team recognized that such a narrow focus was both overly constraining on the scope of the study and somewhat misleading because it implied that any effects on the aquifer system due to additional recharge or pumping could somehow be confined to a particular portion of the groundwater system. Ultimately the project evaluated the effects of exercising both the northern Sacramento Valley's deep aquifer system, which is presently relatively undeveloped, and the shallower, regional aquifer, which is more heavily pumped for both domestic and agricultural needs.

The investigation began with the expectation that surplus water generated through the re-operation of these reservoirs could be banked in the groundwater aquifers in the Sacramento Valley, like other conjunctive use programs in the San Joaquin Valley of California, with water put into groundwater storage in wet years and extracted in dry years. However, initial assessment and site screening revealed that conditions in the Sacramento Valley are not conducive to this mode of conjunctive management, primarily because groundwater aquifers, although extensively developed and pumped in many areas, mostly for agricultural irrigation, generally recover fully during the precipitation season. What emerged was a conjunctive management approach based on reservoir re-operation backstopped by several options for reducing the draw on reservoir storage when refill is insufficient.

Core Conjunctive Management Concept

The central thesis of this investigation is that most major reservoirs that are operated today for a limited set of water supply and flood control objectives could be re-operated to achieve newly defined ecological restoration benefits while also improving water supply reliability, reducing flood risks, and buffering the effects of climate change. The objective of the project was to explore the potential to optimize operations for all of these benefits without compromising any of them.

Reservoirs that have dual water supply and flood control functions, like the CVP and SWP reservoirs, are typically operated under conservative rules designed to maximize water supply while avoiding flood risks. This results in relative high carryover storage levels but frequent “spills” of water during the refill period to create sufficient flood reservation capacity as necessary to prevent flood damage to the development that has occurred in the downstream floodplain. These spills represent the component of the runoff hydrograph that is not controlled and therefore not appropriated for beneficial use under California water law. To capture and manage this water would require creating additional storage capacity. One way to do that without enlarging the reservoir, or constructing additional ones, is to lower the water storage levels going into the refill period, thereby creating more reservoir capacity to capture high flows. Storage levels can be lowered by delivering additional water from the conservation pool to meet new water supply objectives, including enhancing flows for environmental benefits and augmenting water supplies for consumptive uses such as agriculture.

However, making additional reservoir releases before the ensuing refill period incurs a larger risk of water supply shortages in the event that the quantity of runoff during the refill season, which is always uncertain, is not sufficient to recover the reservoir storage to the level that would have occurred if the additional releases had not been made. Failure for the reservoir to refill would impinge on the reservoir’s function, manifest as water supply shortages, inadequate cold water reserves or reduced carryover storage, or some combination of these factors, unless the reservoir deficit can be made up from other sources.

Three strategies for “paying back[1]” the reservoirs in this manner were investigated:[2]

---

[1] The terms reservoir “refill” and reservoir “payback” are used in this report. Reservoir refill refers to recovery of reservoir storage by either capturing surplus surface water flow or by not making reservoir releases that would otherwise need to be made. The latter means of reservoir refill (not making reservoir releases that would otherwise need to be made) is referred to as reservoir payback. Different reservoir payback strategies and mechanisms are described in the report.

[2] A fourth payback strategy that was not considered in this study would be to repay the reservoirs with water conveyed to and banked in aquifers south of the Delta in previous years. This option poses certain advantages to the Sacramento Valley by eliminating or substantially reducing the need to exercise Sacramento Valley aquifers for payback and making surplus water available when and where it has the highest economic value. While, this option is beyond the scope of this phase of investigation, these advantages suggest that it may be a particularly robust alternative that warrants investigation in a subsequent phase of analysis. Notably, this option is only viable if and when additional conveyance capacity through, around or under the Delta becomes available, as is currently being considered in the development of the Bay Delta Conservation Plan (BDCP).

1. Payback from water generated by the project in previous years and stored (or "banked") in aquifers in the Sacramento Valley;

2. Payback from groundwater pumped by cooperating water suppliers served by the CVP or SWP to substitute for water that would otherwise have had to be delivered from the reservoirs; and,

3. Payback from reduction in water demands on the reservoirs, achieved by temporary crop idling on a voluntary, compensated basis.

Project Objectives and Principles

The basic objective of reservoir re-operation is to generate additional water supplies (or "assets") for discretionary uses. In this case, the investigation looked at dedicating additional water supplies generated through re-operation of Shasta and Oroville to two primary in-Valley purposes:

1. **Enhancing ecosystem functions in the Sacramento and Feather Rivers.** Healthy rivers are not just environmentally valuable, they also are central to ensuring reliable, sustainable water supplies. Water supply systems that work in concert with the environment are less likely to be encumbered by court orders, water rights hearings, and other restrictions that can have drastic effects on water supplies for farming and other economic uses.

2. **Improving local water supply reliability, particularly in times of scarcity.** The investigation used historical unmet agricultural water demands to represent the need for additional water supplies in the Valley; however, the additional water supplies could be allocated to other uses and locations.

Design principles were established early on to guide development of project scenarios. The principles were derived in part from public input as well as from the sensibilities of the project sponsors and funding agencies, all aimed at identifying realistic, implementable water management improvements. The primary design principles are as follows:

1. Honor all existing CVP and SWP obligations and operational constraints: The CVP and SWP operate under a complex set of rules and conventions consistent with project water supply and flood control objectives and regulatory requirements, including temperature criteria, State Water Resources Control Board (SWRCB) Decision 1640 (D-1640), and the Central Valley Project Improvement Act (CVPIA). All of these existing objectives and constraints must be observed in any conjunctive management scenario so that water supply obligations to contractors are met to the same extent as under existing operations, and all applicable regulations are satisfied.

2. Achieve net environmental benefits, recognizing that there may be some tradeoffs among different environmental objectives and different times and locations: The Project would be operated to achieve or contribute to achieving certain environmental flow improvements in the mainstem Sacramento and Feather Rivers designed specifically to enhance ecologic functions important to the viability of protected species, particularly Chinook salmon. Three such tradeoffs are acknowledged in the Report:

    - Peak flood control releases, which may be environmentally beneficially, would be captured and released in a controlled pattern to achieve more tailored environmental and geomorphic benefits. In a sense, this is a strategy to use limited environmental water supplies in a more efficient manner.

- When groundwater pumping is needed for reservoir payback (under payback option #2, above), this could result in temporary reductions in base flows in the tributary streams that are also important to protected species.
- More aggressive exercise of the reservoirs to improve flow conditions for ecosystem enhancement may entail a greater risk of depleting cold water reserves needed for downstream temperature maintenance.

Such potential tradeoffs would be addressed through consultation with the listing agencies as part of the NEPA/CEQA compliance by project sponsors. Additional tradeoffs between restoration of more natural river flow regimes and maintenance of cold water pools for river temperature control are also possible and are discussed later in this report.

3. Hold other groundwater users harmless: The participating water districts are legal users of groundwater, and, like all other groundwater users in the basin, enjoy a correlative and co-equal right to increase their groundwater extractions for use by the overlying landowners, subject to the mutual avoidance of harm. Notwithstanding the legality of the participating districts' groundwater withdrawals, the Project would adhere to a "good neighbor" principle and design its mitigation plan to the higher standard of assuring no appreciable, unmitigated harm to existing groundwater users.

4. Generate net economic benefits so that the program can be self-financing: The project must be able to generate revenues that more than offset the expenditures associated with project implementation, including construction, operation, maintenance and any mitigation costs. In the economic analysis conducted for the study, revenues were included only for water sales; no monetary value was attached to ecosystem restoration benefits, although these benefits may be quite appreciable.

Project Site Screening and Selection

A systematic, qualitative assessment of conditions within the Sacramento Valley was conducted to identify particular areas where conjunctive operations appear promising. The team examined fall groundwater elevation maps, water supplier boundaries and distribution system coverages, and water source maps. The project and technical teams developed an initial list of project sites from a review of groundwater maps and their professional knowledge of the Sacramento Valley. Sites were named according to the overlying water districts, though potential sites did not strictly conform to water district boundaries. Information considered in this analysis included the location, water source, existing surface water contracts, current infrastructure and additional infrastructure necessary for delivery of surface water and for extraction of groundwater, operational concepts, and information on existing groundwater conditions. Table ES-1 summarizes this information considered for the nine initial sites.

Evaluation of existing groundwater conditions within the Sacramento Valley shaped the site screening and selection. In general, the evaluation revealed that while groundwater levels are drawn down during the irrigation season in many areas of the basin, levels recover during the precipitation season except during prolonged (multi-year) dry periods. Cones of depression generally do not persist over the

TABLE ES-1
Initial Project Sites and Parameters
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Location	Water Source	Site Type	Annual Surface Water Contract	Project to Integrate With	Currently Integrated?
Butte Basin	Surface	GW Pumping	~ 300 TAF/yr	SWP	Yes
Orland-Artois WD	Mixed	Both	53 TAF/yr	CVP	Yes
Rancho Capay WD	Ground	GW Banking	None	CVP	No
Corning Canal Area	Mixed	Both	33 TAF/yr	CVP	Yes

Olive Percy Davis Ranch	Surface	GW Pumping	32 TAF/yr	CVP	Yes

multiple years necessary to make the dewatered aquifer space suitable for banking[3]. Any additional water recharge induces additional groundwater discharge to the streams. The conclusion from this analysis was that conjunctive operations based on a groundwater banking payback mechanism are not feasible in the Sacramento Valley at this time. Thus, further effort was concentrated on a second option for a payback mechanism: pumping groundwater in lieu of making reservoir deliveries in years when reservoir payback would be necessary.

Two sites were identified on which to conduct more refined analyses with surface and groundwater modeling tools. The GCID and Butte Basin Projects[4], supplied by the CVP and SWP, respectively, provided the potential to pump the largest quantity of groundwater compared to other sites, and are already well integrated with the surface water system. Under this option, conjunctive management operations would utilize wells within GCID and the Butte Basin as a backstop for more aggressive operation of Shasta Reservoir and Oroville Reservoir, respectively.

Ecological Flow and Agricultural Water Supply Targets for Conjunctive Operations

A major element of this investigation was the development of specific ecological flow objectives for the Sacramento and Feather Rivers to use to formulate and evaluate reservoir re-operation scenarios. The ecologic flow objectives fall into two categories, three that were designed for Chinook salmon recovery, and one that was designed for riparian habitat recovery. These may be summarized as follows:

---

[3] Based on the most recent (Fall 2011) data collected by DWR, there appear to be some areas in the northern Sacramento Valley with persistent groundwater level declines, primarily in Glenn and Tehama Counties. These areas should be evaluated for potential groundwater banking operations in future work phases.

[4] The major water surface water suppliers within the Butte Basin are WCWD, RID and Biggs-West Gridley Water District (BWGWD). BWGWD declined to participate in the investigation, so development of the Butte Basin project concentrated on the other two districts. It is noted that WCWD and RID were passive project participants meaning they provided information for the investigation but did not assume a sponsorship role. Additionally, the Stony Creek Fan area and Orland Project was identified as a third potential project. However, upon further evaluation into potential groundwater pumping capacities and the ability to integrate the project with the Sacramento River system, it was determined that this project would not be investigated during this phase of the project. However, this project does deserve additional analysis in future phases of investigation.

For Chinook salmon:

- Geomorphic objectives: Sediment transport, bed mobilization and bed scour; channel migration and floodplain processes; inundation and fine sediment deposition
- Floodplain inundation objectives : inundated floodplain habitat for rearing juveniles during the later winter and early spring; maintain and recruit spawning habitat, but avoid scouring gravels while eggs or alevon are present
- Spring pulse flow objectives: Suitable flow conditions and temperatures for all life stages;

For Riparian Habitat:

- Fremont cottonwood seedbed preparation, seed germination and seedling growth; periodic large-scale disturbance of the riparian zone; riparian stand structure and diversity

In each category, the objectives are expressed as quantitative flow targets for the two rivers, respectively, defined in terms of flow magnitude, duration, frequency and seasonality, by river reach[5]. The various objectives are coupled with a dynamic decision system for prioritizing objectives from year to year.

Historical agricultural water supply shortages in the Sacramento Valley were used to represent the targets for water supply enhancements. Specifically, for the CVP/Sacramento River, unmet demands of CVP contractors within the Tehama-Colusa Canal Authority (TCCA) were used to represent additional demands. Members of the TCCA, including contractors supplied from the Corning Canal, hold agricultural service contracts for approximately 320 TAF of contract supply from the CVP, subject to shortages. Historical shortages (as simulated in CalSim II) were used to quantify unmet demands. On the Feather River system, the majority of SWP contractors have reliable water supplies with the exception of a few small contractors. There are no existing SWP contractors with large, frequently unmet agricultural demands in the Butte Basin. Therefore a more general unmet agricultural demand was defined for the Feather River based on user input and judgment.

Initial Project Scenarios

Four conjunctive operations scenarios were developed for the GCID and Butte Basin project locations for initial analysis. The scenarios are differentiated primarily by the following two parameters:

- Maximum Payback Capacity. This is the maximum volume of groundwater pumping that would occur in any year within the pumping period (see below) in GCID and the Butte Basin, respectively. This capacity essentially establishes the scale of the conjunctive operation, since the water deficit in the reservoirs cannot exceed the capacity to repay it, when that becomes necessary. Maximum capacities were based primarily on professional judgment taking into consideration historical pumping in the two areas and average pumping intensity (acre-feet per acre). The payback capacities selected for analysis were:
    - 100 TAF in GCID and 50 TAF in Butte Basin; total 150 TAF

---

[5] Although developed specifically for the purpose of formulating conjunctive management strategies, the recommended objectives and flows are believed to have broader utility beyond this investigation.

  - 200 TAF in GCID and 100 TAF in Butte Basin; total 300 TAF

- Pumping Period. Pumping must occur when there is a demand for water that would otherwise be satisfied by reservoir releases. In both project areas, the dominant crop is rice, which is typically planted between mid-April and early June and harvested in September. Following harvest, most rice fields are re-flooded between September and November for rice straw decomposition and to create waterfowl habitat. Thus the water delivery season in both areas is from mid-April through November. Based on this, three pumping periods listed below were identified for analysis. Different pumping periods were evaluated primarily to reveal differences in aquifer response to differences in the timing and rate of pumping. Additionally, the pumping period affects the capital investment needed for pumping facilities.
  - “Summer” defined as May through August
  - “Fall” defined as September through November
  - “Summer and Fall” defined as May through November

The combinations of payback capacity and pumping periods selected to form scenarios are listed in Table ES-2.

TABLE ES-2
Project Scenarios Evaluated
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Scenario	GCID Annual Pumping Capacity	Butte Basin Annual Pumping Capacity	Pumping Season
1	100 TAF	50 TAF	Summer (May through August)
2	200 TAF	100 TAF	Summer (May through August)
3	100 TAF	50 TAF	Fall (September through November)
4	100 TAF	50 TAF	Summer and Fall (May through November)

TAF = thousand acre-feet

Additionally, two well field configurations were evaluated for each scenario, one corresponding to existing wells screened at depths between 100 to 500 feet and a second well field corresponding to new wells screened at depths of 900 to 1,100 feet. Thus a total of eight operational scenarios were evaluated.

Analytic Tools

Formulating and evaluating potential conjunctive management projects requires simulation of both surface water and groundwater systems. Simulating the surface water system is necessary to determine when water is available to refill reservoirs and to estimate unmet agricultural demands, environmental objectives, and flow conditions. A groundwater model is necessary to estimate the effects of additional pumping on aquifer systems, including the spatial extent and magnitude of drawdown and potential change in stream-aquifer interaction. Changes in stream-aquifer interactions may affect the surface water system, depending on stream conditions when the changes occur. For example, if additional pumping results in more stream loss to the aquifer or less aquifer contribution to stream flow during the winter season of relatively wet years when the surface water system has surplus flow, there may be little or no impact. However, if pumping reduces stream flow during months and years when the surface water system is being operated to meet specific flow or water quality requirements, any reduction in stream flow will require a corresponding increase in reservoir release to ensure the flow requirement continues to be met. This decreases the water supply benefit of conjunctive management projects.

Evaluating this aspect of conjunctive management projects required coordinated operation of surface water and groundwater models.

The main tool used to evaluate alternative conjunctive management operations strategies and test alternative environmental flow thresholds and priorities was a spreadsheet-based surface water model. The model simulates changes in operation of Lake Shasta and Lake Oroville relative to conditions depicted in a baseline CalSim II simulation of CVP and SWP operations. The CalSim II baseline provides time series of reservoir storage levels, stream flows, and water deliveries which are used by the surface water model. Conjunctive management operations are simulated and layered onto baseline operations based on user inputs, while maintaining compliance with existing CVP and SWP rules, regulation, and operations. Consistent with currently available CALSIM II runs, the surface water model operates over the 82-year period from 1922 through 2003, inclusive.

For the groundwater analysis, an existing simplified groundwater modeling tool was completely re-designed and improved, to yield a powerful analytical package now referred to as the Sacramento Valley Groundwater Model (SACFEM). SACFEM is a full water budget based transient groundwater flow model that incorporates all of the groundwater and surface water budget components on a monthly time step over the period of simulation. The model domain covers the entire Sacramento Valley floor from Redding in the north to Sacramento in the south, and includes explicit representations of all major and many minor streams. The model provides very high resolution estimates of groundwater level and streamflow effects due to conjunctive water management pumping. In contrast to the surface water model, the groundwater model operates over a 17-year period from 1987 to 2003, due to the lack of historical data needed to calibrate the model prior to 1987.

Performance of Initial Project Scenarios

The performance of the initial project scenarios was evaluated by simulating operations with the surface water model. Scenarios 1, 3 and 4 are identical from a surface water operations perspective because they have the same payback pumping capacity in GCID and in the Butte Basin, respectively. Scenario 2 is different because GCID and Butte Basin pumping capacities are higher compared to Scenarios 1, 3 and 4.

The project benefits in terms of environmental flow targets met and agricultural water supplies generated are presented in Table ES-3. In GCID, at the 100 TAF project scale (associated with Scenarios 1, 3 and 4), environmental flow releases are made in 23 years in the 82 year period of analysis, or 28 percent of the years. The average environmental release volume is 46 TAF in the years made, or 13 TAF averaged over the full 82-year period. Agricultural water supply releases were made in 24 years, or 29 percent of the years, with the average release volume being 46 TAF in the years made and 14 TAF averaged over the full 82-year period. When the GCID project scale is doubled to 200 TAF (Scenario 2), project benefits increase appreciably. Environmental flow releases are made in 40 years, or 49 percent of the time, with the average release being 96 TAF in the years of occurrence and the 82-year average being 47 TAF. Agricultural water supply releases also increase but not by as much proportionally as environmental releases. The frequency of agricultural releases stays the same (at 24 years), but the average release increases to 75 TAF in the years of occurrence and 22TAF over the 82-year period.

In Butte Basin, at the 50 TAF project scale (associated with Scenarios 1, 3 and 4), environmental flow releases are made in 28 years in the 82 year period of analysis, or 34 percent of the years. The average environmental release volume is 21 TAF in the years made, or 7 TAF averaged over the full 82-year period. Agricultural water supply releases were made in 30 years, or 37 percent of the years, with the average release volume being 27 TAF in the years made and 10 TAF averaged over the full 82-year

TABLE ES-3
Environmental and Agricultural Water Supply Benefits under Conjunctive Operations
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Scenario(s)	Project/System	Payback Pumping Capacity (TAF)	Environmental Benefits			Agricultural Benefits		
			Number of Years	Avg in Yrs of Occurrence (TAF)	Avg Over All Yrs (TAF)	No. Yrs.	Avg in Yrs of Occurrence (TAF)	Avg Over All Yrs (TAF)
1, 3 and 4	GCID/CVP Lake Shasta-Sac R	100	23	46	13	24	46	14
1, 3 and 4	Butte Basin/SWP Lake Oroville-Feather R	50	28	21	7	30	27	10
2	GCID/CVP Lake Shasta-Sac R	200	40	96	47	24	75	22
2	Butte Basin/SWP Lake Oroville-Feather R	100	44	43	23	30	52	20

period. When the Butte Basin project scale is doubled to 100 TAF (Scenario 2), project benefits increase appreciably. Environmental flow releases are made in 44 years, or 54 percent of the time, with the average release being 43 TAF in the years of occurrence and the 82-year average being 23 TAF. Agricultural water supply releases also increase but not by as much proportionally as environmental releases. The frequency of agricultural releases stays the same (at 30 years), but the average release increases to 52 TAF in the years of occurrence and 20TAF over the 82-year period.

A fundamentally important finding is revealed through inspection of how the reservoirs are refilled following draw down to make project releases (Table ES-4). For the GCID 100 TAF project scale (Scenarios 1, 3 and 4), reservoir refill occurs in 33 years. But in 29 years the refill comes from surplus surface flows. In only 4 years is it necessary to pump from project groundwater. That is less than 5 percent of the years of operation. The average refill from surplus surface flows is 70 TAF in the years of occurrence and 24 TAF over the full period. In contrast, the refill from project groundwater pumping is also 70 TAF in the years of occurrence but just 4 TAF annually averaged over the full period. Importantly, the maximum year pumping is 98 TAF or nearly the full assumed repayment pumping capacity. At the 200 TAF project scale in GCID (Scenario 2), reservoir refill occurs in 41 years, with refill from surplus surface water occurring in 35 years and from project groundwater pumping in 6 years. The average refill from surplus surface flows is 139 TAF in the years of occurrence and 58 TAF annually over the full period.

For the Butte Basin 50 TAF project scale (Scenarios 1, 3 and 4), reservoir refill occurs in 43 years, including 37 years of refill from surplus surface flows and just 6 years from project groundwater pumping. The average refill from surplus surface flows is 32 TAF in the years of occurrence and 14 TAF over the full period. In contrast, the refill from project groundwater pumping is 44 TAF in the years of occurrence but just 3 TAF annually averaged over the full period. Importantly, the maximum year pumping is 50 TAF, the full assumed repayment pumping capacity. At the 100 TAF project scale in Butte Basin (Scenario 2), reservoir refill occurs in 51 years, with refill from surplus surface water occurring in 43 years and from project groundwater pumping in 8 years. The average refill from surplus surface flows is 72 TAF in the years of occurrence and 36 TAF annually over the full period.

TABLE ES-4
Reservoir Refill under Conjunctive Operations
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

			Surplus Surface Water			Project Groundwater Pumping			
Scenario(s)	Project/System	Payback Pumping Capacity (TAF)	Number of Years	Avg in Yrs of Occurrence (TAF)	Avg Over All Yrs (TAF)	No. Yrs.	Avg in Yrs of Occurrence (TAF)	Avg Over All Yrs (TAF)	Maximum Year (TAF)
1, 3 and 4	GCID/CVP Lake Shasta-Sac R	100	29	70	24	4	70	4	98
1, 3 and 4	Butte Basin/SWP Lake Oroville-Feather R	50	37	32	14	6	44	3	50
2	GCID/CVP Lake Shasta-Sac R	200	35	139	58	6	123	9	198
2	Butte Basin/SWP Lake Oroville-Feather R	100	43	72	36	8	75	7	100

For the Butte Basin 50 TAF project scale (Scenarios 1, 3 and 4), reservoir refill occurs in 43 years, including 37 years of refill from surplus surface flows and just 6 years from project groundwater pumping. The average refill from surplus surface flows is 32 TAF in the years of occurrence and 14 TAF over the full period. In contrast, the refill from project groundwater pumping is 44 TAF in the years of occurrence but just 3 TAF annually averaged over the full period. Importantly, the maximum year pumping is 50 TAF, the full assumed repayment pumping capacity. At the 100 TAF project scale in Butte Basin (Scenario 2), reservoir refill occurs in 51 years, with refill from surplus surface water occurring in 43 years and from project groundwater pumping in 8 years. The average refill from surplus surface flows is 72 TAF in the years of occurrence and 36 TAF annually over the full period.

It is evident from this summary that there are opportunities to generate appreciable incremental benefits through conjunctive operations in terms of increased environmental flow releases and agricultural water supplies, without infringing on CVP and SWP operations. Additional results from operations simulations are described in the body of this report.

Impacts of Project Groundwater Pumping

Impacts to Existing Groundwater Pumpers

The effects of the additional project groundwater pumping for reservoir payback were evaluated using the groundwater model. This was done by imposing the payback pumping monthly time series determined by the surface water model on baseline pumping to estimate the effects on groundwater levels. The effects of changes in groundwater levels on the operability of existing wells in the project area and on pumping costs were then evaluated.

There are approximately 15,400 existing groundwater production wells in the project area, with about 9,100 of those wells (59%) being relatively shallow, domestic supply wells and about 4,500 wells (29%) being irrigation wells. The remaining wells are for unknown or other purposes (Table ES-5).

TABLE ES-5
Number of Water Supply Wells in Project Area[6]
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Use	**Number of wells**
Domestic	9,058
Irrigation	4,455
Unknown[7]	1,388
Other	267
Municipal	139
Stock	75
Public	52
Total	15,434

The surface model predicted the need for pumping in about 10 percent of the years in the Butte Basin and about 7 percent of the years in GCID under the 300 TAF pumping scenarios (200 TAF GCID, 100 TAF Butte Basin; see Table ES-6). In years in which pumping occurs, pumping is usually required in either GCID or in the Butte Basin, but not both. However, in exceptionally dry years, pumping would occur in both areas in the same year (see bolded years in Table ES-6).

TABLE ES-6
Occurrence of Pumping
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Maximum Pumping	Number of times pumping occurs (82 years of record)		Years in which pumping occurs		Number of times pumping occurs in GCID and/or Butte Basin
	GCID - Shasta	Butte - Oroville	GCID - Shasta	Butte - Oroville	
150 TAF (100 TAF GCID; 50 TAF Butte Basin)	4	6	1947, 1987, 1988, **1990**	1933, 1961, **1990**, 1992, 1994, 2002	9
300 TAF (200 TAF GCID;100 TAF Butte Basin)	6	8	1923, **1929**, **1947**, 1987, 1988, **1990**	**1929**, 1933, **1947**, 1961, **1990**, 1992, 1994, 2002	11

* **bolded** years indicate that pumping would have occurred in both GCID and Butte Basin under the Project.

The additional (or interference) drawdown in the shallow aquifer caused by project pumping is shown in Table ES-7, indicating that the maximum additional drawdown is generally less than 10 feet and the average is generally less than one foot. Maximum drawdown occurs near project pumping wells but dissipates rapidly moving away from wells.

---

[6] Data provided by California Department of Water Resources Northern District Office. 2009.

[7] May include monitoring wells, vapor recovery wells, or other wells not constructed for water supply purposes.

TABLE ES-7
Summary Statistics of Monthly Average Interference Drawdown in the Shallow Aquifer by Pumping Scenario, 1987 – 2003
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

	Interference Drawdown (ft)				
Pumping Scenario	Min	Max	Mean	Median	Std. Dev.
300 TAF Summer Pumping, New Well Field	0.0	13.6	0.5	0.3	0.7
300 TAF Summer Pumping, Existing Well Field	0.0	8.3	0.4	0.2	0.6
150 TAF Summer Pumping, New Well Field	0.0	6.2	0.3	0.2	0.4
150 TAF Summer Pumping, Existing Well Field	0.0	5.4	0.3	0.2	0.4
150 TAF Fall Pumping, New Well Field	0.0	7.0	0.4	0.2	0.4
150 TAF Fall Pumping, Existing Well Field	0.0	6.1	0.4	0.2	0.5
150 TAF Summer & Fall Pumping, New Well Field	0.0	5.9	0.4	0.2	0.4
150 TAF Summer & Fall Pumping, Existing Well Field	0.0	5.0	0.4	0.2	0.5

Based in the interference drawdown simulated by the groundwater model, the results of the analysis of impacts to existing groundwater users are summarized as follows:

- The operability of some domestic wells is likely to be affected because these wells tend to be shallow and the magnitude of interference drawdown caused by project pumping is significant relative to the screened intervals of these wells. The maximum number of domestic wells impacted is estimated to be between 153 and 284, which is a relatively small percentage (about 3%) of the total number of domestic wells. This impact occurs in 1990 when pumping occurs in both GCID and the Butte Basin and may be overstated to the extent that some of the impacted wells are no longer in operation. It is noted that goal in project implementation would be to minimize or avoid impacts to domestic wells, if possible.

- Impacts to the operability and yields of existing irrigation wells are negligible because the magnitude of interference drawdown from project pumping is small relative to the screened intervals of these wells.

- Energy requirements and costs will be increased for both domestic and irrigation pumping due to increased pumping lifts. On an annualized basis, the increased energy cost for irrigation pumping is estimated to range between $123,000 and $228,000, and for domestic pumping is estimated to range between $3,000 and $5,000.

Impacts on Streamflow

The modeled project pumping scenarios result in some streamflow reductions, due either to increased stream loss to aquifers or decreased aquifer flow into streams (Table ES-8). To compensate for these losses, the modeling incorporated releases from Shasta and Oroville when the system is “in balance.” Although these releases help maintain streamflow in the Sacramento and Feather Rivers, while insuring the system as whole doesn’t experience significant losses, the releases do not directly mitigate the impact of *tributary* streamflow losses to ecosystems and species. As a starting point for the assessing impact to tributary streams, the project analyzed Butte Creek due to its high ecosystem value combined with some of the largest discharge losses due to pumping. An additional consideration is that historical streamflow records are available for Butte Creek but generally not for other smaller streams.

TABLE ES-8
Peak Effects on Streamflow from Conjunctive Management Operations
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

	Scenario 1		**Scenario 2**		**Scenario 3**		**Scenario 4**	
Stream	**Existing (cfs)**	**New (cfs)**	**Existing (cfs)**	**New (cfs)**	**Existing (cfs)**	**New (cfs)**	**Existing (cfs)**	**New (cfs)**
All Streams[a]	54	53	111	105	80	90	64	65
Butte Creek	13	12	72	69	50	48	39	33
Sacramento River – GCID to Wilkins Slough	42	37	32	28	16	18	16	15
Feather River	3	3	6	6	4	4	4	4
Little Chico Creek	3	3	6	5	4	3	4	3
Salt River	1	5	5	8	2	5	2	5
Stone Coral Creek	6	9	11	15	7	10	6	9
Stony Creek	4	5	7	7	4	6	4	4

[a] Includes the 7 streams listed below.

The Butte Creek analysis yielded the following key results:

- Project pumping will not impact the uppermost reach in the project areas, the primary spawning area for Spring-run Chinook and Central Valley steelhead
- Pumping will have a greater impact on the lower reaches of Butte Creek, than the upper
    - In addition to cumulative effects, the *rate* of leakage is higher in downstream reaches
- The largest absolute losses in streamflow occur when discharge is also highest (Jan.-Mar)
    - The magnitude of impacts in relation to the baseflow at this time is not substantial (maximum of 1-3% loss in streamflow)
- The largest percentage loss in stream flow occurs in the lowest reach during summer/ early fall when Spring-run have already migrated upstream and steelhead are only beginning to enter the streams
- Project pumping never causes average monthly discharge to fall below the instream flow standards in the four upstream reaches
- June average monthly discharge in the lowermost reach, falls below the 40 cfs instream standard twice in the 17 year record due to pumping of up to 150K, and four times under pumping of up to 300K
    - Most Spring-run migration has already occurred by June, but some late Spring-run migrants, may experience minimal impacts
    - These impacts occur during the drought years of 1990, 1991, 1992, 1994, when Butte County irrigators participated in the drought water bank

The results of the analysis do not reveal any significant negative impact to Spring-run Chinook or Central Valley Steelhead in Butte Creek due to project pumping. Furthermore, this analysis focused only on those years with stream impacts (water years 1987 - 2003), during which time groundwater would have been pumped more frequently than over the entire period assessed by the surface water model (1922-2003). As such, on average impacts would likely be less significant and rarer than those projected in this analysis.

Economic Analysis

The economic analysis did not assign a monetary value to the environmental benefits that would accrue. This was not because these would be negligible. In fact, the potential increase in salmon productivity could be quite substantial. Rather, the economic analysis was conducted in part to determine whether the revenue from the project's potential water sales alone would be large enough to pay for the capital and operational costs. In sum, the question was not whether the project would be worthwhile, but whether it could pay for itself.

The net benefit of the project considering the associated costs and expected benefits varies depending primarily on where the water generated by the project can be sold and, to some extent, on whether new wells are constructed or the project is operated using primarily existing wells. As summarized in Table ES-9, if the water generated through conjunctive operations is sold in the Sacramento Valley, only one of the scenarios has a positive net benefit, with the others having modest to strong negative net benefits. In contrast, if the water were valued at rates paid in ag sectors outside the Sacramento Valley or by urban customers, only one of the scenarios has a negative net benefit with the others being positive. Interestingly, even though the 150 TAF summer and fall pumping using the existing wells was the least-cost scenario, the analysis demonstrates that the largest net benefit is associated with the 300 TAF summer pumping scenario using the existing wells (if the water could be exported south of the Delta).

It can be seen from Table ES-9 that the existing well scenarios dominate the new well scenarios in terms of net benefits. The high capital costs associated with constructing new wells make this option less economically viable.

TABLE ES-9
Net Benefit under Various Pumping Scenarios
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Scenario	Annual benefits, local use ($M)	Annual benefits, exports ($M)	Total Cost (PV, $M)	Net benefits, local use ($M)	Net benefits, export ($M)
1 300 TAF Summer New Wells	183	365	290	-107	76

8 150 TAF Summer & Fall Existing Wells	73	147	65	8	81

Operational and Analytic Refinements Recommended by Project Operators

Beginning in April 2010, a series of three ½-day workshops were held with a select group of CVP and SWP operators for the purpose of refining project scenarios. The main purposes were: (1) to identify additional project purposes and benefits that could potentially be realized through conjunctive operations as a means of enhancing project economic performance and (2) to ensure that the simulations were as realistic as possible. The workshops were complemented with one-on-one consultations between operators and project team members as needed to clarify comments and develop specific recommendations for incorporation into scenario development and the supporting modeling methodology.

Specific refinements identified through collaboration with the project operators included the following:

- Updated CALSIM II Baseline. The CALSIM II baseline used for the initial modeling pre-dated the 2008 Biological Opinion on delta smelt (smelt BO) and the 2009 Biological Opinion on Chinook salmon (salmon BO). The baseline was updated with a CALSIM II model run with the smelt BO and salmon BO included. This baseline was used for further development and evaluation of project scenarios.

- Shasta and Oroville Reservoir Minimum Release Constraints. CVP operators expressed concerns about the ability to reduce Shasta releases under conditions when releases are driven by temperature compliance in the Sacramento River below the reservoir rather than water supply demands further downstream. Constraints on the ability to reduce Shasta releases were specified in the form of monthly minimum Keswick releases for temperature compliance. Constraints on the ability to reduce Oroville releases for temperature compliance were specified by SWP operators as a function of Oroville releases and time of year. Potential reductions ranged from zero to 1,000 cfs.

- Forecast-Based Operations. The initial surface water model made project asset decisions (volume of additional reservoir release) based on a perfect forecast of September reservoir storage. The implication of this assumption was to minimize the risk of achieving targeted levels of carryover storage due to conjunctive operations. The surface water model was refined to include a forecast of fall storage conditions based on current reservoir storage, runoff forecasts, and an estimate of reservoir releases from the current month through September. This change made the simulations more like actual project operations.

- Oroville Reservoir Carryover Storage Targets. SWP operators specified Oroville storage targets for the purpose of increasing carryover storage when at or below 1.5 million acre-feet (MAF) under base conditions by up to a maximum of 200 thousand acre-feet (TAF). These targets were developed to assist in mitigating effects of damage to the low-elevation outlet that occurred during gate testing several years ago. Damage to the low-elevation outlet has effectively increased dead storage in Lake Oroville leading to a desire to increase carryover storage.

- Crop Idling for Reservoir Payback. The surface water model was modified to simulate crop idling as a payback mechanism to recover reservoir storage. This was done to reduce or avoid the need for project pumping, thereby reducing project costs and enhancing overall project cost-effectiveness. A number of assumptions and constraints were placed on crop idling operations, the main assumptions being that crop idling would be voluntary and incentive-driven and would be limited in extent to no more than 20% of the irrigated area in GCID and the Butte Basin (WCWD and RID).

With these refinements made to the surface water model and project operating objectives and constraints, the project scenarios were reassessed, leading to the following observations:

- Updating the CALSIM II baseline to include the smelt and salmon BOs had negligible effect on project performance.

- The addition of forecast-based operations together with minimum reservoir releases for water temperature compliance dramatically reduced project performance with respect to generating environmental flow releases and agricultural water supplies. Relative to initial conditions, benefits were reduced by one-half to two-thirds. The procedures developed for forecasting end-of-year reservoir storage were deliberately conservative to limit risks to carryover storage; however, the effect of the forecasts was to substantially reduce the estimated project water assets, which severely reduced both environmental flow releases and agricultural water supplies. The effect of minimum reservoir releases was to reduce the times when payback pumping can effectively recover reservoir levels, also diminishing project performance.

- Employing project pumping to assist in meeting Oroville Reservoir carryover targets is not effective because project pumping is called on frequently, to the extent that groundwater impacts could become problematic. Additionally, much of the water held in reservoir storage subsequently spills due to displacement with by surplus surface flows.

- Temporary crop idling is not an effective means of reservoir payback, primarily because crop idling decisions need to be made early in the season and involve making an irreversible commitment to participating growers for purchasing the water generated through crop idling regardless of whether the water can be held in upstream storage or put to beneficial use downstream. Modeling shows that too frequently temperature releases govern reservoir operations and the water generated by crop idling cannot be held in storage.

Fundamental Conclusions

The seminal conclusion of this investigation is that re-operating Shasta and Oroville Reservoirs in conjunction with operation of Sacramento Valley groundwater aquifers could produce appreciable additional water supplies for discretionary allocation to environmental enhancement flows in the Sacramento and Feather Rivers, for increased local and regional water supply reliability and potentially for meeting water demands outside the Sacramento Valley. This can be done with low risk to CVP and SWP reservoir storage levels and water deliveries under most conditions because additional releases made for these purposes are replaced with reservoir refill from surplus surface flows most of the time, with groundwater pumping for reservoir “payback” required relatively infrequently. In the years needed, groundwater pumping would be appreciable but potential impacts to existing Sacramento Valley groundwater conditions in the areas of pumping appear be manageable and could be mitigated. Overall, the project would result in a net gain of groundwater storage in the Sacramento Valley if, as assumed, additional water supplies generated by re-operation are used to meet demands that would otherwise be met by pumping groundwater.

Modeling of conjunctive operations reveals that the ability to recover reservoirs by pumping groundwater when they fail to recover sufficiently from surplus surface flows is constrained at times by the need to sustain reservoir releases for temperature control, in order to provide desirable conditions for salmonids. In effect, the scale of conjunctive operations and the ability to generate one kind of environmental benefits (ecologic flows) is constrained by existing operational requirements for another kind of environmental benefits (temperature control). This tradeoff between different environmental water uses points to the need for comprehensive, holistic approaches to environmental water management. The analytical tools developed for this project are sufficient to support development of such approaches.

While an economically feasible in-Valley operation scenario was not identified by the investigation, prospects of a viable formulation appear promising and further development and integration of the core concept is warranted, particularly if greater revenues can be derived by selling water at higher prices, or there was a willingness to pay for the environmental benefits provided. It is noted that the ecologic benefits that could be achieved by improving flow regimes in the Feather and Sacramento Rivers through conjunctive operations were not included in the assessment of the project's economic feasibility. This is because methodologies for valuing those benefits are somewhat speculative. Additionally, the benefits that would result from improved groundwater conditions within the Sacramento Valley due to the delivery of additional surface water supplies and consequent relaxation of groundwater pumping were not factored into the economic analysis. Valuation and inclusion of these benefits in any future phases of investigation would enhance the economic feasibility of conjunctive operations.

Recommended Further Investigation

A number of specific recommendations for further development and refinement of Sacramento Valley conjunctive water management are provided in the body of this final report. These are primarily technical in nature, involving reconciling tradeoffs among different types of environmental water uses, more detailed water temperature modeling, refined reservoir payback operations, integration with south of Delta groundwater banking and refinement of analytic tools.

Beyond the technical factors lie significant institutional and social challenges that would need to be addressed if there is sufficient interest in advancing the project toward implementation. These include developing protocols and procedures for real-time operations decisionmaking, integrating conjunctive operations into the Coordinated Operations Agreement, developing project governance structures among local political jurisdictions, and developing formulae for allocating project benefits and costs.

However daunting these challenges may appear, the potential benefits relative to risks revealed through this investigation suggest that further efforts to develop and implement conjunctive water management in the Sacramento Valley are warranted.

1. Principal Findings and Conclusions

The main findings and conclusions reached through this investigation are summarized below:

1. The core concept of augmenting yield from Lake Shasta and Lake Oroville by increasing releases before the refill season, and thereby reducing carry-over storage levels to allow subsequent capture of a larger fraction of flood flows, is hydrologically feasible. In most years, the additional reservoir space evacuated is refilled by surplus surface flows that otherwise would have been lost as flood control releases. However, in some years, reservoir storage does not recover to levels that would have occurred without the additional releases, resulting in a reservoir storage deficit compared to baseline conditions.

2. To satisfy CVP and SWP supply obligations at current levels and to comply with current environmental regulations, especially those pertaining to water temperature, it is necessary to have a method for "paying back" any reservoir deficits resulting from the additional releases. The scale of the re-operation that is feasible without risk to water supply and project operations is limited by the capacity to pay back the reservoir because the maximum reservoir deficit cannot be larger than the ability to pay it back in a single year, when necessary.

3. At the two payback scales investigated (see Section 5), simulations indicate that between 27 thousand acre-feet (TAF) and 69 TAF of additional water supplies could be generated on an average annual basis from Shasta re-operation, while Oroville re-operation could yield between 17 TAF to 43 TAF on an average annual basis. However, these estimates do not take into account the minimum mandatory reservoir releases for temperature control or forecast-based reservoir operations as described below.)

4. Four strategies for reservoir payback have been identified as warranting consideration, three of which were analyzed in this phase of the project. The three payback mechanisms analyzed in this phase are:
    a. Drawing on project surplus water that would be banked through intentional recharge of groundwater at sites within the Sacramento Valley;
    b. Pumping groundwater within Glenn Colusa Irrigation District (GCID), a CVP settlement contractor, to pay back Shasta Reservoir and within Western Canal Water District (WCWD) and Richvale Irrigation District (RID), both served through the SWP collectively referred to as the "Butte Basin", to pay back Oroville Reservoir; and
    c. Reducing surface water demands through voluntary, temporary, and compensated idling of crop lands by willing growers in these participating districts[8].

5. Payback through groundwater banking in the Sacramento Valley proved to be infeasible because, under existing levels of groundwater use, the seasonally dewatered aquifer space tends to recharge annually during the following precipitation season. Cones of depression from groundwater pumping typically do not persist over the multiple years necessary for an efficient, actively recharged, banking operation. Therefore, additional recharge for water banking tends to

---

[8] Another strategy for demand reduction is foregoing flooding rice lands at the end of the growing season for rice straw decomposition. The potential to substitute other means of disposing of the straw, such as removal to delta islands to rebuild their elevation, has not been analyzed because this option has the disadvantage of eliminating valuable waterfowl refugia during the late fall and winter seasons.

cause rejection of recharge from other sources or increased aquifer discharge, with little net gain in groundwater storage. Consequently, this payback option was not further pursued.

6. Payback through groundwater pumping within the participating water districts was found to be technically feasible with impacts on other existing groundwater users small enough to be mitigated and compensated. Impacts to the yields and operability of agricultural wells would be negligible, while up to approximately 3 percent of the large number (more than 9,000) of existing domestic wells would become inoperable and would therefore needed to be deepened or replaced. The pumping lift for all wells would increase resulting in increased pumping costs.

7. The investigation also addressed the feasibility of repaying the reservoirs through reducing water demands in the participating districts instead of pumping groundwater. This would have the advantage of avoiding entirely impacts on other groundwater users. This could be accomplished through a program of voluntary crop idling by growers in these districts pursuant to a water buy-back arrangement. This payback strategy proved to be inefficient because the decision to call on crop idling for payback must be made before the planting season begins, when the extent of reservoir refill is still highly uncertain. Particularly because end-of-season reservoir storage forecasts are made conservatively, there is a significant probability that the water made available through crop idling is either not needed or is spilled from the reservoir. Consequently this payback option does not perform as well as groundwater pumping from a cost-effectiveness perspective.[9]

8. The fourth payback mechanism, identified but not evaluated in this phase, involves drawing on project water banked in dewatered aquifers south of the delta. This option becomes much more viable if existing pumping constraints at the Banks and Jones plants in the south delta are alleviated by an isolated diversion and conveyance facility around or under the delta to the state and federal canals, such as is being considered in the Bay Delta Conservation Plan (BDCP). This option will be evaluated in the next phase by which time BDCP options presumably will have been clarified. It is notable that this option would allow the surplus water to be stored and used at times and places of greatest economic value, compared to the other strategies that were evaluated. It is also notable that this option would not entail increasing the volume of water that is exported from the Sacramento Valley currently, but would convert some portion of delta outflow during the flood season to water supply south of the delta.

9. All of the payback mechanisms investigated would be constrained during periods when reservoir releases governed by water quality objectives (mainly temperature) exceed the releases needed to serve downstream demands. Under these conditions, regardless of how it is generated, payback water cannot be held in upstream storage because reservoir releases cannot be reduced and still meet water quality objectives. Minimum releases at Keswick (on the Sacramento River) are prescribed by current water quality regulations imposed by the biological opinions of the National Marine Fisheries Service at the federal level and by the State Water Resources Control Board at the state level to prevent lethal temperature occurrence in the

---

[9] Another strategy for implementing temporary crop idling was identified but not evaluated as part of the investigation. Rather than invoke crop idling prior to planting, the idea would be to trigger idling during the crop season when the determination of the need for and effectiveness of payback could be forecast with much greater reliability. Certain crops, such as alfalfa, are adapted to intermittent irrigation, although production losses more or less proportional to water shortages are expected.

Sacramento River for spring and winter run salmon. Operational protocols to maintain viable temperatures for the Feather River below the Thermalito re-regulation dam are also prescribed in the proposed settlement agreement for the Oroville relicensing by the Federal Energy Regulatory Commission (FERC). The extent to which these may also constrain the payback potential for Oroville should be analyzed further.. Like the other payback options, the extent to which the reservoir carryover storage can be reduced through additional releases for the project purposes (environmental flows and water supply) is limited by the ability to make up any storage deficits that result from insufficient reservoir inflow in subsequent precipitation seasons. Substituting groundwater pumping for surface water deliveries is a means to do that. But in the case of Shasta reservoir (and probably also Oroville reservoir under the FERC relicensing agreement), such substitution will only work to the extent that a commensurate amount of water can be retained in the reservoir. The requirement to release prescribed amounts of water at Keswick dam for temperature control means that in many years, groundwater pumping cannot completely replace reservoir water.

10. Shasta and Oroville Reservoirs are operated at present in a conservative manner that minimizes the risks of temperature stresses for salmonids in the downstream rivers. These conservative operations dramatically reduce potential improvements in environmental flows made possible by project conjunctive operations. Three of the project’s four environmental flow improvements are designed to benefit salmon through increased spring pulses for out-migration, floodplain inundation for rearing and food, and geomorphic flows to improve spawning conditions. Yet the more aggressive reservoir operations to generate these environmental flows unavoidably increase the risks to the cold water pool to some extent. It is apparent that there is a tradeoff between temperature risk reduction and environmental flow benefits. Whether the loss of suitable habitat in some reaches of the rivers due to adverse temperatures, if any, is more than offset by the improvements in habitat for salmon resulting from meeting the other environmental flow improvements more frequently will also be investigated in the next phase of this project. It is also possible that fish passage to access the cold water resources above the dams, such has been recommended by NMFS as a salmon recovery measure, would also alleviate the volume and timing of cold water releases needed for temperature control below the dams. This will also be investigated in the next phase. These subsequent investigations will illuminate whether the optimal strategy can result in less constraining minimum releases at Keswick and larger and more frequent yields of water for environmental flows and water supply.

11. Simulations of conjunctive operations with the effects of minimum reservoir releases for temperature control (in combination with forecast-based simulation techniques) revealed that project benefits are dramatically reduced, by approximately one-half to two-thirds of the levels discussed above in #3. At this scale, the economic benefits are also small in light of the costs of the projects, including primarily the energy cost for pumping payback groundwater and the costs of mitigating the effects of this pumping on other groundwater users.

12. The economic benefits of the project in the near term with this (groundwater pumping) payback mechanism include the market value of the additional water within the Sacramento Valley, estimated to be $50 per AF.

2. Introduction

2.1.Purpose

In 2006, the Glenn Colusa Irrigation District (GCID) and the Natural Heritage Institute (NHI) jointly embarked on this investigation to explore how the largest water storage reservoir in the Federal Central Valley Project (CVP), Shasta, and the only such reservoir in the State Water Project (SWP), Oroville, could be re-operated in conjunction with northern Sacramento Valley groundwater aquifers to increase water supplies for both environmental and economic uses. The investigation was enabled by a combination of state and federal grant funding, including Proposition 50 funding administered by the Department of Water Resources (DWR) and federal funds administered by the Bureau of Reclamation's (Reclamation) Mid-Pacific Region.

The potential of conjunctive water management in the Sacramento Valley has long been perceived as offering significant potential to produce additional water supplies due to the presence of large surface reservoirs and extensive, although not well understood, groundwater aquifers. Conceptual level investigations, including one completed by NHI in 1999, have generally confirmed this potential but have not fully taken into account the myriad factors governing reservoir operations, including the existing water supply obligations of the reservoirs, flood control functions and environmental regulations. The purpose of this investigation was to further investigate Sacramento Valley conjunctive management opportunities taking into consideration these constraints. Additionally, there has been little definitive investigation of the effects that aquifer recharge and additional pumping implicit to conjunctive management might have on groundwater conditions in the Sacramento Valley. This was also an objective of this investigation.

2.2.Evolution of Project Perspective and Scope

At its inception, the investigation focused on the Sacramento Valley's deep aquifers, particularly the Lower Tuscan Formation, which underlies much of the northern portion of the Sacramento Valley. However, as the investigation progressed the study team recognized that such a narrow focus was both overly constraining on the scope of the study and somewhat misleading because it implied that any effects on the aquifer system due to additional recharge or pumping could somehow be confined to a particular portion of the groundwater system. Ultimately the project evaluated the effects of exercising both the northern Sacramento Valley's deep aquifer system, which is presently relatively undeveloped, and the shallower, regional aquifer, which is more heavily pumped for both domestic and agricultural needs.

The investigation began with the expectation that surplus water generated through the re-operation of these reservoirs could be banked in the groundwater aquifers in the Sacramento Valley, like other conjunctive use programs in the San Joaquin Valley of California, with water put into groundwater storage in wet years and extracted in dry years. However, initial assessment and site screening revealed that conditions in the Sacramento Valley are not conducive to this mode of conjunctive management, primarily because groundwater aquifers, although extensively developed and pumped in many areas, mostly for agricultural irrigation, generally recover fully during the precipitation season. What emerged was a conjunctive management approach based on reservoir re-operation backstopped by several options for reducing the draw on reservoir storage when refill is insufficient.

The scope of the investigation included technical, economic, institutional and outreach components. Technical work concentrated on developing coordinated groundwater and surface water models for formulating and evaluating alternative conjunctive management strategies and project configurations. Model development consumed more time and a larger percentage of the project's resources than initially intended, which required reallocation of resources from the economic and institutional analyses. Robust outreach was conducted throughout the course of the effort at many different levels and in different forms.

The investigation was originally scoped to evaluate conjunctive water management opportunities within the Sacramento Valley. However, as the investigation proceeded, it became clear that there may be opportunities to enhance the cost-effectiveness of conjunctive operations through integration with Bay-Delta (Delta) export operations, depending to some degree on the outcomes of current efforts to address Delta issues and governance. Inasmuch as these outcomes are still highly uncertain, and to maintain consistency with the project's original scope, Delta export operations were not investigated but are discussed in the context of possible further investigation. It should be noted that, at a conceptual level, it appears that integration of Sacramento Valley conjunctive management with Delta export operations could provide in-Valley benefits with lower risk compared to the in-Valley configurations evaluated.

The other significant changes that occurred while the investigation was underway were the issuance of the 2008 Biological Opinion on delta smelt (smelt BO) and the 2009 Biological Opinion on Chinook salmon (salmon BO). The project baseline was adjusted during the course of investigation in response to requirements stemming from these changes.

2.3.Report Contents

Following this Introduction, the agencies that sponsored, participated in and funded the investigation are described and the public outreach process is summarized (Section 3). The analytic approach to the investigation is presented in Section 4. The discussion focuses on the core conjunctive operations concept of reservoir re-operation backed by groundwater pumping for reservoir "payback". Additionally, specific reservoir payback mechanisms are described and the objectives, principles and constraints that formed the analytical framework are presented.

The initial project scenarios are presented in Section 5, including descriptions of the scenarios, development of the analytic tools (models) used to formulate and evaluate potential project operations and summaries of how the scenarios performed in physical and economic terms. Section 5 concludes with a discussion of interim findings that shaped further analysis and refinement of project scenarios.

Section 6 describes the phase of the project involving collaboration with the operators of the Central Valley Project (CVP) and State Water Project (SWP). During this phase, in response to operators' suggestions, certain modifications were made to the analytic tools to incorporate constraints that presently govern CVP and SWP operations, particularly reservoir operations for cold water management and additional project objectives were assessed. These factors are described along with the conclusions drawn from the refined and extended analysis.

Finally, in Section 7, ideas and suggestions to guide further investigation of Sacramento Valley conjunctive water management are offered. Among the recommendations are suggestions to investigate integration with Delta export operations.

2.4.Acknowledgements

NHI and GCID are grateful for the opportunity to sponsor this investigation and wish to acknowledge DWR and Reclamation for awarding the enabling grant funds. Additionally, DWR provided groundwater well information and other data without which development of analytic tools and evaluation of impacts of additional groundwater pumping would not have been possible.

In particular, the sponsors wish to thank the individual DWR and Reclamation staff members who operate the CVP and SWP and gave freely of their time during the collaborative phase to enhance the pertinence of the investigation.

Finally, the sponsors are grateful to the many members of the public and representatives of public interest groups who participated in the project's public meetings. The comments received during these meetings were heard and carefully considered.

3. Project Sponsors, Participants and Donors

3.1.Sponsors

3.1.1. Glenn Colusa Irrigation District

The Glenn-Colusa Irrigation District (GCID) appropriative water rights begin on the Sacramento River with an 1883 filing posted on a tree by Will S. Green, surveyor, newspaperman, public official, and pioneer irrigator. His first claim was for 500,000 miner's inches under 4 inches of pressure and was one of the earliest and largest water rights on the Sacramento River.

GCID was organized in 1920, after several private companies failed financially, and a group of landowners reorganized and refinanced the irrigation district, retaining claim to Green's historic water right. The disastrous rice crop failure of 1920–21 nearly destroyed the district at its inception, and the "great depression" took a further toll, making it necessary for the district to refinance in the 1930s. Additionally, the United States purchased lands within GCID during this period which would later become three federal refuges totaling approximately 20,000 acres.

Today, after surviving many challenges, GCID is the largest district in the Sacramento Valley. Located approximately eighty miles north of Sacramento, California, the district boundaries cover approximately 175,000 acres; of which 153,000 acres are deeded property and 138,800 are irrigable. There are 1,076 landowners in the District and an additional 300 tenant water users. There are an additional 5,000 acres of private habitat land, and winter water supplied by GCID to thousands of acres of rice land provides valuable habitat for migrating waterfowl during the winter months.

GCID's main pump station, its only diversion from the Sacramento River, is located near Hamilton City. The District's 65-mile long Main Canal conveys water into a complex system of nearly 1,000 miles of canals, laterals and drains, much of it constructed in the early 1900s. The District headquarters are located in Willows, the county seat of Glenn County, approximately 90 miles north of Sacramento on Interstate 5.

A five-member board of directors, who represent five subdivisions within the District, governs the District. The annual budget is $15 million. GCID's mission is to provide reliable, affordable water supplies to its landowners and water users, while ensuring the environmental and economic viability of the region.

From its first diversions until 1964, GCID relied upon its historic water rights and adequate water supply from the Sacramento River hydrologic system which receives rainfall and snowmelt from a 27,246 square mile watershed with average runoff of 22,389,000 acre-feet, providing nearly one-third of the state's total natural runoff. In 1964, after nearly two decades of negotiations with the United States, GCID along with other Sacramento River water rights diverters entered into "Settlement Water Contracts" with the Bureau of Reclamation (Bureau). These Settlement Contracts were necessary at that time to allow the Bureau to construct, operate, and divert water for the newly constructed Central Valley Project. The contract provided GCID with water supply for the months of April through October for 720,000 acre-feet of base supply, and 105,000 acre-feet of Central Valley Project water that is purchased during the months of July and August. During a designated critical year when natural inflow to Shasta Reservoir is less than 3.2 million acre-feet, GCID's total supply is reduced by 25 percent, to a total of 618,000 acre-feet.

Additionally, the District has rights under a State Water Resources Control Board (SWRCB) permit to "winter water" from November 1 through March 31 at a 1,200 cubic feet per second (cfs) diversion rate. This water supply is used for rice straw decomposition and waterfowl habitat. The permit provides 150,000 acre-feet for rice straw decomposition and 32,900 acre-feet for crop consumption. Groundwater can be used to supplement GCID's supplies, with 5,000 acre-feet available from District wells, and approximately 45,000 acre-feet from privately owned landowner wells.

3.1.2. Natural Heritage Institute

Natural Heritage Institute (NHI) is a non-governmental, non-profit organization founded in 1989 to restore and protect the natural functions that support water-dependent ecosystems and the services they provide to sustain and enrich human life. Its founders foresaw the need for a toolkit for the next era of environmental problem-solving: where the technical challenges are more complex, the solutions more elusive, the economics more central, the ramifications more global, and the conventional pathways less efficacious. NHI is motivated by the realization that, when the earth's limited stock of natural resources is squandered, the legacy bequeathed to future generations is impoverished, sometimes for all time. The only hope for this beleaguered planet is to do more with less and to restore the damage of the past. Increasingly, the environmental challenge is to move from strategies that freeze the status quo to those that ensure that the economic use of natural resources also yields net environmental gains.

Previous work by NHI has shown that re-operating existing Central Valley reservoirs in conjunction with groundwater banks could generate surplus water to restore more natural flow patterns in the eleven regulated tributaries of the Central Valley – comprising by far the largest ecosystem restoration program ever undertaken in this geography – while also satisfying growing demand from agricultural and urban users. Because it utilizes existing infrastructure, conjunctive management is faster and less costly to implement than other water supply augmentation strategies. Indeed, it could generate more new water supply than any other current alternative, and, uniquely, do so without any governmental subsidies.

The system-wide analysis has now progressed through the "proof of concept" stage, and NHI is applying the results in regional demonstration projects. The first regional component is being pursued in the Sacramento Valley through this investigation in collaboration with the Glenn Colusa Irrigation District. This work in the Central Valley of California serves as a model for conjunctive water management in watersheds worldwide through NHI's Global Dam Re-optimization Initiative, which is funded by major foundation, national governments and intergovernmental organizations.

3.2. Participating Water Suppliers

Western Canal Water District (WCWD) and neighboring Richvale Water District (RID) elected to participate in this study in a passive manner by expressing their interest in potential willingness to support a conjunctive management project, subject to the findings of the investigation. WCWD and RID are two of four districts collectively referred to as the Joint Water Districts, the others being Biggs West Gridley Water District (BWGWD) and Butte Water District (BWD). Each year, on average, the Joint Water Districts import about 610 TAF of Feather River water into Butte Basin for irrigation purposes. The unconsumed portion of the imported flows serve in part to recharge underlying aquifers and to sustain flows that serve as supply sources for downstream water users.

3.2.1. Western Canal Water District

Western Canal Water District was formed by an election of District landowners on December 18, 1984, which elected five Directors and authorized the purchase of the District from Pacific Gas and Electric Company. PG&E had obtained the District from their predecessor, The Great Western Power Company, who had developed the hydroelectric power facilities on the Feather River early in the 1900s. The acquisition included pre-1914 water rights on the Feather River for use by the District. These consist of 150,000 acre feet of natural flow of the river and 145,000 acre feet of water stored in the North Fork Feather River Project. The District also has adjudicated rights to a small amount of Butte Creek water.

WCWD is comprised of a gross area of 65,000 acres with irrigable acreage of about 58,500 acres. The primary crop is rice with a small amount of pasture and orchard crops. The District has ten employees and an operations budget of about $1.3M. Two-thirds of the District lies in Butte County, and the rest in Glenn County.

In 1998, the District completed the WCWD Fish Passage Improvement Project, which allowed for removal of four dams on Butte Creek. Butte Creek is one of three remaining tributaries to the Sacramento River that sustain a Spring-Run Chinook salmon population. This award winning project was funded by WCWD, the Department of Interior, and CALFED at a cost of $9.1M.

WCWD supports conjunctive use of groundwater and surface water in order to most efficiently and effectively use the resource for maximum benefit to the local area as well as the entire state, and has participated in several drought years to assist the State Water Bank by facilitating groundwater substitution exchanges. WCWD has developed a Groundwater Management Plan with Rules and Regulations, which provide for conjunctive use in a responsible and safe manner. The District strives to protect their water rights while working in a in a cooperative manner with all users of the water resources, locally and on a statewide basis.

3.2.2. Richvale Irrigation District

Richvale Irrigation District (RID) was formed on July 7, 1930 by purchasing a portion of the Sutter Butte Canal Company. Governance is provided by a three member Board of Directors that appoints a treasurer and employs a District Secretary/General Manager. The director terms are four years and rotate on odd years.

RID holds pre-1914 water rights to the Feather River in conjunction with three other districts (Western Canal Water District, Biggs West Gridley and Butte Water District) that make up the Joint Water Districts. RID consists of approximately 34,000 irrigable acres with rice being the primary crop. RID’s service area includes the Upper Butte Basin Wildlife Area.

RID has a water service contract with DWR for an annual allocation of 149,850 acre feet. All of the district deliveries are made through intake structures utilizing a screw gate or flashboard weir type structures. All water is distributed through earthen canals by gravity flow.

3.3.Funding Agencies

3.3.1. Department of Water Resources

The mission of the California Department of Water Resources (DWR) is to manage the water resources of California in cooperation with other agencies, to benefit the State’s people, and to protect, restore, and enhance the natural and human environments. To this end and in support of the legislative objectives of DWR, development of a System Re-operation Program (SRP) that will identify viable re-operation strategies of California's statewide water system, has been an ongoing process comprised of a diverse set of local, state, and federal agencies. The Glenn Colusa Irrigation District (GCID) is one such local agency that has teamed with DWR to explore the feasibility of an Integrated Regional Water Management Program (IRWMP) in the Northern Sacramento Valley region as a potential integral part of the SRP. Funding for the GCID IRWMP is made possible through DWR's Water Supply Reliability Program (a portion of the voter-approved Proposition 50 water bond measure) and primarily works toward achieving three of DWR eight Strategic Planning Goals as follows:

Goal 2	Plan, design, construct, operate, and maintain the State Water Project to achieve maximum flexibility, safety, and reliability.
Goal 3	Protect and improve the water resources and dependent ecosystems of statewide significance, including the Sacramento-San Joaquin Bay-Delta Estuary.
Goal 6	Support local planning and integrated regional water management through technical and financial assistance.

While a Coordinated Operating Agreement that was initiated in the 1970's and finalized in 1986 has instilled a significant degree of integration between operation of the State's two largest water management systems, the State Water Project (SWP) and the federal government's Central Valley Project (CVP) that were otherwise designed as standalone systems, the GCID IRWMP seeks to further explore opportunities to re-operate portions of California's statewide water system to yield increased water resources related benefits. In addition, recent action by the State Legislature in Senate Bill X2 1 (SB X2 1) (Perata, 2008 – Water Code Section 83002.5), mandates and allocates resources for "planning and feasibility studies to identify potential options for the re-operation of the state's flood protection and water supply systems that optimize the use of existing facilities and groundwater storage capacity. Specifically, SB X2 1 stipulated that the studies shall incorporate appropriate climate change strategies and be designed to determine the potential to achieve, among other things, the following objectives:

- Integration of flood protection and water supply systems to increase water supply reliability and flood protection, improve water quality, and provide for ecosystem protection and restoration.
- Re-operation of existing reservoirs, flood facilities, and other water facilities in conjunction with groundwater storage to improve water supply reliability, flood hazard reduction, and ecosystem protection and to reduce groundwater overdraft.
- Promotion of more effective groundwater management and protection and greater integration of groundwater and surface water resource uses.
- Improvement of existing water conveyance systems to increase water supply reliability, improve water quality, expand flood protection, and protect and restore ecosystems.

3.3.2. Bureau of Reclamation

The mission of the Bureau of Reclamation is to manage, develop, and protect water and related resources in an environmentally and economically sound manner in the interest of the American public. Through leadership, use of technical expertise, efficient operations, responsive customer service and the creativity of people, Reclamation seeks to protect local economies and preserve natural resources and ecosystems through the effective use of water.

The Mid-Pacific Region (MP Region) of the Bureau of Reclamation was created by the Secretary of the Interior in 1942. MP Region comprises numerous dams, reservoirs and conveyances that provide water for urban, industrial, agricultural, and fish and wildlife/environmental uses; generate hydro-electric power; and provide for flood protection, river navigation, and recreation. The Region includes lands from Klamath Falls, Oregon, south to Bakersfield, California, and most of northwestern Nevada. The MP Region is one of five Regions that carry on day-to-day planning, management, and operational activities for the Bureau of Reclamation.

Created by the Secretary of the Interior in 1942, the MP Region is headquartered in Sacramento, California and has Area Offices located at Shasta Lake, Folsom, and Fresno, California; Carson City, Nevada; and Klamath Falls, Oregon. Supporting offices include the Central Valley Operations Office in Sacramento and the Mid-Pacific Construction Office in Willows, CA.

The Mid-Pacific Region is best known for the massive Central Valley Project (CVP) built to tame the flood waters and irrigate the semi-arid acreage of California's vast Central Valley, the CVP grew over the last 50 years to become one of the largest water storage and transport systems in the world. The CVP is a system of 20 reservoirs and more than 500 miles of major canals and aqueducts that encompasses 35 counties. The CVP has a combined storage capacity of more than 11 million acre-feet of water, manages approximately 9 million acre-feet of water, and delivers more than 7 million acre-feet in a year, more than any other single California agency in a normal year. There are 11 hydroelectric power plants providing an average of 5.5 billion kilowatt hours of electricity to supply around 1.5 million people with power throughout the Mid-Pacific Region.

3.4.Public Outreach

Public outreach was conducted in a variety of forms to guide development of the project and to inform interested parties. The various meetings held to effect outreach, as well as achieve technical coordination among the project team, are listed in Table 3-1 and discussed in the following subsections.

3.4.1. Public Outreach

A total of seven public outreach meetings were conducted during the course of the project to both inform the public and to solicit feedback to guide the project’s direction. Initial public outreach concentrated on Sacramento Valley counties and consisted of two formal meetings complemented by informal one-on-one discussions with key county staff and elected officials. These meetings were very useful in framing local and regional sensitivities, and provided good background for scoping and directing the project.

Later, the team engaged the public through publicly noticed meetings, which generally drew sizeable, interested crowds and generated useful dialogue and feedback. Three public meetings were held in the latter half of 2008 and two more in late 2010 for this purpose. All meetings were held in the Chico vicinity. Materials for the two 2010 meetings (October 21 and December 8) are included in Appendix A.

3.4.2. Executive Briefings

Three executive briefings were provided by the team, two with DWR management and staff and one with Reclamation management and staff. These briefings generally consisted of high-level overviews of project status, with emphasis on linkage and coordination with related agency initiatives.

TABLE 3-1
Chronological List of Outreach and Technical Team Meetings
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Event #	Date	Location	Meeting Type	Participants	Purpose/Notes
1	11/16/2006	GCID	Public Oureach	GCID, NHI, Sac Valley county staff	General information; gauge interest; gather feedback
2	12/19/2006	GCID	Public Oureach	GCID, NHI, Sac Valley county staff	General information; gauge interest; gather feedback
3	6/19/2007	MBK Engineers/Sacramento	Technical	GCID, NHI, technical team members	Project site selection, model development, environmental flows
4	7/30/2007	MBK Engineers/Sacramento	Technical	GCID, NHI, technical team members	Project site selection, model development, environmental flows
5	9/21/2007	MBK Engineers/Sacramento	Project Coordination	GCID-NHI	Comprehensive review of technical work; strategic issues
6	9/21/2007	MBK Engineers/Sacramento	Technical	GCID, NHI, technical team members, DWR staff	Project site selection, model development, environmental flows; Delta issues
7	10/23/2007	MBK Engineers/Sacramento	Technical	GCID, NHI, technical team members, DWR staff	Model develop and interaction; environmental flows
8	2/25/2008	MBK Engineers/Sacramento	Technical	GCID, NHI, technical team members, DWR staff	Model develop and interaction; environmental flows
9	5/23/2008	MBK Engineers/Sacramento	Technical	GCID, NHI, technical team members, DWR staff	Model develop and interaction
10	5/29/2008	MBK Engineers/Sacramento	Technical	Modeling subteam (selected technical team members)	Model development and calibration
11	6/18/2008	MBK Engineers/Sacramento	Technical	Modeling subteam (selected technical team members)	Model update and demonstration
12	7/8/2008	MBK Engineers/Sacramento	Technical	Modeling subteam (selected technical team members)	Model update and demonstration
13	8/4/2008	Chico City Hall	Public Oureach	GCID, NHI, Chico area interested/concerned parties	Respond to particular concerns and quesitons raised by participants
14	9/5/2008	DWR/Sacramento	Executive Briefing	NHI, Tracie Billington/DWR	General information/update
15	9/16/2008	GCID Pump Station/Hamilton City	Public Oureach	GCID, NHI, Sacramento Valley public	Update public and receive comment on recent project activities
16	12/8/2008	Durham	Public Oureach	GCID, NHI, Sacramento Valley public	Update public and receive comment on recent project activities
17	1/6/2009	CirclePoint/Sacramento	Planning Meeting	GCID, NHI, program manager	Comprehensive review of technical work and public outreach
18	5/1/2009	MBK Engineers	Technical	Tech Team	Develop methodology for assessing groundwater impacts
19	8/11/2009	USBR/Sacramento	Executive Briefing	NHI, GCID, Don Glaser/USBR, USBR staff	General information/update
20	1/6/2010	Davids Engineering/Davis	Technical	GCID, NHI, technical team members	Project economics
21	4/8/2010	CVO/Sacramento	Workshop	CVP and SWP operators	Collaborative Workshop #1
22	6/11/2010	San Francisco	Executive Briefing	NHI Annual Board Meeting	General information
23	7/9/2010	CVO/Sacramento	Workshop	CVP and SWP operators	Collaborative Workshop #2
24	9/8/2010	MBK Engineers/Sacramento	Workshop	CVP and SWP operators	Collaborative Workshop #3
25	10/21/2010	Chico	Public Oureach	GCID, NHI, Sacramento Valley public	Update public and receive comment on recent project activities
26	12/8/2010	Masonic Lodge/Chico	Public Workshop/Oureach	GCID, NHI, Sacramento Valley public	Update public and receive comment on recent project activities
27	3/17/2011	DWR/Sacramento	Executive Briefing	Ajay, Goyal and DWR	Coordination with other DWR initiatives

3.4.3. Workshops

Three of the four workshops conducted for the project were held specifically to engage the CVP and SWP operators. These workshops were used to present the results of technical analyses and to frame and discuss the various assumptions being made by the team regarding existing operation of the CVP and SWP and implications and opportunities associated with conjunctive operations. These workshops were invaluable in refining the project's analytic tools and operations simulations. (Also see section 6.)

The fourth project workshop was designed to engage the Chico area public specifically to walk through the unique conjunctive operation strategy identified for the project (which emphasizes reservoir re-operation backed by limited groundwater pumping).

3.4.4. Technical and Other Team Meetings

During the initial technical formulation of the project from roughly mid-2007 through mid-2008, a series of rigorous meetings were held among the technical team, but also including agency staff. It was during these meetings that the core conjunctive operations concept was developed, project areas screened and models developed and tested. In some cases, adjunct meetings of the project sponsors were conducted before or after the technical team sessions to discuss project strategic issues.

Other project coordination and planning meetings were held occasionally, as needed, to ensure adequate coordination among team members and with the funding agencies.

4. Analytic Approach

4.1.Overview

Development of project scenarios evolved over the period from 2007 to 2011 including efforts to develop appropriate analytic tools (or models) and to evaluate model outputs and project performance (Figure 4-1). Scenario development began by framing projects objectives and principles consistent with the original project proposals but also reflecting input received through initial public outreach. Once these guiding materials were developed, efforts branched onto two parallel, coordinated tracks, one to develop specific environmental flow targets for the Sacramento and Feather Rivers, and another to identify areas within the Sacramento Valley for more detailed investigation. Information compiled for project site screening also provided a basis for assessing different conjunctive operations modes at a conceptual level, leading to identification of the most promising conjunctive management approaches.

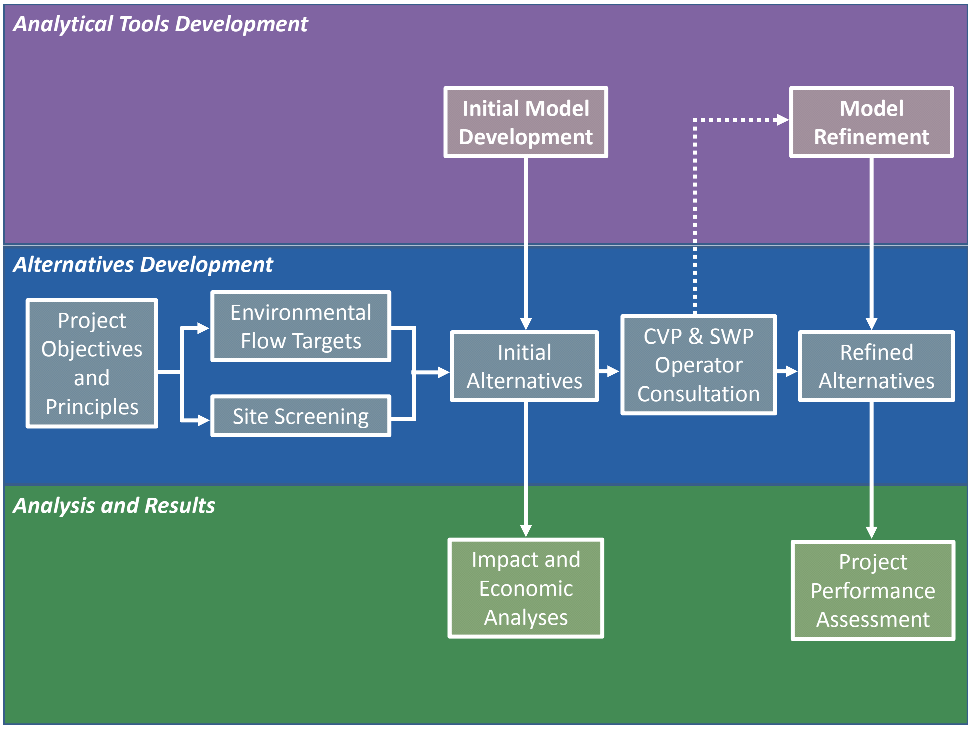

FIGURE 4-1
Project Analytical Components
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

With environmental flow targets established and a clear vision of the conjunctive operations strategy, work began on development of the scenarios themselves and supporting analytical tools. The initial project scenarios that resulted were analyzed in detail, providing a basis for additional public outreach and focused consultations with the operators of the Central Valley Project and State Water Project. The consultation with project operators was particularly instructive, leading to important refinement of the project scenarios and identification of additional project objectives to be tested, along with some as refinement of the models themselves.

The project's core conjunctive operations concept, site screening process and develop of environmental flow targets are discussed in detail in this section (Section 4). Initial model development and scenario development and evaluation are discussed in Section 5, with Section 6 covering model and scenarios refinement and assessment of project performance. The relationship between the analytic components and report structure are presented below in Figure 4-2.

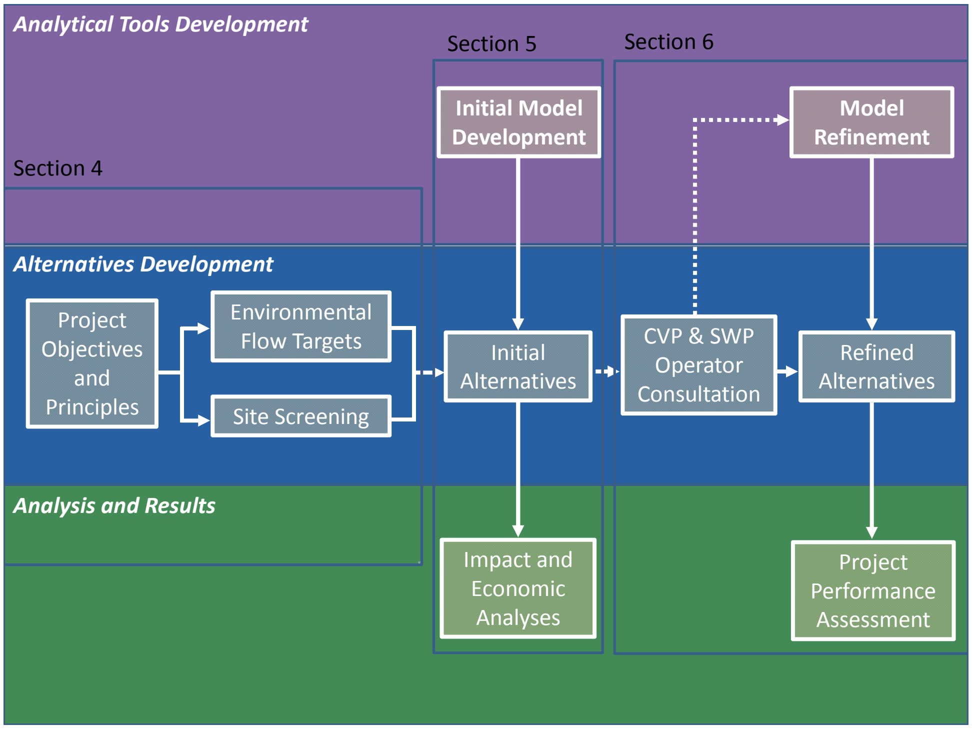

FIGURE 4-2
Relationship between Analytical and Report Organization
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

4.2.The Core Reservoir Re-operation and Payback Concept

The central thesis of this investigation is that most major reservoirs that are operated today for a limited set of water supply and flood control objectives could be re-operated to achieve newly defined ecological restoration benefits while also improving water supply reliability, reducing flood risks, and buffering the effects of climate change. The objective of the project was to explore the potential to optimize operations for all of these benefits without compromising any of them. This opportunity was recognized by the authors of CALFED's Strategic Plan for Ecosystem Restoration:

> "There is underutilized potential to modify reservoir operations rules to create more dynamic, natural high-flow regimes in regulated rivers without seriously impinging the water storage purposes for which the reservoir was constructed. Water release operating rules could be changed to ensure greater variability of flow, provide adequate spring flows for riparian vegetation establishment, simulate effects of natural floods in scouring riverbeds and creating point bars, and increase the frequency and duration of overflow onto adjacent floodplains[10]."

---

[10] CALFED Bay-Delta Program, Ecosystem Restoration Program Plan, Strategic Plan for Ecosystem Restoration, Final programmatic EIS/EIR technical Appendix, July 2000.

Reservoirs that have dual water supply and flood control functions, like the CVP and SWP reservoirs, are typically operated under conservative rules designed to maximize water supply while avoiding flood risks. This results in relative high carryover storage levels but frequent “spills” of water during the refill period to create sufficient flood reservation capacity as necessary to prevent flood damage to the development that has occurred in the downstream floodplain. These spills represent the component of the runoff hydrograph that is not controlled and therefore not appropriated for beneficial use under California water law. To capture and manage this water would require creating additional storage capacity. One way to do that without enlarging the reservoir, or constructing additional ones, is to lower the water storage levels going into the refill period, thereby creating more reservoir capacity to capture high flows. Storage levels can be lowered by delivering additional water from the conservation pool to meet new water supply objectives, including enhancing flows for environmental benefits and augmenting water supplies for consumptive uses such as agriculture.

However, making additional reservoir releases before the ensuing refill period incurs a larger risk of water supply shortages in the event that the quantity of runoff during the refill season, which is always uncertain, is not sufficient to recover the reservoir storage to the level that would have occurred if the additional releases had not been made. Failure for the reservoir to refill would impinge on the reservoir’s function, manifest as water supply shortages, inadequate cold water reserves or reduced carryover storage, or some combination of these factors, unless the reservoir deficit can be made up from other sources.

The concept of re-operation described above was investigated in relation to Sacramento Valley reservoirs, including three options for filling any reservoir storage deficits caused by re-operation. The three options, referred to as reservoir “payback”, are listed below. It should be noted that payback does not involve sending water to the reservoir from other sources. Rather, the reservoir is “paid back” by not releasing water from it that otherwise could be called on, and meeting the water demands that would have been met with reservoir releases with other supplies, or by reducing water demands. The three payback options considered in this study are:

1. Payback from water generated by the project in previous years and stored (or “banked”) in aquifers in the Sacramento Valley;

2. Payback from groundwater pumped by cooperating water suppliers served by the CVP or SWP to substitute for water that would otherwise have had to be delivered from the reservoirs; and,

3. Payback from reduction in water demands on the reservoirs, achieved by temporary crop idling on a voluntary, compensated basis.

Each of these payback options is discussed in greater detail later in this section.

A fourth option that was not considered in this study is to repay reservoirs with water conveyed to and banked in aquifers south of the Delta in previous years. This option poses certain advantages to the Sacramento Valley by eliminating or substantially reducing the need to exercise Sacramento Valley aquifers for payback. However, this option is beyond the scope of this phase of investigation and would be overly speculative at this time given the uncertainty in the status and configuration of Delta conveyance and export options presently being evaluated under the Bay Delta Conservation Plan (BDCP).

4.3.Project Objectives, Design Principles and Constraints

The basic objective of reservoir re-operation is to generate additional water supplies (or “assets”) for discretionary uses. In this case, the investigation looked at dedicating additional water supplies generated through re-operation of Sacramento Valley reservoirs to two primary in-Valley purposes:

1. **Enhancing ecosystem functions in the Sacramento and Feather Rivers.** Healthy rivers are not just environmentally attractive, they also are central to ensuring reliable, sustainable water supplies. Water supply systems that work in concert with the environment are less likely to be encumbered by court orders, water rights hearings, and other restrictions that can have drastic effects on water supplies for farming and other economic uses.

2. **Improving local water supply reliability, particularly in times of scarcity**, to help fill water supply shortages that occur occasionally during hydrologically dry periods. The investigation used historical unmet agricultural water demands to represent the need for additional water supplies in the Valley; however, the additional water supplies could be allocated to other uses and locations.

While not an explicit component of the investigation, it should be noted that the additional water released for ecosystem enhancement becomes additional Delta inflow, which could be used for meeting Delta water quality objectives, for export from the Delta to meet water demands elsewhere in the state or some combination of the two. As discussed later in this report, to the extent that additional Delta exports could be generated while Sacramento Valley water supply reliability is increased and Delta water quality requirements are satisfied, the economic viability of reservoir re-operation and payback would be dramatically improved. Further investigation is needed to examine how these benefits could be optimized.

Design principles were established early on to guide development of project scenarios. The principles were derived in part from public input as well as from the sensibilities of the project sponsors and funding agencies, all aimed at identifying realistic, implementable water management improvements. The primary design principles are as follows:

1. Honor all existing CVP and SWP obligations and operational constraints: The CVP and SWP operate under a complex set of rules and conventions consistent with project water supply and flood control objectives and regulatory requirements, including temperature criteria, State Water Resources Control Board (SWRCB) Decision 1640 (D-1640), and the Central Valley Project Improvement Act (CVPIA). All of these existing objectives and constraints must be observed in any conjunctive management scenario so that water supply obligations to contractors are met to the same extent as under existing operations, and all applicable regulations are satisfied.

2. Achieve net environmental benefits, recognizing that there may be some tradeoffs among different environmental objectives and different times and locations: The Project would be operated to achieve or contribute to achieving certain environmental flow improvements in the mainstem Sacramento and Feather Rivers designed specifically to enhance ecologic functions important to the viability of protected species, particularly Chinook salmon. When groundwater pumping is needed for reservoir payback (under payback option #2, above), this could result in temporary reductions in base flows in the tributary streams that are also important to protected species. Such potential tradeoffs would be addressed through consultation with the listing

agencies as part of the NEPA/CEQA compliance by project sponsors. Additional tradeoffs between restoration of more natural river flow regimes and maintenance of cold water pools for river temperature control are also possible and are discussed later in this report.

3. Hold other groundwater users harmless: The participating water districts are legal users of groundwater, and, like all other groundwater users in the basin, enjoy a correlative and co-equal right to increase their groundwater extractions for use by the overlying landowners, subject to the mutual avoidance of harm. Notwithstanding the legality of the participating districts' groundwater withdrawals, the Project would adhere to a "good neighbor" principle and design its mitigation plan to the higher standard of assuring no appreciable, unmitigated harm to existing groundwater users.

4. Generate net economic benefits so that the program can be self-financing: The project must be able to generate revenues that more than offset the expenditures associated with project implementation, including construction, operation, maintenance and any mitigation costs. In the economic analysis conducted for the study, revenues were included only for water sales; no monetary value was attached to ecosystem restoration benefits, although these benefits may be quite appreciable.

Given the project objectives and design principles set forth above, certain constraints emerged during formulation and evaluation of project scenarios that limit the feasible scale of reservoir re-operation. These are listed below and are described at length later in this report.

- Capacity to produce water for reservoir payback. The capacity to produce water for reservoir payback governs the scale of reservoir re-operation, considering that the water debt owed to any reservoir cannot exceed the capacity to repay the reservoir payback in a single year, if necessary. However, particularly for reservoir payback based on additional groundwater pumping (option #2 above), the greater the payback capacity the greater the risk of impacting existing groundwater pumpers and critical streams.

- Minimum reservoir releases governed by temperature control criteria. There are conditions under which Lake Shasta reservoir releases are governed by temperature management in the Sacramento River between Keswick and Red Bluff, upstream of the locations were payback water would be generated. Under these conditions, the payback mechanism is rendered ineffective because reservoir releases cannot be reduced commensurate with the production of payback water. (The prospective temperature standards for the Feather River under the relicensing settlement for Oroville may also pose a constraint on re-operation of Lake Oroville for project purposes, but this has not yet been evaluated).

Within these limits, the investigation considered whether it is feasible through reservoir re-operation to increase the benefits that can be derived from a fixed hydrology and surface storage infrastructure.

4.4. Reservoir Payback Mechanisms

4.4.1. Groundwater Banking

Groundwater banking for reservoir payback involves making additional reservoir releases at certain times and storing the water in aquifers for recovery months or years later. Releases generally are made in above normal or wetter years with recovery occurring in relatively dry years. Surface water can be placed in storage by artificial recharge (surface spreading or injection wells) or by supplying it to water users who would otherwise pump groundwater (in-lieu recharge). Conditions required for groundwater banking include available storage space in an aquifer where water can be retained over periods of several years and a feasible means of recharge. Typically, in-lieu recharge is more cost-effective than artificial recharge; however, in-lieu recharge requires that there is baseline groundwater pumping that can be suspended at times when additional reservoir releases are being made. Thus, in areas where groundwater pumping is negligible or would not occur when reservoir releases would be made, in-lieu recharge is not feasible.

4.4.2. Groundwater Pumping

Groundwater pumping for reservoir payback without having first banked the water underground implies depleting groundwater storage. In order to be sustainable, groundwater storage depletion must be temporary with depletions eventually offset by additional recharge induced by the pumping. Additionally, practical restrictions need to be placed on the location, frequency, magnitude and duration of pumping to avoid or minimize any impacts to streams and existing groundwater users.

4.4.3. Temporary Crop Idling

Temporary crop idling involves not planting crops that would otherwise be grown and irrigated. Suspension of irrigation in this manner reduces demands on the reservoir being re-operated, allowing water to be held in storage that would otherwise be released. In order to attract farmers into voluntary participation in temporary crop idling programs, they must be compensated at a level that, at a minimum, provides a net benefit equivalent to production of the crop not planted. One of the main challenges to effective crop idling is the timing of decisionmaking by participating farmers relative to decisions that need to be made for project operations. Farmers typically are making crop decisions and purchasing production inputs in late winter into early spring meaning that offers to participate in crop idling must be presented in the same timeframe. However, at that time, the need for refill water cannot be forecast accurately while the commitments to idling and the associated payments are irrevocable. Thus, with crop idling, there is the possibility that actual reservoir inflow turns out to be greater than forecast, potentially rendering the water produced by crop idling unusable.

4.5. Project Site Screening

A systematic, qualitative assessment of conditions within the Sacramento Valley was conducted to identify particular areas where conjunctive operations appear promising. This process did not conclusively identify the very best or most feasible sites within the Valley, but did identify relatively attractive sites for conjunctive operations based on a comparative assessment using certain criteria.

The team examined fall groundwater elevation maps, water supplier boundaries and distribution system coverages, and water source maps. Initially it was assumed that conjunctive management operations would follow groundwater banking type operations wherein water is stored in aquifers during years of above normal water supply and extracted during years of below normal supply. These operations are typical in the San Joaquin Valley and other areas in which aquifers have been depleted and appreciable storage space exists. Following this initial assumption, the following two types of sites were identified:

- Areas in which existing groundwater levels may be lower than surrounding areas and overlying lands are supplied almost exclusively from groundwater. This type of site may provide the potential for groundwater banking in underlying aquifers.

- Areas in which minimal groundwater pumping exists because overlying areas are supplied almost exclusively from surface water. This type of site may provide a potential area for groundwater pumping.

The project and technical teams developed and initial list of project sites from a review of groundwater maps and their professional knowledge of the Sacramento Valley. Sites were named according to the overlying water district, though potential sites did not strictly conform to water district boundaries. Information considered in this analysis included the location, water source, existing surface water contracts, current infrastructure and additional infrastructure necessary for delivery of surface water and for extraction of groundwater, operational concepts, and information on existing groundwater conditions. Table 4-1 summarizes this information considered for the nine initial sites.

TABLE 4-1
Initial Project Sites and Parameters
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Location	Water Source	Site Type	Annual Surface Water Contract	Project to Integrate With	Currently Integrated?
Butte Basin	Surface	GW Pumping	~ 300 TAF/yr	SWP	Yes
Orland-Artois WD	Mixed	Both	53 TAF/yr	CVP	Yes
Rancho Capay WD	Ground	GW Banking	None	CVP	No
Corning Canal Area	Mixed	Both	33 TAF/yr	CVP	Yes
Yolo-Zamora WD	Ground	GW Banking	None	CVP	No
Glenn-Colusa ID	Surface	GW Pumping	825 TAF/yr	CVP	Yes
Stony Creek Fan area	Surface	GW Pumping	~ 100 TAF/yr	Orland	No
Colusa County WD	Mixed	Both	68 TAF/yr	CVP	Yes
Olive Percy Davis Ranch	Surface	GW Pumping	32 TAF/yr	CVP	Yes

The goal was to identify at least one site that is served by the CVP (Shasta), one by the SWP (Oroville), and one by the Orland Project. The CVP and SWP are the principal surface water systems in the Sacramento River basin and their operations are linked to the Sacramento and Feather Rivers, respectively, both of which are targeted for environmental restoration. The Orland Project, although not among the largest surface water systems in the Valley, is an area where conjunctive operations have been viewed as a possibility for many years.

The nine sites were evaluated qualitatively based on their potential to generate reservoir payback water, an estimate of the volume of water that may be developed, and relative (compared to the other sites) ease and cost of integrating the project with existing surface water systems.

The following additional criteria were used to identify prospective sites:

- Availability of reliable surface water supplies that could be substituted with groundwater to enable conjunctive operations

- The presence of highly productive, underlying groundwater aquifers that could be economically developed (or were already developed to some extent)

- The ability to locate and design production wells in a manner that would minimize effects on existing groundwater users and surface streams

Evaluation of existing groundwater conditions within the Sacramento Valley shaped the site screening and selection. In general, the evaluation revealed that while groundwater levels are drawn down during the irrigation season in many areas of the basin, levels recover during the precipitation season except during prolonged (multi-year) dry periods. Figures 4-1 through 4-15 of the Sacramento Valley Conjunctive Water Management Technical Investigation Modeling Report in Appendix B, which depict historic groundwater fluctuations in wells distributed throughout the valley, illustrate this point. Cones of depression generally do not persist over the multiple years necessary to make the dewatered aquifer space suitable for banking[11]. Any additional water recharge induces additional groundwater discharge to the streams. The conclusion from this analysis was that conjunctive operations based on a groundwater banking payback mechanism are not feasible in the Sacramento Valley at this time. Thus, further effort was concentrated on a second option for a payback mechanism: pumping groundwater in lieu of making reservoir deliveries in years when reservoir payback would be necessary.

Two sites were identified on which to conduct more refined analyses with surface and groundwater modeling tools. The GCID and Butte Basin Projects, supplied by the CVP and SWP, respectively, provided the potential to pump the largest quantity of groundwater compared to other sites, and are already well integrated with the surface water system. Under this option, conjunctive management operations would utilize wells within GCID and the Butte Basin as a backstop for more aggressive operation of Shasta Reservoir and Oroville Reservoir, respectively.

The major water surface water suppliers within the Butte Basin are WCWD, RID and Biggs-West Gridley Water District (BWGWD). BWGWD declined to participate in the investigation, so development of the Butte Basin project concentrated on the other two districts. It is noted that WCWD and RID were passive project participants meaning they provided information for the investigation but did not assume a sponsorship role.

Additionally, the Stony Creek Fan area and Orland Project was identified as a third potential project. However, upon further evaluation into potential groundwater pumping capacities and the ability to integrate the project with the Sacramento River system, it was determined that this project would not be investigated as part of this investigation. However, this project should be considered for further analysis in any future investigations.

Project site screening is discussed in additional detail in Appendix C.

4.6. Environmental Flow Objectives

A major element of this investigation was the development of specific ecological flow objectives for the Sacramento and Feather Rivers to use to formulate and evaluate reservoir re-operation scenarios. The objectives are expressed as quantitative flow targets for the two rivers, respectively, and are coupled with a dynamic decision system for prioritizing objectives from year to year. The target flows are defined in terms of magnitude, duration, frequency and seasonality, by river reach. Although developed specifically for the purpose of formulating conjunctive management strategies, the recommended objectives and flows are believed to have broader utility beyond this investigation.

---

[11] Based on the most recent (Fall 2011) data collected by DWR, there appear to be some areas in the northern Sacramento Valley with persistent groundwater level declines, primarily in Glenn and Tehama Counties. These areas should be evaluated for potential groundwater banking operations in future work phases.

The general approach and rationale are briefly summarized in the following section, followed by a discussion of how the quantitative flow objectives and dynamic prioritization process are represented in the surface water model (described in Section 5). The process for developing recommended environmental flow objectives is described in detail in Appendix D.

4.6.1. General Approach and Rationale

It should be noted that the development of environmental flow regimes is as much an art as a science. However, the team attempted, to the extent possible, to use established methods to develop a transparent and replicable approach for identifying an environmental flow regime. The team conducted a detailed literature review of various methods and approaches previously utilized to develop environmental flow recommendations, and to employ a version of the holistic approach practiced in South Africa and Australia (King et. al. 2000) to identify an environmental flow regime for the Sacramento and Feather Rivers. This approach relies heavily on hydrological evaluations, previous studies and modeling analysis of historical hydrology, and expert opinion to estimate environmental flow requirements.

The approach consists of five basic steps:

1. Identify specific environmental objectives (i.e. target species, aquatic and riparian communities, and desired ecological conditions that are flow dependent).

2. Approximate the timing, magnitude, frequency, and duration (TMDF) of flows necessary to achieve identified environmental objectives.

3. Compare and analyze existing and historical hydrology to understand natural hydrologic patterns and how they have been altered.

4. Identify obvious gaps between flows necessary to achieve objectives and existing flows.

5. Modify the existing hydrograph into an environmental flow hydrograph based on an understanding of natural hydrology and the flows necessary to achieve key objectives.

Employing this approach, the team designed the environmental hydrograph to achieve the following three types of objectives.

- Geomorphic Functionality: Bed mobility, channel migration, and floodplain inundation

- Riparian Habitat Sustainability: Recruitment and maintenance of Fremont Cottonwood

- Chinook Salmon: Improved habitat, particularly rearing habitat, for all runs

The team relied on field data, modeling results, and studies, particularly the recent Nature Conservancy Study of the Sacramento River[12], to identify the minimum flows and critical thresholds to achieve each of the three types of objectives. Then historical and existing hydrology were analyzed to understand how the objectives may have been achieved under pre-dam conditions and to evaluate how existing

---

[12] Sacramento River Ecological Flows Study Final Report, CALFED Ecosystem Restoration Program, The Nature Conservancy, et al, March 2008.

hydrology may fall short of meeting those objectives. The gaps identified in this manner are the basis for identifying flow objectives.

Analyses of the hydrology on both rivers reveals that the most obvious and significant change between pre-dam and post-dam eras is a sharp reduction in the magnitude and duration of the late winter and early spring hydrograph and a corresponding reduction of inundated floodplain habitat. The reduction in late winter and spring flows reduces the frequency of geomorphic and riparian flows and substantially reduces the extent and frequency of occurrence of inundated floodplain rearing habitat for salmonids. Thus, for both the Sacramento and Feather Rivers, an increase in late winter and early spring flow is the primary component of the recommended environmental flow regime, but a corresponding reduction in summer base flows is also recommended. Reduced summer flows are primarily needed to free-up water needed to restore the spring hydrograph but may also provide ecological benefits by better approximating the natural hydrograph. Reducing summer base flows could, however, increase summer temperatures and harm salmonids including the endangered winter-run Chinook salmon. On the other hand, cool water temperatures in the upper Sacramento River are largely controlled by the volume of cold water storage behind Shasta Dam and the environmental flow regime identified here does not involve modifying coldwater pool management.

The summer temperature issue is one of several key uncertainties that are inherent in establishing environmental flow targets and must be addressed before any significant modifications to the flow regime can be refined and implemented for environmental purposes. However, articulating a hypothetical environmental flow regime is the first step in identifying and addressing constraints and uncertainties associated with improving environmental flow regimes on regulated rivers. To that end, the team welcomes constructive comments and criticisms that can be used to improve upon the recommendations presented here as we learn more about the rivers and the people who depend upon them for their livelihood.

This study focuses on the magnitude and timing of flows necessary to replicate key ecological and geomorphic processes, and considers the flows necessary to provide suitable conditions for various life stages of Chinook salmon and steelhead. This study does not identify specific population targets for salmonid restoration, nor does it address important non-flow objectives such as habitat area required for restoration of target species or augmentation of coarse sediment supplies necessary to restore full geomorphic structure and function. Rather this study focuses on magnitude, pattern, and quantity of water necessary to restore ecological functions assuming that adequate physical habitat exists or will be created to complement a suitable environmental flow regime. The rationale of this focus is to identify a hypothetical environmental flow regime for the purpose of evaluating whether it is possible to reestablish ecological and geomorphic flows on the rivers of the Sacramento Basin without reducing water supply deliveries to existing water users.

Analysis of historical (pre-dam) hydrology and the habitat it created were analyzed to provide a reference point for identifying ecosystem restoration goals, recognizing that it is not possible to restore historic conditions in highly altered systems such as the Sacramento River. Historical hydrologic analysis is useful for identifying patterns in the timing, magnitude, duration, and frequency of flows that may be important for maintaining native species, but it is less useful in developing specific flow prescriptions, because physical habitat has been so profoundly changed by dams and levees and there are now competing demands for the water. We recognize that it is not possible to fully restore historical hydrology or habitat conditions in the Sacramento Valley, but ecosystem restoration will require reestablishment of a minimum threshold of both hydrologic and physical habitat conditions.

Although this study identifies hypothetical restoration flow regimes for the Sacramento and Feather Rivers, we recognize that the most reliable method for developing a restoration flow regime is through a long-term adaptive management program including a series of trials that test the effectiveness of various flow prescriptions. The hypothetical flow regime serves as a reasonable starting point for evaluating the economic feasibility of re-operating reservoirs and a long-term adaptive management program. The assumptions and uncertainties associated with the hypothetical flow regime are important to acknowledge and understand. To cost effectively achieve restoration, managers will ultimately need to test these assumptions and limit the uncertainties through an adaptive management program consisting of a combination of modeling, pilot flow studies, model calibration, and long-term implementation.

The ecologic flow objectives fall into two categories, three that were designed for Chinook salmon recovery, and one that was designed for riparian habitat recovery. These may be summarized as follows:

For Chinook salmon:

- Geomorphic objectives: Sediment transport, bed mobilization and bed scour; channel migration and floodplain processes; inundation and fine sediment deposition

- Floodplain inundation objectives : inundated floodplain habitat for rearing juveniles during the later winter and early spring; maintain and recruit spawning habitat, but avoid scouring gravels while eggs or alevon are present

- Spring pulse flow objectives: Suitable flow conditions and temperatures for all life stages;

For Riparian Habitat:

- Fremont cottonwood seedbed preparation, seed germination and seedling growth; periodic large-scale disturbance of the riparian zone; riparian stand structure and diversity

4.6.2. Representing Environmental Flow Objectives in the Surface Water Model

The different flow objectives developed for the Sacramento and Feather Rivers are simulated as all-or-nothing thresholds, meaning that a decision to satisfy an objective is made only if the full target flow can be sustained for the specified duration. As discussed in Appendix D, environmental objectives are based on the magnitude and duration of flows required to replicate certain ecological and geomorphic processes. Environmental objectives are specified and prioritized by water year type. The Sacramento River Water Year Type Index (Sacramento River Index), sometime referred to as the 40-30-30 Index, is used to classify each year as either wet, above normal, below normal, dry, or critical.

Each of the environmental flow objectives is described quantitatively below.

4.6.2.1. Geomorphic Flow Objectives

Geomorphic releases are short-duration, high-flow events for the purpose of sediment transport, channel migration, and flood plain processes, such as inundation and fine sediment transport. Geomorphic releases are targeted from March through April and are only required to last several hours. The surface water model simulates geomorphic events lasting one day due to the ramping requirements when making these large releases from reservoirs. Table 4-2 presents geomorphic flow objectives for Sacramento and Feather Rivers.

TABLE 4-2
Geomorphic Flow Objectives for Sacramento and Feather Rivers
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Sacramento River Index	Sacramento River (cfs)	Feather River (cfs)
Wet	105,000	50,000
Above Normal	85,000	35,000
Below Normal	65,000	20,000
Dry	35,000	10,000

No objective specified in critical year types.

4.6.2.1. Riparian Establishment

The purpose of riparian establishment flows is to recruit and grow cottonwoods in the riparian areas along the rivers. Riparian establishment flows are designed to assist in several phases of early cottonwood growth including seedbed preparation, seed germination, and seedling growth. These flows also create periodic large-scale disturbances of the riparian zone. Riparian establishment objectives (see Figure 4-3) are specified for the period of mid-April through mid-June to coincide with the cottonwood reproductive cycle. Riparian recruitment flows are large-magnitude flows for extended periods of time and are typically only possible during years of above average runoff. Therefore these objectives are only specified in years classified as wet or above normal by the Sacramento River Index.

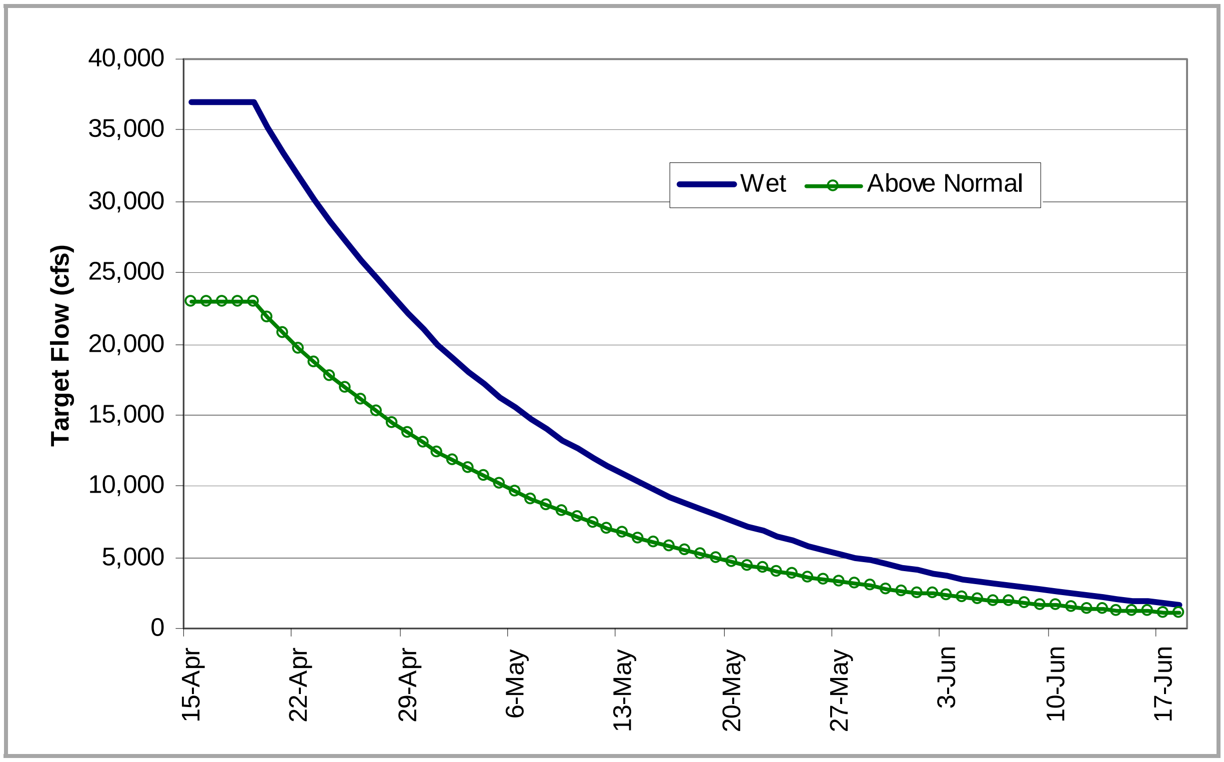

FIGURE 4-3
Sacramento River Riparian Establishment Objective
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Figure 4-3 illustrates the shape of the of riparian establishment objectives. The objective begins with a high-flow event held for a period of 5 days followed by a 60-day recession limb when the target each day is 5 percent less than the previous day's target. Table 4-3 summarizes the objectives for both the Sacramento and Feather Rivers.

4.6.2.2. Spring Pulse Flows

Spring pulse flows are designed to simulate a portion of the historic unimpaired runoff of the river to help create suitable flow conditions and temperatures for Chinook salmon migration. These flows also are designed to help maintain and recruit spawning habitat and avoid scour when eggs are in redds. Spring pulse flow targets are specified in all but critical year types, though the magnitude and duration of the target is reduced in years with less runoff. Tables 4-4 and 4-5 summarize the spring pulse objectives.

4.6.2.3. Flood Plain Inundation

Inundation of the Sutter and Yolo Flood Bypass channels is another environmental objective. It is assumed for this study that the weirs that currently block flow into the bypasses below certain river stages can be modified to allow inundation at lower river stages and flows. Inundation of the flood bypasses provides rearing habitat for juvenile salmonids. These inundation flows are targeted to correspond with outmigration of salmonids in the spring months and designed to last for 45 days. Flood plain inundation flows can be set for one of three different time-periods in the surface water model: February 15 to March 30, March 1 to April 15, or March 15 to April 30. Table 4-6 presents flood inundation objectives for Sacramento and Feather Rivers.

4.6.2.4. Prioritization of Environmental Flow Objectives and Decision Month

Environmental objectives are prioritized based primarily on hydrologic year type and the frequency with which the various objectives are satisfied. Considering the frequency of when objectives have been satisfied places higher priority on objectives that have not been met in recent years relative to those that have. For example, if the spring pulse objective is typically the highest priority in an above normal year but was met in the previous year (either in the base condition or with a project release) it may be desirable to shift the highest priority to the flood plain inundation objective instead.

To implement this dynamic prioritization scheme that shifts the priority from one year to the next depending on year type and occurrence interval a user-specified relative priority value is combined with the number of years since an objective was last satisfied to determine the final priority of objectives each year.

Table 4-7 contains the relative priority matrix developed by the project team for use in the surface water model. Lower numbers denote higher priorities.

Final priority is determined by subtracting the relative priority from the number of years since the objective was met and comparing the results for all objectives.

Table 4-8 provides an example prioritization calculation for a hypothetical wet year on the Feather River system.

TABLE 4-7
Relative Priority Matrix for Environmental Objectives

Wet	10	2	10	10	10	2	10
Above Normal	15	6	2	4	15	5	2
Below Normal	2	99	1	3	2	99	1
Dry	5	99	2	90	5	99	2
Critical	80	99	1	90	80	99	1

TABLE 4-8
Example Prioritization of Environmental Objectives, Feather River, Wet Year
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

	Flood	Geo	Rip.	Spring
Years Since Met	6	1	4	25
Relative Priority	10	10	2	10
Final Priority	-4	-9	2	15

The objectives are prioritized by descending final priority scores, as follows: Spring Pulse, Riparian Recruitment, Flood Plain Inundation, and Geomorphic. In this example, because it had been 25 years since the spring objective had been met, Spring Pulse became the first priority objective, though its relative priority was lower than the Riparian Objective.

A decision must be made each spring to determine which objectives the model will attempt to meet that year. Several of the environmental objectives have variable start times and durations. To avoid always meeting the objective that starts earliest in the year or miss meeting an objective in hopes of satisfying a future objective, a user-specified decision month is used in the model. Project assets, water costs, and prioritization of environmental objectives are all determined during the decision month and results are used for operations that year. The decision month is used to determine what objectives the model will attempt to meet each year.

4.7. Agricultural Water Supply Objectives

As previously mentioned, historical agricultural water supply shortages in the Sacramento Valley were used to represent the targets for water supply enhancements. Specifically, for the CVP/Sacramento River, unmet demands of CVP contractors within the Tehama-Colusa Canal Authority (TCCA) were used to represent additional demands. Members of the TCCA, including contractors supplied from the Corning Canal, hold agricultural service contracts for approximately 320 TAF of contract supply from the CVP. Annual allocations to CVP contractors are simulated in CalSim II based on forecasted reservoir inflows, reservoir storage conditions, and the ability to deliver water. Simulated allocations range from 0 to 100 percent of full contract supply. When simulated allocations are less than 100 percent, it is assumed that the difference between simulated allocations and full contract supply is an unmet agricultural demand within the TCCA.

Figure 4-4 illustrates the annual unmet agricultural demand as a function of simulated allocations to the TCCA for each year of the study. The annual unmet demand illustrated in Figure 4-4 was assumed to occur on a typical agricultural demand pattern during the irrigation season.

On the Feather River system, the majority of SWP contractors have reliable water supplies with the exception of a few small contractors. There are no existing SWP contractors with large, frequently unmet agricultural demands in the Butte Basin. Therefore a more general unmet agricultural demand was defined for the Feather River based on user input and judgment. Table 4-9 summarizes the assumed unmet agricultural demand that could be met from Feather River supplies for purposes of modeling.

Figure 4-5 illustrates the annual volume of demand based on the assumptions in Table 4-9.

It should be noted again that the estimates of unmet agricultural demands described above are regarded as surrogates for any type of water supply need that might be identified for the Sacramento and Feather River systems.

5. Development and Assessment of Initial Project Scenarios

5.1.Initial Project Scenarios

Four conjunctive operations scenarios were developed for the GCID and Butte Basin project locations for initial analysis. The scenarios are differentiated primarily by the following two parameters:

- Maximum Payback Capacity. This is the maximum volume of groundwater pumping that would occur in any year within the pumping period (see below) in GCID and the Butte Basin, respectively. This capacity essentially establishes the scale of the conjunctive operation, since the water deficit in the reservoirs cannot exceed the capacity to repay it, when it becomes necessary. Maximum capacities were based primarily on professional judgment taking into consideration historical pumping in the two areas and average pumping intensity (acre-feet per acre). The payback capacities selected for analysis were:
  - 100 TAF in GCID and 50 TAF in Butte Basin; total 150 TAF
  - 200 TAF in GCID and 100 TAF in Butte Basin; total 300 TAF

- Pumping Period. Pumping must occur when there is a demand for water that would otherwise be satisfied by reservoir releases. In both project areas, the dominant crop is rice, which is typically planted between mid-April and early June and harvested in September. Following harvest, most rice fields are re-flooded between September and November for rice straw decomposition and to create waterfowl habitat. Thus the water delivery season in both areas is from mid-April through November. Based on this, three pumping periods listed below were identified for analysis. Different pumping periods were evaluated primarily to reveal differences in aquifer response to differences in the timing and rate of pumping. Additionally, the pumping period affects the capital investment needed for pumping facilities.
  - “Summer” defined as May through August
  - “Fall” defined as September through November
  - “Summer and Fall” defined as May through November

The combinations of payback capacity and pumping periods selected to form scenarios are listed in Table 5-1.

TABLE 5-1
Project Scenarios Evaluated
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Scenario	GCID Annual Pumping Capacity	Butte Basin Annual Pumping Capacity	Pumping Season
1	100 TAF	50 TAF	Summer (May through August)
2	200 TAF	100 TAF	Summer (May through August)
3	100 TAF	50 TAF	Fall (September through November)
4	100 TAF	50 TAF	Summer and Fall (May through November)

TAF = thousand acre-feet

Additionally, two well field configurations were evaluated for each scenario, one corresponding to existing wells screened at depths between 100 to 500 feet and a second well field corresponding to new wells screened at depths of 900 to 1,100 feet. Thus a total of eight operational scenarios were evaluated.

The well field configurations corresponding to the different payback capacities and pumping depths are illustrated in Figures 5-1 through 5-4.

5.2.Initial Model Approach and Development

5.2.1. Overview

Formulating and evaluating potential conjunctive management projects requires simulation of both surface water and groundwater systems. Simulating the surface water system is necessary to determine when water is available to refill reservoirs and estimate unmet agricultural demands, environmental objectives, and flow conditions. A groundwater model is necessary to estimate the effects of additional pumping on aquifer systems, including the spatial extent and magnitude of drawdown and potential change in stream-aquifer interaction. Changes in stream-aquifer interactions may affect the surface water system, depending on stream conditions when the changes occur. For example, if additional pumping results in more stream loss to the aquifer or less aquifer contribution to stream flow during the winter season of relatively wet years when the surface water system has surplus flow, there may be little or no impact. However, if pumping reduces stream flow during months and years when the surface water system is being operated to meet specific flow or water quality requirements, any reduction in stream flow will require a corresponding increase in reservoir release to ensure the flow requirement continues to be met. This decreases the water supply benefit of conjunctive management projects. Evaluating this aspect of conjunctive management projects requires interaction between surface water and groundwater models.

The main tool used to evaluate alternative conjunctive management operations strategies and test alternative environmental flow thresholds and priorities is a spreadsheet-based surface water model (Figure 5-5). It is set up to simulate changes in operation of Lake Shasta and Lake Oroville relative to conditions depicted in a baseline CalSim II simulation of CVP and SWP operations. The CalSim II baseline provides time series of reservoir storage levels, stream flows, and water deliveries which are used by the surface water model. Conjunctive management operations are simulated and layered onto baseline operations based on user inputs, while maintaining compliance with existing CVP and SWP rules, regulation, and operations.

The surface water model is configured by defining target river flows through specification of environmental objectives and inputting other user-defined parameters, including groundwater (payback) pumping capacity, reservoir operations objectives and constraints and other factors. The groundwater model is not operated for each surface water model run because it is much more computationally intensive and takes much longer to run. Instead, the groundwater model was used to develop functions that describe general surface water-groundwater interactions. These functions reside in the surface water model and are used to account for increases in stream leakage caused by project pumping that must be offset by additional project releases under certain conditions. This approach allows quick testing and evaluation of alternative conjunctive operations scenarios without having to make matching groundwater model runs.

The groundwater model was used to evaluate the particular scenarios previously described with respect to changes in groundwater levels and stream leakages caused by additional groundwater pumping. This was done by simulating the time series of project pumping determined through the surface operations simulations in the groundwater model.

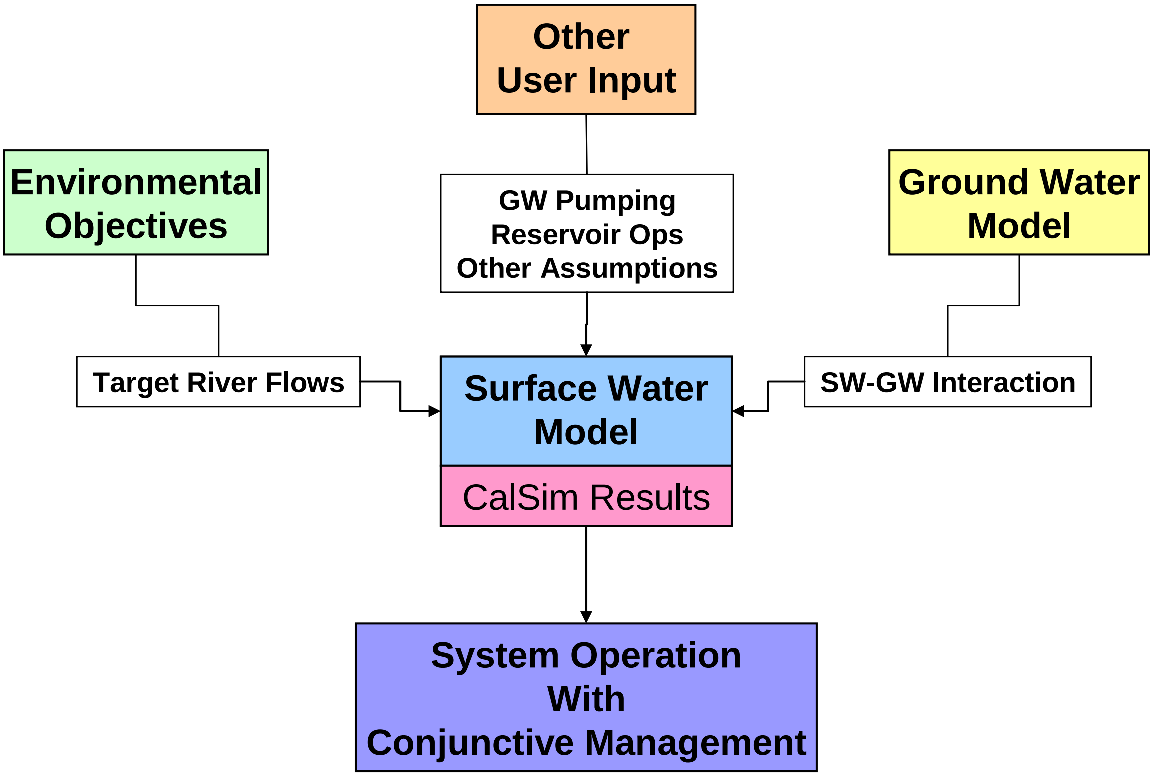

FIGURE 5-5
Surface Water Model Inputs and Operations
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

5.2.2. Surface Water Model

The surface water model includes a forecast of fall storage conditions based on current reservoir storage, runoff forecasts, and an estimate of reservoir releases from the current month through September[13]. The model simulates risk associated with making decisions based on imperfect information. Runoff forecasts at different exceedance levels are used during the spring with more conservative forecasts, 99 or 90 percent exceedance, used in February and March, respectively. A method to estimate reservoir release volumes was developed for Shasta and Oroville by correlating simulated CalSim II releases with a system-wide CVP water supply index and SWP allocations, respectively. The CVP water supply index is the sum of current storage in Trinity, Shasta, Folsom, and CVP San Luis plus runoff forecasts on the Sacramento and American Rivers, plus Kings River flow to Mendota Pool. The CVP water supply index and runoff forecasts for the Sacramento, Feather, and American Rivers are the same as used in CalSim II for simulation of CVP/SWP operations. Initial correlations were developed and adjusted to balance how forecasted storage compared with CalSim II simulated storage across various year types.

The surface water model treats the groundwater system as a source of water and does not simulate groundwater flows or conditions. It does, however, include features to account for estimated effects of groundwater pumping on stream flow accretion and depletion through use of functions derived from

---

[13] This methodology for forecasting fall reservoir storage was added as part of model refinements made in response to suggestions provided by CVP and SWP operators (see Section 6). For the initial analysis, the model used future (September) reservoir storage levels to make project operation decisions.

complementary simulations of pumping in the groundwater model. These functions provided a coarse but adequate representation of stream-aquifer interaction so that the surface water model could be used for gaming sessions without having to operate the groundwater model. Final scenarios were evaluated using actual changes in stream-aquifer interaction based on complimentary groundwater model simulations.

5.2.3. Groundwater Model

Numerous improvements were made to previously existing modeling tools, and new tools were developed for this analysis of conjunctive management projects. For the groundwater analysis, an existing simplified groundwater modeling tool was completely re-designed and improved, to yield a powerful analytical package now referred to as the Sacramento Valley Groundwater Model (SACFEM). The basis for the SACFEM model was a simplified superposition-based groundwater model previously developed to support the Sacramento Valley Water Management Program. That model represented a very simplified depiction of the Sacramento Valley aquifer system as no recharge components to the aquifer system (deep percolation of precipitation and applied water) or discharge components (regional agricultural pumping) were included, and therefore the model could only compute the incremental change in groundwater levels and streams flows during the irrigation season. It was assumed that the aquifer system fully re-filled every winter, and each year of pumping was independent of previous aquifer stresses.

The SACFEM model is a full water budget based transient groundwater flow model that incorporates all of the groundwater and surface water budget components on a monthly time step over the period of simulation. This model provides very high resolution estimates of groundwater level and streamflow effects due to conjunctive water management pumping across the valley.

The surface water model is a new tool designed specifically to analyze conjunctive management projects for agricultural and environmental benefits. Its flexibility for use in gaming sessions and for sensitivity and tradeoff analysis helped provide understanding of conjunctive management concepts, operations, and limitations.

The integration of surface water and groundwater modeling tools and the simulation of effects of additional groundwater pumping on the surface water system is a significant advancement over previous modeling tools. Simulation of changes in stream-aquifer interaction, the spatial and temporal variations in those changes, and conditions in the surface water system when changes occur are key components for evaluating conjunctive management projects and understanding their benefits and risks.

Development and calibration of the surface water and groundwater models used to develop and analyze the project scenarios is documented in detail in Appendix B.

5.2.4. Surface and Groundwater Model Interaction

As previously mentioned, evaluation of conjunctive management projects requires simulation of both surface water and aquifer systems. However, regional groundwater models with the needed level of refinement to adequately simulate pumping projects require run times that prohibit their use in gaming situations and for quickly evaluating multiple scenarios. Therefore, the surface water and groundwater model were used in an iterative fashion to simulate conjunctive management operations in both systems (see Figure 5-6).

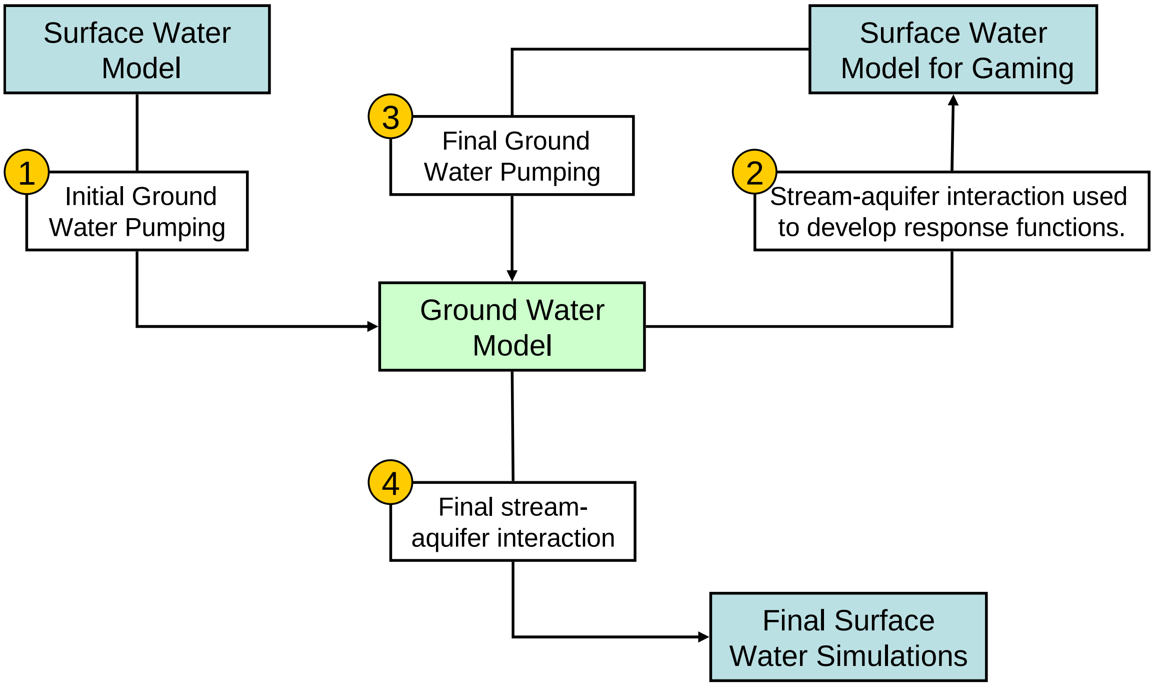

FIGURE 5-6
Surface Water and Groundwater Model Interaction
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

An initial surface water model was developed to simulate project operations and develop the time series of groundwater pumping at each project site. Pumping time series were simulated in the groundwater model and results were reviewed, including changes in stream-aquifer interactions. These initial changes were used to develop response functions for use in the gaming model to quickly approximate changes in stream-aquifer interaction when simulating various conjunctive management operations.

Response functions were used during the gaming sessions and when conducting tradeoff analyses to determine the final project scenarios. Pumping time series from the final project scenarios were then provided to the groundwater model for final simulation and resulting changes in stream-aquifer interactions associated with the pumping schedules were input back into the final surface water simulations.

5.2.5. Qualifications

Modeling analyses were performed at a planning level to help prove concepts and define conjunctive management projects and operations. Analyses were conducted for general projects, locations, and operations. More specific and refined analyses will be required as specific projects are defined. Most analysis was conducted in a comparative, rather than absolute, manner and results must be interpreted as such.

Additionally, mathematical modeling tools typically report results at a level of precision that exceeds their level of accuracy. For example, planning-level surface water models may provide estimates of water supply accurate to within a range of several thousand acre-feet, but results with a precision down to an acre-foot. Model results presented in subsequent sections are rounded to levels of precision appropriate for comparison with results from other scenarios. Planning-level modeling tools used in this analysis are not necessarily accurate to this level.

5.3.Performance of Initial Scenarios

The performance of each of the initial scenarios is summarized in this section in terms of the effects of project operations on the surface water system including reservoir storage, the frequency and magnitude of environmental flow and water supply releases and reservoir refill. Scenarios 1, 3 and 4 all have the same effects on the surface water system because they have the same payback pumping capacity. (Scenarios 1, 3 and 4 are differentiated by pumping season, not by pumping volume; therefore, each scenario has its unique effects on groundwater conditions.) Scenario 2 has different effects because it has a different payback capacity. The material presented here is also presented and discussed in greater detail in Appendix B.

5.3.1. Scenarios 1, 3 and 4 – Shasta Reservoir and Sacramento River

Scenarios 1, 3 and 4 are defined by maximum seasonal groundwater pumping capacities of 100 TAF in GCID and 50 TAF in the Butte Basin. Environmental objectives and unmet agricultural demands are as presented in preceding sections. The model first determines ability to meet environmental objectives and then uses remaining project assets to meet agricultural demands. Sensitivity to prioritization of environmental objectives and agricultural demands was evaluated and is explained in subsequent sections of this report.

The following series of plots summarize the annual operations with conjunctive management. The first series of plots summarize Sacramento River and Shasta Reservoir operations and the second series summarize Feather River and Oroville Reservoir operations. Plots are arranged in order of how operations occur each year. In winter and spring months, additional water is released from reservoirs to satisfy environmental objectives. During summer months additional water is released to meet agricultural demands. The result is that fall reservoir storage levels are lower than they would be under operations without conjunctive management projects, as shown on Figure 5-7. Reservoir storage space is typically refilled with surplus surface water during subsequent winter and spring periods. If reservoirs do not refill with surplus surface water and fall reservoir storage levels are forecasted to be low, reservoirs are refilled by pumping groundwater in conjunctive management projects and holding a similar volume of surface water in the reservoir.

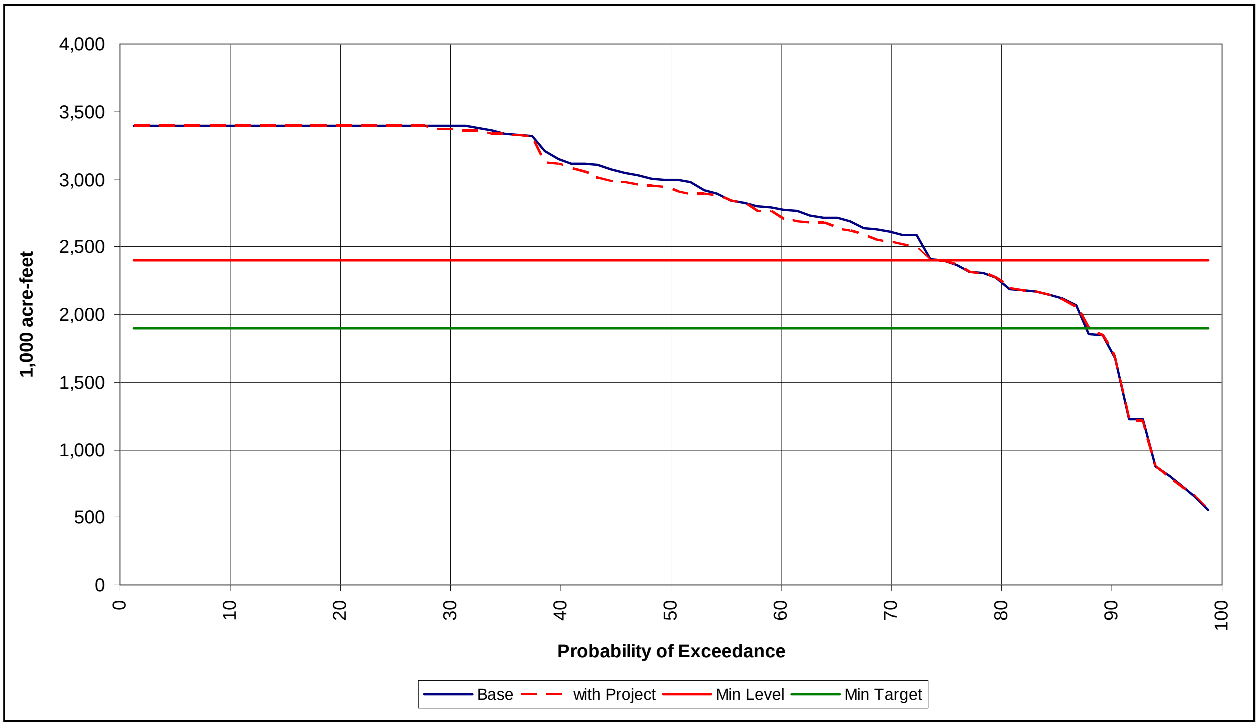

FIGURE 5-7
Shasta Reservoir September Storage Exceedance Probability with Conjunctive Management, Scenarios 1, 3 and 4
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Figure 5-8 illustrates annual volumes of water released to satisfy various environmental objectives on the Sacramento River. Color-coded bars and the legend refer to relative priority of objectives in each year. For example, in 1928 the red bar indicates that water was released to meet objective 4, the lowest priority objective. The type of objective, either geomorphic (Geo), riparian recruitment (Rip), spring pulse (Spring), or flood plain inundation (Flood) is labeled above the corresponding bar. Geomorphic objectives are met most frequently due to lower water costs associated with the short duration objective. Average annual release for environmental objectives is 13 TAF.

Figure 5-8 shows only years when environmental objectives are met through project release. Environmental objectives are also met at times under existing (baseline) system operation. This information is summarized in Table 5-2. For the flood plain inundation objective, the project includes modifications to the Freemont Weir to allow inundation with less Sacramento River flow than is required under existing conditions. The existing Fremont Weir crest limits inundation of the Yolo Bypass for flows less than approximately 62,000 cfs. The project assumes it is possible to modify the weir to allow inundation with flows of approximately 35,000 cfs. Therefore this objective can be met by the project, either under base condition flows between 35,000 and 62,000 cfs (flows in excess of 62,000 cfs meet the objective in the base condition) or through additional reservoir release to create flows of approximately 35,000 cfs.

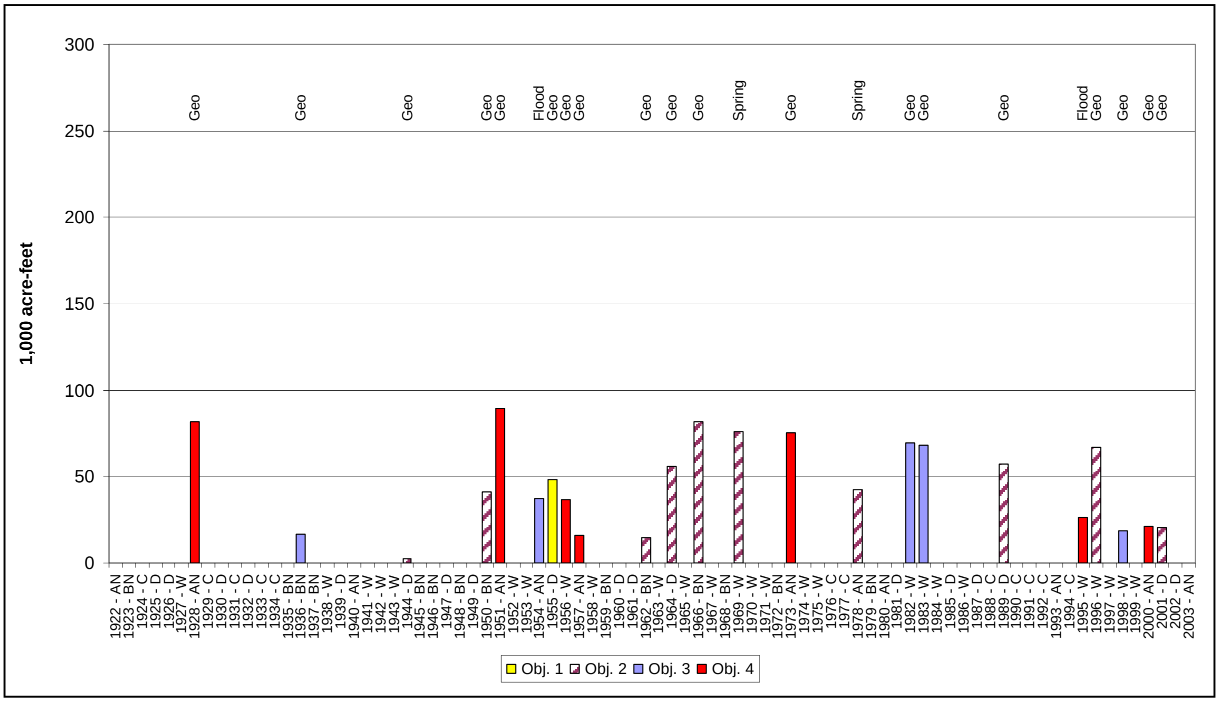

FIGURE 5-8
Sacramento River Environmental Objectives Met with Conjunctive Management, Scenarios 1, 3 And 4
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

TABLE 5-2
Number of Years Sacramento River Environmental Objectives are Met, Scenarios 1, 3 and 4
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Objective	Met with Base Conditions Flows	Met with Project Flows	Total
Spring Pulse	5	2	7
Riparian Recruitment	0	0	0
Geomorphic	25	18	43
Flood Plain Inundation	21	20	41

Table 5-2 show the flood plain objective is met in 20 years with the project, though there are only 2 years with releases for this objective illustrated on Figure 5-8. This indicates that the objective was met with base condition flows between 35,000 and 62,000 cfs (without additional reservoir release) in 18 years.

In some years, an objective may be met with base condition flows either before or after it is met with project releases during that same year. Results presented in Table 5-2 account for these occurrences and assume the objective is met in the base condition to prevent double counting in any year. For example, Figure 5-8 shows that releases were sufficient to meet the geomorphic objective in 19 of the 82 years analyzed. However, in one year (1956) the objective was met both under base conditions and then simulated to be met through project release. Results presented in Table 5-2 only show this objective being met during base condition flows to prevent potential double counting.

Figure 5-9 illustrates annual releases from Shasta Reservoir to meet additional agricultural demand in the TCCA service area. Dashed lines show annual unmet contract supply from CalSim II results and green bars illustrate the portion of unmet contract supply satisfied with conjunctive management operations.

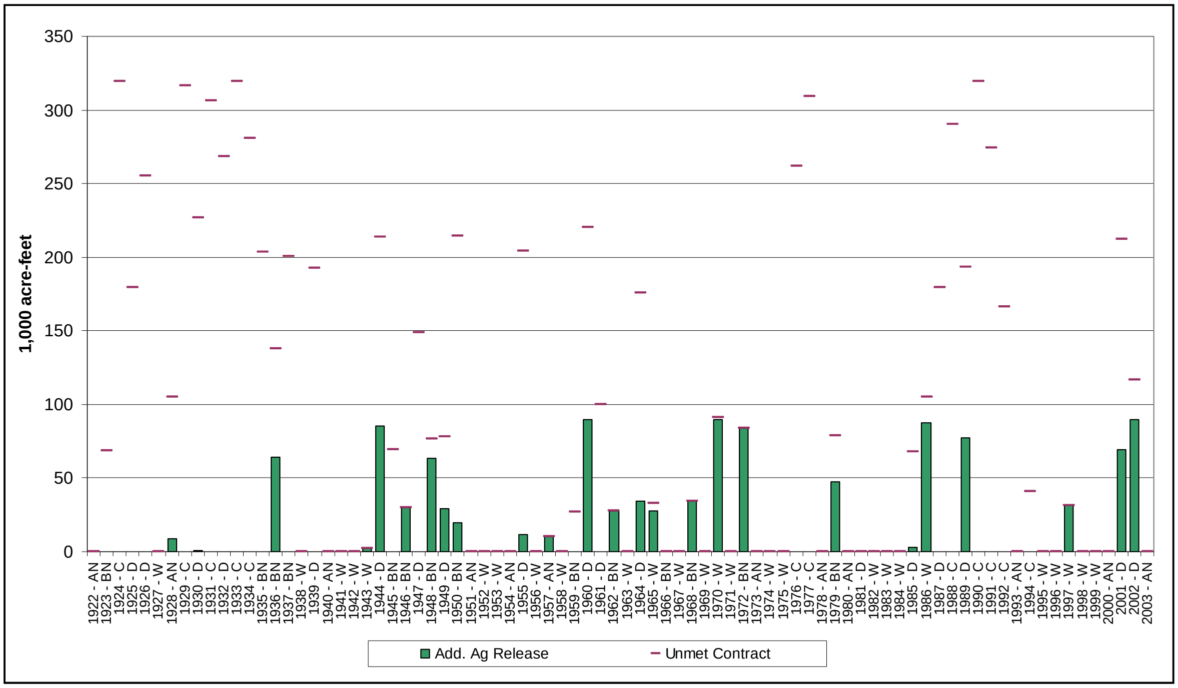

FIGURE 5-9
Sacramento River Additional Agricultural Demand Met with Conjunctive Management, Scenarios 1, 3 and 4
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Additional agricultural releases are made in 24 of the 82 years simulated, or approximately 29 percent of the years. The average release in those years is 46 TAF, while the average annual agricultural delivery over the 82-year simulation period is 14 TAF.

Figure 5-9 illustrates that in many years when unmet contract supply for the TCCA is highest, there are no deliveries with conjunctive use. This is because in these years, project assets are typically low, either because fall reservoir storage is forecast to be low and no additional releases would be made or it is a Shasta Critical year and additional groundwater pumping for conjunctive management is assumed to be zero[14].

Additional reservoir releases for either environmental objectives or for additional agricultural delivery result in lower fall carryover storage in Lake Shasta. Figure 5-7 illustrates this with a probability of exceedance plot for end of September storage conditions. The solid blue line indicates fall storage conditions under base (without project) conditions. The red dashed line indicates conditions with conjunctive management. A solid red line at 2,400 TAF indicates the level when conjunctive management operations would not occur to limit the risk to cold water pool management in future years. Storage conditions below the solid green line at 1,900 TAF are when conjunctive management operations attempt to increase storage by pumping groundwater and holding water in Shasta above base levels[15].

---

[14] Curtailment of project pumping in Shasta Critical years was imposed to avoid potential conflicts with the incremental groundwater pumping that typically occurs in those years as Sacramento River settlement contractors attempt to make up for water supply shortages.

[15] The Shasta Reservoir storage levels at which project pumping would be suspended for project purposes or would be invoked for purposes of sustaining Shasta storage are user defined values. Values of 2,400 TAF and 1,900 TAF for these parameters were established through parametric analyses and discussion with CVP operators.

Figure 5-7 illustrates that fall storage levels are lower in approximately 45 percent of the years and only when end of September storage is above 2,400 TAF. In wet years, when fall storage is at the flood control level of 3,400 TAF, releases in spring may refill in later months within the same year resulting in no change in fall storage conditions.

Figure 5-10 illustrates how storage deficits presented on Figure 5-7 are frequently refilled by the capture of surplus surface water. Surplus is water that would otherwise be released from the reservoir to maintain flood control storage and is not diverted downstream. This water is now stored in reservoir space created by making additional releases to meet agricultural and environmental objectives. Refill from surplus surface water occurs in 29 years with an average annual refill of 70 TAF in those years. Average annual refill with surplus surface water for the 82-year simulation is approximately 24 TAF.

In some years, following additional reservoir releases for agricultural and environmental objectives, there is no surplus surface water, and reservoir storage levels continue to decline putting future water supplies and cold water pool management at risk. In these years groundwater pumping in the conjunctive management projects is used to recover reservoir storage levels. Figure 5-11 illustrates this annual pumping. Conjunctive management pumping occurs in 4 of the 82 years simulated, or 5 percent of years. The average annual pumping in those years is 70 TAF. The average annual pumping for the entire 82-year simulation is approximately 3 TAF with a maximum annual pumping of nearly the full 100 TAF of payback capacity. Pumping typically occurs in drier year types when reservoirs do not refill with surplus surface water.

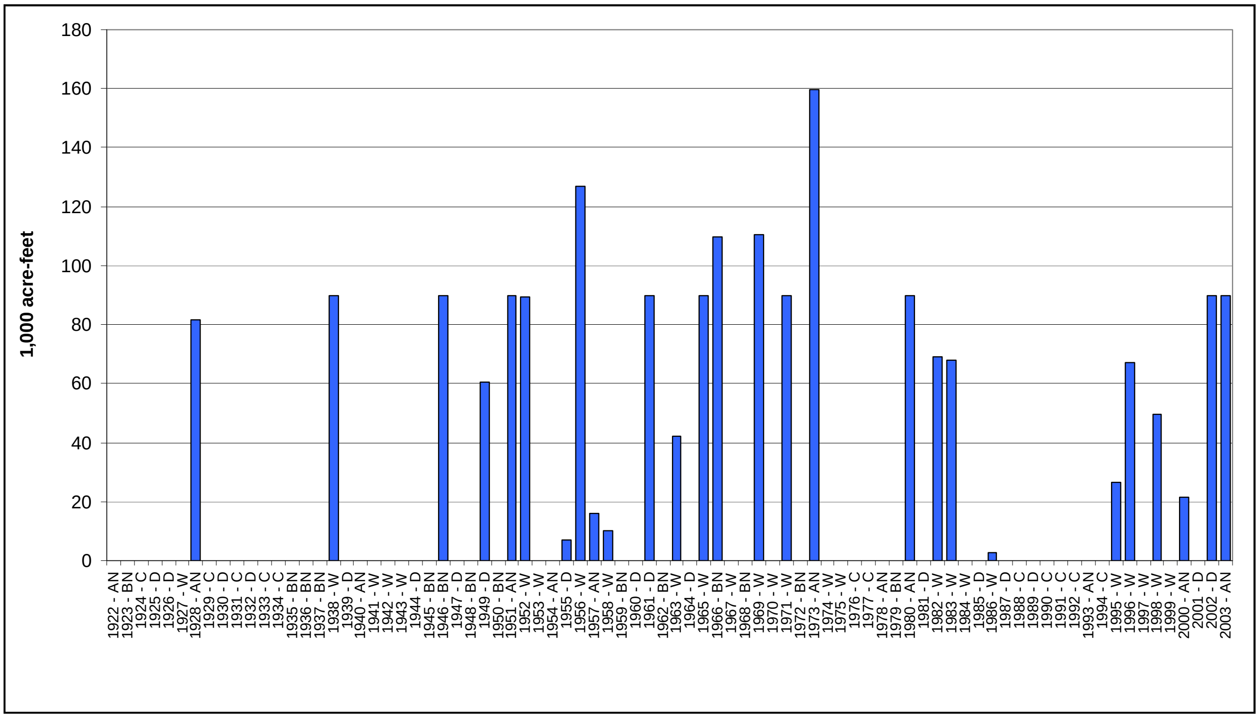

FIGURE 5-10
Refill of Shasta Reservoir from Surplus Surface Water, Scenarios 1, 3 And 4
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

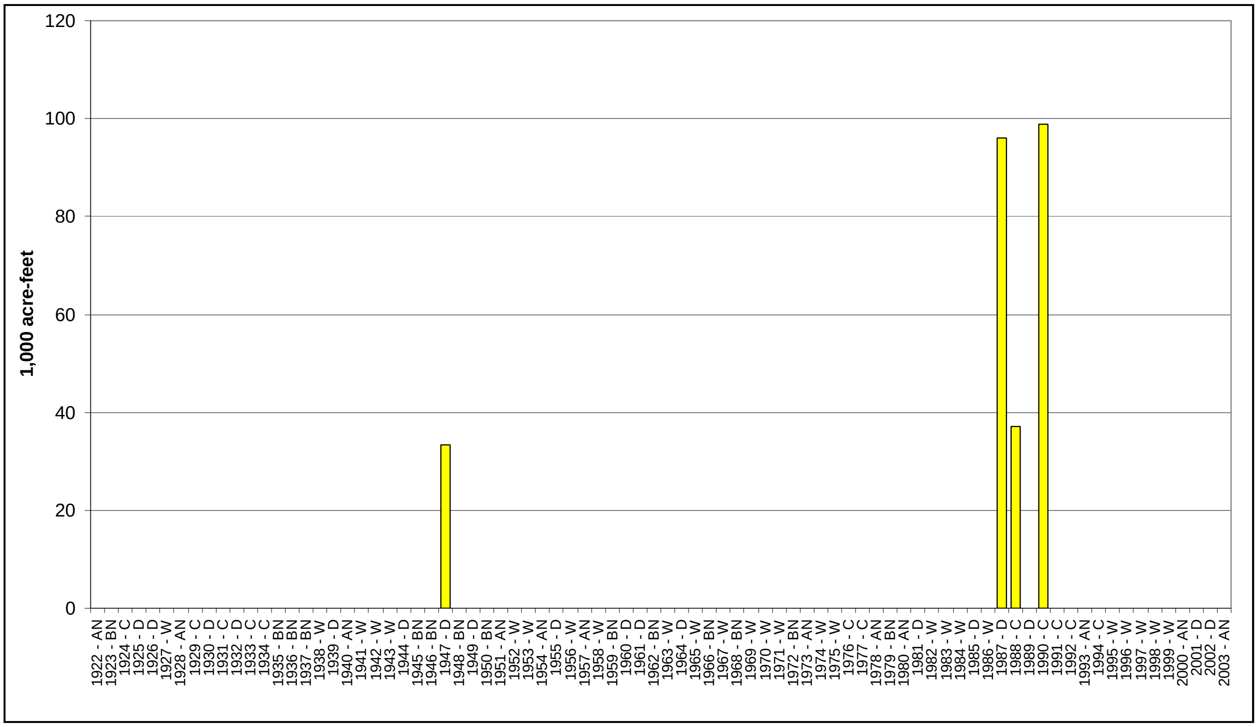

FIGURE 5-11
Refill of Shasta Reservoir from Conjunctive Management Pumping, Scenarios 1, 3 And 4
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Over the 82-year simulation period, additional reservoir releases are made in 37 years, or 45 percent of the years. Reservoir refill is accomplished with surplus surface flows in 29 years and with project pumping in 4 years. The number of years with additional releases exceeds the number of years with refill because reservoir storage deficits do not have to be completely refilled before making additional releases, as long as the total reservoir storage deficit does not exceed the capacity of the project to refill the reservoir in a single year. Of the total average annual additional releases of 27 TAF (14 TAF for agriculture and 13 TAF for environmental objectives), 24 TAF is refilled from surplus surface water and 3 TAF from conjunctive management pumping. Over the 82-year period of analysis, a total of 1,148 TAF would be delivered to satisfy agricultural demands that would otherwise be met from groundwater pumping. Over the same period, the total volume of project pumping required for reservoir payback would be just 246 TAF. Thus, conjunctive operations would result in a net gain to the groundwater system of more than 900 TAF over the analysis period.

5.3.2. Scenarios 1, 3 and 4 – Oroville Reservoir and Feather River

Figure 5-12 illustrates annual volumes of water released to meet environmental objectives on the Feather River. Hydrology and operations on the Feather River result in meeting different objectives in different years compared to the Sacramento River. Similar to the Sacramento River operations, the geomorphic objective is satisfied most frequently due to lower water cost associated with meeting the shorter duration objective. Average annual release for environmental objectives on the Feather River is 7 TAF.

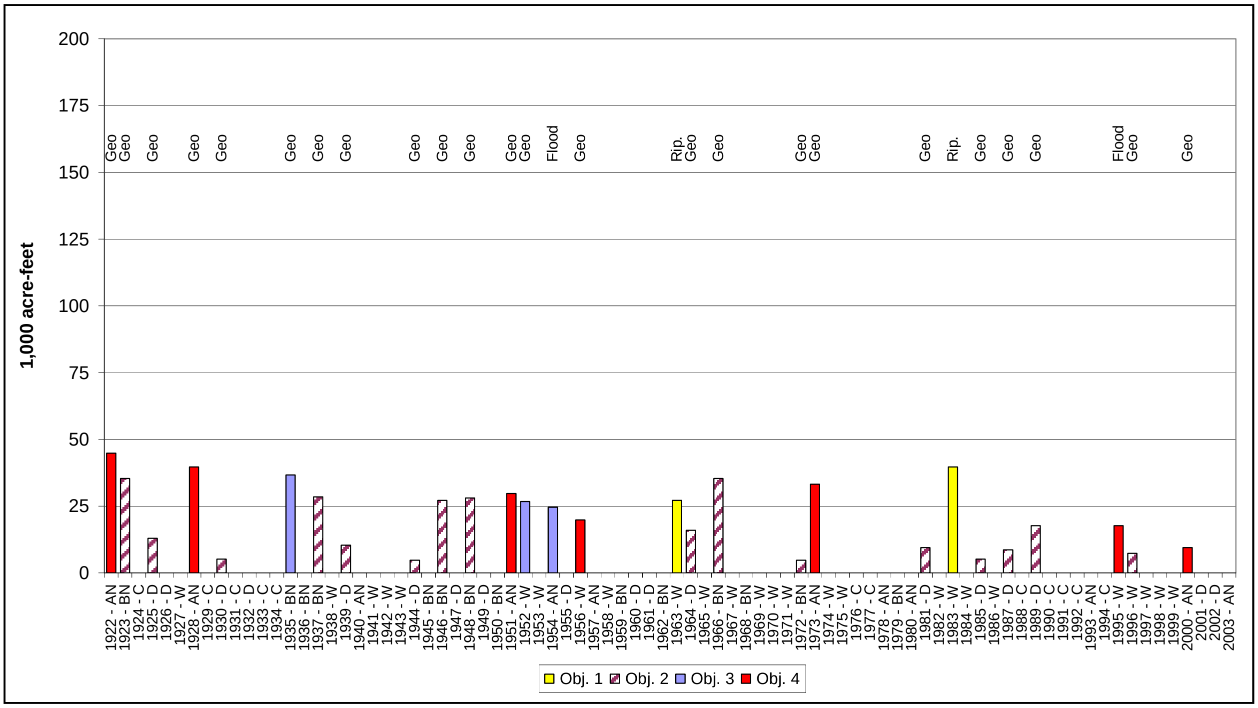

FIGURE 5-12
Feather River Environmental Objectives Met With Conjunctive Management, Scenarios 1, 3 and 4
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Table 5-3 provides a summary of the number of times each objective is met by reservoir release and under base operations on the Feather River. Values reported in the table for the geomorphic objective only include years when the objective is not met under base operations. Therefore this value is less than the number of releases shown on 5-12. The flood plain inundation objective can be met with the project under base condition flows with the modified weir, or with a combination of project releases and the modified weir.

Table 5-3
Number of Years Feather River Environmental Objectives are Met, Scenarios 1, 3 and 4

Geomorphic	31	17	48
Flood Plain Inundation	21	20	41

Figure 5-13 illustrates additional agricultural deliveries possible with conjunctive management on the Feather River. Dashed lines relate to assumed unmet demands within the Feather River basin and correspond to the Sacramento Valley Index. Similar to operations on the Sacramento River, project assets do not allow additional releases for either environmental or agricultural objectives during drier year types when agricultural demands are higher. Additional agricultural releases are made in 30 of the 82 years simulated, or approximately 37 percent of the years. The average release in those years is 27 TAF, while the average annual agricultural delivery over the 82-year simulation period is 10 TAF.

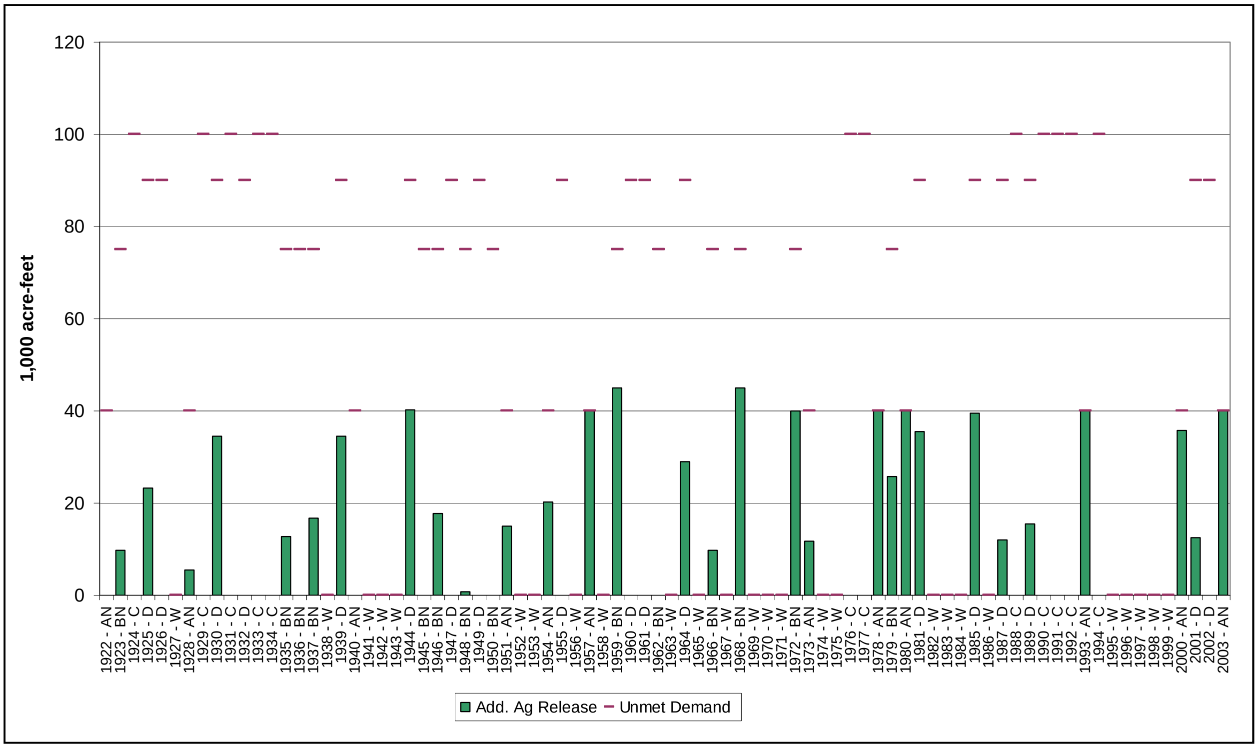

FIGURE 5-13
Feather River Additional Agricultural Demand Met with Conjunctive Management, Scenarios 1, 3 and 4
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Figure 5-14 illustrates how conjunctive management operations result in slightly lower Oroville Reservoir fall storage conditions in approximately 60 percent of the years. Fall storage is not affected below the minimum level of 1,500 TAF. The solid green line at 1,200 TAF denotes target storage for cold water pool management when conjunctive management may be used to increase storage.

Figure 5-15 shows how storage space created in Oroville Reservoir through additional releases for agricultural and environmental objectives is frequently refilled with surplus surface water. Refill from surplus surface water occurs in 37 years with an average annual refill of 32 TAF in those years. The average annual refill with surplus for the 82-year simulation period is 14 TAF.

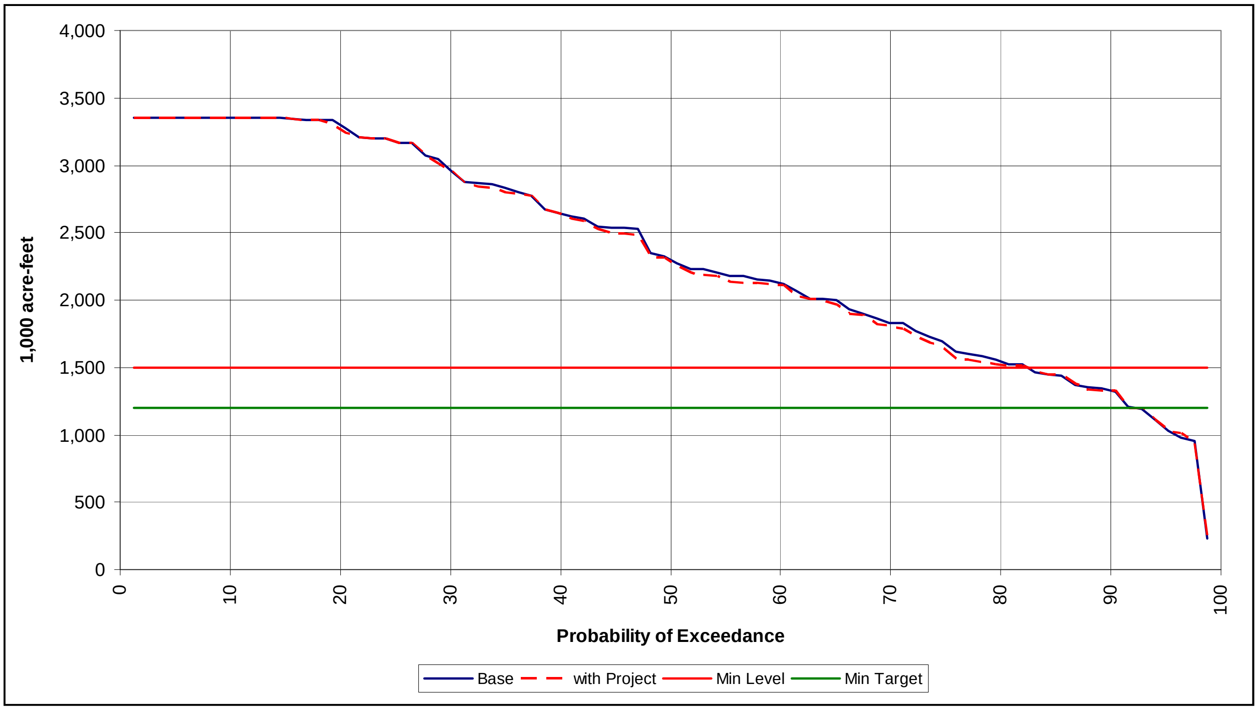

FIGURE 5-14
Oroville Reservoir September Storage Exceedance Probability with Conjunctive Management, Scenarios 1, 3 and 4
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

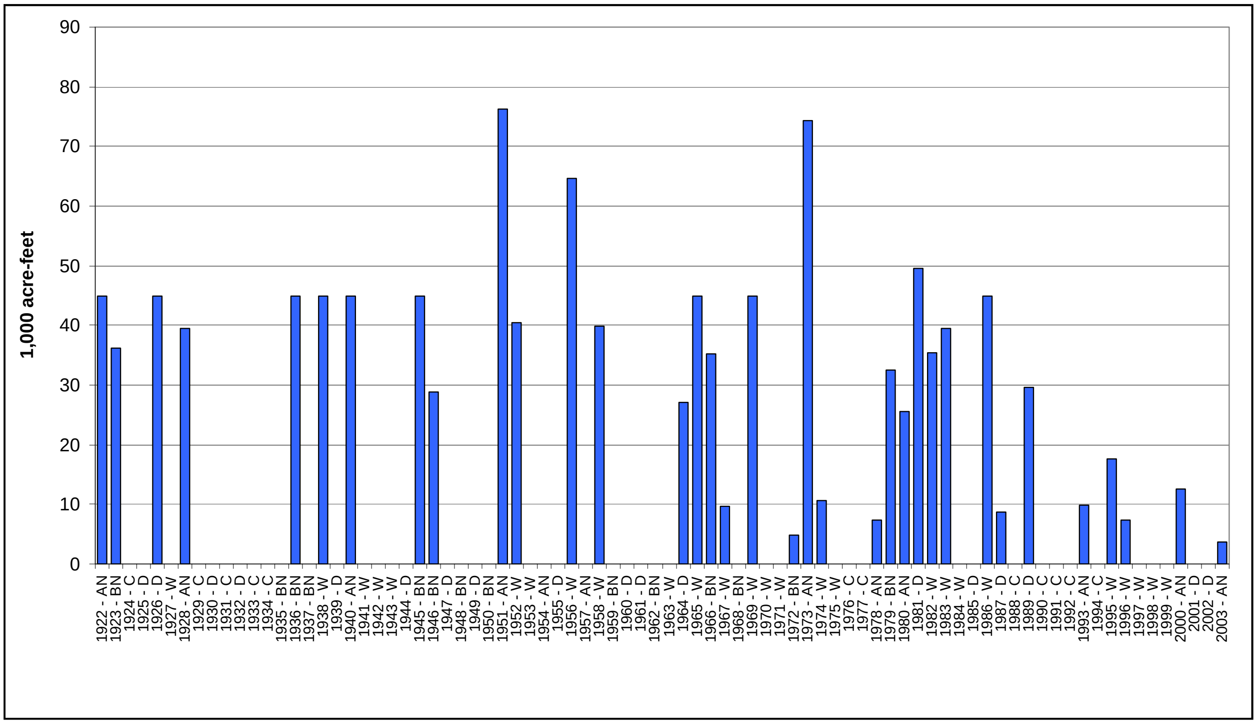

FIGURE 5-15
Refill of Oroville Reservoir from Surplus Surface Water, Scenarios 1, 3 and 4
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Figure 5-16 presents annual conjunctive management pumping in the Butte Basin project. Conjunctive management pumping occurs in 6 of the 82 years simulated or 7 percent of the years. The average annual pumping in those years is 44 TAF. The average annual pumping for the entire 82-year simulation is approximately 3 TAF with a maximum annual pumping of the full 50 TAF of pumping capacity.

Over the 82-year simulation period, additional reservoir releases are made in 37 years, or 45 percent of the years. Reservoir refill is accomplished with surplus surface flows in 37 years and with project pumping in 6 years. The number of years with refill exceeds the number of years with additional release because reservoir storage deficits may not completely refill in a single year, but instead refill over the course of several years. In summary, of total average annual additional releases of 17 TAF (10 TAF for agriculture and 7 TAF for environmental objectives), 14 TAF is refilled from surplus surface water and 3 TAF from conjunctive management pumping. Over the 82-year period of analysis, a total of 820 TAF would be delivered to satisfy agricultural demands that would otherwise be met from groundwater pumping. Over the same period, the total volume of project pumping required for reservoir payback would be just 246 TAF. Thus, conjunctive operations would result in a net gain to the groundwater system of 574 TAF over the analysis period.

5.3.3. Scenario2 – Shasta Reservoir and Sacramento River

Scenario 2 is defined by maximum seasonal pumping capacities of 200 TAF in GCID and 100 TAF in the Butte Basin. This scenario is the same as Scenarios 1, 3 and 4 with respect to environmental and water supply objectives and operating constraints, but with twice the pumping capacity.

Figure 5-17 illustrates annual volumes of water released to satisfy various environmental objectives on the Sacramento River. The geomorphic objective is met most frequently due to lower water cost associated with the short duration, but the larger pumping capacity increases project assets and allows other objectives to be met more frequently than in Scenario 1. Additionally, in some years more than one objective may be met as indicated by stacked bars. Average annual release for environmental objectives under Scenario 2 is 45 TAF.

Figure 5-17 shows only years when environmental objectives are met through project release. Environmental objectives may also be met under the base operations of the system.

Table 5-4 provides a summary of the number of times each objective is met by reservoir release and under base operations on the Sacramento River. Values reported in the table for the geomorphic objective only include those years when the objective is not met under base operations. Therefore this value is less than the number of releases shown on Figure 5-17. The flood plain inundation objective can be met with the project under base condition flows with the modified weir, or with a combination of project releases and the modified weir.

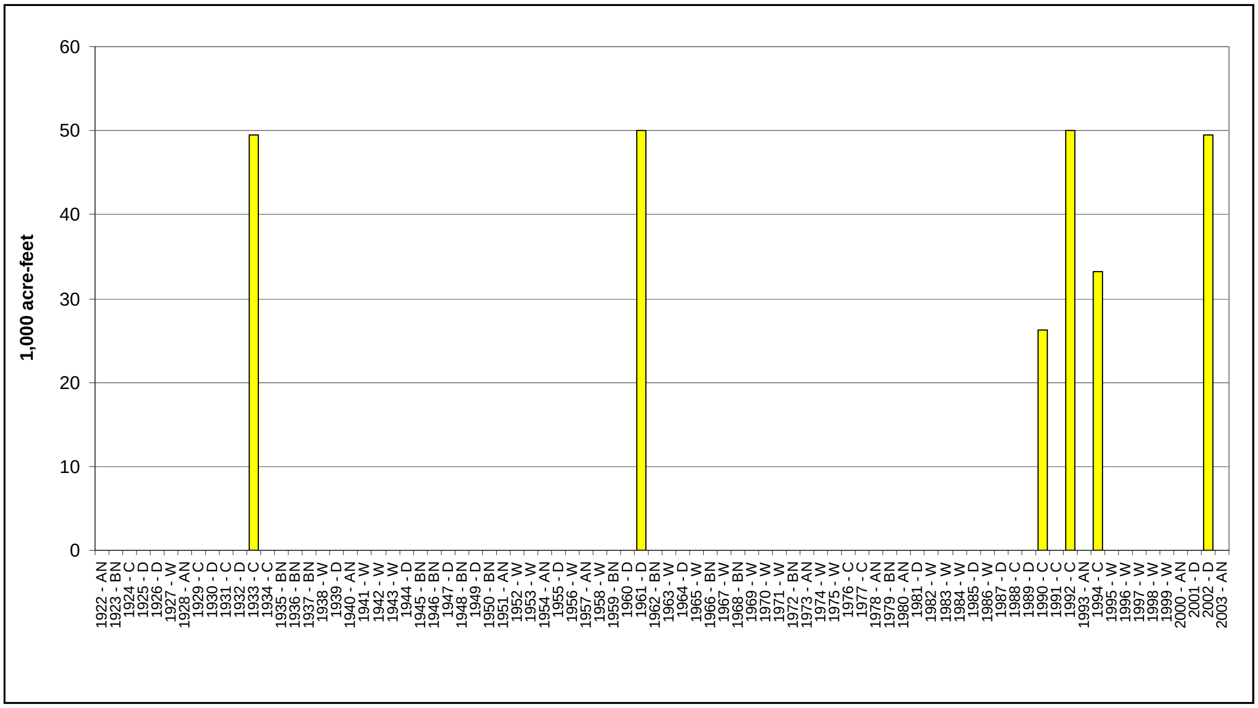

FIGURE 5-16

Geomorphic	25	30	55
Flood Plain Inundation	21	20	41

Figure 5-18 illustrates annual release from Shasta to meet additional agricultural demand in the TCCA service area. Additional agricultural releases are made in 24 of the 82 years simulated, or approximately 29 percent of the years. The average release in those years is 75 TAF, while the average annual agricultural delivery over the 82-year simulation period is 22 TAF. Additional agricultural deliveries are made in many of the same years as in Scenario 1, but at higher volumes.

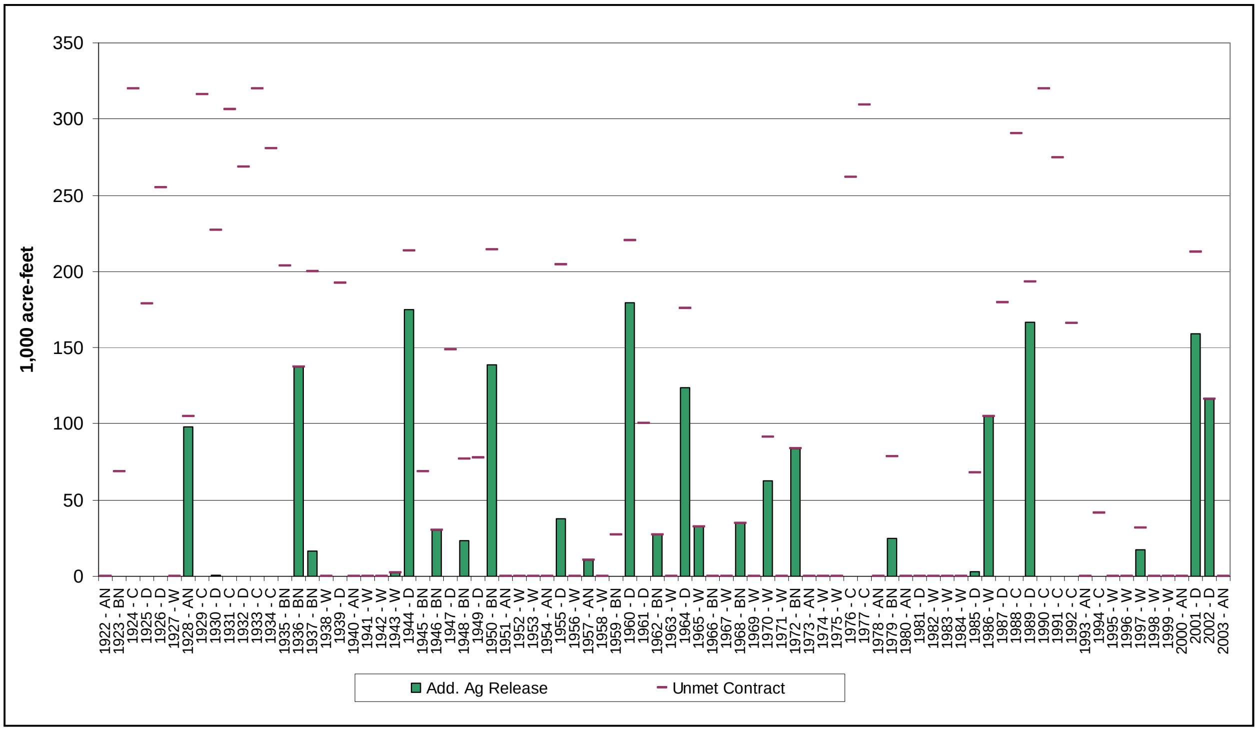

FIGURE 5-18
Sacramento River Additional Agricultural Demand Met With Conjunctive Management, Scenario 2
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Additional reservoir releases for either environmental objectives or for additional agricultural delivery result in lower fall carryover storage in Lake Shasta. Figure 5-19 illustrates that fall storage levels are lower in approximately 45 percent of the years and only when end of September storage is more than 2,400 TAF. During these years fall storages are lower compared to Scenario 1 because larger pumping capacity allows for more aggressive operation of the reservoir. Additionally, a small increase in fall storage below the 1,900 TAF target may also be possible.

Figure 5-20 illustrates how storage deficits presented on Figure 5-19 are frequently refilled by capture of surplus surface water. Refill with surplus surface water occurs in 35 years with an average annual refill of 139 TAF in those years. Average annual refill with surplus surface water for the 82-year simulation is approximately 58 TAF.

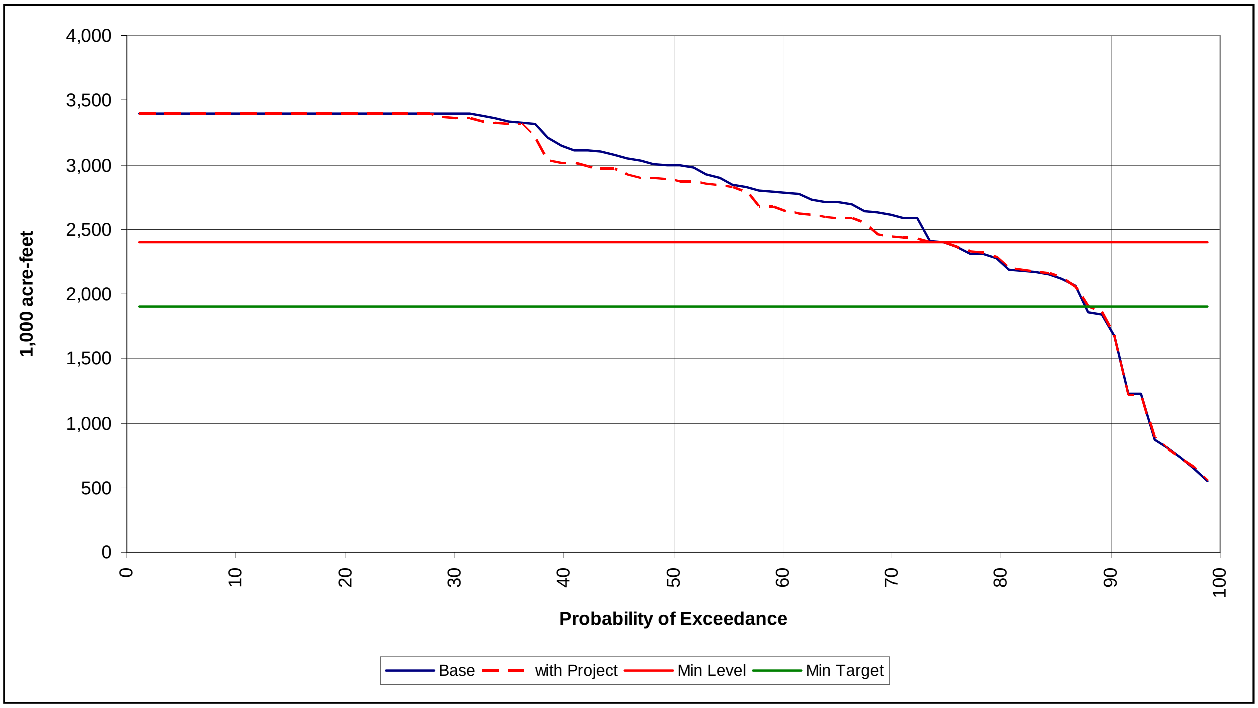

FIGURE 5-19
Shasta Reservoir September Storage Exceedance Probability with Conjunctive Management, Scenario 2
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

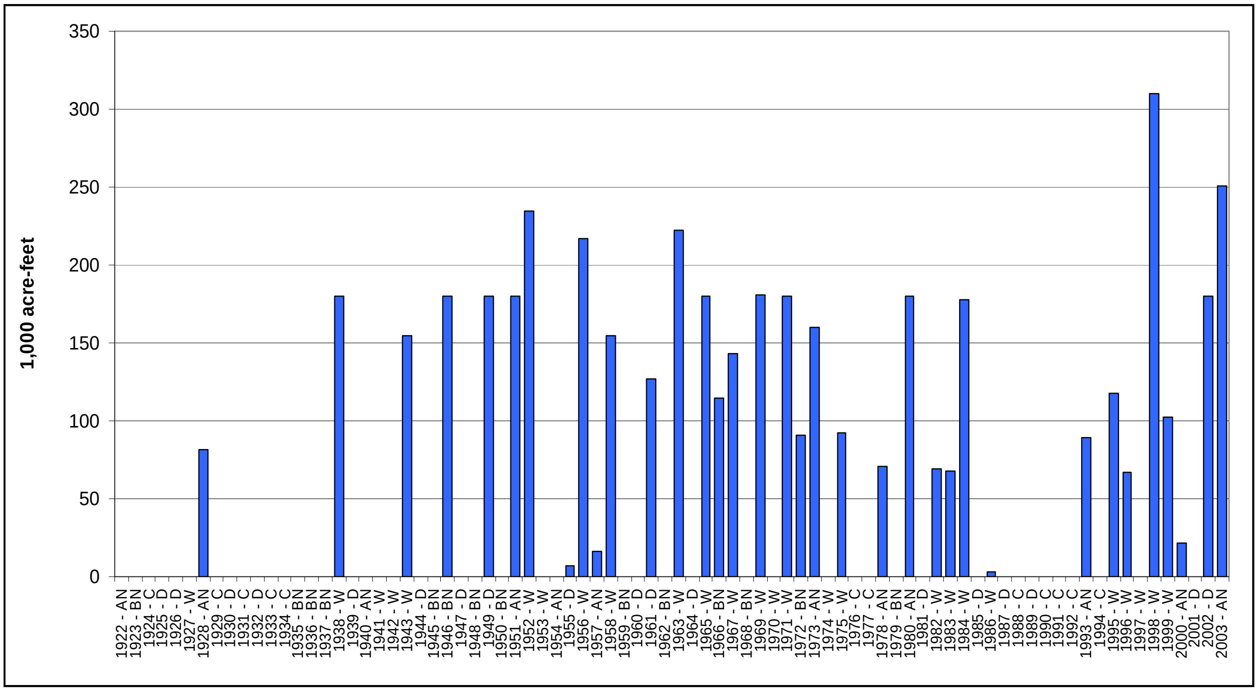

FIGURE 5-20
Refill of Shasta Reservoir from Surplus Surface Water, Scenario 2
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Figure 5-21 illustrates annual conjunctive management groundwater pumping for Scenario 2. Conjunctive management pumping occurs in 6 of the 82 years simulated, or 7 percent of years. The average annual pumping in those years is 123 TAF. The average annual pumping for the entire 82-year simulation is approximately 9 TAF with a maximum annual pumping of nearly the full 200 TAF of capacity. Pumping typically occurs in drier year types when reservoirs do not refill with surplus surface water.

Over the 82-year simulation period, additional reservoir releases are made in 48 years, or 59 percent of the years. Reservoir refill is accomplished with surplus surface flows in 35 years and with project pumping in 6 years. The number of years with releases exceeds the number of years with refill because reservoir storage deficits do not have to be completely refilled before making additional releases, as long as the total reservoir storage deficit does not exceed the capacity of the project to refill the reservoir in a single year. In summary, of total average annual additional releases of 67 TAF (22 TAF for agriculture and 45 TAF for environmental objectives), 58 TAF is refilled from surplus surface water and 9 TAF from conjunctive management pumping. Over the 82-year period of analysis, a total of 1,804 TAF would be delivered to satisfy agricultural demands that would otherwise be met from groundwater pumping. Over the same period, the total volume of project pumping required for reservoir payback would be just 738 TAF. Thus, conjunctive operations would result in a net gain to the groundwater system of 1,066 TAF over the analysis period.

5.3.4. Scenario 2 – Oroville Reservoir and Feather River

Figure 5-22 illustrates annual volumes of water released to meet environmental objectives on the Feather River. Similar to the Sacramento River operations, the geomorphic objective is satisfied most frequently, but increased groundwater pumping capacity allows for more aggressive reservoir operations allowing other objectives to also be satisfied. Average annual release for environmental objectives on the Feather River is 23 TAF.

Table 5-5 provides a summary of the number of times each objective is met by reservoir release and under base operations on the Feather River. Values reported in the table for the geomorphic objective only include those years when the objective is not met under base operations. Therefore this value is less than the number of releases shown on Figure 5-22. The flood plain inundation objective can be met with the project under base condition flows with the modified weir, or with a combination of project releases and the modified weir.

Figure 5-23 illustrates additional agricultural deliveries under Scenario 2. Additional agricultural releases are made in 30 of the 82 years simulated, or approximately 37 percent of the years. The average annual release in those years is 52 TAF, while the average annual agricultural delivery over the 82-year simulation period is 20 TAF.

Figure 5-24 illustrates how conjunctive management operations result in lower Oroville fall storage conditions in approximately 60 percent of the years. Fall storage may be increased in a few years when it is below the minimum target level of 1,200 TAF.

Figure 5-25 shows how storage space created in Oroville Reservoir through additional releases for agricultural and environmental objectives is frequently refilled with surplus surface water. This occurs in 43 years with an average annual refill of 72 TAF in those years. Average annual refill with surplus for the 82-year simulation period is approximately 36 TAF.

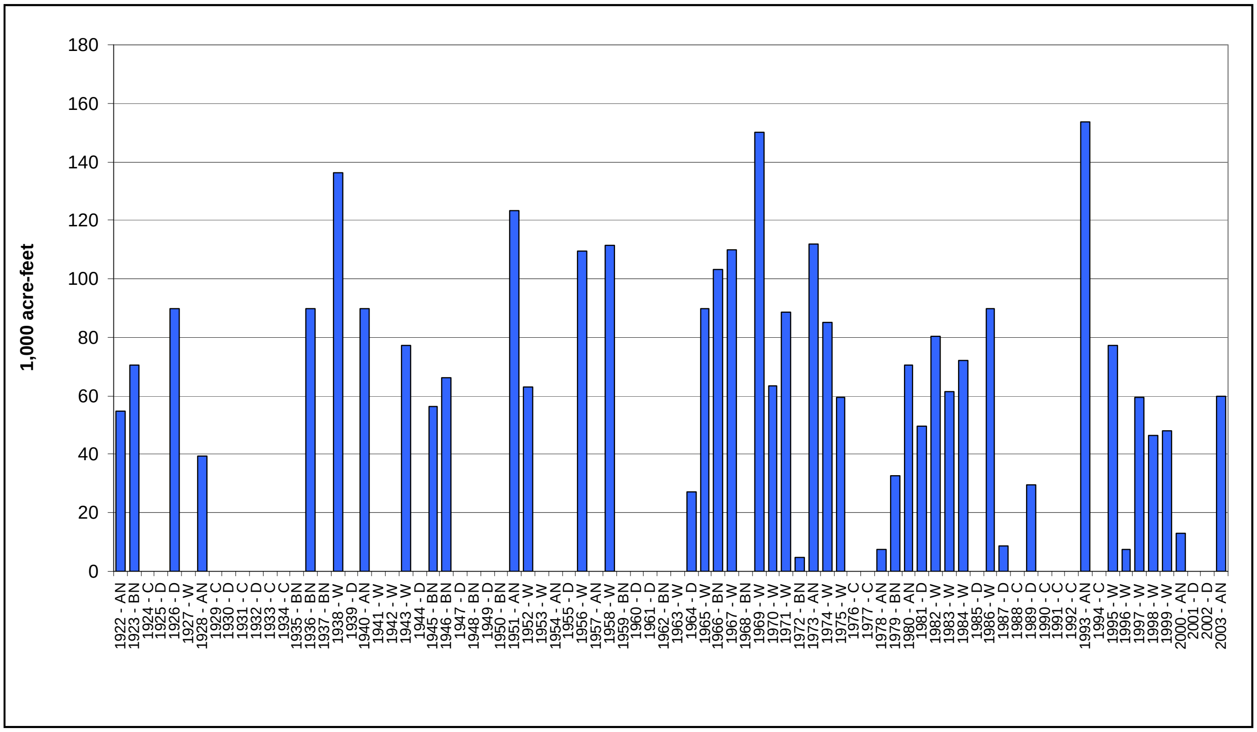

FIGURE 5-25
Refill of Oroville Reservoir from Surplus Surface Water, Scenario 2
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Figure 5.26 presents the annual conjunctive management pumping in the Butte Basin project for Scenario 2. Conjunctive management pumping occurs in 8 of the 82 years simulated or 10 percent of the years. The average annual pumping in those years is 75 TAF. The average annual pumping for the entire 82-year simulation is approximately 7 TAF with a maximum annual pumping of the full 100 TAF of pumping capacity.

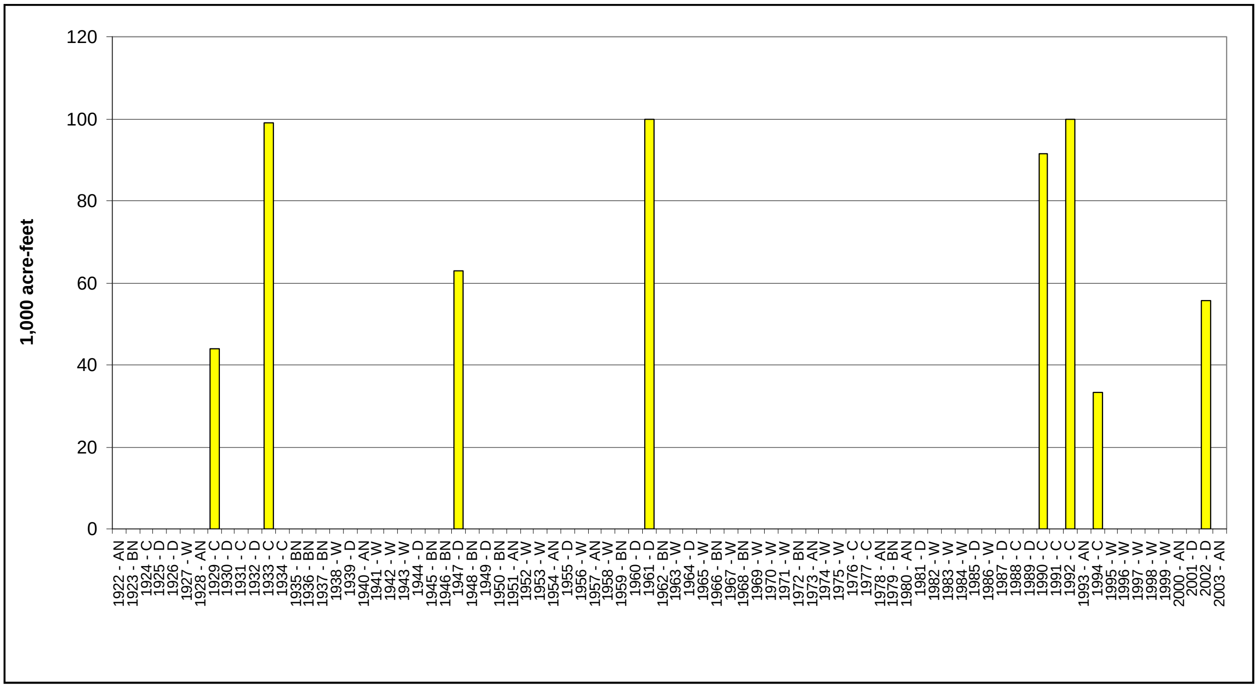

FIGURE 5-26
Refill of Oroville Reservoir from Conjunctive Management Pumping, Scenario 2
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Over the 82-year simulation period, additional reservoir releases are made in 51 years, or 62 percent of the years. Reservoir refill is accomplished with surplus surface flows in 43 years and with project pumping in 8 years. For Scenario 2 on the Feather River system, out of total additional releases of 43 TAF (23 TAF for agriculture and 20 TAF for environmental objectives), 36 TAF is refilled from surplus surface water and 7 TAF from conjunctive management pumping. Over the 82-year period of analysis, a total of 1,886 TAF would be delivered to satisfy agricultural demands that would otherwise be met from groundwater pumping. Over the same period, the total volume of project pumping required for reservoir payback would be just 574 TAF. Thus, conjunctive operations would result in a net gain to the groundwater system of 1,312 TAF over the analysis period.

5.4.Impacts and Evaluation of Initial Scenarios

In the preceding section the initial project scenarios are described with respect to their performance; that is, the ability to achieve targeted project objectives (environmental flows and agricultural water supplies) subject to identified constraints. In this section, the scenarios are described in terms of how project pumping would affect groundwater conditions with particular emphasis on impacts to existing groundwater users, groundwater pumping costs and streamflows.

5.4.1. Impacts on Groundwater Users

During average rainfall years, groundwater supplies 18 percent of the total demand for the Sacramento River Basin, and during drought years groundwater supplies 25 percent of total demand.[16] Wells in the Project area primarily provide groundwater directly to homes and farms. A few municipal water supply agencies also utilize groundwater on the fringes of the Project area, including Chico and Durham.

The great majority of wells in the area are associated with domestic use, with groundwater supplying water to essentially all households. Conversely, surface water is the primary source of irrigation supply for the majority of the farmers. Most of these are incorporated into water or irrigation districts, the largest of which are the partners in this Project, Glenn-Colusa Irrigation District, Western Canal Water District, and Richvale Irrigation District, and various smaller reclamation and irrigation districts and water user associations. However, for those agricultural users outside these districts, many of which are orchardists, groundwater is the main source of supply. It is the domestic well users and farmers growing permanent crops that are most vulnerable to increases in groundwater extractions.

Based on well log data maintained by the Department of Water Resources, there are approximately 15,000 water supply wells (in contrast to monitoring wells) within the Project area, of which approximately two thirds are domestic wells and one third are irrigation wells (Table 5-6). Municipal and irrigation wells are typically screened at lower levels than domestic wells, yet there is a wide range of depths for all types of wells. Approximately 335 wells in the Sacramento Valley extract water from the Lower Tuscan Formation, and these tend to be larger irrigation or public water supply wells. Most of these are located on the east side of the Valley in Butte County, while several agricultural wells on west side of the Valley in GCID and other districts also tap into the Lower Tuscan aquifer.[17]

TABLE 5-6
Number of Water Supply Wells in Project Area[18]
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Use	Number of wells
Domestic	9,058
Irrigation	4,455
Unknown[19]	1,388
Other[4]	267
Municipal	139
Stock	75
Public	52
Total	15,434

Agriculture is the major industry throughout the Project area. Primary crops consist of rice and orchards (almonds, grapes, walnuts). The proportion of agricultural land planted as orchards is increasing as the

[19] May include monitoring wells, vapor recovery wells, or other wells not constructed for water supply purposes.

area transitions from row crops to perennial crops and from low-value agronomic crops to higher value vegetable or other row crops. Many individual growers' livelihoods are dependent on having an adequate and affordable supply of groundwater to meet crop water requirements at all times. Of these users, growers of perennial crops and particularly orchardists are often solely dependent on groundwater and are especially vulnerable to even temporary decreases in supply.

5.4.1.1. Occurrence of Project Pumping and Potential Impacts

The Project pumping scenarios designate an annual maximum volume of water that can be released from existing reservoirs to meet local irrigation demands and environmental flow targets. As noted above, in most years, the reservoir space created by additional Project releases is naturally refilled with surplus surface water, which dam operators would otherwise release for flood control. However, in years when refill is less than would have otherwise occurred, pumping of groundwater in lieu of diverting surface water is implemented to make up the difference. This allows a volume of water equivalent to the foregone diversions to remain in reservoir storage.

The surface model predicted the need for pumping in about 10 percent of the years in the Butte Basin and about 7 percent of the years in GCID under the 300 TAF pumping scenarios (see Table 5-7). In years in which pumping occurs, pumping is usually required in either GCID or in the Butte Basin, but not both. However, in exceptionally dry years, pumping would occur in both areas in the same year.

TABLE 5-7
Occurrence of Pumping
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Maximum Pumping	Number of times pumping occurs (82 years of record)		Years in which pumping occurs		Number of times pumping occurs in GCID and/or Butte Basin
	GCID - Shasta	Butte - Oroville	GCID - Shasta	Butte - Oroville	
150 TAF (100 TAF GCID; 50 TAF Butte Basin)	4	6	1947, 1987, 1988, 1990	1933, 1961, **1990**, 1992, 1994, 2002	9
300 TAF (200 TAF GCID;100 TAF Butte Basin)	6	8	1923, **1929**, **1947**, 1987, 1988, **1990**	**1929**, 1933, **1947**, 1961, **1990**, 1992, 1994, 2002	11

* **bolded** years indicate that pumping would have occurred in both GCID and Butte Basin under the Project.

The groundwater model results reveal that the project pumping scenarios will result in increased energy requirements and associated costs to maintain existing pumping volumes.[20] However, at the scale of feasible operations under the Keswick minimum release constraint, the additional drawdown is not expected to reduce the yield of either agricultural or domestic wells. This is particularly clear for the irrigation wells because the screened interval (which provides a bases for estimating minimum saturated thickness under pumping conditions) and well depth tend to be much greater than peak interference drawdown associated with the payback pumping.

The numbers of wells experiencing reduced yield due to interference drawdown were estimated for individual domestic wells within the Project area based on comparison of the length of the screened

---

[20] Well yield impacts and increases in energy costs associated with increased lift were assessed using a combination of data provided by DWR describing screened interval lengths within the Project area in conjunction with interference drawdown estimated using the groundwater model.

interval to peak interference drawdown. Because screened interval length data were not available for all wells, results for wells with available data were scaled upwards to provide estimates of the total probable range of wells impacted.

Individual domestic wells were considered to be adversely impacted under the following conditions:

1. When the amount of peak interference drawdown from project pumping results in less than 25 percent of the total screened interval remains saturated, assuming that 50 percent of the screened interval would remain saturated under baseline pumping drawdown,. This criterion was established to provide an estimate of the maximum probable number of wells impacted.

2. When the amount of peak interference drawdown from project pumping results in less than 33 percent of the remaining screened interval (17% of the total) remaining saturated, assuming that 50 percent of the screened interval remains saturated under baseline pumping drawdown. This criterion was established to provide an estimate of the minimum probable number of wells impacted.

A summary of the estimated probable range of wells impacted within potential impact zones, delineated as areas experiencing peak interference drawdown greater than or equal to 2 feet, is provided in Table 5-8. A summary of average monthly interference drawdown within the Project area calculated at the section scale over the 17 year analysis period for each scenario is provided in Table 5-9. In general, the pumping of new wells, screened at 900 to 1100 feet below ground surface (ft-bgs), results in less yield impacts than the equivalent volume of water pumped on the same schedule from existing domestic wells screened at 0 to 300 ft-bgs. This is the case notwithstanding that production from new wells results in greater drawdown in the shallow aquifer, on average, than pumping the same quantities at the same rates from existing wells. This is explained by the hypothesis that greater yield impacts occur with less interference drawdown for the pumping scenarios relying on existing wells because existing production wells are closer to existing domestic wells than the new well field. Also, for a given project production capacity and well field, the greatest peak drawdown is observed in fall pumping simulations because pumping is concentrated within three months as compared to four months for the summer pumping scenarios and seven months for the summer and fall pumping scenarios. As expected, an intermediate magnitude of drawdown is observed for pumping over the four month summer period, and the least drawdown is predicted for the seven month summer and fall pumping period.

5.4.1.2. Timing of Peak Interference Drawdown and Associated Impacts

Under each of the pumping scenarios, peak interference drawdown occurs for most domestic wells in 1990, when Project pumping occurred in both GCID and the Butte Basin. Additionally, in the simulations, the largest volume of water was pumped out of GCID in 1990, and the largest total volume of water was pumped for the Project as a whole in that year (Table 5-10). Thus, 1990 represents a “worst-case scenario” for the period of record.

Within the potential impact area for yield impacts (interference drawdown of 2 feet or more) for each pumping scenario, the maximum number of domestic wells experiencing peak drawdown occurs in 1990. Peak drawdown at a well lags project pumping by a few months due to the time required for pumping in the lower aquifer to result in drawdown in the shallow aquifer. The time series of project pumping and domestic wells experiencing peak drawdown is shown for the 300 TAF summer pumping scenarios in Figure 5-27.

TABLE 5-8
Estimated Probable Range of Domestic Well Yield Impacts
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

		Minimum Probable Impacts[2]		Maximum Probable Impacts[3]	
Pumping Scenario	Total Wells[1]	Percent Impacted[4]	Total Impacted[5]	Percent Impacted[4]	Total Impacted[5]
300 TAF, Summer Pumping, New Well Field	756	8%	58	21%	158

Project Pumping for 300 TAF Summer Pumping Scenarios and Number of Domestic Wells Experiencing Peak Interference Drawdown
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

5.4.1.3. Increase in Pumping Energy Costs

Project pumping will result in amounts of drawdown that will not be great enough to adversely impact yield in nearby wells in most cases; however, the drawdown will require all groundwater users (agricultural and domestic) to lift water from slightly greater depths, resulting in additional pumping costs. Additional pumping costs associated with increased lift were estimated for irrigation wells based on baseline groundwater pumping from the surface water model, interference drawdown from the groundwater model, estimated mean overall pumping plant efficiency for irrigation wells, and the estimated agricultural energy cost per kilowatt-hour. For domestic wells, additional pumping costs were estimated based on baseline pumping estimated from the combination of spatially distributed U.S. Census data for 2000 and per-capita non-irrigation groundwater pumping for 2005 from USGS, interference drawdown from the groundwater model, estimated mean overall pumping plant efficiency for domestic wells, and the estimated residential energy cost per kilowatt-hour. Increased energy requirements and associated costs were estimated for individual sections within the Project area on a monthly time step for water years 1987 to 2003.

Baseline pumping and interference drawdown vary with time and location within the project area. As a result, associated increases in pumping costs vary. Summary statistics of increased annual energy requirements per acre to maintain existing levels of groundwater pumping for irrigation are provided for each pumping scenario in Table 5-11. Summary statistics of increased annual energy requirements per acre to maintain existing irrigation pumping are provided in Table 5-12. The summary statistics describe the increased energy requirements for 1589 of 1786 sections within the Project area that pump groundwater for irrigation based on the results of the surface water model. Summary statistics of total annual increases to energy costs within the Project area for the 17 years of analysis are provided in Table 5-13.

Increases in energy requirements and associated costs are greatest for the 300,000 ac-ft pumping scenarios due to greater interference drawdown resulting from greater Project pumping volumes.

150 TAF Summer & Fall Pumping, New Well Field	$44,736	$294,296	$140,169	$120,727	$ 81,830
150 TAF Summer & Fall Pumping, Existing Well Field	$47,471	$345,330	$151,533	$132,451	$ 91,202

Increases in energy requirements are least for the fall pumping scenarios due to the lesser volume of Project pumping (as compared to the 300 TAF summer pumping scenarios) and due to Project pumping occurring after the peak irrigation season, when baseline irrigation pumping is less. Costs tend to be similar whether Project pumping relies on a new or existing well field.

Annual baseline irrigation pumping, Project pumping, and increased energy costs by water year are shown for the 300 TAF summer pumping scenario with a new well field in Figure 5-28. Annual baseline irrigation pumping, Project pumping, and increased energy costs by water year are shown for the 300 TAF summer pumping scenario with an existing well field in Figure 5-29.

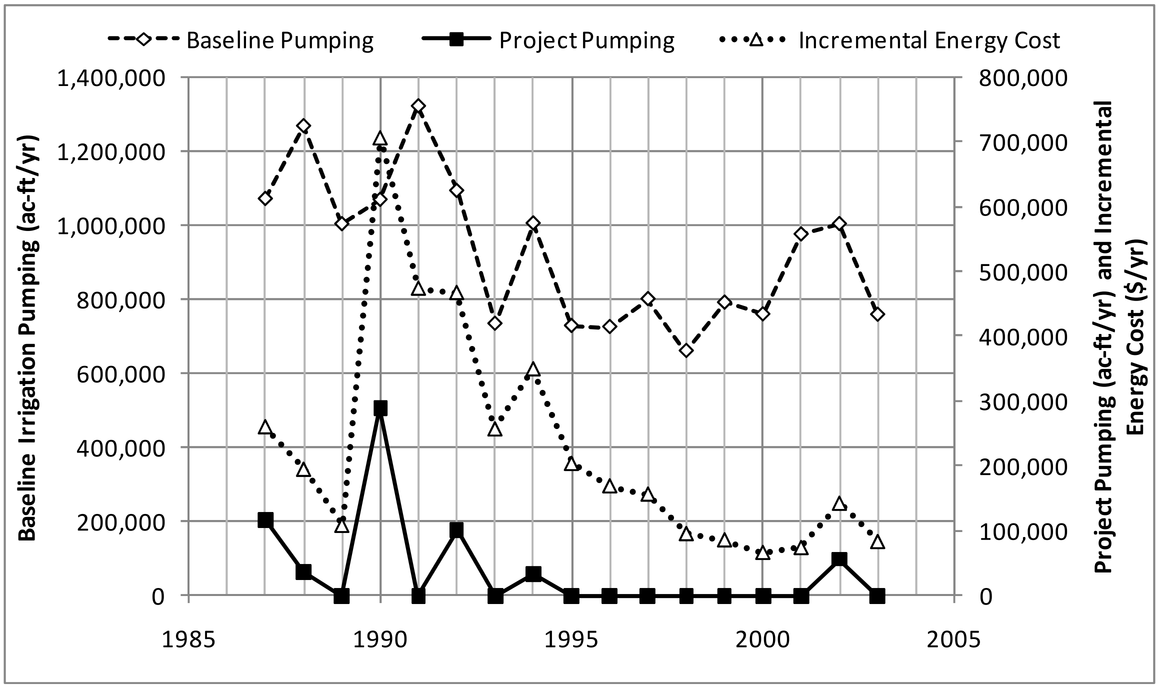

FIGURE 5-28
Annual Baseline Irrigation Pumping, Project Pumping, and Increased Energy Cost: 300 TAF Summer Pumping, New Well Field
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

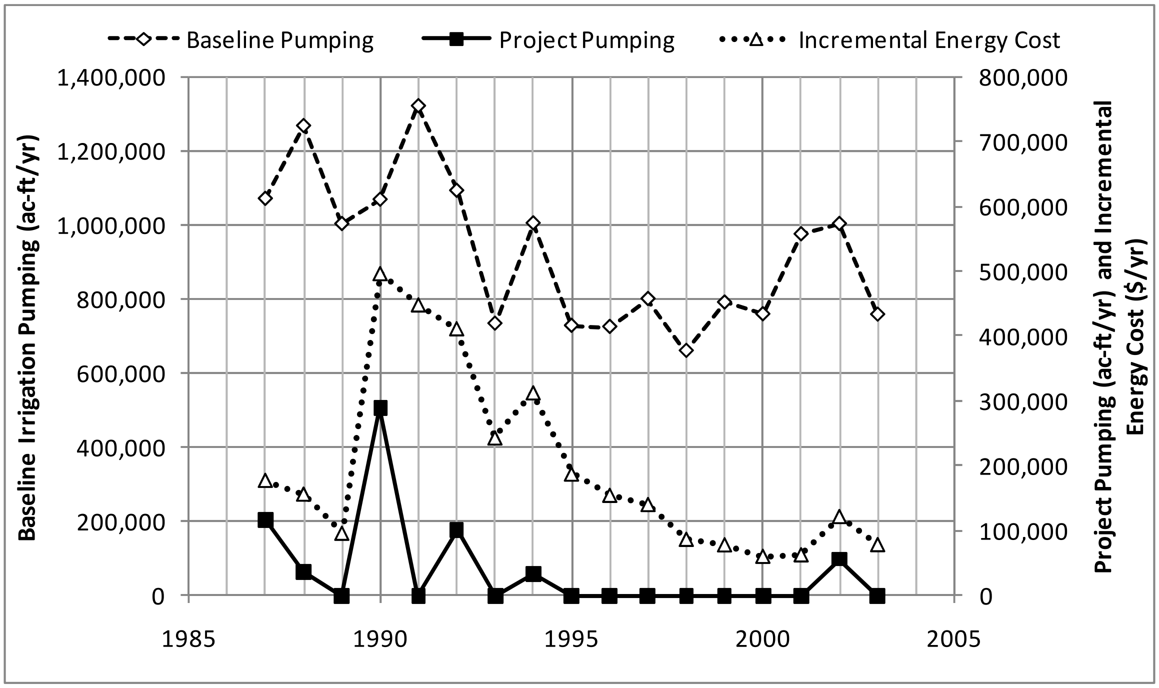

FIGURE 5-29
Annual Baseline Irrigation Pumping, Project Pumping, and Increased Energy Cost: 300 TAF Summer Pumping, Existing Well Field
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Incremental energy costs are greatest in years when project pumping is greatest but are also directly proportional to the amount of baseline irrigation pumping, all else equal. Project pumping in 1990 results in interference drawdown that causes increased lift and associated increased energy costs for the years to follow. The incremental energy costs resulting from Project pumping with the new well field are substantially greater than the incremental energy costs for the existing well field in 1990, the year of maximum pumping in GCID and maximum total project pumping.

Summary statistics of increased annual energy requirements per acre to maintain existing levels of groundwater pumping for non-irrigation (primarily domestic) use are provided for each pumping scenario in Table 5-14. Summary statistics of increased annual energy requirements per acre to maintain existing non-irrigation pumping are provided in Table 5-15. The summary statistics describe the increased energy requirements for 1329 of 1786 sections within the Project area that pump groundwater for non-irrigation uses based on the analysis of year 2000 Census data. Summary statistics of total annual increases to energy costs within the Project area for the 17 years of analysis are provided in Table 5-16.

Similar to the results for irrigation pumping, increases in energy requirements and associated costs are greatest for the 300,000 ac-ft pumping scenarios due to greater interference drawdown resulting from greater Project pumping volumes. Increases in energy requirements are least for the fall pumping scenarios due to the lesser volume of Project pumping (as compared to the 300 TAF summer pumping scenarios) and due to Project pumping occurring after the peak irrigation season, when baseline irrigation pumping is less (non-irrigation pumping, which includes landscape watering for purposes of this analysis, tends to follow a similar distribution as irrigation pumping, with the greatest use during peak demand periods). Costs are similar whether Project pumping relies on a new or existing well field.

Annual baseline non-irrigation pumping, Project pumping, and increased energy costs by water year are shown for the 300 TAF summer pumping scenario with a new well field in Figure 5-30. Annual baseline irrigation pumping, Project pumping, and increased energy costs by water year are shown for the 300 TAF summer pumping scenario with an existing well field in Figure 5-31. As indicated in the figures, non-irrigation pumping has been assumed to remain constant from year to year for purposes of this analysis.

Incremental energy costs are greatest in years following substantial project pumping. The lag between peak project pumping and peak incremental costs results from gradual reductions in water levels in the shallow aquifer as the regional aquifer and/or lower aquifer is refilled. Interference drawdown in the shallow aquifer in some areas of the Valley may occur more quickly following peak project pumping, but the incremental energy costs may be low if little or no non-irrigation pumping occurs in these areas. The incremental energy costs resulting from project pumping with the new well field are somewhat less than the incremental energy costs for the existing well field but follow a similar trend over time.

In summary, the greatest costs associated with increased lift resulting from interference drawdown will be incurred by agricultural groundwater users due primarily to the greater volume of water pumped. Additionally, project pumping and associated interference drawdown tends to be greatest in agricultural areas away from population centers. Costs are highly variable from location to location and over time but, in aggregate, are similar among pumping scenarios of the same volume (e.g., 300 TAF or 150 TAF). Peak incremental energy costs may occur multiple years after project pumping, particularly for non-irrigation pumping from the shallow aquifer.

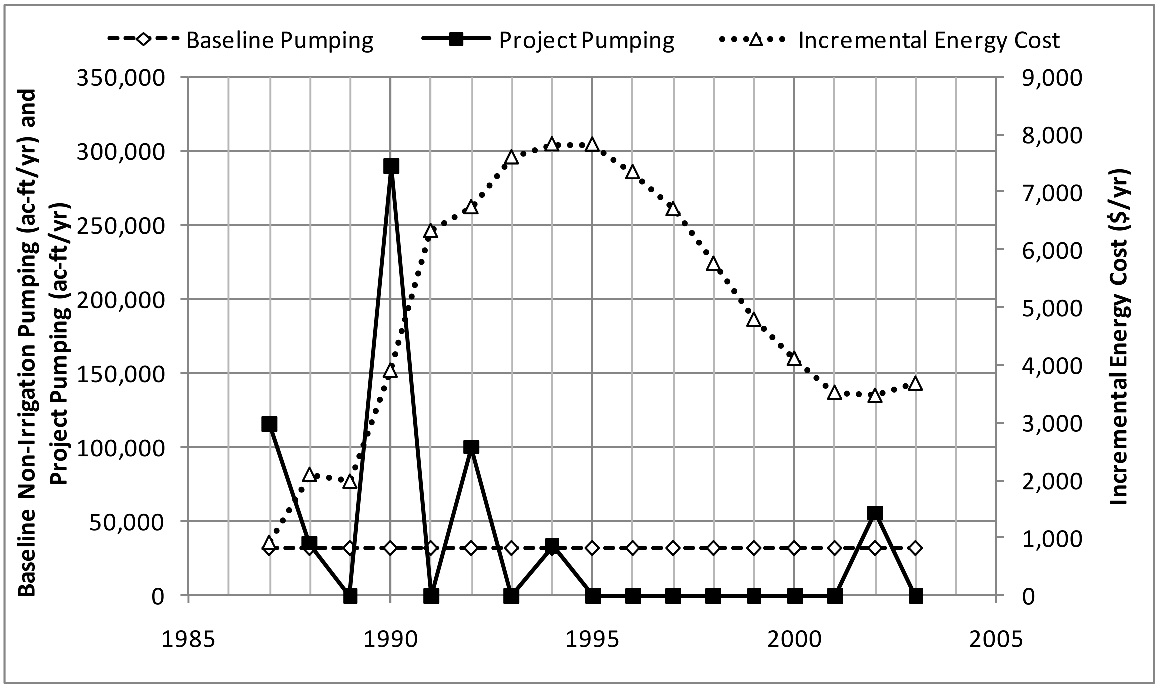

FIGURE 5-30

Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Spreading the payback pumping over two seasons (summer and fall) will moderate the impact. The volume and timing of the pumping will also be efficiently managed by assessing the condition of the groundwater basin in the spring while evaluating its capacity for pumping that year.

If some form or degree of the groundwater pumping payback method is eventually adopted, a mitigation program will be instituted to compensate the owners of the impacted domestic or municipal wells for the expected increase in their pumping cost due to the increased lift.

As yield impacts are not expected at the permissible level and scheduling of the pumping, it should not be necessary to improve their wells or build new and more efficient ones in order to deal with yield impacts.

5.4.1.4. Groundwater Levels

Production of 150 TAF of groundwater from existing wells over the summer/fall period (May through November) results in a maximum of about 30 feet of drawdown in the pumped aquifer compared to a maximum of approximately 40 feet of drawdown if the same production occurs in the summer only.

Simulated drawdown in the vicinity of the eastern well fields in the Butte Basin Project are significantly lower than those observed on the west. This is due to a combination of lower overall production rates from the east and a greater production well spacing.

5.4.2. Impacts on Streamflow

Peak effects on streamflow due to groundwater production in the Sacramento Valley are summarized in Table 5-17.

TABLE 5-17
Peak Effects on Streamflow from Conjunctive Management Operations
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Stream	Scenario 1		Scenario 2		Scenario 3		Scenario 4	
	Existing (cfs)	**New (cfs)**	**Existing (cfs)**	**New (cfs)**	**Existing (cfs)**	**New (cfs)**	**Existing (cfs)**	**New (cfs)**
All Streams	54	53	111	105	80	90	64	65
Butte Creek	13	12	72	69	50	48	39	33
Sacramento River – GCID to Wilkins Slough	42	37	32	28	16	18	16	15
Feather River	3	3	6	6	4	4	4	4
Little Chico Creek	3	3	6	5	4	3	4	3
Salt River	1	5	5	8	2	5	2	5
Stone Coral Creek	6	9	11	15	7	10	6	9
Stony Creek	4	5	7	7	4	6	4	4

Specific conclusions regarding surface water effects are as follows:

The modeled project pumping scenarios result in some streamflow reductions, due either to increased stream loss to aquifers or decreased aquifer flow into streams. To compensate for these losses, the modeling incorporated releases from Shasta and Oroville when the system is “in balance.” Although these releases help maintain streamflow in the Sacramento and Feather Rivers, while insuring the system as whole doesn't experience significant losses, the release do not directly mitigate the impact of *tributary* streamflow losses to ecosystems and species. As a starting point for the assessing impact to tributary streams, the project analyzed Butte Creek due to its high ecosystem value combined with some of the largest discharge losses due to pumping. An additional consideration is that historical streamflow records are available for Butte Creek but generally not for other, smaller tributary streams. The analysis yielded the following key results:

- Project pumping will not impact the uppermost reach in the project areas, the primary spawning area for Spring-run Chinook and Central Valley steelhead
- Pumping will have a greater impact on the lower reaches of Butte Creek, than the upper
    - In addition to cumulative effects, the *rate* of leakage is higher in downstream reaches
- The largest absolute losses in streamflow occur when discharge is also highest (Jan.-Mar)
    - The magnitude of impacts in relation to the baseflow at this time is not substantial (maximum of 1-3% loss in streamflow)
- The largest percentage loss in stream flow occurs in the lowest reach during summer/ early fall when Spring-run have already migrated upstream and steelhead are only beginning to enter the streams
- Project pumping never causes average monthly discharge to fall below the instream flow standards in the four upstream reaches

- June average monthly discharge in the lowermost reach, falls below the 40 cfs instream standard twice in the 17 year record due to pumping of up to 150K, and four times under pumping of up to 300K
    - Most Spring-run migration has already occurred by June, but some late Spring-run migrants, may experience minimal impacts
    - These impacts occur during the drought years of 1990, 1991, 1992, 1994, when Butte County irrigators participated in the drought water bank

The results of the analysis do not reveal any significant negative impact to Spring-run Chinook or Central Valley Steelhead in Butte Creek due to project pumping. Furthermore, this analysis focused only on those years with stream impacts (water years 1987 - 2003), during which time groundwater would have been pumped more frequently than over the entire period assessed by the surface water model (1922-2003). As such, on average impacts would likely be less significant and rarer than those projected in this analysis.

5.4.3. Stream Impact Analysis

The modeled project pumping results in some streamflow reductions, due either to increased stream loss to aquifers or decreased aquifer flow into streams. The greatest impact to surface streams occurs to the Sacramento River, between GCID and Wilkins Slough, and Butte Creek, with smaller impacts estimated to occur to surrounding streams. Project modeling and operations account for the effects of stream leakage when the system is “in balance”, the condition when there is no excess flow in the system and the reservoirs are releasing to satisfy critical conditions. Depending on location and timing of stream leakage, upstream reservoirs may be required to make additional releases to compensate for streamflow reductions due to groundwater pumping. However, if leakage occurs at times when the system is "in surplus", additional reservoir releases may not be necessary. Although this helps maintain flow conditions on the Feather and Sacramento Rivers, as well as minimizing losses to the system as a whole, it does not account for potential stream leakage impacts on fisheries in tributaries, which were examined.

The Sacramento River and several of its tributaries are designated as critical habitat for Spring-run Chinook salmon (SRCS) and Central Valley steelhead, both listed as "threatened" species, as well as the fall and late-fall run Chinook, which are listed as a “species of concern”. The stream analysis in this report focuses on the National Marine and Fisheries Service (NMFS) designated critical habitat within the project area. At this time, the assessment is primarily limited to impact to stream discharge, although other factors, such as water quality parameters, may need to be further assessed if the project proceeds.

The first time pumping occurs within the 17-year groundwater model simulation period (1987 to 2003) is in 1987 to refill Shasta and in 1990 to refill Oroville. Impacts from the initial pumping, as well as additional groundwater pumping in 1988 and 1990 to refill Shasta and in 1992, 1994, and 2002 to refill Oroville, produce stream impacts through 2003. This stream impact analysis focuses only on those years with stream impacts, water years 1987 - 2003. It should be noted that pumping occurred more frequently during this span of the groundwater model than during the longer period assessed by the surface water model (1922-2003). The surface model predicted the need for pumping at most once every seven years, yet pumping occurred six times in the 17-year time span of this analysis.

An initial and conservative assessment of potential pumping impacts to the critical habitat streams in the project area demonstrated that the maximum impact (under up to 300K pumping of existing wells) would yield a less than one cubic foot per second decrease in average monthly streamflow in the majority of critical streams. Table 5-18 lists the streams located in the project area, which are designated as critical habitat for Spring-run Chinook salmon and steelhead, along with the potential impact to streamflow due to pumping.[21] As mentioned above, additional releases from Shasta and Oroville mitigate any negative impact on streamflow in the Sacramento or Feather. The rarity in occurrence of the maximum decrease in discharge, noted in the following table, further nullifies most concerns about any negative impact to fisheries.

The impact to the three highlighted streams (Butte Creek, Little Chico Creek, and Stony Creek) in relation to their actual streamflow did warrant further investigation. The noted ecosystem value of Butte Creek, in conjunction with non-trivial projected project impacts, justified a more in-depth analysis, which is subsequently described. Based on the analysis of Butte Creek, the impact of pumping on Little Chico and Stony Creek, which experience a much less significant loss in stream flow, is determined to also be minimal at this time. If the Project does proceed, more detailed analysis of the impact to Little Chico and Stony Creek may be warranted. With respect to the streamflow impacts, the Project would be operated to assure a net improvement in streamflow parameters important to the viability of protected species, specifically Chinook salmon. Reductions in base flows that may occur in the tributary streams due to additional pumping of groundwater would be more than offset by improvements to environmental flow parameters in the mainstem Sacramento and Feather Rivers and in the resulting inflows to the Delta. Indeed, this Project is designed to contribute substantially to the recovery of these species. That result will be demonstrated to the listing agencies in the consultation process that the CVP, SWP and participating districts will engage in as part of their NEPA/CEQA compliance.

5.5.Economic Analysis

The team compared the costs and benefits of the eight different initial scenarios as a means of evaluating the economic feasibility of the project. This analysis is summarized below.

The economic analysis did not assign a monetary value to the environmental benefits that would be achieved by project ecologic flows releases. This was not because these benefits would be negligible. In fact, the potential increase in salmon productivity could be quite substantial. Rather, methods for valuing environmental benefits are somewhat speculative so, to avoid basing economic feasibility on uncertain benefits, the economic analysis was conducted in part to determine whether the revenue from the project's potential water sales alone would be large enough to pay for the capital and operational costs. Additionally, the benefits that would result from improved groundwater conditions within the Sacramento Valley due to the delivery of additional surface water supplies and consequent relaxation of groundwater pumping were not factored into the economic analysis. In sum, the question was not whether the project would be economically justified, but whether it could pay for itself.

5.5.1. Cost Assessment

The costs of the different scenarios are presented in Table 5-19, including costs capital outlays for project facilities (primarily existing production well rehabilitation or new well construction), project operation and maintenance, compensation for increased pumping costs (ag and domestic), replacement of a certain number of domestic wells and project legal and administrative charges. These costs are described in detail in Appendix E. The present value of these costs based on a real discount

	Scenario	Capital	O&M	Dom. & Ag. Energy Compensation	Domestic Well Replacement	Admin & Legal	Total Cost (PV)
1	300 TAF Summer New Wells	$220,604,741	$61,940,720	$3,287,267	$1,776,873	$1,919,003	$289,528,604
2	300 TAF Summer Existing Wells	$140,118,788	$63,962,075	$2,804,880	$3,594,878	$1,919,003	$212,399,624
3	150 TAF Summer New Wells	$108,940,613	$23,368,466	$733,017	$99,285	$1,704,928	$134,846,308
4	150 TAF Summer Existing Wells	$67,481,217	$22,826,909	$777,553	$794,280	$1,704,928	$93,584,886
5	150 TAF Fall New Wells	$176,120,657	$31,067,457	$647,334	$105,034	$1,704,928	$209,645,410
6	150 TAF Fall Existing Wells	$110,980,583	$29,442,275	$727,303	$792,257	$1,704,928	$143,647,345
7	150 TAF Summer & Fall New Wells	$65,364,368	$19,670,551	$721,787	$96,963	$1,704,928	$87,558,597
8	150 TAF Summer & Fall Existing Wells	$42,168,421	$20,133,635	$778,535	$567,088	$1,704,928	$65,352,605

rate of 3 percent ranges from $65M to $298M, with the lower cost scenarios being those relying on existing wells or having longer repayment pumping period and the higher costs scenarios being those relying on new wells and having shorter pumping periods. The scenarios that involve development of new wells are more expensive compared to their sister scenario using existing wells primarily because of the higher capital investment required to build the new wells. The capital cost is almost 60 percent higher to develop new wells than use existing wells.

The results show that the 150 TAF summer and fall pumping scenario using the existing wells is the least expensive scenario. Under the 150 TAF summer and fall pumping scenarios (scenarios 7 and 8) the number of wells required to accommodate project pumping is relatively low because users can withdraw water during a longer period (almost 7 months), which results in a need for fewer wells and the least amount of groundwater level drawdown.

The analysis reveals that the costliest scenarios (in terms of average cost per AF of pumping) are the 150 TAF summer and 150 TAF fall pumping scenarios using new wells (Scenarios 3 and 5) which result in the highest drawdown (Table 5-20). This is due to the shorter pumping period (three or four months) compared to the summer and fall pumping scenarios (seven months). Our analysis shows that the optimal scenario, considering only costs, is the 150 TAF summer and fall pumping scenario using existing wells.

5.5.2. Valuing Benefits

To value the benefits of the additional water supply, potential market value of various time series of additional reservoir releases were considered. The releases will become supplemental streamflow and may be left in the Feather and Sacramento rivers to augment flow, or possibly exported. Benefits are directly linked to the timing of the releases and how far in advance the buyers can be informed about the quantity of these surplus releases. Additional water supplies could be delivered in the Sacramento Valley, or could be left instream to become Delta inflow.

The value of additional water supplies generated through conjunctive operations was estimated in two ways to bracket the economic analysis. Consistent with the in-Valley focus of the investigation one valuation was based on the water being integrated into CVP and SWP project deliveries according to existing water service contracts in the Sacramento Valley. The second valuation, intended to serve as an upper bound, was based on an assumption that the additional supplies could be exported south of the Delta and made available to urban users as a dry year supply[22].

Under the assumption that the water is used within the Sacramento Valley when it is made available, the main feasible uses are groundwater recharge and environmental flows. An examination of water market data reveals that over the past decade, water sold on the Sacramento Valley market for these purposes averaged around $50/AF.[23]

If it were feasible to export the additional water supplies south of the Delta, the additional yield of the project would be worth more. To approximate the value of exportable supplies, the net willingness

---

[22] Consistent with the in-Valley scope of the investigation, no analysis was conducted concerning the feasibility of exporting project water supplies. Additional analyses would be needed to determine the frequency with which project releases might be exported and the economic analysis revised accordingly.

[23] Stratecon Inc., "Water Strategist: Analysis of Water Marketing, Finance, Legislation and Litigation," Monthly publications January 2000 – December 2009. The actual average was $57/AF in average to wet hydrologic years.

TABLE 5-20
Average Cost of Pumping and Releases for Each Pumping Scenario
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

	Scenario	Total Cost (PV)	Pumping Volume (AF)	Avg Cost of Pumping ($/AF)	Avg Annual Releases (AF)	Avg Cost of Annual Releases ($/AF)
1	300 TAF Summer New Wells	$289,528,604	1,307,759	$221	109,596	$79
2	300 TAF Summer Existing Wells	$212,399,624	1,307,759	$162	109,596	$58
3	150 TAF Summer New Wells	$134,846,308	523,547	$258	43,609	$93
4	150 TAF Summer Existing Wells	$93,584,886	523,547	$179	43,609	$64
5	150 TAF Fall New Wells	$209,645,410	608,963	$344	44,298	$142
6	150 TAF Fall Existing Wells	$143,647,345	608,963	$236	44,298	$97
7	150 TAF Summer & Fall New Wells	$87,558,597	574,129	$153	43,955	$60
8	150 TAF Summer & Fall Existing	$65,352,605	574,129	$114	43,955	$45

of urban agencies in the South Coast to pay for dry year water was calculated, and then expenses for conveyance and storage were subtracted, while accounting for carriage and storage losses. Currently, the WD Tier 2 rate for untreated, delivered water is $594/AF.[24] The cost of conveyance to transport the water from Shasta and Oroville to the South Coast is around $220/AF.[25] We used information from Semitropic-Rosamond Water Bank Authority (SRWBA) to approximate the cost of groundwater storage necessary to convert wet year water to dry year water. The volumetric cost of using SRWBA facilities is approximately $230/AF.[26] Water sold south of the Delta will incur storage and carriage losses, which are set at 30 percent based on SRWBA contract terms and pre-Wanger conveyance losses. Taking these numbers together, it follows that the value of additional supply under the assumption that it could be exported through the Delta under pre-Wanger conditions is approximately $100/AF.

It is noted here that under current Delta restrictions, it would not be possible to export additional supplies south of the Delta. To the extent that this option turns out to be economically beneficial, it is another demonstration of the economic cost of current Delta pumping restrictions and the type of benefit that would result from construction of some type of through-or around-Delta conveyance facility.

5.5.3. Results of Economic Analysis

The net benefit of the project considering the associated costs and expected benefits varies depending primarily on where the water can be sold and, to some extent, on whether new wells are constructed or the project is operated using primarily existing wells. As summarized in Table 5-21, if the water generated through conjunctive operations is sold in the Sacramento Valley, only one of the scenarios has a positive net benefit, with the others having modest to strong negative net benefits. In contrast, if the water is valued at export rates, only one of the scenarios has a negative net benefit with the others being positive. Interestingly, even though the 150 TAF summer and fall pumping using the existing wells was the least-cost scenario, the analysis demonstrates that the largest net benefit is associated with the 300 TAF summer pumping scenario using the existing wells (if the water could be exported south of the Delta).

It can be seen from Table 5-21 below that the existing well scenarios dominate the new well scenarios in terms of net benefits. The high capital costs associated with constructing new wells make this option less economically viable.

Overall, Sacramento Valley conjunctive operations appear to be more attractive in the event the additional supplies could be exported south of the Delta.

5.6.Provisional Conclusions Guiding Refinement of Scenarios

The main conclusion derived from the formulation and evaluation of preliminary project scenarios is that conjunctive management based on re-operating reservoirs to release additional water supplies for environmental flow enhancements or water supply, backstopped by groundwater pumping when necessary, is hydrologically feasible. Modeling indicates that reservoir re-operation can produce appreciable additional water supplies while meeting all existing CVP and SWP obligations and regulatory requirements governing project operations, provided that groundwater pumping can be exercised when needed. The additional storage space evacuated by making additional reservoir releases is refilled primarily by retaining in storage high flows that otherwise would be released for flood control purposes. Groundwater pumping is called on in only about 1 year in 10, on average, and contributes roughly 10 percent to 20 percent of the reservoir payback with 80 percent to 90 percent of refill coming from surplus surface water that would otherwise have been lost.

Because groundwater is called on infrequently for reservoir payback, impacts to existing groundwater users and to flows in surface streams are modest. Effects on the operability and productivity of existing agricultural wells of additional groundwater pumping to backstop reservoir re-operation are negligible because the estimated changes in groundwater levels are small relative to the screened intervals of agricultural wells. Agricultural pumpers will incur some additional cost for pumping due to the moderately higher lifts caused by drawdown; however, these costs are very small relative to baseline pumping costs and could be mitigated. Because they are much shallower and have shorter screened intervals compared to agricultural wells, it is likely that some existing domestic wells would need to be deepened or replaced. It was estimated that between 6 and 284 domestic wells would need to be replaced depending on assumptions and the scenario considered. This is between 3 and 41 percent of the estimated number of wells in the estimated impact areas (areas with incremental drawdown greater than 2 feet), and between just 0.1 percent and 3 percent of the 9,000+ domestic wells in the region.

The most significant conclusion is that the net benefits of Sacramento Valley conjunctive operations are strongly dependent on where the water could be marketed and the price received. If the water is sold in the Sacramento Valley at current market rates, the project appears not to be economically justified. On the other hand, if the water could be conveyed south of the Delta for storage in a groundwater bank and sold at dry year market rates, the project appears to be economically viable. Of course, such an export operation would require resolution of current Delta conveyance and export constraints and further analysis beyond that performed in this phase of investigation.

Alternatively, if an in-Valley scenario is desired, there is a need to reduce project costs or increase benefits or some combination of the two. One means of reducing costs would be to avoid the large, infrequently utilized capital investments in groundwater production wells by relying to the maximum practical extent on existing groundwater wells. It should be noted, however, that using existing wells rather than constructing new ones does not completely eliminate capital investment because growers would need to be compensated for their sunk costs at a level that would attract them to willingly sell their wells or enter into use agreements. Additionally, some wells would need to be rehabilitated or re-equipped with electrical motors to avoid air emission regulations.

Another potential means of reducing costs would be to employ temporary crop idling as a payback mechanism because crop idling payments would be required only in the years when reservoir payback is triggered.

For purposes of expanding or enhancing project benefits, the decision was made to engage the CVP and SWP operators to see whether they could assist the project team in identifying additional objectives that might achieved through conjunctive operations. Consultation with the CVP and SWP operators is discussed in the next section along with the various refinements made to the surface water model to simulate project operations more realistically and to achieve additional project benefits.

6. Collaboration with CVP and SWP Operators for Refinement of Project Scenarios

6.1.Collaborative Workshops with CVP and SWP Operators

Beginning in April 2010, a series of three ½-day workshops were held with a select group of CVP and SWP operators for the purpose of refining project scenarios. The main purposes were: (1) to identify additional project purposes and benefits that could potentially be realized through conjunctive operations as a means of enhancing project economic performance and (2) to ensure that the simulations were as realistic as possible. The workshops were complemented with one-on-one consultations between operators and project team members as needed to clarify comments and develop specific recommendations for incorporation into scenario development and the supporting modeling methodology. The dates, purposes and outcomes of the workshops are summarized below. Outcomes are discussed in additional detail in the following sections.

- Workshop #1: April 8, 2010. The project team presented the particular conjunctive operations concept being develop (reservoir re-operation with groundwater pumping payback) and an overview of development and performance of the initial project scenarios with particular focus on the surface water model. The main outcomes of the workshop were the following operator recommendations:
    - Update the surface water model to operate from a baseline condition (represented in CALSIM II model outputs) that includes current environmental objectives and constraints (primarily the smelt and salmon BOs)
    - Modify the model to include a forecast-based method for estimating end of year (September) Shasta and Oroville reservoir storage levels (which are used quantifying project assets and project reservoir releases) rather than the method used for initial scenario analysis based on perfect foresight

- Workshop #2: July 9, 2010. The project team presented the refined surface model reflecting the updated CALSIM II baseline with smelt BO and salmon BO operating requirements, and a forecast-based reservoir storage estimating routine. The effects of these changes on project performance were presented and discussed. Further dialogue focused on project operation for additional benefits, including the ability to generate additional environmental flows, support in complying with smelt BO and salmon BO operational requirements, water supply reliability, operational flexibility and cold water pool management in Shasta and Oroville. The main outcome from the meeting was a decision that the project team would work with the CVP and SWP operators to explore two primary interests:
    - Project operations for the purpose of holding water in storage to recover reservoir storage levels
    - Balancing reservoir releases with risk to reservoir carryover storage and related cold water pool management

- Workshop #3: September 9, 2010. A meeting/gaming session was held with operators and the project team at which the surface water model was used to demonstrate effects of additional constraints suggested by the operators in Workshop #2. Generally these constraints reduced project benefits relative to the initial project scenarios and identified areas of risk due to project operations, particularly cold water pool management. Several options for additional analysis were discussed at this meeting, including: revising operator constraints to be less conservative, temperature modeling to refine operating rules, and further modeling to identify system-wide effects.

6.2. Surface Water Model Refinements

The collaborative engagement with CVP and SWP operators resulted in a number of suggestions for refinement to the initial surface water model. Each of these is described below.

6.2.1. Updated CALSIM II Baseline Conditions

As previously explained, the surface water model simulates conjunctive operations by tracking incremental changes from a baseline condition of flows and reservoir storage levels generated by a CALSIM II model run. The CALSIM II baseline used for the initial modeling pre-dated the 2008 Biological Opinion on delta smelt (smelt BO) and the 2009 Biological Opinion on Chinook salmon (salmon BO). The baseline was updated with a CALSIM II model run with the smelt BO and salmon BO included. This baseline was used for further development and evaluation of project scenarios.

6.2.2. Ability to Reduce Shasta Reservoir Releases to Recover Storage

CVP operators expressed concerns about the ability to reduce Shasta releases under conditions when releases are driven by temperature compliance in the Sacramento River below the reservoir rather than water supply demands further downstream. Constraints on the ability to reduce Shasta releases were specified in the form of monthly minimum Keswick releases for temperature compliance, presented below in TABLE 6-1.

TABLE 6-1
Minimum Keswick Release for Temperature Compliance (cfs)
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep
6,000	5,000	4,000	4,000	4,000	6,000	7,000	9,000	11,000	13,000	12,000	11,000

The values presented in Table 6-1 are the minimum flows that operators thought were possible while achieving Sacramento River temperature compliance. The significance of these minimum flows is that only the portion of baseline Keswick releases in excess of the minimum flows in TABLE 6- can be held in storage and offset by a similar quantity of groundwater pumping or water made available through crop idling. These minimum Keswick release constraints significantly reduced the ability of the project to recover reservoir storage through reservoir payback mechanisms.

Constraints on the ability to reduce Oroville releases for temperature compliance were specified by SWP operators in a different manner, expressed as a function of Oroville release according to the following Table 6-2.

This constraint allows project operations to recover reservoir storage lowered due to project releases, or to increase carryover storage levels above those in the baseline simulation.

TABLE 6-2
Ability to Reduce Oroville Release (cfs)
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Oroville Release (cfs)	Oct	Nov	Dec-Jun	Jul	Aug	Sep
< 3,000	0	0	0	0	0	0
3,000 – 6,000	500	500	0	500	500	500
> 6,000	1,000	1,000	0	1,000	1,000	1,000

6.2.3. Forecast-Based Operations

The initial surface water model made project asset decisions (volume of additional reservoir release) based on a perfect forecast of September reservoir storage. The implication of this assumption was to minimize the risk of achieving targeted levels of carryover storage due to conjunctive operations. In actual operation, decisions would have to be made based on assumed reservoir inflows and releases to forecast fall reservoir storage. To the extent that actual conditions differ from those assumed for the forecast, actual fall reservoir storage could fall short of certain targets or could impact temperature compliance operations, in some years. The initial model did not simulate these risks.

The surface water model was refined to include a forecast of fall storage conditions based on current reservoir storage, runoff forecasts, and an estimate of reservoir releases from the current month through September. Runoff forecasts at different exceedance levels are used during the spring with more conservative forecasts (user-defined 90 or 99 percent exceedance) used in February and March, respectively. A method to estimate reservoir release volumes was developed for Shasta and Oroville by correlating simulated CalSim II releases with a system-wide CVP water supply index and SWP allocations, respectively. The CVP water supply index is the sum of current storage in Trinity, Shasta, Folsom, and CVP San Luis plus runoff forecasts on the Sacramento and American Rivers, plus Kings River flow to Mendota Pool. The CVP water supply index and runoff forecasts for the Sacramento, Feather, and American Rivers are the same as used in CalSim II for simulation of CVP/SWP operations. Initial correlations were developed and adjusted to balance how forecasted storage compared with CalSim II simulated storage across various year types.

6.2.4. Oroville Carryover Targets

SWP operators expanded a previous project objective related to carryover storage in Lake Oroville. Oroville storage targets were defined to increase carryover storage when at or below 1.5 million acre-feet (MAF) under base conditions by up to a maximum of 200 thousand acre-feet (TAF). These targets were developed to assist in mitigating effects of damage to the low-elevation outlet that occurred during gate testing several years ago. Damage to the low-elevation outlet has effectively increased dead storage in Lake Oroville leading to a desire to increase carryover storage.

6.2.5. Crop Idling for Reservoir Payback

The surface water model was modified to simulate crop idling as a payback mechanism to recover reservoir storage. Assumptions used in the model to simulate crop idling include annual evapotranspiration of applied water (ETAW) for rice (the dominant crop in both project areas), the monthly pattern of ETAW, total number of acres available for crop idling within the project areas, and the decision month for implementing crop idling. An estimate of the maximum total number of acres available for crop idling within each project area was made based on requirements for crop idling contained in an April 2009 Memorandum from the United States Fish and Wildlife Service (USFWS) on

Endangered Species Consultation on the Proposed 2009 Drought Water Bank (2009 USFWS Memo) and the February 2010 Final Environmental Assessment for the 2010-2011 Water Transfer Program (2010 EA) by the United States Bureau of Reclamation (Reclamation). Limitations on acres available for crop idling are established to protect endangered species habitat for the Giant Garter Snake. An additional assumption that no more than 20 percent of the total rice acreage with the project area would be idled in any year was made based maximum potential participation by growers and local acceptability.

Total rice acreage, maximum acres available for crop idling, and maximum annual quantities of surface water made available by crop idling are summarized in TABLE 6-3. Rice ETAW was assumed to be 3.3 acre-feet per acre for the may through September period, distributed monthly as follows: May, 15 percent; June, 22 percent; July and August, 24 percent each; and September, 15 percent.

TABLE 6-3
Summary of Rice Acreage and Maximum Acres for Crop Idling with each Project Area
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Project Area	Total Rice Acreage (acres)	Max. Percent of Acres Idled in Any Year	Max. Acres Idled (acres)	Max. Annual Quantity of Surface Water Made Available by Crop Idling (acre-feet)
GCID	105,000	20%	21,000	69,300
Butte Basin	78,000	20%	15,600	51,480

It was assumed that decisions on acres idled would be made in March, the same decision month for project assets and releases. Compared to decisions involving groundwater pumping for reservoir payback, crop idling decisions must be made earlier in the year, prior to planting before growers make financial outlays for rice production (field preparation, seed, fertilizer, pesticides, and other costs). The earlier decisions necessary for implementing crop idling can result in more frequent crop idling compared to groundwater pumping. Additionally, the fixed pattern of when water is made available with crop idling can result in water made available when it is impossible for it to be held in upstream reservoirs or put to beneficial use downstream. For example, 37 percent of water made available from crop idling occurs in May and June, but it is not possible to reduce Oroville releases in these months (see TABLE 6-2).

6.3.Refined Model Simulation Results

The surface water model was refined to include the first three operator recommendations discussed above; namely, to use an updated CALSIM II baseline; to include restrictions on the extent to which reservoir releases could be reduced due to temperature considerations; and to include a forecast-based estimate of September reservoir levels to use as a basis for calculating project assets and determining additional environmental releases and agricultural deliveries. All of these features make the project simulations more realistic. Once the model was refined, it was used to reevaluate the initial project scenarios and to evaluate the feasibility of operating the project to sustain Oroville carryover storage and using temporary crop idling as a reservoir payback mechanism.

The refined model resulted in differences between how the project operates with the CVP/Shasta Reservoir versus the SWP/ Oroville Reservoir. Therefore results and conclusions are presented below for the CVP and SWP, respectively.

6.3.1. CVP and Shasta Reservoir Results

6.3.1.1. Operations for Core Project Purposes

A comparison of initial and refined simulation results are presented in Table 6-4 for the 100 TAF and 200 TAF GCID project scales (pumping capacity). For the 100 TAF scale, project benefits are reduced by more than 50 percent, from 27 TAF to 12 TAF, with environmental releases reduced by almost two-thirds and agricultural deliveries reduced by half. Corresponding to the reduction in project benefits, reservoir payback is accomplished almost entirely by refill with surplus surface water. Project pumping is reduced from 4 years over the 82-year simulation to just 1 year and the maximum year pumping is reduced from 98 TAF to just 6 TAF. Average annual project pumping was 3 TAF.

TABLE 6-4
Comparison of Initial to Refined Simulation or Project Scenarios (Shasta/CVP)
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

			Project Benefits (TAF)			Reservoir Payback (TAF)			Project Pumping		
Scenario #	Project Scale (Pumping Capacity)	Model	Enviro. Release	Ag. Deliveries	Total Project Benefit	Surplus Surface Water	Project Groundwater Pumping	Total	Number of Years	Peak Year Pumping (TAF)	Peak Pumping Year
1, 3 and 4	100 TAF	Initial	13	14	27	24	3	27	4	98	1990
		Revised	5	7	12	12	0	12	1	6	1976
		Difference	-8	-7	-15	-12	-3	-15	-3	-92	N/A
2	200 TAF	Initial	45	22	67	58	9	67	6	195	1990
		Revised	15	8	23	23	0	23	1	6	1976
		Difference	-30	-14	-44	-35	-9	-44	-5	-189	N/A

Results for the 200 TAF project scale are even more dramatic, with project benefits reduced by roughly two-thirds for both environmental releases and agricultural deliveries. Even at this scale, reservoir refill is accomplished almost entirely with surplus surface water and negligible groundwater pumping.

The dramatically reduced benefits under the refined operations are due primarily to the effects of forecast-based operations added to the model. The forecast of September storage is deliberately conservative to avoid excess risk to reservoir storage; it is based on a 90 percent exceedance forecast for March runoff and 50 percent exceedance in later months. This frequently results in an under estimation of available project assets and therefore much smaller reservoir releases for environmental flows and agricultural water supplies compared to the initial modeling based on perfect storage forecasts.

The minimum Shasta (Keswick) release constraints prescribed by the operators, together with the forecast-based simulation, also resulted in some additional risk to reservoir carryover storage relative to baseline conditions. The risk was greatest when Shasta storage is below 2.0 MAF when project releases in one year are not refilled from surplus surface water in subsequent years and the project is not able to recover the storage deficit due to an inability to reduce reservoir releases and retain payback water into Shasta. The project is not able to recover the storage deficit due to the minimum Keswick release requirement prescribed by operators for purposes of complying with Sacramento River temperature requirements for protection of endangered species. Simulated project operations resulted in slightly diminished ability to meet Shasta carryover targets specified in the salmon BO relative to the CALSIM II baseline.

Because the minimum Keswick releases had such a strong effect on project performance, the model was used to test the sensitivity of Shasta carryover storage to relaxed minimum release targets relative to those specified by the operators. Relaxing the minimum releases by 2,000 cfs in all months (relative to those listed in Table 6-1) revealed only limited potential to improve carryover storage conditions when below approximately 2.0 MAF. Because of the significant constraints posed to project operation by the Keswick releases, it was concluded that temperature modeling should be performed to better evaluate relaxed minimum reservoir releases and the resulting implications to temperature compliance operations.

6.3.1.2. *Effectiveness of Temporary Crop Idling as a Payback Mechanism*

The operator-prescribed constraints on the ability to retain payback water in Lake Shasta discussed above also apply to crop idling. However, there are additional factors associated with crop idling related to the timing of decision making and the inflexibility in when the water is produced that affect its performance as a payback mechanism.

As previously explained, crop idling decisions need to be made earlier in the season and involve making an irreversible commitment to participating growers for purchasing the water generated through crop idling regardless of whether or not the water can be held in upstream storage or put to beneficial use downstream.

A scenario was evaluated where idling provided 70 TAF of payback capacity (requiring idling of 21,000 acres of rice land) and groundwater pumping 130 TAF to achieve a total of 200 TAF of payback in GCID (corresponding to Scenario 2). Payback priority was placed on crop idling in order to minimize groundwater pumping. Under these assumed conditions, crop idling was called on about 1/3 of the time during the 82-year simulation, in most cases utilizing the maximum 70 TAF of payback capacity and associated land idling (21,000 acres). It was found that only 17 percent of the water generated by idling was actually retained in Shasta to recover reservoir storage due to much of the water being produced when minimum Shasta releases for temperature control were controlling. It was shown that the effectiveness of crop idling is sensitive to the magnitude of the specified minimum releases. When releases were relaxed by 2,000 cfs in all months as described above, the portion of idling payback water retained in storage increased to 58 percent and the frequency with which idling was called on was reduced.

As expected, placing priority on idling for reservoir payback was found to appreciably reduce the magnitude of groundwater pumping needed for Shasta payback.

While the effectiveness of crop idling probably could be improved through refinement in when and how it is called on, and despite the fact that it can be used to offset groundwater pumping for payback, it is doubtful that crop idling offers a cost-effective means of reservoir payback due to the risks associated with the early timing of the decision, the irreversible commitment to follow through once a decision has been made, and the inflexible pattern on which water is made available.

6.3.1.3. *Operation for Cold Water Pool Management*

During collaborative discussions with operators, interest was expressed in evaluating how project operations could be used to improve carryover storage and management of cold water resources in Lake Shasta. An additional analysis was conducted with the refined surface water model to estimate the upper limit of potential project contributions to carryover storage (based on 200 TAF of pumping capacity in GCID). The minimum Keswick release constraints discussed above were maintained for this analysis; however, it was assumed that project pumping capacity would be used whenever it was possible to back water into storage, regardless of storage conditions.

This analysis revealed that project pumping frequency and magnitude were significantly increased relative to the levels observed for operations for generating additional reservoir releases, probably to levels that would be problematic from the standpoint of groundwater impacts. Additionally, the analysis showed that most of the water placed in storage was subsequently lost as reservoir spillage due to the high probability of reservoir refill from runoff. This scenario was simulated with only groundwater pumping as a payback mechanism to simplify the analysis. Although crop idling is not precluded as a payback mechanism and could be explored, it is likely that it would perform even less efficiently due to the issues discussed above.

Operating the project in this manner to maintain Shasta storage is fundamentally in conflict with operations for increasing reservoir releases to generate project benefits; nevertheless, project reservoir releases were included in the simulation because they are fundamental to the project goals. As expected, benefits increase slightly due to project water stored in Shasta in previous years being available in subsequent years for release.

This scenario could be refined to limit pumping based on Shasta storage, thereby reducing both pumping and project spills and creating a more efficient operation; however, the high probability of reservoir refill from runoff puts project generated storage at high risk of spilling. Additionally, the relatively high frequency and large magnitudes of pumping involved would likely create unacceptable impacts. The scenario was useful for understanding the upper limit of conjunctive operations to increase carryover storage but it does not appear to be a feasible mode of project operation.

6.3.1.4. Yolo Bypass Inundation

The CVP and SWP operators also expressed interest in evaluating methods to increase the frequency, duration, and magnitude of flooding in the Yolo Bypass. Results from the initial analyses indicated the Yolo Bypass could be inundated more frequently if it was possible to notch the Fremont Weir, which currently blocks flow into the bypass below certain river stages, to allow inundation at lower river stages and flows. Weir modifications were the cause of increased Yolo Bypass inundation in 19 out of 20 years when the project (as opposed to base operations) inundated the bypass in the phase 1 analysis. Increased project releases inundated the bypass in the other year.

An additional analysis was conducted with the refined surface water model to estimate the upper limit of the ability of the project to increase inundation in the Yolo Bypass. This analysis included turning off all other environmental objectives to ensure inundation was the first priority objective every year and would not be affected by releases for lower priority objectives in previous years. It was revealed that the project would enable Yolo Bypass inundation in an additional 20 years relative to baseline operations; however, as with the initial analysis, all 20 years were due to weir modification, not additional project release. Therefore, in all years the water cost associated with inundating the Yolo Bypass exceeded project assets. This is not an unexpected result given the significant reduction in project assets caused by the addition of forecast-based operations as recommended by the project operators.

6.3.2. SWP and Oroville Reservoir Results

The results discussed below are for simulations made with the addition of forecast-based operations, restrictions on ability to reduce Oroville releases, and addition of carryover storage targets as described above. Additionally, it should be noted that updating the base conditions to include the smelt and salmon BOs had a more significant effect on Oroville operation than on Shasta operations. Operations under the smelt BO and salmon BO result in lower storage in Oroville. This occurs because winter and spring Delta export restrictions reduce the SWP's ability to capture Delta surplus in those months, which results in increased reliance on Oroville storage releases into the Delta in the summer and early fall.

6.3.2.1. *Operations for Core Project Purposes*

A comparison of initial and refined simulation results are presented in Table 6-5 for the 50 TAF and 100 TAF Butte Basin project scales (pumping capacity). For the 50 TAF scale, project benefits are reduced by about 40 percent, from 17 TAF to 10 TAF, with agricultural deliveries being reduced by 50 percent and environmental releases by 30 percent. For both the initial and refined simulation about 80 percent of reservoir refill is accomplished by surplus surface water and 20 percent by project pumping, although the total refill is reduced in the refined simulation corresponding to the reduction in project benefits. Average annual project pumping is reduced from 3 TAF to 2 TAF, but the number of years of pumping and peak annual pumping are not appreciably reduced.

The disproportionate reduction of agricultural benefits noted above is due to the combination of lower base storage conditions, higher carryover storage targets, and assumptions on additional agricultural demands that are based on water year types. Lower base storages combined with higher carryover storage targets reduce the frequency and volume of project assets and typically result in assets being available in only wetter year types (when agricultural shortages tend not to occur). Additional agricultural demands are assumed to be higher in drier year types, when project assets are less, thereby reducing average annual project agricultural deliveries and shifting more of the deliveries into wetter year types. Overall, project benefits are reduced by 30 percent relative to the initial 100 TAF Butte Basin scenario.

TABLE 6-5

		Revised	18	9	27	24	3	27	6	99	1925
		Difference	-5	-11	-16	-12	-4	-16	-2	-1	N/A

Modification of carryover storage targets results in more frequent project pumping (or crop idling) and spill of project water stored in Oroville. Average annual pumping increases from

Additional pumping and storage also provides a slight increase in project agricultural and environmental benefits because water stored in Oroville is a project asset and available for meeting project objectives in future years. This results in a less efficient operation (with efficiency defined as refill of project releases for agricultural and environmental purposes from capture of surplus surface water as opposed to groundwater pumping), but a similar level of benefits.

6.3.2.2. *Effectiveness of Temporary Crop Idling as a Payback Mechanism*

As noted above (see Table 6-4), crop idling in the Butte Basin has the potential to provide approximately 50 TAF of water in a year by idling approximately 15,600 acres, or 20 percent of the rice acreage in Western Canal Water District and Richvale Irrigation District. A scenario was evaluated where idling provided the 50 TAF of payback capacity noted above and groundwater pumping 50 TAF to achieve a total of 100 TAF of payback in GCID (corresponding to Scenario 2). Payback priority was placed on crop idling in order to minimize groundwater pumping.

Under these assumed conditions, crop idling was called on about 40 percent of the time during the 82-year simulation, in most cases utilizing the maximum 50 TAF of payback capacity and associated land idling (15,600 acres). It was found that about 50 percent of the 23 TAF of water generated by crop idling was retained in Oroville to recover reservoir storage with the remainder spilled.

As expected, placing priority on idling for reservoir payback was found to appreciably reduce the magnitude of groundwater pumping needed for Oroville payback. Average annual payback pumping was reduced from 20 TAF to 10 TAF.

6.4. Conclusions Drawn from Refined Model and Scenario Analyses

Several conclusions were drawn from the refined modeling and scenario analyses to guide development of project scenarios that are most likely to provide cost-effective opportunities for achieving the environmental and water supply benefits possible through conjunctive operation Sacramento Valley surface water and groundwater reservoirs. These conclusions are discussed below:

1. The input and recommendations provided by CVP and SWP operators for refining project scenarios reflect the challenges and risks that they routinely face in balancing project operations for water supply and complying with environmental regulations governing project operations. In particular, as described above, project operators were primarily interested in conjunctive operations for the purpose of maintaining reservoir levels when reservoir storage dropped below certain thresholds as a means of observing carryover storage and increasing the probability of complying with temperature standards. While logical from a risk management perspective, operating conjunctively for this purpose cuts deeply into the ability to generate additional water supplies for environmental releases and water supply. Additionally, the efficiency of reservoir payback operations is reduced appreciably because much of the project water placed in storage eventually spills due to subsequent reservoir refill from surplus flows.

   These findings reveal important and complex tradeoffs among environmental objectives that are embedded in project operations. By definition, producing additional water supplies to dedicate to environmental flows without infringing on base supplies to CVP and SWP contractors involves making additional reservoir releases. However, increasing reservoir releases reduces reservoir storage and unavoidably introduces some additional risk to coldwater pool management.

2. The minimum Keswick releases specified by the CVP operators as surrogates for temperature targets in the Sacramento River dramatically reduce the effectiveness of reservoir payback operations because payback is possible only when reservoir releases exceed the minimum specified values. This reduces the time during which water generated by payback operations can actually be used to offset reservoir releases. This is another manifestation of the tradeoffs among environmental objectives, with the objective of maintaining river temperature constraining the ability to operate conjunctively for other environmental benefits.

3. The general conclusion to be drawn from 1) and 2) above is that the tradeoffs among environmental objectives call for further investigation and development of operating strategies and criteria that best balance competing objectives for maximum net environmental benefit.

Addressing this need is foundational to moving ahead with development of conjunctive management strategies for the Sacramento Valley. However, until tradeoffs among environmental objectives are reconciled, planning must account for the operational constraints as they are currently defined.

4. Crop idling is an inefficient payback mechanism in comparison to groundwater pumping. The main reasons are that crop idling must be triggered early in the year before farmers commit to planting crops, which introduces additional risk in forecasting the need for the payback water, and that once the commitment is made, it cannot be undone. These factors result in frequent, unnecessary crop idling with associated lost production, with much of the water made available being lost as reservoir spillage or surplus Delta outflow. The original attraction to temporary crop idling was that it does not require up front capital investment and can be exercised as needed on a year to year basis. However, the inefficiencies revealed through the simulations suggest that crop idling is likely to be a less viable, and undoubtedly less acceptable, payback mechanism as compared to groundwater pumping, especially if pumping can be achieved with existing groundwater production wells to minimize required capital inputs.

5. All of the various suggestions for refinement of the project scenarios and model have the effect of either reducing project benefits (relative to the initial analysis) or reducing the efficiency of payback operations, thereby detracting from project cost-effectiveness.

Based on these conclusions, further planning and modeling proceeded within a framework defined by the following parameters:

1. The project baseline will be represented by a CALSIM II run that includes the effects of the smelt and salmon BO's.

2. Forecast based operations will be used because they are more realistic.

3. Restrictions on reservoir releases as specified by CVP and SWP operators will be observed because they are the best available representation of temperature compliance conditions.

4. The objective will be to generate benefits through additional environmental releases and water supplies, not through operations to sustain reservoir levels.

5. Payback operations will be based on groundwater pumping, not temporary crop idling.

6.5. Analysis of Project Scale

Within the planning and modeling framework defined above, a set of model runs was made for the two project areas to examine the relationship between project payback capacity, simulated project pumping and project benefits. In addition to the parameters specified above, a decision was made to use a summer and fall payback pumping period, rather than summer only, to maximize the opportunity for payback operations, thereby minimizing the constraint posed by minimum reservoir releases. The results are presented and discussed separately for the two project areas.

6.5.1. GCID/CVP-Shasta

A set of 11 model runs were made with specified payback pumping ranging from 20 TAF to 300 TAF and all other model parameters held constant. This wide range was selected to better understand project performance from the surface water perspective and does not reflect an assumption or an assertion that annual pumping volumes of up to 300 TAF would be feasible in GCID. Results are summarized Table 6-6.

TABLE 6-6
GCID/CVP-Shasta Average Annual Project Benefits, Reservoir Payback and Project Pumping in Relation to Project Pumping Capacity
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

	Avg. Annual Project Benefits (TAF)			Average Annual Reservoir Payback (TAF)			Project Pumping		
Payback Pumping Capacity	Enviro. Release	Ag. Deliveries	Total	Surplus Surface Water	Groundwater Pumping	Total	Peak Annual Pumping	Percentage of Payback Capacity Used	Peak Pumping Year
20	0	3	3	3	0	3	3	15%	1930
40	1	4	5	5	0	5	6	15%	1930
60	3	4	7	7	0	7	9	15%	1930
80	4	5	9	9	0	9	11	14%	1930
100	5	7	12	12	0	12	11	11%	1930
120	7	8	15	15	0	15	11	9%	1930
150	11	8	19	19	0	19	11	7%	1930
200	15	8	23	23	0	23	11	6%	1930
240	20	9	29	28	1	29	96	40%	1939
270	24	7	31	30	1	31	98	36%	1939
300	25	7	32	30	2	32	98	33%	1939

It can be seen that, as pumping capacity increases, average annual project benefits are initially weighted in favor of agricultural deliveries but then switch in favor of environmental releases when capacity exceeds about 120 TAF. This is due primarily to environmental release targets being large and being made only when they can be completely satisfied. Smaller pumping capacities and associated project assets reduce the likelihood of being able to make these large releases. In contrast, agricultural deliveries are typically smaller than environmental releases and do not need to be fully satisfied; thus, some agricultural releases are possible even with very small project pumping capacities. Project benefits in relation to project pumping capacity are plotted in Figure 6-1.

It is important to note that the average annual total project benefit (sum of environmental releases and agricultural deliveries) is much smaller than the specified pumping capacity over the full capacity range evaluated. As previously discussed, this stems primarily from the nature of forecast-based operations and the associated conservative estimates of project assets used to avoid excessive risk to reservoir storage.

As expected, average annual reservoir payback is weighted strongly in favor of surplus surface water over the full range of pumping capacity, due to priority being placed on refill from surplus surface flows and pumping being called on only when needed. Simulated average annual project pumping is negligible until the specified pumping capacity exceeds 200 TAF, and then is modest on an average annual basis.

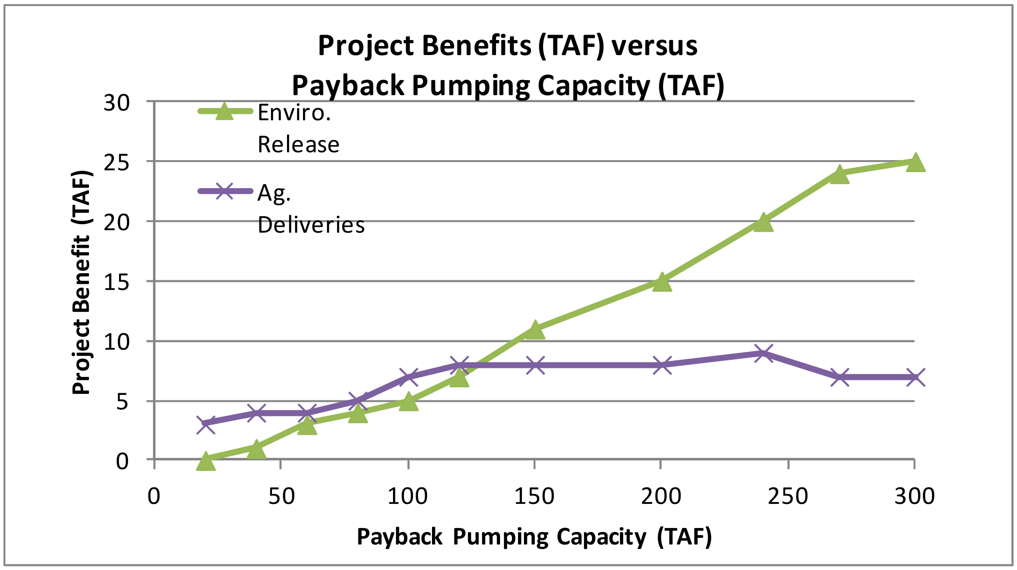

FIGURE 6-1
GCID/CVP-Shasta Average Annual Project Benefits in Relation to Payback Pumping Capacity
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Peak year pumping is negligible below a pumping capacity of 200 TAF, ranging between 3 TAF and 11 TAF (Table 6-6, Figure 6-2). Above pumping capacity 200 TAF, when larger project assets are available and large environmental releases become possible, peak year pumping increases appreciably, utilizing more of the available pumping capacity. However, even at these levels, simulated peak year pumping is less than half of the pumping capacity. This is explained by the same factors discussed above in relation project benefits being small in relation to pumping capacity. Additionally, simulated pumping is constrained when minimum Keswick releases govern and it is not possible to hold payback water in storage.

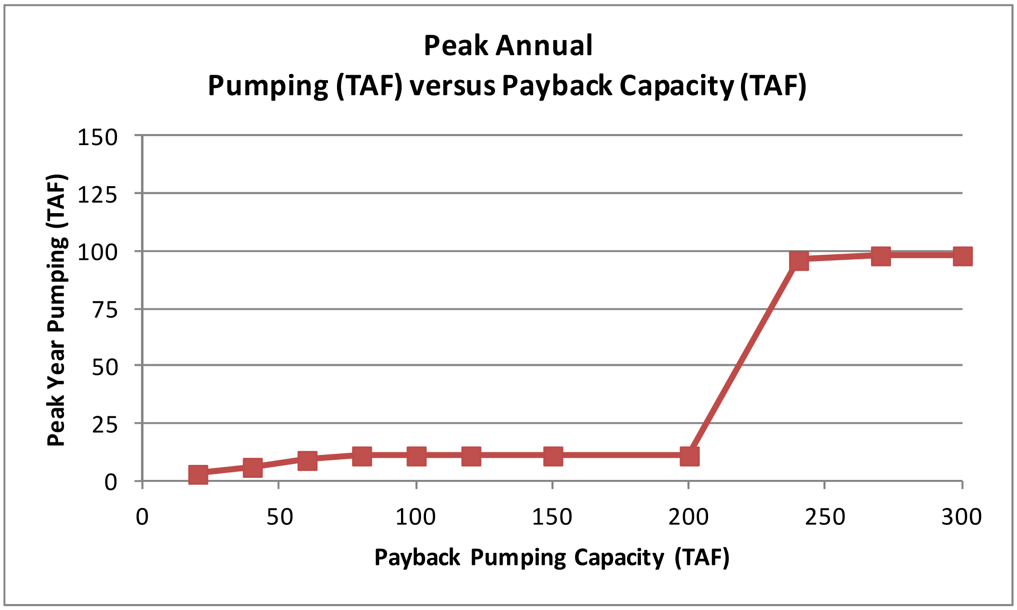

FIGURE 6-2
GCID/CVP-Shasta Peak Annual Project Pumping in Relation to Payback Pumping Capacity
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

6.5.2. Butte Basin/SWP-Oroville

A set of model runs analogous to those made for GCID were also made for the Butte Basin, with specified payback pumping ranging from 20 TAF to 300 TAF and all other model parameters held constant. As noted above, this wide range was selected to better understand project performance from the surface water perspective and does not reflect an assumption or an assertion that annual pumping volumes of up to 300 TAF would be feasible in Butte Basin. Results, summarized in Table 6-7, are similar to those for GCID, with certain exceptions.

TABLE 6-7
Butte Basin/SWP-Oroville Average Annual Project Benefits, Reservoir Payback and Project Pumping in Relation to Project Pumping Capacity
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

	Avg. Annual Project Benefits (TAF)			Average Annual Reservoir Payback (TAF)			Project Pumping		
Payback Pumping Capacity	Enviro. Release	Ag. Deliveries	Total	Surplus Surface Water	Groundwater Pumping	Total	Peak Annual Pumping	Percentage of Payback Capacity Used	Peak Pumping Year
20	0	3	3	2	1	3	12	60%	1925
40	3	4	7	6	1	7	24	60%	1925
60	8	5	13	11	1	12	36	60%	1925
80	13	7	20	17	2	19	48	60%	1925
100	18	9	27	24	3	27	59	59%	1925
120	19	10	29	26	3	29	71	59%	1925
150	19	11	30	26	4	30	89	59%	1925
200	23	9	32	29	4	33	91	46%	1925
240	36	10	46	41	4	45	125	52%	1955
270	42	11	53	47	5	52	130	48%	1955
300	51	10	61	55	5	60	130	43%	1955

Similar to GCID, as pumping capacity increases, average annual project benefits are initially weighted in favor of agricultural deliveries but switch more quickly in favor of environmental releases. Above about 40 TAF of pumping capacity, environmental benefits gradually increase while agricultural deliveries plateau at about 10 TAF above 100 TAF of capacity. The factors explaining this are generally the same as for GCID. Project benefits in relation to project pumping capacity are plotted in Figure 6-3.

As in GCID, the average annual total project benefit (sum of environmental releases and agricultural deliveries) is small relative to the specified pumping capacity over the full capacity range evaluated.

As expected, average annual reservoir payback is weighted strongly in favor of surplus surface water over the full range of pumping capacity, due to priority being placed on refill from surplus surface flows and pumping being called on only when needed. However, in contrast to GCID, both refill from surplus surface water and from project pumping increase gradually over the full range of project pumping.

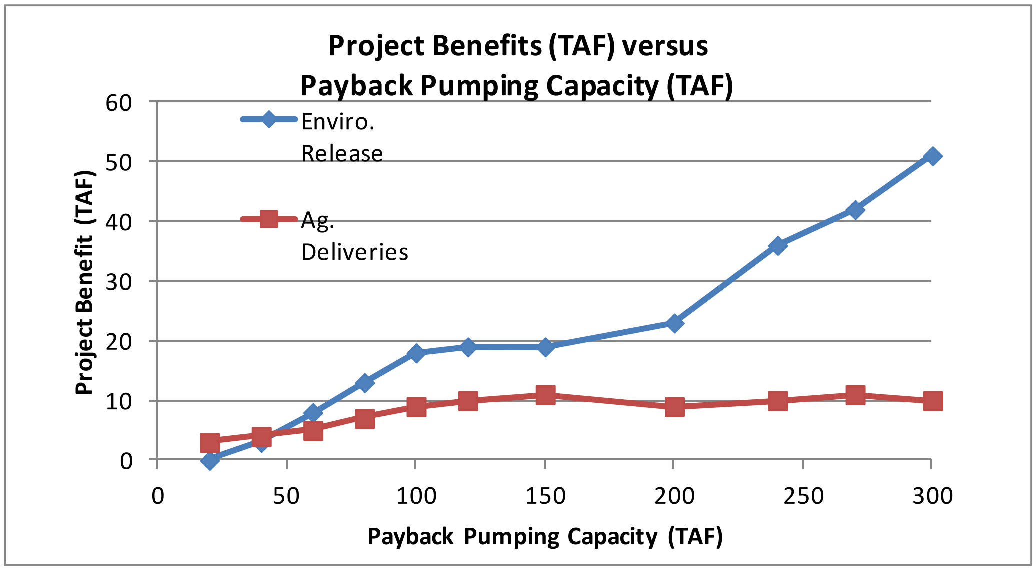

FIGURE 6-3
Butte Basin/SWP-Oroville Average Annual Project Benefits in Relation to Payback Pumping Capacity
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

Somewhat different than in GCID, peak year pumping increases more or less in proportion and is larger relative to project pumping capacity (Table 6-7, Figure 6-4). Peak year pumping ranges from 12 TAF to 130 TAF, representing between 43 percent and 60 percent of specified pumping capacity.

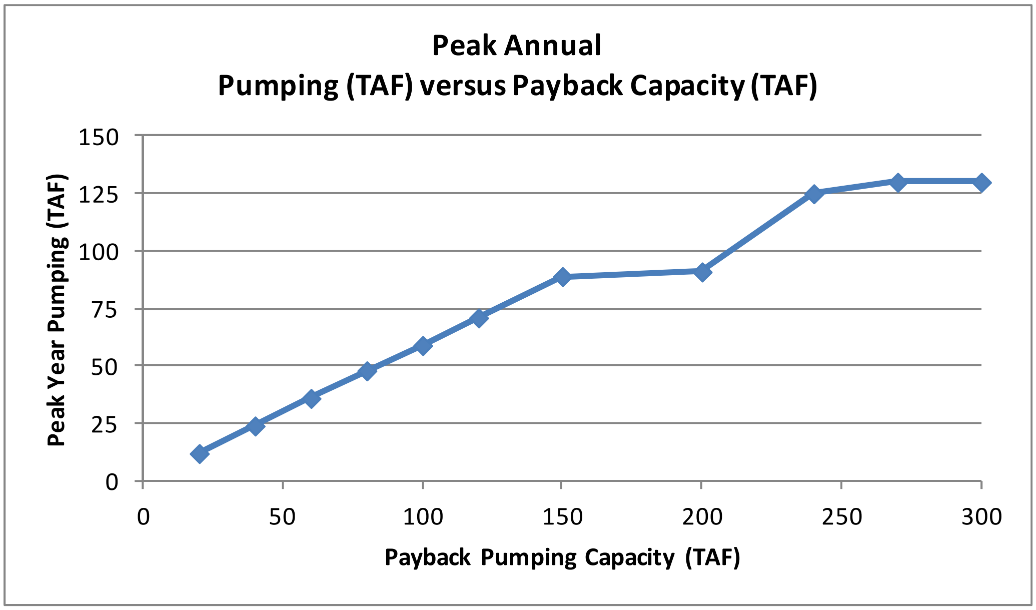

FIGURE 6-4
Butte Basin/SWP-Oroville Peak Annual Project Pumping in Relation to Payback Pumping Capacity
Northern Sacramento Valley Conjunctive Water Management Investigation Final Report

6.5.3. Discussion

The most important revelation from the foregoing analysis of project scale is the significant underutilization of payback pumping capacity in both project locations. Over the 82-year period of analysis and the range of payback capacities evaluated (20 TAF to 300 TAF), the maximum annual payback pumping in GCID was just 40 percent (at 240 TAF capacity; see Table 6-7) and was just 60 percent of capacity in Butte Basin (between capacity 20 and 80 cfs; see Table 6-7). Average annual pumping is even more extreme in both locations, with less than 1 percent of capacity used on average in GCID and less than 2 percent used on average in Butte Basin.

The low utilization of project pumping capacity stems in part from the conservative nature of the forecast September reservoir storage, which tends to underestimate project assets, and in part from constraints on payback pumping posed by minimum reservoir releases made for temperature control purposes. However, regardless of its cause, the low utilization of project pumping capacity combined with its high capital cost is economically infeasible and indicates that other approaches should be pursued to enhance project economics. One alternative would be to not attempt to recover reservoir levels reduced by project operations and instead incur some level of increased risk that CVP and SWP water deliveries would be reduced. This approach violates one of the original project principles, but may be a reasonable solution all factors considered. This idea is explored further as a recommendation for further investigation (see Section 7).

7. Recommendations for Further Investigation

The seminal conclusion of this investigation is that re-operating Shasta and Oroville Reservoirs in conjunction with operation of Sacramento Valley groundwater aquifers could produce appreciable additional water supplies with low risk to CVP and SWP reservoir storage levels and water deliveries, including requirements to maintain environmentally mandated water temperatures under most conditions. While an economically feasible in-Valley operation scenario was not identified by the investigation, prospects of a viable formulation appear promising and further development and integration of the core concept appears warranted.

The particular topics described in the following sections are in the opinion of the project team the highest priority issues to be addressed moving ahead. These are primarily technical in nature, involving reconciling tradeoffs among different types of environmental water uses, more detailed water temperature modeling, refined reservoir payback operations, integration with south of Delta groundwater banking and refinement of analytic tools.

Beyond the technical factors lie significant institutional and social challenges that would need to be addressed if there is sufficient interest in advancing the project toward implementation. These include the following:

- Developing protocols and procedures for real-time operations decisionmaking that are more nuanced and realistic than the procedures and criteria that have been used to simulate conjunctive operations for planning purposes. Ultimately, these procedures would need to be integrated into the Coordinated Operations Agreement, which governs the combined operation of the CVP and SWP.

- Developing project governance structures among local political jurisdictions. This phase of project planning was conducted without regard to ultimate project sponsorship. The presumption, however, is that a Sacramento Valley conjunctive water management project like that described in this document would most logically be sponsored and operated by a coalition of local political jurisdictions, potentially including counties and existing water suppliers (local districts).

- Developing formulae for allocating project benefits and costs, which would be needed to develop plan for financing project implementation, if the project moves ahead.

7.1.Reconcile Tradeoffs among Environmental Project Functions

A major revelation of this investigation is that opportunities for enhancement of Sacramento and Feather River ecologic functions (as well as opportunities to produce additional water supplies for in-Valley uses) are dramatically constrained by existing environmental requirements placed on CVP and SWP operations. In particular, the study revealed that CVP operations are frequently governed by releases for temperature compliance in the Sacramento River below Shasta, which has the effect of reducing the ability to recover Shasta by project pumping because pumped water cannot be retained in storage. In effect, the magnitude of the water asset that could be developed through conjunctive operations is diminished, which reduces the ability to fulfill the geomorphic, flood plain inundation and spring pulse flow objectives identified by the study.

Efforts are urgently needed to establish the relative benefits of alternative, competing environmental water uses so that ecosystem functions can be restored and species can be recovered while overall water use efficiency is enhanced. This calls for cooperation and compromise among the various fish and wildlife management agencies as well as ongoing research and adaptive management.

7.2.Refine Reservoir Operation Rules Based on Temperature Modeling

In the simulations conducted for this investigation, water temperature objectives were represented indirectly by minimum reservoir releases provided by project operators. These flows are based on operator judgment and provided useful guidance for investigation thus far. However, because the minimum flows were found to dramatically reduce the efficiency of payback operations, as noted above, it is recommended that more sensitive operating rules be developed through application of temperature models.

The recommended approach is to conduct a series of parametric CALSIM II model runs where operating objectives and constraints are held constant while minimum reservoir releases are varied over a range between the relatively conservative flows that were used in this investigation down to flows that would likely be inadequate to achieve temperature targets. Then one (or possibly more) of the existing temperature models would operate on the CALSIM II outputs to estimate the water temperatures that would occur under each flow regime. This would presumably provide insights into the nature of water temperature fluctuations as they relate to flows, time of year and other factors, and provide a basis for developing more sensitive operating rules. The refined rules would then be incorporated into the surface water model for use in formulating, comparing and evaluating project scenarios.

7.3.Refine Reservoir Payback Pumping Strategies and Costs

The investigation revealed that developing new groundwater production wells for payback pumping is not cost-effective because the wells are expensive, they are called on only infrequently and their operation for recovering reservoirs is limited by other operation requirements, particularly, by reservoir releases made to comply with temperature requirements. Large investment in capital works that are rarely used simply does not make good economic sense. This is why temporary crop idling was investigated as an alternative payback mechanism, because costs are incurred only when idling is called on. Unfortunately, however, crop idling is not compatible with the project’s operational requirements and would be triggered in many cases when it is not ultimately needed or the water generated cannot be held in storage.

In the next phase of work, three alternative payback strategies should be explored. Each of these is described below; however, it should be kept in mind that the strategies could be combined for optimal project performance.

7.3.1. Revised Temporary Crop Idling

The investigation revealed that temporary crop idling is not an efficient form of reservoir payback, mainly because much of the water generated by crop idling is either later found to not be needed or is stored in project reservoirs and subsequently spills. These outcomes result from the decision to exercise crop idling being made in February when forecasts of September reservoir storage are relatively uncertain. Once made the commitment to idle land (by paying voluntarily enrolled growers) is irreversible and the water generated is frequently not used.

Rather than make the decision to idle land in February, the possibly of making the decision later, when better forecasts of reservoir storage can be made, should be explored. Under this arrangement, growers would commit to growing their crops but they would enter voluntarily into agreements that would allow the project to interrupt water supplies at any time. For example, a grower might commit to growing a corn crop on the usual schedule with a certain probability that he would be asked to suspend irrigation with surface sometime during the crop season. He would be required to suspend irrigation in exchange for payments designed to compensate for lost production. (Alternatively, the grower could access a groundwater source and continuing irrigation. The farther into the season the idling call was made, the more incentive the grower would have to find an alternative water supply to finish the crop.) A crop that is particularly well suited to mid-season irrigation interruption is alfalfa because, when water is withheld, the crop goes dormant as soil moisture is depleted and resumes growth when irrigation is resumed.

Analysis would focus on the cost and efficiency of generating payback water in this manner.

7.3.2. Incurring Managed Increased Risk to Reservoir Carryover Storage

The objective of paying reservoirs back is to avoid impacts to water supply due to project operations. Analyses to date reveal that re-operated reservoirs frequently recover from surplus surface flows and need to be paid back only infrequently. Given infrequent need for and high cost of reservoir payback, one alternative is simply to deal with the occasional shortages caused by project operations when they occur. Essentially this means passing water supply shortages on to existing CVP and SWP water users. The first step in exploring this option would be to characterize the frequency and magnitude of water supply shortages and then develop strategies for compensating water users accordingly. For example, some users might alternative supplies that could be called on or conservation measures that could be invoked to deal with temporary shortages.

7.3.3. Sharing Private Groundwater Wells

Two options for establishing project groundwater pumping capacity have been explored thus far, including constructing new groundwater production wells and purchasing existing groundwater wells from willing sellers. Both of these are expensive options. The objective of further investigation would be to explore ways to access existing private wells in a manner that avoids the full capital outlay associated with new well construction (or existing well purchase) yet offers reasonably reliable access to payback capacity for project operations, when needed. This would be approached through interviews with landowners to test their willingness and the terms under which they would share production well costs and groundwater supplies with the project.

7.4.South of Delta Groundwater Banking

As previously noted, this investigation was conducted consistent with its original Sacramento Valley focus. Accordingly, reservoir releases made for project environmental purposes were tracked into the Delta but no analyses were performed to estimate whether or to what extent those inflows might be exported from the Delta. The economic analysis did reveal that project economics are dramatically improved if project water supplies could be sold at the higher rates associated with south of Delta water markets compared to Sacramento Valley rates. Beyond higher water sales revenues, banking project water in south of Delta groundwater banks might reduce reliance on Sacramento Valley reservoir payback operations. For example, there may be times when CVP and SWP reservoir releases can be reduced in exchange for water withdrawn from south of Delta groundwater banks. However, this is unlikely to be the case in very dry conditions when reservoir releases are being made exclusively for temperature control and not for export. Operations analyses are needed to reveal whether such opportunities exist.

A major challenge to the analysis will be the current uncertainty in Delta conveyance capacity and operating conventions, presently under consideration in development of the Bay-Delta Conservation Plan.

7.5.Develop System-wide Project Accounting Conventions

The central tenant of the conjunctive operations strategy developed through this project is that existing project beneficiaries can be kept whole while additional environmental flow and water supply benefits are generated. Keeping existing beneficiaries whole requires that an accounting be maintained of project assets, debts and repayment. In the simulations conducted for the project, operational changes (incremental project releases and refill) were isolated in either Shasta or Oroville and therefore easily accounted for. In actual operations, such an explicit accounting would not be practical considering that operations are highly interconnected and effects would likely be distributed among CVP and SWP reservoirs. This point was emphasized by the CVP and SWP project operators.

The purpose of this task would be to identify and evaluate alternative approaches to accounting for the effects of conjunctive operations on reservoir operations throughout the CVP and SWP systems. One approach would be to keep two sets of records, once for actual operations and another set for hypothetical operations as if the project was not operating. This is not considered to be practical or advisable due to the uncertain and, at times, arbitrary nature of maintaining the shadow records. Instead, a more practical approach would be to develop simplified accounting conventions based on simulated project operations.

7.6.Update and Refine Surface Water and Groundwater Models

The surface water and groundwater models developed for this investigation were adequate for planning level analyses but should be refined if further investigations are conducted. The main opportunities for improvements are as follows:

- A preliminary assessment of the accuracy of SACFEM at matching a limited number of historic hydrographs was performed, and the model appears to generally replicate historically observed water levels quite well over the 22-year period of simulation (1982 through 2003). It is recommended that a rigorous transient calibration be conducted of the SACFEM groundwater model to observed historic water level hydrographs across the valley. This effort would help improve the level of confidence that the model is accurately simulating transient patterns in groundwater levels seen historically.

- Another area of potential SACFEM refinement is to further evaluate hydrology of smaller unregulated tributaries across the valley, specifically to better understand timing and magnitude of groundwater recharge that occurs from these surface water features. In the current analysis, it was assumed that unregulated streams were dry from June through October. While this assumption is reasonable, it is likely that behavior of these streams is more complex. Further, some of these tributary streams are used as conveyance facilities to deliver water within various water districts. This would result in streams being active over summer months, and potential sources of recharge to the groundwater system. An analysis of these stream characteristics could improve the accuracy of the simulation of recharge sources to the groundwater system, especially over the summer months.

- Conjunctive management operations as simulated for this investigation may have impacts on the generation and use of CVP and SWP hydropower. For example, in some years, making large reservoir releases for certain environmental objectives may be constrained by power plant capacities and may occur at times when power is less valuable. A better understanding of these constraints and simulation of resulting effects is necessary if further investigation is undertaken.

- Analysis presented in this report focused on operation of only part of the CVP/SWP system. Shasta and Oroville Reservoirs and the Sacramento and Feather Rivers are part of a larger system that is operated in a coordinated manner. Simulation of only part of the system may underestimate benefits or impacts to other areas of the system. Preliminary analysis of systemwide effects based on how conjunctive management operations change, Delta inflows need to be refined and expanded to other areas of the system

Materials from October 21, 2010 and December 8, 2010 Public Meetings

October 21, 2010
Public Meeting Materials

Northern Sacramento Valley Conjunctive Water Management Investigation

Public Workshop

Glenn-Colusa Irrigation District Main Pump Station
7854 County Road 203
Hamilton City, California

October 21, 2010

3:00 to 5:00 PM

Workshop Objectives

- Provide a status report on the investigation progress
- Listen/Respond to stakeholder questions
- Describe next steps to investigation, public meetings, and final report

Agenda

1. Welcome, Introductions, Workshop Process
2. Workshop Objectives
3. Recent Regulatory and Legislative Changes and Impacts
4. Investigation Review and Update – Presentation
5. Q&A
6. Regional Water Issues
7. Next Steps
8. Closing

Northern Sacramento Valley Conjunctive Water Management Investigation

The Glenn-Colusa Irrigation District and
The Natural Heritage Institute

October 21, 2010

Today's Workshop Objectives

- Provide a status report on the investigation progress
- Listen/Respond to stakeholder questions
- Describe next steps to investigation, public meetings, and final report

Motivating Factors - Regulatory and Legislative Changes

- Significant Values are at Risk: Regional Sustainability
  - Environmental
  - Water supply
  - Economy
- New Challenges
  - SWRCB Flow Report: 75% unimpaired flow to the Delta November-June
  - DFG Report confirms similar flow needs
  - Delta species (smelt) dominate, salmon at risk
  - Delta Stewardship Council: All Delta all the time
  - Scott Valley/Siskiyou County Groundwater Pumping Lawsuit
- The Past is the past, How do we control our destiny?
- Historical operations and uses are constantly changing
- Local needs and flexibility are now challenged in the Delta context
- Increasing costs and fees
- Long term stability and reliability?

Emerging Values

- What does the region want, what values should be protected?
  - Water supply reliability (surface/groundwater)?
  - Environmental protection/enhancement, both instream and terrestrial?
  - System sustainability, what is it?
  - Others…?
- What strategies should be pursued to achieve regional goals?
  - Status quo?
  - Regional water investigations and planning?
  - Others…?
- Just say no…will that do?

Overview of Investigation to Date

Program Objective

- Examine whether and how operation of groundwater aquifers in the Sacramento Valley could be integrated with operation of existing surface water reservoirs to produce additional firm water supplies
- Potential benefits:
  - Improved water supply reliability (local, regional, State)
  - Ecosystem restoration (Sacramento and Feather Rivers)
  - Improved Delta inflow per BDCP
  - Increased operational flexibility (CVP, SWP, local)
  - Buffer effects of climate change

Program Requirements

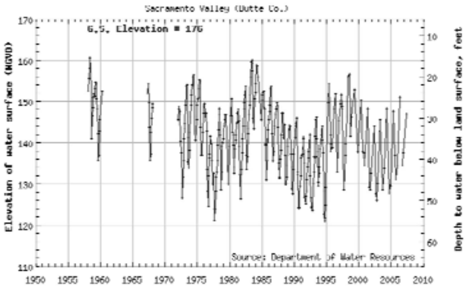
- New net benefits for Sacramento Valley environment and water users
- CVP and SWP commitments honored (to the extent they presently are)
- No unmitigated impacts to existing groundwater users
- Economic feasibility

Initial Site Screening

What Makes for an Attractive __Water Banking__ Site?

- Groundwater conditions
  - Available aquifer storage space
  - Viable recharge mechanism
  - Productive groundwater wells
  - Suitable GW quality
- Surface water conditions
  - Surplus flows at times
  - Connection to CVP, SWP or other surface water reservoirs
  - Dual SW and GW use option
- Impacts/mitigation
  - Isolation from important surface streams
  - Isolation from existing groundwater production wells
  - Ability to mitigate or compensate impacts that cannot be avoided

Typical Sacramento Valley GW Hydrograph (Butte Co.)



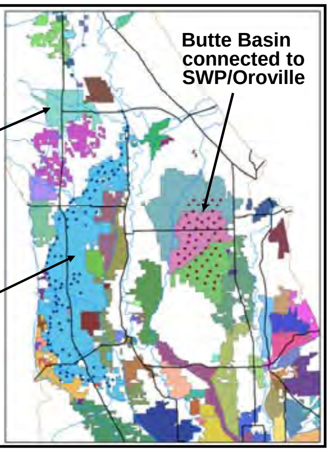
Source: Department of Water Resources

Early Finding: Traditional water banking generally not viable in the Sacramento Valley due to lack of aquifer storage space.

Re-operate Surface Reservoirs with Groundwater "Backstop"

- Reservoir re-operation
  - Additional releases to meet program objectives
  - Hope for reservoir refill from surplus surface flows
  - Honor existing CVP and SWP delivery obligations and operations constraints
- Groundwater operation
  - Pump groundwater to "repay" reservoirs if storage conditions put contract deliveries or temperature control at risk
  - Groundwater used in lieu of surface entitlements that then remain in storage

Three Sites Identified

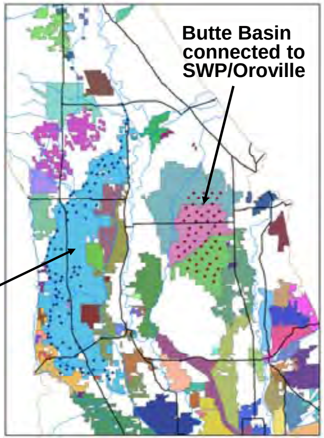


Butte Basin connected to SWP/Oroville

Orland Unit connected to Stony Creek Reservoirs

Glenn-Colusa ID connected to CVP/Shasta

Two Sites Selected for Modeling



Butte Basin connected to SWP/Oroville

Glenn-Colusa ID connected to CVP/Shasta

Re-operation Conceptual Example

- Release water from CVP and/or SWP reservoirs to meet project objectives:
  - Unmet local ag demands
  - Regional environmental flow targets
- <u>If reservoirs refill</u>, no subsequent GW pumping is needed
- <u>If reservoirs do not refill</u>, pump GW and forego use of surface water in following year as needed for reservoir "payback"
- New SW supplies can be generated with infrequent additional GW pumping, because reservoirs refill most years

Project Scenarios Defined by Groundwater Pumping Capacity and Season

Scenario	Groundwater Pumping Capacity (thousand acre-feet)			Pumping Season
	GCID (CVP)	Butte Basin (SWP)	Total	
1	100	50	150	summer
2	200	100	300	summer
3	100	50	150	fall
4	100	50	150	summer & fall

All scenarios modeled with an existing (shallow) and new (deep) well field to reveal range of potential impacts to streams and existing pumpers.

Surface Water Model Results

(Example for Scenario 1, Shasta/CVP, 100 TAF Pumping Capacity in GCID)

- Environmental flow releases
- Agricultural deliveries
- Refill from surplus surface water
- Refill from groundwater pumping

Environmental Flow Objectives

- Geomorphic
  - Single day large event
  - February or March
- Riparian establishment
  - Five day large flow with 60 day recession
  - April start
- Flood plain inundation
  - Single day large event with 45 day recession
  - Between February and April
- Spring pulse flow
  - Simulate more natural spring runoff period

Scenario 1—CVP/Shasta

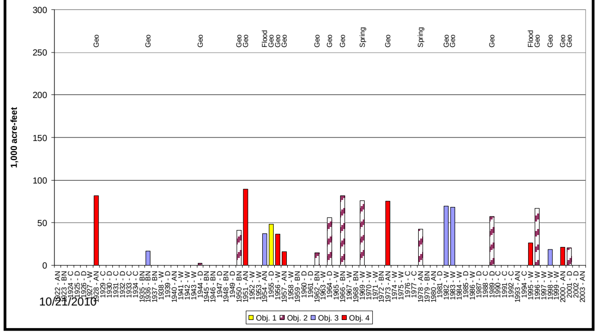
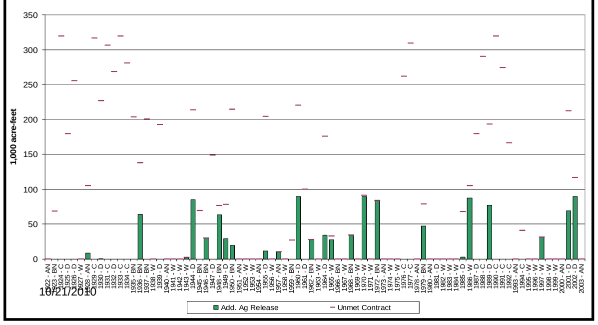
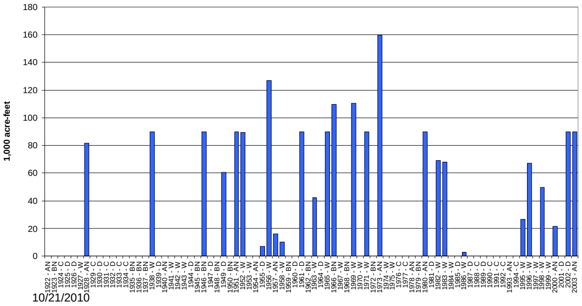
Environmental Flow Releases



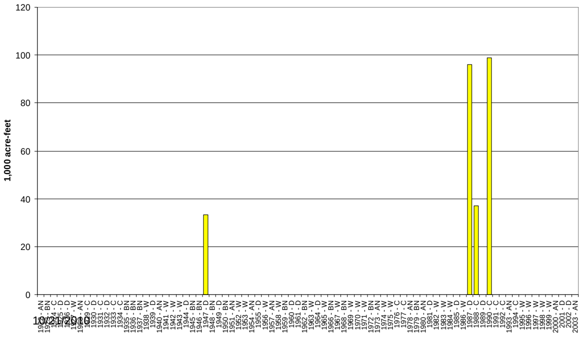
Scenario 1—CVP/Shasta
100 TAF Pumping Capacity in GCID
Sac River Agricultural Deliveries



Scenario 1—CVP/Shasta
100 TAF Pumping Capacity in GCID
Refill from Surplus Surface Water



Scenario 1—CVP/Shasta
100 TAF Pumping Capacity in GCID
Refill from Groundwater Pumping



SW Modeling Summary
(Annual averages 1922-2003, taf)

Scenario	CVP/Sacramento River				SWP/Feather River			
	Env. Rel.	Ag. Del.	Refill from SW	GW Pump	Env. Rel.	Ag. Del.	Refill from SW	GW Pump
1,3 and 4	13	14	24	3	7	10	14	3
2	45	22	58	9	23	20	36	7

SW Modeling Summary
(Average in years of occurrence 1922-2003, taf)

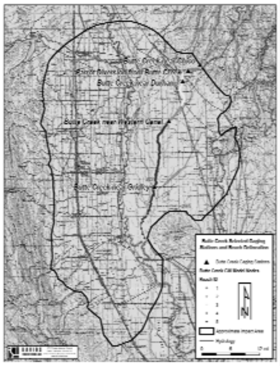
Scenario	CVP/Sacramento River				SWP/Feather River			
	Env. Rel.	Ag. Del.	Refill from SW	GW Pump	Env. Rel.	Ag. Del.	Refill from SW	GW Pump
1,3 and 4	94	46	70	70	49	27	32	44
2	187	75	139	123	95	52	72	75

Project Impacts Due to Additional Groundwater Pumping

- Streamflow
  - Butte Creek in affected area
  - Other critical streams not in affected areas
  - Ephemeral streams not analyzed
- Groundwater levels and existing wells
  - Well yield impacts
  - Incremental pumping costs (due to additional lift)

Butte Creek Impacts

- Develop baseline flow from available gauging stations
- Synthesize "with-project" flows based on cumulative reductions in streamflow from changes in stream leakance from GW model



Butte Creek Impacts

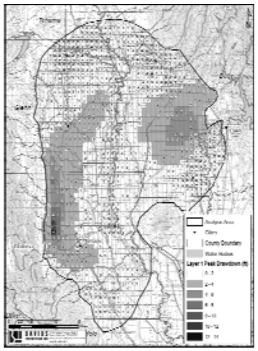
- No impact in upper reaches (primary spawning and holding areas)
- Greatest flow reduction in Jan. – Mar.
  - During times of highest discharge
- Greatest % reduction in summer/early fall
  - Spring-run have already migrated
  - Steelhead just beginning to enter stream
- Rarely drops below in-stream standards
  - June during early '90s drought
- Tradeoffs between Butte Creek impacts and main stem benefits

Impacts to Existing Wells

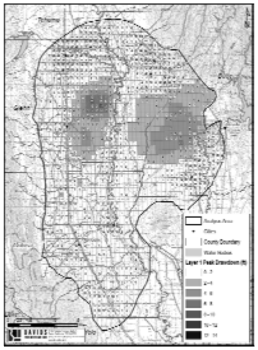
- Used DWR well inventory data
- No appreciable impact on irrigation well performance
  - Increased pumping costs accounted for
- Some impact on non-irrigation wells
  - 9,000 non-irrigation wells in analysis area
  - Up to ~800 non-irrigation wells in impact zones
  - Maximum of 25 (0.2%) to 284 (3%) of wells needing deepening or replacement

Groundwater Levels and Impacts to Wells

Potential Impact Zones:
Worst Case, New Wells



Potential Impact Zones:
Worst Case, Existing Wells



Incremental Pumping Costs

Summary Statistics of Interference Drawdown by Pumping Scenario

	Interference Drawdown (ft)				
Pumping Scenario	Min	Max	Mean	Median	Std. Dev.
300 kaf Summer Pumping, New Well Field	0.0	13.6	0.5	0.3	0.7
300 kaf Summer Pumping, Existing Well Field	0.0	8.3	0.4	0.2	0.6
150 kaf Summer Pumping, New Well Field	0.0	6.2	0.3	0.2	0.4
150 kaf Summer Pumping, Existing Well Field	0.0	5.4	0.3	0.2	0.4
150 kaf Fall Pumping, New Well Field	0.0	7.0	0.4	0.2	0.4
150 kaf Fall Pumping, New Well Field	0.0	6.1	0.4	0.2	0.5
150 kaf Summer & Fall Pumping, New Well Field	0.0	5.9	0.4	0.2	0.4
150 kaf Summer & Fall Pumping, New Well Field	0.0	5.0	0.4	0.2	0.5

Incremental Pumping Costs

Summary Statistics of Total Increased Annual Energy Costs to Maintain Existing Groundwater Pumping for Irrigation.

	Increased Annual Energy Cost (Total $)				
Pumping Scenario	Min	Max	Mean	Median	Std. Dev.
300 TAF Summer Pumping, New Well Field	$65,770	$705,326	$228,397	$168,480	$177,411
300 TAF Summer Pumping, Existing Well Field	$60,110	$497,233	$194,859	$154,452	$140,481
150 TAF Summer Pumping, New Well Field	$37,538	$377,222	$139,402	$104,710	$ 94,209
150 TAF Summer Pumping, Existing Well Field	$39,866	$367,467	$148,075	$126,209	$ 97,078
150 TAF Fall Pumping, New Well Field	$10,993	$344,156	$122,601	$124,133	$ 80,913
150 TAF Fall Pumping, Existing Well Field	$10,292	$401,570	$138,222	$134,018	$ 95,827
150 TAF Summer & Fall Pumping, New Well Field	$44,736	$294,296	$140,169	$120,727	$ 81,830
150 TAF Summer & Fall Pumping, Existing Well Field	$47,471	$345,330	$151,533	$132,451	$ 91,202

(Incremental costs for non-irrigation pumping on the order of $3000 - $5000 per year depending on pumping scenario)

Benefit-Cost Summary

All present values in million dollars [2009]

Scenario				
No.	**Description**	**Benefits**	**Costs**	**Benefit – Cost**
1	150 TAF Summer, New Wells	73	135	-62
1	150 TAF Summer, Existing Wells	73	94	-21
2	300TAF Summer, New Wells	183	290	-107
2	300 TAF Summer, Existing Wells	183	212	-29
3	150 TAF Fall, New Wells	74	210	-136
3	150 TAF Fall, Existing Wells	74	144	-70
4	150 TAF Summer & Fall, New Wells	73	88	-15
4	150 TAF Summer & Fall, Existing Wells	73	65	8

Latest Activities and Findings

Exploring Operations for Additional Environmental Benefits

- Consultation with CVP and SWP operators
- Complying with temperature requirements of greatest concern
  - Operators provided “unofficial” operations criteria for modeling
- Operating for temperature benefit involves tradeoffs with project environmental flow objectives

Temporary Crop Idling to Reduce Payback Cost

- Investigated crop idling as an alternative to GW pumping for reservoir payback
  - Voluntary, incentive driven
- Less cost-effective than pumping due to:
  - High cost: crop idling decisions have to be made early before hydrologic conditions are known
  - Marginal effectiveness: not all of the avoided water use results in reservoir payback

Principal Findings to Date

- SWP and CVP operational requirements are complex and constraining
  - Must honor all Project commitments and operations rules
  - Cold water pool management has dominant effect
- Cost of payback water is appreciable
  - Groundwater pumping
  - Temporary crop idling
- Project cost-effectiveness is marginal
  - Use of Sac groundwater to “backstop” entails mitigation costs
  - Project water produced in wetter years because it cannot be banked
  - Modest value of water in Sac Valley

Concluding Phase 1

Final Phase 1 Steps

- Technical
  - Frame existing operational constraints and tradeoffs
  - Formulate and model best performing scenario under existing conditions
  - Analyze impacts and economics
- Final Report: draft, final
- Public meetings (between draft and final)
- Scope Phase 2 of Investigation
- Continue regional dialogue

Question & Answer

Discussion

Northern Sacramento Valley Conjunctive Water Management Investigation
Conjunctive Water Management Investigation
Public Workshop
Meeting Notes
October 21, 2010

Present:
Thad Bettner, General Manager, GCID
Grant Davids, Davids Engineering
John Clerici, Outreach Communications Specialist
Gregory Thomas, President, Natural Heritage Institute
Walter Bourez, MBK Engineers
Lee Bergfield, MBK Engineers
Cynthia F. Davis, Director of Communications, GCID
Laurie Merrill Murray, Executive Assistant, GCID

Thad Bettner, General Manager, Glenn-Colusa Irrigation District, welcomed the attendee's and introduced consultant John Clerici, outreach communications specialist, Grant Davids of Davids Engineering, Gregory Thomas, President of Natural Heritage Institute, Walter Bourez, MBK Engineers, and Lee Bergfield, MBK Engineers.

Mr. John Clerici called the public meeting to order at 3 p.m. and explained ground rules for participation during the meeting. Approximately 50 members of the public attended (see sign-in sheet).

Mr. Bettner reported that there is currently a significant risk for water in the north state. The State Water Resources Control Board released a flow report that calls for the current state of the Delta. The report recommends that 75% of all runoff goes to the Delta, and farmers in the Sacramento Valley cannot rely on a 25% supply. The Delta Stewardship Council – all the Delta – all the time. The Council is looking upstream for fixes to the Delta. Scott Valley – Siskiyou County groundwater historical operations are changing. New rules will be set up to serve the Delta. Water supply reliability. Change is upon us, outside factors are upon us.

Grant Davids presented a PowerPoint presentation, and provided information on the investigation covering the last four years. Examined how operation of aquifers in the Sacramento Valley environmental and water users. CVP and SWP have commitments to honor.

The following are general categories (in bold) of interest with some specific comments/questions as examples.

Voracity and specificity with the technical tools used to perform the evaluation.

Some commenters asserted that more detail was required in the areas of the economic analysis such as the value assigned to the groundwater, impacts to specific segments of the agricultural community, etc.

One person asked if the time-step used to develop the groundwater model (monthly) didn't miss some spatial or temporal peculiarities associated with a specific location.

Would like to see more sophistication in terms of groundwater, particularly as it relates to permanent crops/orchards.

Why no critical dry years used in the analysis?

One lady questioned the impacts of groundwater pumping in the valley and its impacts on foothill aquifers. I assume she is confusing the Tuscan Formation and the Lower Tuscan aquifer.

Impacts as described in the investigation.

One foot impact to Big Chico Creek is a big deal in the summer.

What is the extent of the impact on domestic (and other wells)? You show 0 to 6 feet, but you also say that near the wells that are pumping payback water it could be 50 or 60 feet? Even a few feet can have a large impact. This needs to be clarified.

What are the critical recharge months in the upper reaches? In the area in general?

How the project works.

Frequency and severity of payback vs the benefits.

What are the benefits? This was a particular challenge for the Feather River folks. Some examples might help.

How will the reservoir releases be measured? When will we know that water needs to be repaid (what triggers payback)? How does the payback water get used?

Which aquifer are we talking about (deep or surface)? Does this study (can this study) be expanded to show the total groundwater picture?

Where does the water for environmental enhancements come from?

Do commitments still exist if Delta mandates are imposed?

Real project drivers.

Why are we here? There were water rights hearings before (she mentioned NHI but I did not get it all). The elephant in the room is junior water rights holders south of the Delta that are trying to get at our water. We need to save this area?

Land use and cropping decisions in the San Joaquin Valley were also sighted, as well as local growth concerns.

Water transfers and GCID's role in them. How do they benefit the region?

Desire to be part of the discussion.

More meetings to work out the information with the public. Time of day and location, and more focused in terms of subject matter.

There are a lot of resources available from the local groups and individuals. We can help but you need to talk to us more proactively.

Many of these questions do not have clear answers, or are not answerable within the context of the investigation. Some of them like wanting more specific economic analysis or reducing the time-step on the model may either be impractical, or are better left to the more extensive environmental analysis required a the project level.
However providing concrete answers when they are available, as well as providing more detail around how an example project might function, its benefits and impacts, can only help to improve stakeholder understanding of what we have in mind.

I have some thoughts about how we can structure our response but would like to hear what the team has to say before discussing them further.

These are the questions and comments from the 10-21 workshop as I wrote them down. Some appear in the text above as well.

How does this relate to the planning process (city and county general plans)?

Why no critical dry years used in analysis? Doesn't make sense.

The information is going to be used and not used appropriately. There seems to be a lot of pumping.

Confused about the water storage issue. Growth and demand is south of delta which is where he water would seem to go. There is a great deal of risk and uncertainty with what you are doing.

Where does the water for environmental enhancements come from (surface or groundwater)?

Which aquifer are we talking about (deep or surface)? Does this study (can this study) be expanded to show the total groundwater picture?

What's the local/regional share of the 2.5 million af groundwater pumping figure? Need to be more specific.

What is the time step on the groundwater model? We notice changes weekly and even daily based on pumping. May not be reflected in the model.

Explain how there can be no impact in upper reaches of creeks? Does valley pumping impact aquifers in foothills (they think so)? Does the Tuscan aquifer extend into the foothills (Tuscan Formation vs Tuscan Aquifer?)

What are the critical recharge months in the upper reaches? In the area in general?

Seems like more detailed investigation needed to determine impacts of valley pumping on upper reaches.

What is the extent of the impact on domestic (and other wells)? You show 0 to 6 feet, but you also say that near the wells that are pumping payback water it could be 50 or 60 feet? Even a few feet can have a large impact. This needs to be clarified.

Payback issue needs to be explained. How does it work? Accounting?

1 foot of drop in local streams (Big Chico) are significant. Team needs perspective on this.

There are a lot of resources available from the local groups and individuals. We can help but you need to talk to us more proactively.

What is meant by “marginal impacts” at Butte Creek?

What if you end up pumping more than you expect (as a response to prolonged drought)?

Why are we here? There were water rights hearings before (she mentioned NHI but I did not get it all). The elephant in the room is Junior water rights holders south of the Delta that are trying to get at our water. We need to save this area?

Needs more community meetings, but thinks this effort might harm the area. Mentioned drought water bank.

Did you assign any value to the water in the aquifer?

Impacts of local land use decisions need to be taken in account? Have they been?

Explain the externalities in the economic impacts evaluation.

Public wants assurance that there is adequate thought going into monitoring and mitigation.

Can you do just reservoir re-operation without doing the pumping for repayment?

Do commitments still exist if Delta mandates are imposed?

What are the existing contractual obligations?

Would like to see more sophistication in terms of groundwater, particularly as it relates to permanent crops/orchards.

Clarification requested on groundwater and surface water.

Models are tools – assign value to aquifer. Add to next agenda.

December 8, 2010

6:00 to 8:00 PM

Workshop Objectives

- Respond to questions from October 21, 2010 workshop

Agenda

1. Welcome, Introductions, Workshop Process
2. Discuss questions from 10-21 Workshop
   a. How does the proposed project work?
   b. Investigation Tools and Data
   c. Project Benefits
   d. Project Impacts
3. Next Steps/Closing

Public Workshop

Northern Sacramento Valley Conjunctive Water Management Investigation

December 8, 2010

6:00 p.m. – 8:00 p.m.

Masonic Lodge
1110 W. East Avenue
Chico, CA 95926

The Glenn-Colusa Irrigation District (GCID) and the Natural Heritage Institute (NHI) are in the process of evaluating water management opportunities in the northern Sacramento Valley. This effort, the Northern Sacramento Valley Conjunctive Water Management Investigation (Investigation), is nearing completion of several years of work with a draft final report currently under preparation.

This workshop is being sponsored specifically to provide responses to the questions and comments received at the Investigation workshop held on October 21, 2010. Topics to be addressed include potential project benefits and impacts, conjunctive operations concepts, project economics, and other issues brought up at the previous session. Time will be allowed for the public to engage in a discussion of the questions and answers and relevant issues related to the Investigation.

Northern Sacramento Valley
Conjunctive Water Management Investigation

Public Workshop

December 8, 2010

Background

On October 21, 2010, the Glenn-Colusa Irrigation District (GCID) and Natural Heritage Institute (NHI) held a public workshop to provide a status report on their Northern Sacramento Valley Conjunctive Water Management Investigation. Meeting participants were also provided an opportunity to ask questions of the investigation team.

As a result of the significant number of questions and comments provided by attendees, GCID and NHI agreed to hold a follow-up workshop. The purpose of the workshop is two-fold: to either respond to questions that could not be addressed at the last meeting, or provide clarification to questions that were answered but warranted additional follow-up; and, to allow for more substantive dialogue between the investigation team and stakeholders on these issues.

Organizing Questions

Questions and comments from the October workshop varied widely but seemed to be focused in four critical areas:

1. Project Operations (How does the proposed project work?)
2. Investigation Tools and Data
3. Project Benefits
4. Project Impacts

These four categories were used to develop the format for today's workshop. For discussion purposes, and to facilitate providing responses, comments were put into the form of a question, and multiple questions of similar nature were consolidated into a single question. Additionally, the technical team assessed which questions could be answered within the context of the current investigation, and which questions either cannot be resolved by this phase of the investigation, or required a venue more suited to a longer-term regional dialogue. The majority of questions fell into the first group and will be responded to in this workshop.

Questions by Category

Project Operations (How does the proposed project work?)

- Can you do just reservoir re-operation without doing the pumping for repayment?
- Where does the water for environmental enhancements and other project benefits come from?
- How does the payback water get used?
- How do the project benefits compare to the frequency and magnitude of payback?
- How would the reservoir releases be measured?
- How would it be determined that water needs to be repaid…what triggers reservoir payback?
- Which aquifer are we talking about, the deep or shallow?
- Does the study address the total groundwater picture?
- What are the existing contractual obligations?
- Public wants assurance that there is adequate thought going into monitoring and mitigation.

Investigation Tools

- Why are critical dry years not used in the analysis?
- What is the time-step used to develop the groundwater model? Is the time-step appropriate for capturing localized effects of day to day well operation and aquifer response?
- Were economic impacts beyond just project costs and benefits considered, such as impacts to specific segments of the agricultural community?

Project Benefits

- What are the project benefits?
- Are there benefits to the groundwater systems and were they considered in the economic analysis?

Project Impacts

- What are the impacts of groundwater pumping in the valley on foothill aquifers?
- What are the critical recharge months in the upper reaches? In the area in general?
- Project pumping may be a small share of Valley wide pumping but what proportion is it of pumping within the project area?
- Is the interconnection between streams and underlying aquifers sufficiently defined to predict the effects of even modest changes in groundwater levels (e.g., Butte and Big Chico Creeks)?
- What is the extent of the impact on domestic (and other wells)? You show 0 to 6 feet, but you also say that near the wells that are pumping payback water it could be 50 or 60 feet? Even a few feet can have a large impact. This needs to be clarified.

Northern Sacramento Valley Conjunctive Water Management Investigation

Public Workshop

December 8, 2010

The Glenn-Colusa Irrigation District and
The Natural Heritage Institute

Workshop Objective & Process

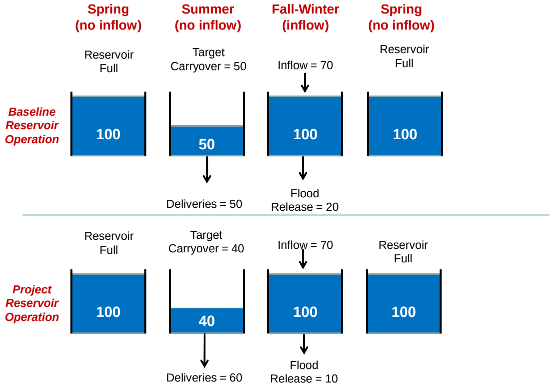
- Objective
  - – Respond to questions from October 21, 2010 workshop 1
- Process
  - – Organized questions into topics
  - – Describe each topic
  - – Provide response
  - – Engage in discussion

How Does The Proposed Project Work?

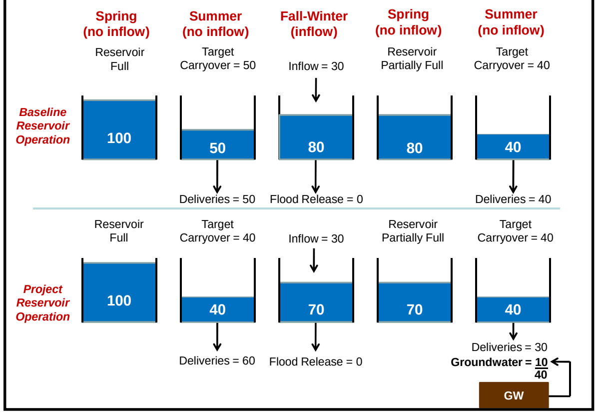
Re-operate Surface Reservoirs with Groundwater "Backstop"

- Reservoir re-operation
  - – Additional releases to meet program objectives (North of Delta water supply and environmental enhancement)
  - – Expect reservoir refill from surplus surface flows
  - – Honor existing CVP and SWP delivery obligations and operations constraints
- Groundwater operation
  - – Pump groundwater to "repay" reservoirs if storage conditions put contract deliveries or temperature control at risk
  - – Groundwater used in lieu of surface entitlements that then remain in storage
  - – Minimize or avoid GW impacts

Re-Operation Case 1- Reservoir Refills



Re-operation Case 2- Reservoir <u>Does Not</u> Refill



Project Performance Summary

Project Scenario 2 Evaluated with Revised Model Including Biological Opinions, Forecast-based Operation and Minimum Reservoir Release Criteria

Performance Metric	Sac R (Shasta)	Feather R (Oroville)
Total number of years in simulation (1922-2003)	82	82
Number of years no project releases made	62	45
Number of years project releases made	20	37
Average annual (82 years) project release, (TAF) (Roughly 2/3 environmental and 1/3 ag benefits) **Cumulative benefit over 82 years (TAF) =**	25 **2,050**	30 **2,460**
Maximum year project release (TAF) (Includes environmental and ag)	180	102
Number of years "payback" pumping is needed	4	11
Average annual (82 years) project pumping (TAF) **Cumulative pumping over 82 years (TAF) =**	2 **164**	9 **738**
Maximum year project pumping (TAF) (Maximums do not occur in same year)	100	100
Average annual (82 years) reservoir refill from surplus flows (TAF)	23	23
Spillage of payback water	0	-2

Questions

How Does The Proposed Project Work?

- Can you do just reservoir re-operation without doing the pumping for repayment?
- Where does the water for environmental enhancements and other project benefits come from?
- How does the payback water get used?
- How do the project benefits compare to the frequency and magnitude of payback?

Questions, continued

How Does The Proposed Project Work?

- How would the reservoir releases be measured?
- How would it be determined that water needs to be repaid…what triggers reservoir payback?
- Which aquifer are we talking about, the deep or shallow?
- Does the study address the total groundwater picture?

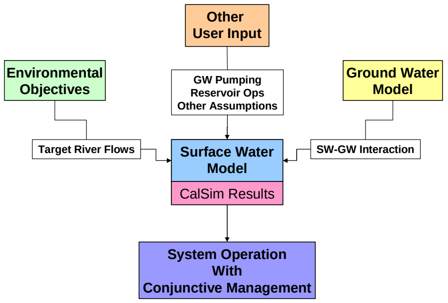
Questions, continued

How Does The Proposed Project Work?

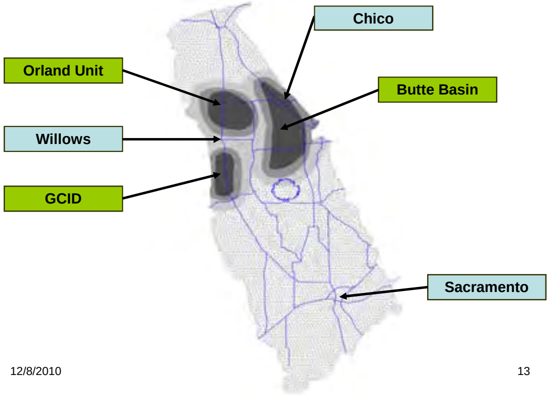
- What are the existing contractual obligations?
- Public wants assurance that there is adequate thought going into monitoring and mitigation.

Investigation Tools and Data

Overview of Analysis Tools



Groundwater Model Area and Grid Density



Groundwater Flow Model

- Regional scale with high spatial detail
  - – 5,950 square miles (3.8 million acres)
  - – 88,922 surface nodes
  - – 7 vertical layers
- Aquifer properties based on analysis of more than 1,000 production wells
- Calibration
  - – Static calibration for year 2000
  - – Water levels from 257 monitoring wells
- Monthly time step, 1982 through 2003

Surface Water Operations Model

- Spreadsheet-based for ease and speed of operation
- Re-operates Shasta and Oroville Reservoirs relative to a baseline condition depicted by CalSim II outputs (1922 through 2003)
- Driven by additional target deliveries for:
  - – Environmental restoration in Sac and Feather Rivers
  - – Unmet Sac Valley agricultural demands
- Various operational constraints
- Uses generalized SW-GW interaction functions derived from GW model

Questions

Investigation Tools and Data

- Why are critical dry years not used in the analysis?
- What is the time-step used to develop the groundwater model? Is the time-step appropriate for capturing localized effects of day to day well operation and aquifer response?
- Were economic impacts beyond just project costs and benefits considered, such as impacts to specific segments of the agricultural community?

Project Benefits

Questions

Project Benefits

- What are the project benefits?
- Are there benefits to the groundwater systems and were they considered in the economic analysis?

Project Benefits

- Increased Sac Valley surface water supply
  - More local benefit (water supply) from CVP and SWP
  - Reduced overall reliance on Sac Valley groundwater, though increased local pumping in certain years
- Improved habitat in Sac and Feather Rivers through
  - Recovery of salmon populations
  - Ecosystem sustainability

Project Impacts

Questions

Project Impacts

- What are the impacts of groundwater pumping in the valley on foothill aquifers?
- What are the critical recharge months in the upper reaches? In the area in general?
- Project pumping may be a small share of Valley wide pumping but what proportion is it of pumping within the project area?

Preface

This report was prepared by CH2M HILL and MBK Engineers for Glenn Colusa Irrigation District (GCID) and the Natural Heritage Institute (NHI).The report documents technical analyses conducted to examine potential future coordinated operation of Sacramento Valley groundwater aquifers with California's State Water Project and the federal Central Valley Project. The work was enabled by state and federal grant funds.

Principal investigators were Peter Lawson of CH2M HILL and Walter Bourez and Lee Bergfeld of MBK Engineers. Program management and technical oversight were provided by Grant Davids of Davids Engineering on behalf of GCID and NHI.

Any questions regarding the information presented in this report should be addressed to GCID, NHI, or Davids Engineering.

Executive Summary

Project Description

Glenn Colusa Irrigation District (GCID) and the Natural Heritage Institute (NHI) are conducting an analysis of conjunctive management opportunities in the Sacramento Valley (Project). The purpose is to examine whether and how groundwater production from the Lower Tuscan Aquifer and related deep aquifers in the Sacramento Valley can be integrated with the operations of existing surface water reservoirs to produce additional water to satisfy unmet agricultural demands in the Valley (preferentially), or south of the Sacramento-San Joaquin River Delta (Delta). A secondary objective is to evaluate the potential to increase the operational flexibility of these reservoirs so that they can contribute to meeting environmental flow targets in the Sacramento and Feather Rivers.

Technical Analysis

The Project includes conducting planning-level technical analyses and modeling of the following:

- How conjunctive management projects may operate
- How additional water supplies may be developed
- How reservoirs can be reoperated to generate environmentally beneficial flow patterns
- What effects the Project could have on both the surface and groundwater systems in the Sacramento Valley.

This report documents the development of the surface water and groundwater modeling tools used in the analysis, the assumptions made during the development process, and presents results of the modeling analyses.

Technical analysis was performed using two models: one for the surface water system and one for the groundwater system. The surface water model was developed to analyze operations of conjunctive management projects, reservoir operations, environmental objectives, and agricultural water demands quickly for a variety of different project, operations, and objectives. The surface water model was used in gaming sessions and by members of the project team to understand benefits, risks, and limitations of various conjunctive management configurations.

A regional groundwater model was also developed to simulate the effects of conjunctive management operations on the aquifer system with a spatial resolution at project sites capable of evaluating effects on a well field scale. The groundwater model was used to investigate differences in aquifer drawdown and changes in stream-aquifer interaction for different pumping capacities, seasons, and well field configurations.

The two models were used in an interactive fashion to simulate project operations and better understand the interactions between the surface water and groundwater systems. The surface water model was used to determine timing and quantity of conjunctive management pumping. Pumping time series were then simulated in the groundwater model and changes in stream-aquifer interactions were input back into the surface water model to understand how those changes might affect system operations.

Technical analyses were performed at a planning level to help prove concepts and define potential conjunctive management configurations and operations. Analyses were conducted for general projects, locations, and operations. More specific and refined analysis will be required as specific projects are defined. Most of the analyses contained herein were conducted in a comparative (rather than absolute) manner, and results must be interpreted with this in mind. Comparisons of benefits and impacts between different scenarios or well fields help inform decisions on what projects work better than others.

Projects, Operations, and Scenarios

The project team developed an initial list of nine prospective project sites and screened these down to two project sites for more in-depth analysis and modeling. One project site is located within GCID and is integrated with the Central Valley Project's (CVP) operation of Shasta Reservoir. The second project site is located in Western Canal Water District and Richvale Irrigation District (Butte Basin) and integrated with the State Water Project's (SWP) operation of Oroville Reservoir.

The team used its understanding of annual aquifer drawdown and recovery to develop a conjunctive operation configuration that relies primarily on re-operation of existing reservoirs to achieve the project objectives, drawing on groundwater as a backstop. The term "backstop" refers to the potential to use groundwater supplies on a temporary basis to make up for shortfalls in surface water supplies due to modified operations. Groundwater provides an additional source of water to protect surface water reservoirs from being excessively depleted. This type of operation offers different opportunities and challenges than conventional groundwater banking. Surface water is not banked in the aquifer in wet years and recovered during dry years. Instead, additional water is released from surface reservoirs for delivery to meet Project objectives (unmet local irrigation demands and environmental flow targets). These releases result in lower end-of-year reservoir storage levels and more reservoir space available to capture winter runoff.

The goal of this operation is to develop additional water supply by refilling reservoir space vacated by additional Project releases with captured surplus surface water that otherwise would be released for flood control. In years when refill is not complete, Project pumping produces groundwater for use in Project areas in lieu of surface water deliveries that would otherwise be made from reservoirs. This allows an equivalent volume of water to remain in reservoir storage to recover from prior year project releases.

This mode of conjunctive operation, in which reservoir operation is used as the primary means to develop new water supply and groundwater is used infrequently as a backstop, is highly efficient because it reduces the frequency and volume of groundwater pumping in comparison to conventional groundwater banking operations. Groundwater pumping is relied upon only as needed to maintain reservoir storage when refill from surplus winter flows is insufficient.

In some years, conditions in the Sacramento Valley may be so critically dry that Project pumping would be suspended altogether. For instance, if groundwater levels were already at levels of concern (according to county Basin Management Objectives or other standards), Project wells would be turned off and the Project would generate no new supplies under these conditions.

Project operations were simulated for the four different conjunctive management scenarios summarized in Table ES-1.

TABLE ES-1
Summary of Project Scenarios Evaluated
Sacramento Valley Conjunctive Water Management Technical Investigation Modeling Report

Scenario	GCID Annual Pumping Capacity	Butte Basin Annual Pumping Capacity	Pumping Season
1	100 TAF	50 TAF	Summer (May through August)
2	200 TAF	100 TAF	Summer (May through August)
3	100 TAF	50 TAF	Fall (September through November)
4	100 TAF	50 TAF	Summer and Fall (May through November)

TAF = thousand acre-feet

Additionally, pumping for each scenario was evaluated for two different well fields. The first well field simulated pumping from existing wells screened in the current aquifer production zones at depths between 100 and 500 feet. The second well field simulated pumping from new wells screened in the deep aquifers at depths between 900 and 1,100 feet.

Results and Conclusions

Table ES-2 presents a summary of results for each scenario and well field configuration. Water supply results are average annual new water supplies developed to meet project objectives. Groundwater results show only the peak impacts to groundwater levels and streams.

Table ES-2 shows that for the two pumping capacities evaluated, the average annual additional water supply is approximately one third of pumping capacity. Additionally, approximately 85 percent of the new water supply developed comes from capture of surplus surface water with the remaining 15 percent from additional groundwater pumping. Average annual groundwater pumping volumes are the result of infrequent but large pumping quantities up to the total project capacity in a given year.

Surface water operations and the resulting groundwater pumping are primarily driven by reservoir storage levels. Therefore, differences in the season of conjunctive management pumping evaluated with Scenarios 3 and 4 have little effect on water supply. However, the duration of the pumping season has a more significant effect on the magnitude of drawdown produced in the aquifer system, and results in differences in projected stream impacts.

TABLE ES-2
Summary of Results for Each Project Scenario and Well Field Configuration
Sacramento Valley Conjunctive Water Management Technical Investigation Modeling Report

	Pumping Capacity (TAF)				Source of New Water Supply			Max Local Drawdown[a] (feet)		
Scenario	**GCID**	**Butte Basin**	**Pumping Season**	**New Water Supply[b] (TAF)**	**Surplus Surface Water[b] (TAF)**	**GW Pumping[b] (TAF)**	**Well Field**	**GCID**	**Butte Basin**	**Peak Streamflow Impact[c] (cfs)**
1	100	50	Summer	44	38	6	Existing	30-40	<10	54
							New	~100	10-20	53
2	200	100	Summer	110	94	16	Existing	~100	20-30	111
							New	~200	20-30	105
3	100	50	Fall	44	38	6	Existing	40-50	10-20	80
							New	~125	30-40	90
4	100	50	Summer and Fall	44	38	6	Existing	20-30	<10	64
							New	40-50	10-20	65

[a] Maximum local drawdown is the maximum monthly simulated drawdown within the pumped aquifer for that particular conjunctive management project during the period of simulation

[b] Annual Average

[c] Peak stream impact is the maximum monthly aggregated reduction in stream flow for all streams explicitly simulated in the groundwater model during the period of simulation

Note:

cfs = cubic feet per second

Table ES-2 shows that for a given project production capacity, the greatest drawdown occurs during fall pumping simulations because pumping occurs over 3 months, resulting in higher instantaneous rates. An intermediate magnitude of drawdown is observed for pumping over a 4-month summer period, and the least drawdown is predicted for the 7-month summer/fall pumping period.

Production of groundwater from new wells screened in the deeper aquifer results in greater drawdown than pumping the same quantities at the same rates from existing wells. This is because the pumping from new wells is assumed to occur from the 200-foot thickness that comprises model layer 6 (approximately 900 to 1,100 feet below ground surface ([bgs]), whereas the pumping from existing wells occurs from the approximate 400-foot thickness of the regional aquifer (200 to 600 feet bgs). This greater aquifer thickness provides a significantly greater aquifer transmissivity to provide water to the pumping wells, and therefore less drawdown is simulated for a given pumping rate. Additionally, the new well field for the GCID Project is assumed to be located closer to the low permeability bedrock that borders the western edge of the alluvial aquifer; therefore, less water is available to satisfy pumping demands. These assumptions, combined with the larger pumping volumes, help explain why the differences in drawdown between a new and existing well field are larger in the GCID Project than the Butte Basin Project.

Simulated drawdown near the Butte Basin Project is lower than simulated drawdown near the GCID Project. This is due to a combination of lower overall production rates and a greater production well spacing.

Comparisons of peak streamflow impacts between scenarios show that higher production rates generally result in greater peak impacts with the exception of a comparison between Scenario 1 and 4. Differences in peak stream impacts between Scenarios 1 and 4 can be explained by the timing of when ephemeral streams are simulated to flow in the model. The peak drawdown effects for Scenario 4 were evaluated in November (the end of the production season), when west side ephemeral streams are assumed to be active. These streams provide an additional source of recharge to the aquifer system, resulting in a lesser magnitude of predicted drawdown. This can also be seen in the cumulative peak stream impact, which is greater for Scenario 4 than for Scenario 1.

Lower project pumping rates of Scenarios 1 and 4 predict similar peak stream impacts for new and existing well fields. Moderate production rates in Scenario 3 show greater peak impacts of new wells than those produced by existing wells. At the highest production capacity in Scenario 2 the existing well field produces greater peak impacts to streams than the new well field.

SECTION 1

Introduction and Background

Glenn Colusa Irrigation District (GCID) and the Natural Heritage Institute (NHI) are conducting an analysis of conjunctive management opportunities in the Sacramento Valley (Project). The purpose is to examine whether and how groundwater production from the Lower Tuscan Aquifer and related deep aquifers in the Sacramento Valley can be integrated with the operations of existing surface water reservoirs to produce additional water to satisfy unmet agricultural demands in the Valley (preferentially), or south of the Delta. A secondary objective is to evaluate potential to increase the operational flexibility of these reservoirs so that they can contribute to meeting environmental flow targets in the Sacramento and Feather Rivers.

The Project planning area encompasses the entire Sacramento River basin, although primary attention focuses on areas of the northern Sacramento Valley. This includes portions of Butte, Colusa, Glenn, and Tehama counties. Operational strategies developed do not necessarily depend on the Lower Tuscan and related deep aquifers, or any particular portion of the groundwater system for that matter. The strategies are generally applicable wherever productive aquifers exist regardless of their depth or extent.

The scope of the planning effort includes technical analyses with emphasis on surface water and groundwater modeling to define conjunctive management operations and their benefits and impacts. This report provides specific documentation on modeling tools developed for this analysis, projects and scenarios simulated, and model results. Additionally, the report supports preliminary engineering analyses and development of project cost and benefit estimates to allow for economic evaluation of prospective projects.

Any new groundwater pumping in the Sacramento Valley would have at least temporary effects on groundwater conditions and could affect existing groundwater users and flow in rivers and streams. Therefore a major component of the Project is to address risks to existing water users and streams. Risk management strategies that will be investigated include risk avoidance and minimization, such as locating and designing production wells in ways to isolate impacts, and risk mitigation to compensate for effects that cannot be avoided. An overarching principle of the Project is that existing water users, at a minimum, would not be adversely impacted and preferably will benefit from conjunctive operations.

SECTION 2

Conclusions

2.1 Surface Water System

Conjunctive management in which groundwater pumping capacity is used as a backstop to allow more aggressive operation of surface water reservoirs in the Sacramento Valley may be an efficient method to increase water supply. More aggressive operation of reservoirs produces additional water supply primarily through capture of surplus surface water and to a lesser extent through additional groundwater pumping. Table 2-1 summarizes average annual water supply developed for agricultural and environmental objectives and the source of additional supply, either surplus surface water or groundwater, for the two different project capacities evaluated.

TABLE 2-1
Summary of Average Annual Water Supply Benefits and Source of Additional Supply
Sacramento Valley Conjunctive Water Management Technical Investigation Modeling Report

	Additional Water Supply (TAF)			**Capture of Surplus Surface Water**	**Additional Groundwater Pumping**
Project Capacity	**Agricultural**	**Environmental**	**Total**		
150 TAF	24	20	44	38	6
300 TAF	42	68	110	94	16

Table 2-1 shows that for the two capacities evaluated, additional water supply is approximately one-third of project groundwater pumping capacity. Additionally, approximately 85 percent of the water supply developed comes from capture of additional surface water with the remaining 15 percent from additional groundwater pumping. Average annual groundwater pumping volumes are the result of infrequent but large pumping quantities up to the total project capacity in a year.

Surface water operations and the resulting groundwater pumping are primarily driven by reservoir storage levels. Therefore the season of conjunctive management pumping whether summer, fall, or summer and fall has only minor operational affects. However, pumping season may have more significant effects on aquifers and current groundwater users.

Additional important conclusions can be drawn from the sensitivity/tradeoff analysis. Projects with larger pumping capacities tend to contribute more toward meeting environmental objectives, while smaller capacity projects contribute more to agricultural objectives for the following two reasons:

- Water costs associated with meeting environmental objectives are typically high and require larger project capacities to meet.
- Environmental objectives were assumed to be all-or-nothing thresholds while any additional water supply could be used to meet agricultural objectives.

These two factors also result in the two objectives being less competitive for additional water supply than may be expected. A different prioritization between the two objectives did not result in a one-for-one tradeoff of benefits.

Tradeoff analysis also provided insight into risks associated with more and less aggressive conjunctive management operations. For the surface water system, these risks are focused on reservoir storage levels and ability to meet contract requirements and temperature control criteria in future years if reservoirs are drawn down too far.

Sensitivity analysis conducted when environmental flow targets were varied demonstrated that for most objectives changes of 10 percent did not erase, or greatly increase, project benefits. Therefore, conjunctive management projects, as defined in this study, could likely be used to meet environmental objectives, even with the uncertainty inherent in flow targets and real-time operations.

Conjunctive management operations within the Sacramento Valley may make additional water supply available south of Delta if reservoir releases to meet environmental objectives can be exported. There exists some ability to export these releases when not considering export restrictions for the protection of Delta smelt. However, export restrictions as proposed in the recently release Operations Criteria and Plan (OCAP) Biological Opinion likely reduce or eliminate this potential benefit.

2.2 Groundwater System

The eight simulations described in this study were designed to test four different project scenarios while holding remaining variables constant. Parameters evaluated in the four scenarios included quantity of groundwater pumped, duration of production (which influences production rate), seasonality of production, and spacing and location of production well fields, including proximity to surface streams. Conclusions are divided into those regarding groundwater level effects followed by those regarding effects on surface water flows. Drawdown estimates provided are regional drawdown estimates. The magnitude of local drawdown adjacent to individual production wells will be significantly greater.

2.2.1 Groundwater Levels

Production of 150 TAF of groundwater from existing wells over the summer (May through August) results in a maximum drawdown of approximately 40 feet in the pumped aquifer, whereas production of 300 TAF of groundwater results in a maximum of approximately 75 feet of drawdown.

Production of 150 TAF of groundwater from new deeper wells over the same months results in a maximum of approximately 75 feet of drawdown in the pumped aquifer, whereas the production of 300 TAF of groundwater results in approximately 150 feet of drawdown.

Production of 150 TAF of groundwater from existing wells over the fall period (September through November) results in a maximum drawdown of about 50 feet in the pumped aquifer compared to a maximum of approximately 40 feet of drawdown if the same production occurs in the summer.

Production of 150 TAF of groundwater from new deeper wells over the fall period results in a maximum of approximately 125 feet of drawdown in the pumped aquifer compared to a maximum of approximately 75 feet of drawdown if the same production occurs in the summer.

Production of 150 TAF of groundwater from existing wells over the summer/fall period (May through November) results in a maximum of about 30 feet of drawdown in the pumped aquifer compared to a maximum of approximately 40 feet of drawdown if the same production occurs in the summer only.

Production of 150 TAF of groundwater from new deeper wells over the summer/fall period results in a maximum of approximately 50 feet of drawdown in the pumped aquifer compared to a maximum of approximately 75 feet of drawdown if the same production occurs in the summer only.

For a given project production capacity, the greatest drawdown is observed in fall pumping simulations because the pumping occurs over 3 months, resulting in the highest instantaneous rate. An intermediate magnitude of drawdown is observed for the 4-month summer period, and the least drawdown is predicted for the 7-month summer/fall pumping cycle.

The production of groundwater from the deeper aquifer from new production wells results in the greatest predicted magnitude of drawdown. This is because the pumping is simulated to occur in a 200-foot thickness of model Layer 6 (approximately 900 to 1,100 feet bgs) whereas the pumping from existing wells is assumed to occur from wells screened throughout the approximately 400-foot thickness of the regional aquifer (200 to 600 feet bgs). Further, the new well field identified on the western side of the valley is located further west, relative to the location of the existing wells, transferring the groundwater pumping stresses closer to the low permeability bedrock which borders the western edge of the alluvial aquifer.

Simulated drawdown in the vicinity of the eastern well fields in the Butte Basin Project are significantly lower than those observed on the west. This is due to a combination of lower overall production rates from the east and a greater production well spacing.

2.2.2 Effects on Surface Water Flows

Peak effects on stream flow due to groundwater production in the Sacramento Valley are summarized in Table 2-2.

TABLE 2-2
Peak Effects on Streamflow from Conjunctive Management Operations
Sacramento Valley Conjunctive Water Management Technical Investigation Modeling Report

	Scenario 1		**Scenario 2**		**Scenario 3**		**Scenario 4**	
Stream	**Existing (cfs)**	**New (cfs)**	**Existing (cfs)**	**New (cfs)**	**Existing (cfs)**	**New (cfs)**	**Existing (cfs)**	**New (cfs)**
All Streams	54	53	111	105	80	90	64	65
Butte Creek	13	12	72	69	50	48	39	33

TABLE 2-2
Peak Effects on Streamflow from Conjunctive Management Operations
Sacramento Valley Conjunctive Water Management Technical Investigation Modeling Report

	Scenario 1		**Scenario 2**		**Scenario 3**		**Scenario 4**	
Stream	**Existing (cfs)**	**New (cfs)**	**Existing (cfs)**	**New (cfs)**	**Existing (cfs)**	**New (cfs)**	**Existing (cfs)**	**New (cfs)**
Sacramento River – GCID to Wilkins Slough	42	37	32	28	16	18	16	15
Feather River	3	3	6	6	4	4	4	4
Little Chico Creek	3	3	6	5	4	3	4	3
Salt River	1	5	5	8	2	5	2	5
Stone Coral Creek	6	9	11	15	7	10	6	9
Stony Creek	4	5	7	7	4	6	4	4

Specific conclusions regarding surface water effects are as follows:

- The higher pumping rates associated with the 300-TAF projects clearly result in significantly larger peak stream impacts.
- For a conjunctive management project of a given size, new well fields pumping from deeper aquifers tend to produce greater peak stream impacts on western streams than pumping from existing wells tapping the regional aquifer. This is likely due to the greater magnitude of drawdown predicted on the western side of the valley from new wells as discussed above. Effects on eastern and central streams (Sacramento River) are similar.
- When looking at the cumulative peak impacts to all streams, the lower project pumping rates (150 TAF over 4 or 7 months) predict similar peak impacts for both new and existing well fields. At moderate production rates (150 TAF over 3 months), peak impacts of new wells is greater than those produced by existing wells. At the highest production capacity (300 TAF over 4 months), the existing well field produces greater peak impact to streams than the new well field.
- For all projects evaluated, peak stream impacts occur in 1990, as do peak impacts on the Sacramento River. This is also generally true of the west side streams of Stone Corral and Stony Creek.
- For all projects evaluated, peak stream impacts on the east side streams (Little Chico Creek and Butte Creek) occur in early 1995. One exception is that for the 300 TAF projects, peak impact on Butte Creek occurs in early 1993.
- Peak impacts on the Feather River occur in late 1994 or early 1995.

SECTION 3
Technical Analysis and Modeling

Technical analysis and modeling of conjunctive management operations require consideration of both surface water and groundwater systems and their interaction. This project developed and used models that simulate each system using similar water demands and system operations. Information is passed between the models to depict conjunctive management operations and effects between the surface and groundwater systems. These tools were developed to simulate and compare a baseline condition and a project condition to determine benefits and effects of conjunctive management.

Technical analyses were performed at a planning level to help prove concepts and define potential conjunctive management configurations and operations. Analyses were conducted for general projects, locations, and operations. More specific and refined analysis will be required as specific projects are defined. Most of the analyses contained herein were conducted in a comparative, rather than absolute, manner, and results must be interpreted as such. Comparisons of benefits and impacts between different scenarios or well fields help inform decisions on what projects work better than others. Interpretation of the results should not be interpreted in a highly predictive manner, such as pumping “X” amount of groundwater results in a deficit of “Y” stream flow, or release of “A” volume of water from a reservoir accomplishes “B” amount of environmental restoration.

3.1 Objectives of Groundwater Analysis

Conjunctive water management, or groundwater substitution projects, can result in depressing local groundwater levels, which could affect yields and performance of nearby water supply wells and cause a reduction of groundwater discharge to surface streams or direct leakage from streams to underlying aquifers. Timing these impacts is critical, especially for surface water. Acceptable impacts to surface water flows during certain times of year might be unacceptable during other parts of the year. As part of the technical analysis, a numerical groundwater modeling tool was developed to evaluate impacts of proposed conjunctive water management projects on groundwater levels and streamflows near proposed project sites. The groundwater model is regional in scale, covering the Sacramento Valley Groundwater Basin. This model uses transient surface water budgets developed from spatially referenced land use data, water district operations, surface water availability, and required supplementary groundwater pumping to meet agricultural demands. Specific objectives of the groundwater modeling effort included the following:

- Calculating transient valley-wide and project-specific drawdown in groundwater levels resulting from implementing conjunctive management projects at two general locations with the northern Sacramento Valley.
- Quantifying transient impacts to streams resulting from implementing conjunctive management projects.

- Considering the effects of operating conjunctive water management projects in both wet and dry hydrologic periods and operating projects only in certain selected years within a longer hydrologic period.

3.2 Objectives of Surface Water Analysis

A surface water model was developed to simulate coordinated operation of select Central Valley Project (CVP) and State Water Project (SWP) reservoirs with conjunctive management projects. The surface water model was designed for use in gaming sessions and to help improve understanding of tradeoffs associated with different project objectives and operations. Specific objectives of the surface water modeling included the following:

1. Quantifying additional water supply that might be developed with conjunctive management projects and how that water supply can be used to meet agricultural and environmental objectives.
2. Understanding how conjunctive management projects might change the operation of CVP and SWP reservoirs, including effects on storage, spills, and risks to existing contracts and cold water pool management.
3. Understanding tradeoffs and risks associated with different conjunctive management operations, project sizes, and project objectives.
4. Improving understanding of how changes in stream-aquifer interactions might result in changes to the surface water system.
5. Understanding the effects on other parts of the system, including other reservoirs, hydropower operations, the Sacramento-San Joaquin River Delta (Delta), and south-of-Delta water supplies.

SECTION 4

Current Basin Groundwater Conditions

The initial intent of the Project was to identify areas within the Sacramento Valley groundwater basin in which groundwater levels were significantly lowered due to agricultural pumping for extended periods of time and persisted through the winter recharge period. Conditions of this type would indicate the presence of a large unsaturated aquifer volume that could be used to implement a put-then-take groundwater banking program. Under a program of this type, surface water is delivered to existing groundwater users in the target area during years of above average precipitation, resulting in a replenishing aquifer storage characterized by increased groundwater levels. When dry conditions return to the area, groundwater held in storage within the aquifer is pumped to yield additional supply to meet project objectives.

The first step in the evaluation process was to identify areas within the Sacramento Valley groundwater basin that would be suitable for a put-then-take type conjunctive management project. This was done by collecting and evaluating numerous historical groundwater level hydrographs from wells throughout the basin. Results of this analysis indicated that while numerous areas within the basin show drawdown during the irrigation season, groundwater levels in most areas essentially recover during subsequent winter months, with the exception of the occurrence of multiple years of critically dry conditions. Figures 4-1 through 4-15, which depict historic groundwater fluctuations in wells distributed throughout the valley. The conclusion from this analysis was that a put-then-take water bank was not feasible in the Sacramento Valley north of the American River Basin. Providing surface water for irrigation demands in lieu of groundwater does not result in increased groundwater in storage because groundwater levels recover due to natural recharge over the winter months.

SECTION 5

General Operational Scenario

The team used its understanding of annual aquifer drawdown and recovery to develop a conjunctive operation configuration that relies primarily on re-operation of existing reservoirs to achieve the project objectives, drawing on groundwater as a backstop. The term "backstop" refers to the potential to use groundwater supplies on a temporary basis to make up for shortfalls in surface water supplies due to modified project operations. Groundwater provides an additional source of water to protect surface water reservoirs from being excessively depleted. This type of operation offers different opportunities and challenges than the conventional put-then-take groundwater banking discussed above. Surface water is not banked in the aquifer in wet years and recovered during dry years. Instead, additional water is released from surface reservoirs for delivery to meet Project objectives (unmet local irrigation demands and environmental flow targets). These releases result in lower end-of-year reservoir storage levels and more reservoir space available to capture winter runoff.

The goal of this operation is to develop additional water supply by refilling reservoir space vacated by additional Project releases with surplus surface water that otherwise is released for flood control. In years when refill is not complete, Project pumping produces groundwater for use in Project areas in lieu of surface water deliveries that would otherwise be made from reservoirs. This allows an equivalent volume of water to remain in reservoir storage to recover from prior year project releases.

This mode of conjunctive operation, in which reservoir operation is used as the primary means to develop new water supply and groundwater is used infrequently as a backstop, is highly efficient because it reduces the frequency and volume of pumping as compared to traditional banking operations. Groundwater pumping is relied upon only as needed to maintain reservoir storage when refill from surplus winter flows is insufficient.

In some years, conditions in the Sacramento Valley may be so critically dry that Project pumping would be suspended altogether. For instance, if groundwater levels were already at levels of concern (according to county Basin Management Objectives or other standards), Project wells would be turned off and the Project would generate no new supplies under these conditions.

SECTION 6
Initial Project Site Identification

The project team completed a systematic, qualitative assessment of conditions within the Sacramento Valley to identify particular areas in which conjunctive operations appear promising. This process did not conclusively identify the very best or most feasible sites, but did identify particularly promising sites for conjunctive operations.

The team examined fall groundwater elevation maps, water district maps, and water source maps. Initially it was assumed that conjunctive management operations would follow groundwater banking type operations wherein water is stored in aquifers during years of above normal precipitation and extracted during years of below normal precipitation. These operations are typical in the San Joaquin Valley and other areas in which aquifers have been depleted and appreciable storage space exists. Following this initial assumption, the following two types of sites were identified:

- Areas in which existing groundwater levels may be lower than surrounding areas and overlying lands are supplied almost exclusively from groundwater. This type of site may provide the potential for storage of surplus surface water in underlying aquifers.
- Areas in which minimal groundwater pumping exists because overlying areas are supplied almost exclusively from surface water. This type of site may provide a potential area for groundwater extraction.

6.1 Initial Project Sites

An initial list of project sites was developed from a review of groundwater maps and knowledge of the Sacramento Valley. Sites were identified by the overlying water district, though projects did not strictly conform to water district boundaries. Information considered in this analysis included the location, water source, existing surface water contracts, infrastructure available and additional infrastructure necessary for delivery of surface water and extraction of groundwater, conceptual operations, and information on existing groundwater conditions. Table 6-3 summarizes this information for the nine initial sites.

6.2 Selection Criteria

The main goal was to identify at least one site that is served by the CVP (Shasta), one by the SWP (Oroville), and one by the Orland Project. The CVP and SWP are the principal surface water systems in the Sacramento River basin and their operations are linked to the Sacramento and Feather Rivers, respectively, both of which are targeted for environmental restoration. The Orland Project, although not among the largest surface water systems in the Valley, is an area where conjunctive operations have been viewed as a possibility for many years.

TABLE 6-1
Initial Project Sites and Parameters
Sacramento Valley Conjunctive Water Management Technical Investigation Modeling Report

Location	Water Source	Site Type	Annual Surface Water Contract	Project to Integrate With	Currently Integrated?
Butte Basin	Surface	Extraction	~ 300 TAF/yr	SWP	Yes
Orland-Artois WD	Mixed	Both	53 TAF/yr	CVP	Yes
Rancho Capay WD	Ground	Storage	None	CVP	No
Corning Canal Area	Mixed	Both	33 TAF/yr	CVP	Yes
Yolo-Zamora WD	Ground	Storage	None	CVP	No
Glenn-Colusa ID	Surface	Extraction	825 TAF/yr	CVP	Yes
Stony Creek Fan area	Surface	Extraction	~ 100 TAF/yr	Orland	No
Colusa County WD	Mixed	Both	68 TAF/yr	CVP	Yes
Olive Percy Davis Ranch	Surface	Extraction	32 TAF/yr	CVP	Yes

These nine sites were evaluated based on whether they could meet project objectives of providing additional water supply to meet agricultural and environmental objectives, an estimate of the volume of water that may be developed, and relative (compared to the other sites) ease and cost of integrating the project with existing surface water systems.

The following additional criteria were used to identify prospective sites:

- Availability of reliable surface water supplies that could be substituted with groundwater to enable conjunctive operations
- The presence of highly productive, underlying groundwater aquifers that could be economically developed
- The ability to locate and design production wells in a manner that would minimize effects on existing groundwater users and surface streams

6.3 Selected Project Sites and Operational Scenarios

Using the selection criteria described in Section 5.2, the Project identified two sites on which to conduct more refined analyses with surface and groundwater modeling tools. The GCID and Butte Basin Projects, supplied by the CVP and SWP, respectively, provided the potential to develop the largest quantity of water compared to other sites, and are already well integrated with the surface water system.

Additionally, the Stony Creek Fan and Orland Project was identified as a third potential project. However, upon further investigation into potential groundwater pumping capacities and the ability to integrate the project with the Sacramento River system, it was determined that this project would not be modeled during this phase of the project. This project is retained for additional analysis in future phases of investigation.

6.3.1 Glenn-Colusa Irrigation District Project

GCID is the largest, single Sacramento River diverter, serving about 141,000 acres of irrigated land and 20,000 acres of managed waterfowl habitat within its gross service area of 170,000 acres. GCID is served by the CVP (pursuant to underlying senior water rights) and is underlain by productive aquifers. There are about 200 existing private wells in GCID, but groundwater production in most years is small. Conjunctive management operations would utilize wells within GCID as a backstop for a more aggressive operation of Shasta Reservoir.

6.3.2 Butte Basin Project

The initial project site of Western Canal Water District was expanded to include neighboring Richvale Water District. These districts are all served by the SWP (pursuant to underlying senior water rights) and are adjacent to each other comprising a total irrigated area of roughly 110,000 acres. They are generally underlain by productive groundwater systems and there is limited existing use of groundwater. Conjunctive management operations would utilize wells within the two districts as a backstop for a more aggressive operation of Oroville Reservoir.

SECTION 7

Modeling Overview

Evaluating conjunctive management projects requires simulation of both surface water and groundwater systems. Simulating the surface water system is necessary to determine when water is available to refill reservoirs and estimate unmet agricultural demands, environmental objectives, and flow conditions. A groundwater model is necessary to estimate the effects of additional pumping on aquifer systems, including the spatial extent and magnitude of drawdown and potential change in stream-aquifer interaction. Changes in stream-aquifer interactions may affect the surface water system, depending on stream conditions when the changes occur. For example, if additional pumping results in more stream loss to the aquifer or less aquifer contribution to stream flow during the winter season of relatively wet years when the surface water system has surplus flow, there may be little or no impact. However, if pumping reduces stream flow during months and years when the surface water system is being operated to meet specific flow or water quality requirements, any reduction in stream flow will require a corresponding increase in reservoir release to ensure the flow requirement continues to be met. This decreases the water supply benefit of conjunctive management projects. Evaluating this aspect of conjunctive management projects requires interaction between surface water and groundwater models.

The main tool used to evaluate alternative conjunctive management operations strategies and test alternative environmental flow thresholds and priorities is a spreadsheet-based surface water model. It is set up to simulate changes in operation of Lake Shasta and Lake Oroville relative to conditions depicted in a baseline CalSim II simulation of CVP and SWP operations. The CalSim II baseline provides time series of reservoir storage levels, stream flows, and water deliveries which are used by the surface water model. Conjunctive management operations are simulated and layered onto baseline operations based on user inputs, while maintaining compliance with existing CVP and SWP rules, regulation, and operations.

The surface water model treats the groundwater system as a source of water and does not simulate groundwater flows or conditions. It does, however, include features to account for estimated effects of groundwater pumping on stream flow accretion and depletion through use of functions derived from complementary simulations of pumping in the groundwater model. These functions provided a coarse but adequate representation of stream-aquifer interaction so that the surface water model could be used for gaming sessions without having to operate the groundwater model. Final scenarios were evaluated using actual changes in stream-aquifer interaction based on complimentary groundwater model simulations.

Figure 7-1 illustrates inputs to the surface water model and resulting simulation of conjunctive management projects integrated into CVP and SWP operations.

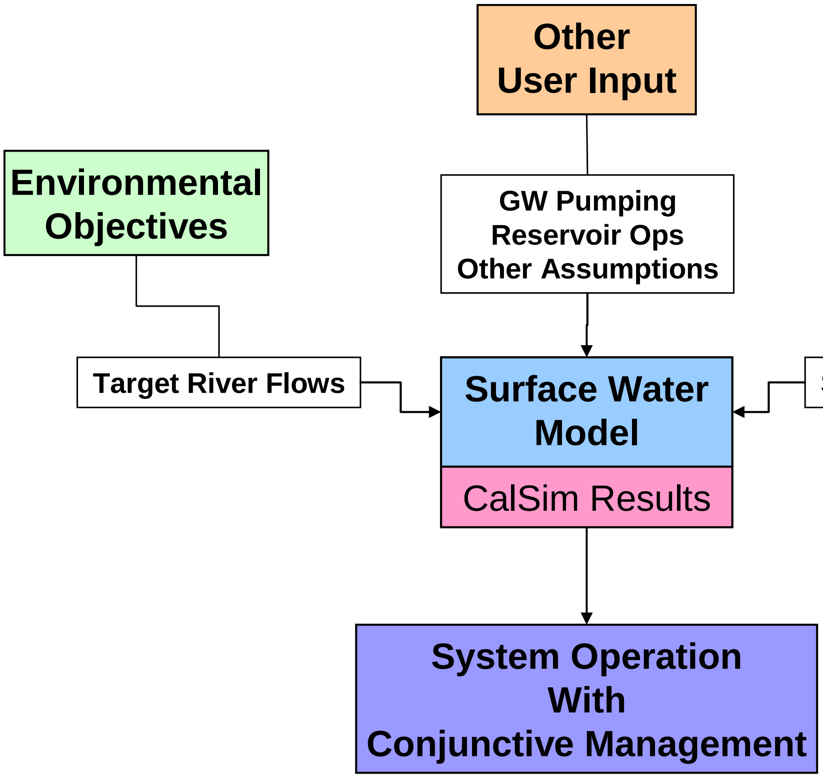

FIGURE 7-1
SURFACE WATER MODEL INPUTS AND OPERATIONS
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

Numerous improvements were made to previously existing modeling tools, and new tools were developed for this analysis of conjunctive management projects. For the groundwater analysis, an existing simplified groundwater modeling tool was completely re-designed and improved, to yield an extremely powerful analytical package now referred to as the Sacramento Valley Groundwater Model (SACFEM). The basis for the SACFEM model was a simplified superposition-based groundwater model previously developed to support the Sacramento Valley Water Management Program. That model represented a very simplified depiction of the Sacramento Valley aquifer system as no recharge components to the aquifer system (deep percolation of precipitation and applied water) or discharge components (regional agricultural pumping) were included, and therefore the model could only compute the incremental change in groundwater levels and streams flows during the irrigation season. It was assumed that the aquifer system fully re-filled every winter, and each year of pumping was independent of previous aquifer stresses.

The SACFEM model is a full water budget based transient groundwater flow model that incorporates all of the groundwater and surface water budget components on a monthly time step over the period of simulation. This model provides very high resolution estimates of groundwater level and streamflow effects due to conjunctive water management pumping across the valley.

The surface water model is a new tool designed specifically to analyze conjunctive management projects for agricultural and environmental benefits. Its flexibility for use in gaming sessions and for sensitivity and tradeoff analysis helped provide understanding of conjunctive management concepts, operations, and limitations.

The integration of surface water and groundwater modeling tools and the simulation of effects of additional groundwater pumping on the surface water system is a significant advancement over previous modeling tools. Simulation of changes in stream-aquifer interaction, the spatial and temporal variations in those changes, and conditions in the surface water system when changes occur are key components for evaluating conjunctive management projects and understanding their benefits and risks.

SECTION 8

Groundwater Model

MicroFEM© (Hemker, 1997), an integrated groundwater modeling package developed in The Netherlands, was chosen to simulate the groundwater flow systems in the Sacramento Valley Groundwater Basin. The current version of the program (3.60) has the ability to simulate up to 25 layers and 250,000 surface nodes. MicroFEM© is capable of modeling saturated, single-density groundwater flow in layered systems. Horizontal flow is assumed in each layer, as is vertical flow between adjacent layers.

MicroFEM© was the chosen modeling platform for both basins for the following reasons:

- The finite-element scheme allowed the construction of a model grids covering large geographic areas (over 5,955 square miles in the Sacramento Valley Groundwater Basin) with coarse node spacings outside of the simulated project areas and finer node spacings in areas of interest (e.g., near potential project areas). The finer node spacing near simulated production wells provides greater resolution of simulated groundwater levels and stream impacts.
- The graphical interface allows rapid assignment of aquifer parameters and allows proofing of these values by graphical means.
- The flexible post-processing tools allow for rapid evaluation of transient water budgets for model simulations and identification of changes to stream discharges and other water fluxes across the model domain.

8.1 Geologic Setting

The Sacramento Valley Groundwater Basin is a north-northwestern trending asymmetrical trough filled with as much as 10 miles of both marine and continental rocks and sediment (Page, 1986). On the eastern side, the basin overlies basement bedrock that rises relatively gently to form the Sierra Nevada, and on the western side, the underlying basement bedrock rises more steeply to form the Coast Ranges. Marine sandstone, shale, and conglomerate rocks that generally contain brackish or saline water overlie the basement bedrock. The more recent continental deposits, overlying the marine sediments, contain fresh water. These continental deposits are generally 2,000 to 3,000 feet thick (Page, 1986). The depth (below ground surface [bgs]) to the base of fresh water typically ranges from 1,000 to 3,000 feet (Bertoldi et al., 1991).

In the Sacramento Valley Groundwater Basin, groundwater users pump primarily from deeper continental deposits. Groundwater is recharged by deep percolation of applied surface water and rainfall, infiltration from streambeds, and lateral inflow along the basin boundaries. The quantity and timing of snowpack melt and precipitation events are the predominant factors affecting the surface water and groundwater hydrology, and peak runoff in the basin typically lags peak precipitation by 1 to 2 months (Bertoldi et al., 1991).

8.2 Hydrology

The Sacramento River is the main surface water feature in the Sacramento Valley Groundwater Basin. It has several major tributaries draining the Sierra Nevada, including the Feather, Yuba, and American Rivers. Stony, Cache, and Putah Creeks drain the Coast Range and are the main westside tributaries of the Sacramento River.

8.3 Model Construction

8.3.1 Spatial Grid

The SACFEM model grid consists of 88,922 nodes and 177,095 elements. Nodal spacing varies from as large as 5,800 feet (1,750 meters) near the model boundary and in areas with no water management projects to as small as 500 feet (150 meters) in areas where groundwater production is being investigated. Three zones of refined nodal spacing are located throughout the model domain in proximity to the areas that were previously identified as showing the greatest potential for successful conjunctive water management operations (NHI, 2007). These three areas are located in the west-central portion of GCID, the areas southwest of Chico encompassing the Western Canal and Richvale Water Districts, and the area east of Black Butte Lake on the Stony Creek Fan (see Figure 8-1).

The finer spacing in these areas of interest allows for a more refined estimate of the groundwater levels and groundwater-surface-water interaction in the potential project areas. The model boundary represents the extent of the freshwater aquifer in the Sacramento Valley.

8.3.2 Vertical Layering

The total model thickness represents the thickness of the freshwater aquifer (less than 3,000 micromhos per centimeter) as defined by Berkstresser (1973) and subsequently refined in the northern portion of the valley by the California Department of Water Resources (DWR) (2002). For the southern portion of the model area, defined by Berkstresser data, elevation contour lines of the base of fresh water, along with information from boring locations (point measurements of the elevation of the base of fresh water) were digitized and used to generate an x, y, z file containing the elevation of the base of fresh groundwater at regularly spaced intervals. For the northern portion of the model area, the locations of the geologic cross-sections were plotted, along with the estimated base of freshwater elevations obtained from the cross-section information, and a base of freshwater elevation contour map was constructed. These data sets were then merged to yield a single interpretation of the structural contour map of the base of freshwater across the Sacramento Valley. This map is presented on Figure 8-2.

Total Aquifer Thickness

To develop a total aquifer thickness distribution and, therefore, a total model thickness distribution, it was necessary to develop a groundwater elevation contour map and subtract the depth to the base of freshwater from the groundwater elevation contour map. The water level calibration targets for this groundwater modeling tool are the steady-state groundwater heads measured in calendar year 2000. Therefore, to develop a target groundwater elevation contour map, all available groundwater elevation measurements in the DWR Water Data Library were obtained from DWR central and northern district staff. These measurements were primarily collected biannually during spring and fall periods, and these values were averaged at each well location to compute an average water level at each well point. These values were then contoured, in conjunction with the streambed elevations for the 37 major streams included in the model, to develop a target groundwater elevation contour map for the year 2000. The distribution of the elevation of the base of freshwater was subtracted from this groundwater elevation contour map to yield an estimate of the distribution of the total aquifer thickness across the model domain.

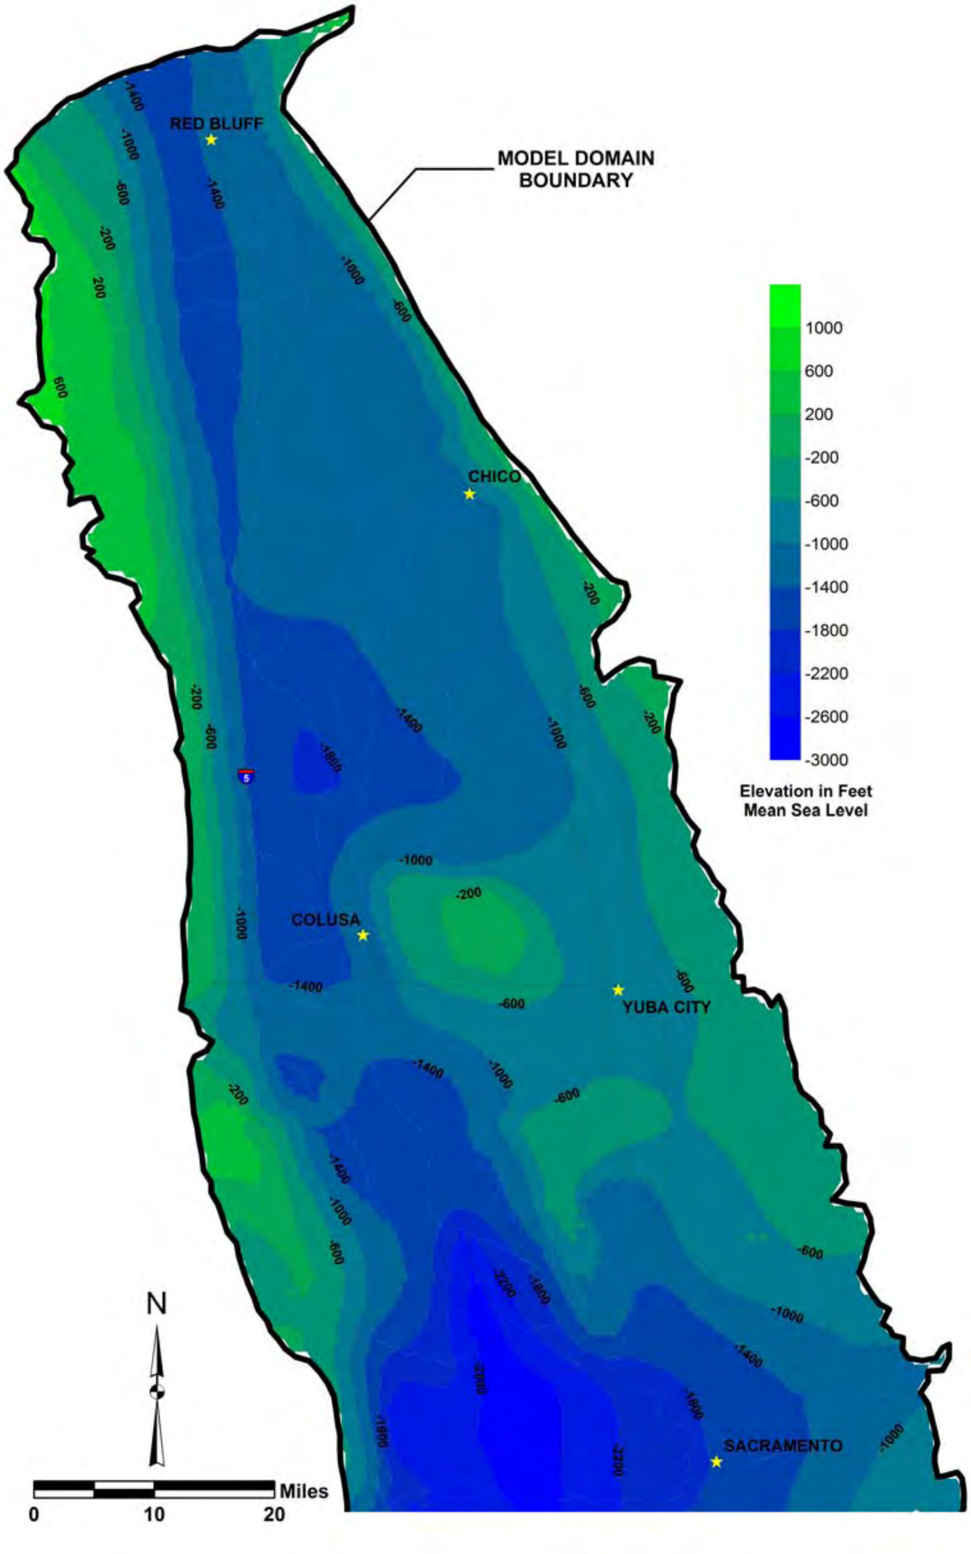

FIGURE 8-2
DEPTH TO FRESHWATER LOWER TUSCAN CONJUNCTIVE WATER MANAGEMENT INVESTIGATION
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

Model Layer Thickness

Because one of the primary objectives of this analysis was to investigate the potential to implement conjunctive water management projects within the lower Tuscan aquifer, the strategy used to layer the model was to assign two layers to explicitly represent this aquifer system: layers 6 and 7. Where the lower Tuscan is present, the elevation of the top of layer 6 was defined by the structural contour surface of the top of the lower Tuscan. Two layers were assigned to represent this unit because in many areas of the model, the depth to the base of freshwater (the base of the model) is as much as 900 feet below the upper surface of the lower Tuscan. Groundwater production wells drilled into the lower Tuscan would almost certainly be screened over a much smaller depth interval. To represent this condition in the model, layer 6 was assigned a thickness of between 200 and 250 feet, with the remaining lower Tuscan thickness assigned to layer 7. The exception to this convention is in the northeastern portion of the model near the City of Chico. The lower Tuscan outcrops in the foothills above Chico; therefore, in these areas, all layers of the model represent the lower Tuscan aquifer. Moving west from Chico, a transition zone exists where a decreasing number of layers represent the lower Tuscan until it is limited to layers 6 and 7. In areas where the lower Tuscan is not present, the thicknesses of layers 6 and 7 represent 18 and 27 percent of the total aquifer thickness, respectively.

Layers 1 through 5 represent shallower producing zones within the valley. The thicknesses of these layers were assigned based on a specified percentage of the available aquifer thickness at a given location, to provide multiple depth zones within which to assign regional pumping. The assumed layer thicknesses for layers 1 through 5 were also selected to reflect typical screened intervals of production wells in the Sacramento Valley. Layer 1 represents approximately 6 percent of the total aquifer thickness, except along certain portions of model perimeter where the total aquifer thickness became very small. In these areas, layer 1 thickness was increased to up to 24 percent of the total aquifer thickness to improve numerical stability of flow calculations. The thicknesses of layers two through four each represent approximately 10 percent of the total aquifer thickness, and the thickness of layer 5 represents approximately 15 percent of the total aquifer thickness.

8.3.3 Boundary Conditions.

A combination of no-flow, specified flux, and head-dependent boundary conditions were used to simulate the groundwater flow system within the Sacramento Valley.

Head-Dependent Boundaries.

Rivers. A head-dependent boundary condition was chosen to simulate the streams within the Sacramento Valley. The MicroFEM© wadi system was used to implement streams within the model domain. MicroFEM©'s wadi package calculates the magnitude and direction of nodal fluxes based on the relative values of the user specified stream stage (wh1) and the calculated head in the upper aquifer (h1), but is limited by a critical depth (wl1). When calculated groundwater elevations fall below this critical depth, it is assumed that the water table de-couples from the river system, and the leakage rate from the river to the aquifer becomes constant. The equations that govern operation of the wadi package are as follows:

Groundwater discharge to a stream is simulated if h1 >wh1:

$$Q_{inflow} = a * (h1 - wh1) / | wc1 | \quad (1)$$

In coupled streams (groundwater elevation is above the stream bottom elevation), groundwater recharge from a stream is simulated if h1 <wh1:

$$Qinflow = a * (wh1 - h1) / | wc1 | \quad (2)$$

In de-coupled streams (groundwater elevation is below the stream bottom elevation), groundwater recharge from a stream is simulated:

$$Qinflow = a * (wh1 - wl1) / | wc1 | \quad (3)$$

Where:

Q = volumetric flux

a = nodal area

h1 = simulated groundwater elevation in layer 1

wh1 = simulated stream stage

wl1 = stream bottom elevation

wc1 = resistance across the streambed

Nodal area is a grid-dependent parameter that can be automatically calculated within MicroFEM©. In general, the nodal area around a node that represents a discrete reach in a stream is greater than the surface area of that stream along the reach in the field. The effective resistance term (wc1) incorporates an areal correction factor to account for this discrepancy. Additionally, streambed resistance terms account for the relationship between the streambed sediments and aquifer properties in the upper half of model layer 1 when calculating stream seepage. River resistances are calculated as follows:

$$wc1 = ((Dr/Kr) +((0.5 * mt1)/Kv1))* (a/LW) \quad (4)$$

Where:

Dr = thickness of streambed sediments

Kr = vertical hydraulic conductivity of streambed sediments

mt1 = thickness of model layer 1

Kv1 = vertical hydraulic conductivity of model layer 1

L = stream length represented by the model node

W = field-width of the wetted river channel within the stream reach represented by L

Most major streams in the Sacramento Valley were included in the groundwater flow model. A total of 37 streams are represented. Stream locations and elevations were digitized from existing base maps and USGS topographic quad sheets and imported into the model domain. Stream length within a given node is a grid-dependent variable calculated by MicroFEM© at each river node. The stream-length term is generally overestimated by MicroFEM© at stream confluences. Manual corrections of this term were made where necessary. Streambed thickness was assumed to be 3.28 ft (1 meter) for all river nodes.

Assumptions of streambed Kv were based on the type of streambed deposits expected based on stream size. Wetted stream width was calculated from aerial photographs at two locations along each stream.

Drains. Drain boundary conditions were specified across the top surface of the model excluding nodes where wadi boundaries exist. Drain boundary conditions are head-dependent boundaries that allow the transfer of water out of the model domain only. The elevation of the drain boundaries were set at the land surface. The drain boundaries were included in the model to represent a combination of surficial processes that occur in areas of shallow groundwater including evapotranspiration and groundwater discharge to the surface.

Groundwater discharge to a drain is simulated if h1 >dh1:

$$Q_{outflow} = a * (h1 - dh1) / | dc1 | \text{ (where a = nodal area)} \tag{5}$$

Groundwater discharge to a drain if h1 <dh1:

$$Q_{outflow} = 0 \tag{6}$$

The parameter dc1 represents the drain conductance and is a measure of the resistance to flow across the drain boundary. The dc1 parameter is computed as:

$$dc1 = ((Td/Kd) \tag{7}$$

Where:

Td is the drain interface thickness and Kd is the hydraulic conductivity of the drain materials.

Specified Flux Boundaries. There are three sets of specified flux boundary conditions used in the SACFEM model. They represent the following three primary components of the agricultural water budget:

- Deep percolation of applied water and precipitation along with agricultural pumping
- Mountain front recharge
- Urban pumping

Deep Percolation of Applied Water and Precipitation and Agricultural Pumping. The first set reflects the deep percolation of precipitation and applied water across the valley, as well as the regional agricultural pumping. The deep percolation flux values were applied to every surface node in the model. The pumping stresses due to agricultural and urban pumping were applied at selected locations in model layers 2 through 4. These layers were selected as they represent the common depths of production wells within the valley. The spatial distribution and magnitudes of these fluxes were derived from the surface water budget calculations described in greater detail in the subsection titled Surface Water Budget.

Mountain Front Recharge. The second set of specified flux boundary conditions represent the subsurface inflow of precipitation falling within the Sacramento River Watershed but outside the extent of the model domain. To estimate these flux values, the USGS 10-meter Digital Elevation Model (DEM) along with existing hydrography geographic information system (GIS) coverages for the Sacramento Valley were used to delineate the drainage areas that are tributary to the model domain but fall outside of the rivers watersheds explicitly represented in the model. It is these areas that can contribute water to the model domain but are not accounted for in the wadi boundary conditions defined in the model. Once the areas of these watersheds were defined, they were intersected with (PRISM) rainfall data using GIS PRISM tools, and the volume of precipitation falling on the watershed computed. Based on the computed total volume of precipitation, the deep percolation to the groundwater system was calculated using the empirical relationship developed by Turner (1991).

$$DP = (PPT-2.32)*(PPT)^{0.66} \tag{8}$$

Where:

DP = Average annual deep percolation of precipitation (in/yr)
PPT = Annual precipitation (in/yr)

Following is a summary of the process that was used to estimate the quantity of subsurface inflow, otherwise known as mountain front recharge:

1. The area of each drainage basin tributary to the model domain that is not represented by streams explicitly simulated in SACFEM was computed using a GIS-based analysis of the land surface topography. The extent of these smaller watersheds is shown on Figure 8-3.
2. Each drainage area polygon was then intersected with a GIS coverage of annual average rainfall estimated using the PRISM model (reference). This distribution of annual average rainfall was then used to calculate the total volume of rainfall falling on the watershed, and an overall average rainfall rate computed (inches per year).
3. The average rainfall rate was then used to compute a deep percolation quantity using the relationship between annual rainfall and deep percolation rate developed by Turner (1991).
4. The annual volume of deep percolation computed in step 3 was then converted into monthly values based on the monthly distribution of stream flow measured in unregulated sections of Deer Creek. These monthly deep percolation quantities were then introduced at the model domain boundary of each small watershed polygon using injection wells into layer 1. The quantity applied to each model boundary node was proportional to boundary length of each element versus to the total boundary length of the drainage polygon.

Urban Pumping. The final set of specified flux boundary conditions reflect urban pumping within the model domain. The distribution of agricultural pumping developed using the surface water budgeting methodologies described in the Surface Water Budget subsection do not include urban pumping. To estimate the quantity of urban pumping to apply to the model the year 2000 census data were used. Each municipal area with a population greater than 5,000, that uses groundwater as a source of municipal supply, was assigned a pumping volume based on an annual average per capita value of 250 gallons per capita per day. The urban pumping assigned to the Chico area as well as several northern Sacramento County municipal areas required a higher per capita rate to match the observed groundwater elevations in those areas. The monthly variability in urban pumping quantity was distributed based on typical seasonal trends for municipal water use.

SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION
MODELING REPORT

No-Flow Boundaries. A no-flow boundary was specified across the bottom boundary of the model, representing the freshwater/brackish water interface.

8.3.4 Surface Water Budget

One of the most critical components to the successful operation of the SACFEM model is computation of transient surface water budget components. These water budget components were estimated based on a variety of spatial information including land use, cropping patterns, source of irrigation water, surface water availability in different year types and locations, and the spatial distribution of precipitation. Surface water budget components included in the model are deep percolation of applied water, deep percolation of precipitation, and agricultural pumping.

Surface water budgets were developed by intersecting existing GIS data developed by DWR with the groundwater model grid to develop land use for each groundwater model node. Additionally, GIS data on water districts and surrounding areas were used to identify district and non-district areas. The resulting intersection provided land use, water district, and water source information for each of the approximately 89,000 groundwater model nodes.

A semiphysically based soil moisture accounting model and historical precipitation data were used to simulate the root zone and calculate applied water demand and deep percolation past the root zone for each node. Calculated deep percolation was split between applied water and precipitation based on the season and the availability of water from each source.

Calculated values for deep percolation were compared to estimated values prepared by DWR’s Northern District for the year 2000. Northern District staff calculated detail water budgets in 2000 that included some of the best available estimates of regional deep percolation. In some areas soil parameters in the root zone model were adjusted to provide similar volumes of deep percolation. However, considerable uncertainty still exists in any estimate of regional deep percolation because soil conditions vary widely and it is not possible to measure deep percolation on a regional basis.

The total demand for applied water was used in conjunction with the water source and water district attributes from the GIS intersection to estimate agricultural groundwater pumping. Some areas are supplied solely from groundwater and calculated total applied water demand represents groundwater pumping. Other areas are supplied by a mix of groundwater and surface water. For these areas, estimates of the availability of surface water each year were made to determine the fraction of applied water demand met from surface and groundwater. In these areas, additional information on the overlying water district was combined with district water rights and contracts to estimate available surface water. For example, districts within the Tehama Colusa Canal Authority have water contracts with the Bureau of Reclamation (Reclamation) that receive different allocations each year. An estimate of those allocations from an existing level of development simulation of CVP operations was used to calculate the availability of surface water for groundwater model elements within those districts. Any remaining applied water demand, after consideration of available surface water, is assumed to be met from groundwater pumping.

Annual values of calculated agricultural pumping for the Sacramento Valley were reviewed and compared well to the generally accepted estimate of approximately 2.5 million acre-feet (DWR, 2005).

8.3.5 Aquifer Properties

The distribution of aquifer properties across the Sacramento Valley is poorly understood. In certain areas with significant levels of groundwater production, the collection of aquifer test data, and the measurement of historic groundwater level trends in response to known groundwater production rates have provided valuable information on aquifer properties. However in the majority of the valley, these data are not available.

To estimate the spatial distribution of aquifer properties across the model domain for this numerical modeling effort, a database of well productivity information was used. In consultation with DWR staff, a database was obtained that included all of the specific capacity yield data that were available from well log records. These data were compiled along with well construction information for each production well to yield a representative data set of well productivity across the valley. Wells that did not have available construction data were omitted from further consideration. To protect owner privacy, the exact location of each well was modified by DWR staff to reflect the center of the section in which each well was located. This modification in well location did not adversely affect the use of the data to estimate the spatial distribution of aquifer properties, given the extremely large area encompassed by the model domain. The total number of wells in the database within the model domain used in this analysis was approximately 1,000 wells.

The intent of the modeling analysis described herein is to simulate the operation of high-productivity irrigation wells screened within the major producing zones in the valley to support conjunctive water management projects. Therefore, the aquifer properties that are of primary interest are those of the major aquifer zones tapped by large-diameter irrigation wells. The well database described above was filtered to remove data obtained from tests on low yield and/or shallow domestic type wells. All test data from wells that reported a well yield below 100 gallons per minute (gpm) were eliminated from consideration as was the test data from wells with a total depth of less than 100 feet. The only exception to this second consideration was for wells that were located along the basin margins, where aquifers are thin, that reported what appeared to be valid test results. Data from these wells was considered as they were often the only data available in the basin margin areas.

Once the data set for consideration was finalized, the reported specific capacity data for each well was used to estimate an aquifer transmissivity for that location. The relationship used to estimate aquifer transmissivity was the following form of a simplified version of the Jacob non-equilibrium equation:

$$Sc = T/2000 \qquad (9)$$

Where:

Sc = specific capacity of an operating production well (gpm per foot of drawdown)
T = aquifer transmissivity (gallon per day [gpd] per foot)

After a transmissivity estimate was computed for each location, the transmissivity value was divided by the screen length of the production well to yield an estimate of the aquifer hydraulic conductivity. The final step in the process was to smooth the hydraulic conductivity field to provide regional scale information. Individual well tests produce aquifer productivity estimates that are local in nature, and may reflect small scale aquifer heterogeneity that is not necessarily representative of the basin as a whole. To average these smaller scale variations present in the data set, a FORTRAN program was developed that evaluated each independent hydraulic conductivity estimate in terms of the available surrounding estimates. When this program is executed, each K value was considered in conjunction will all other K values present within a user-specified radius, and the geometric mean of the available K values calculated. This geometric mean value is then assigned as the representative regional K value for that location. The radius used in this analysis was 10,000 meters, or approximately 6 miles. The point values obtained by this process were then kriged to develop a hydraulic conductivity distribution across the model domain. The aquifer transmissivity at each model node within each model layer was then computed at the geometric mean K values at that node times the thickness of the model layer. Insufficient data were available to attempt to subdivide the data set into depth varying K distributions and it was therefore assumed that the computed mean K values were representative of the major aquifer units in all model layers. Effectively this approach averages the aquifer K values at a given location. In reality, there is certainly vertical heterogeneity present in the Sacramento Valley aquifer system. However any inaccuracies in the assumed vertical distribution of K values will result primarily in local scale errors in computed vertical gradients. In the extremely heterogeneous aquifer system of the Sacramento Valley, it is the distribution of total aquifer transmissivity, along with the imposed water budget boundary conditions, that determine the regional distribution of hydraulic head. The efficacy of this approach at replicating the observed transient water level fluctuations across the valley will be demonstrated in the calibration section discussion below. The final distribution of hydraulic conductivity used in the SACFEM model is shown on Figure 8-4.

Model Calibration

Calibration Approach. The calibration approach used to develop the modeling tool described herein was significantly influenced by the resources available to fund the project. While a fully transient calibration approach, wherein the model is used to replicate groundwater levels and flow conditions throughout some period of record would be the more desirable approach, the resources were not available to fund such an effort. Instead, a more limited steady-state calibration approach was implemented. In a steady-state calibration process, the monthly water budget components for a selected period are averaged, and the model is calibrated to both average groundwater levels and stream discharges that occur during the calibration period. The calibration period selected for this effort was calendar year 2000. Calendar year 2000 was selected because it is the most recent year where water budget information is available that was characterized by average hydrologic conditions. A calendar year instead of a water year was used to facilitate the development of average groundwater elevation calibration targets. The available water-level data were obtained from DWR, and much of that data are collected in the spring and the fall. If a water year was used, the cut-off between water years is the end of September, which coincides with the mid-point of the fall sampling event. The result would be that when average groundwater elevation values were calculated, some of the measurements would be from October of the previous year and some would be from September of the subsequent year, which would introduce error in the data set, especially if the year types were different. The use of a calendar year eliminates this potential for error.

While a rigorous transient calibration was not possible as part of this effort, because the model was being used to simulated transient operation of conjunctive water management projects, simulated transient groundwater elevations were compared to observed groundwater elevation hydrographs from a collection of monitoring wells located throughout the model domain. The period of record over which the transient analysis was performed was water years 1982 through 2003. Therefore, simulated and observed transient groundwater elevations were compared over this period as well.

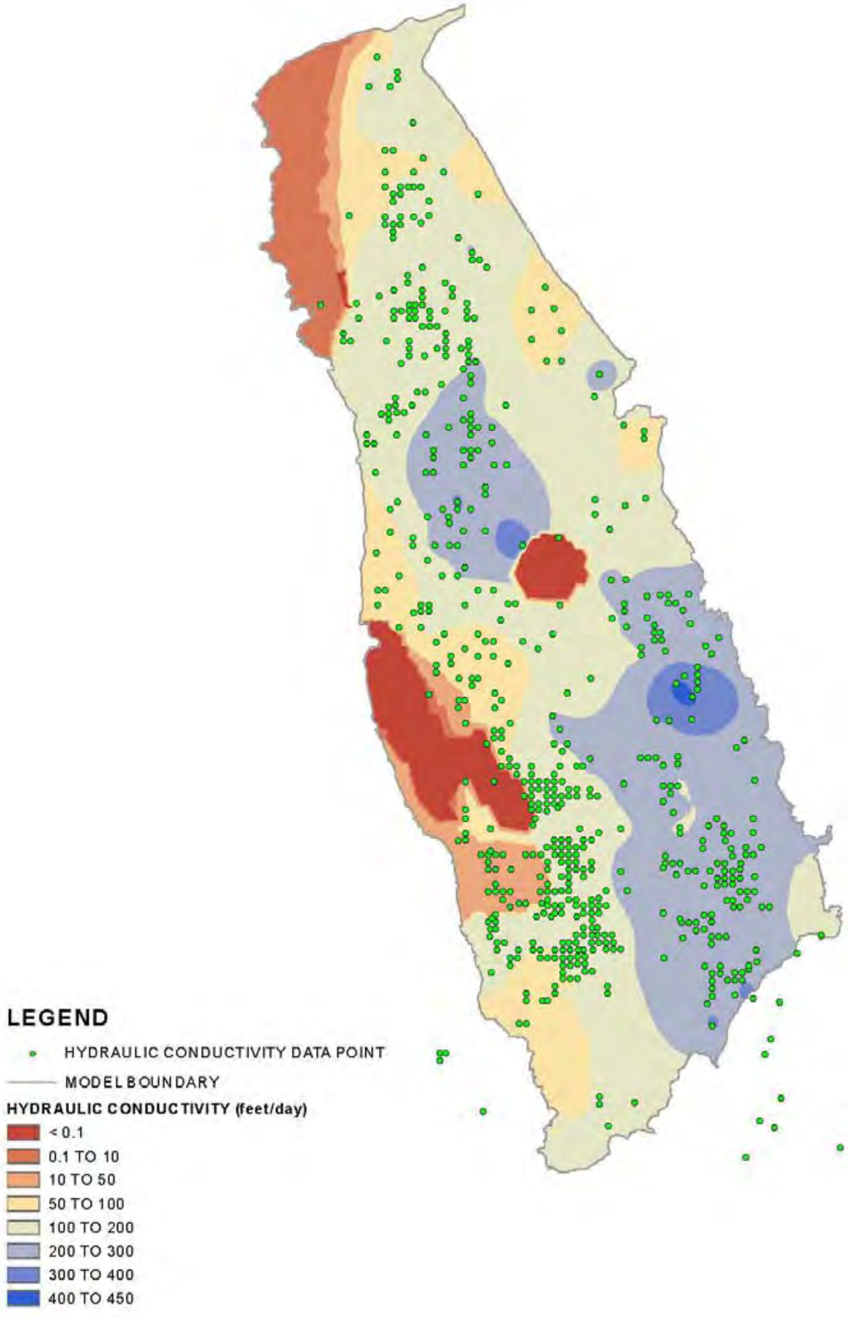

FIGURE 8-4
SACFEM HYDRAULIC CONDUCTIVITY DISTRIBUTION
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL
INVESTIGATION MODELING REPORT

Steady-State Calibration Targets. Several quantitative and qualitative calibration targets were used in the calibration process. These calibration targets are as follows:

- Average year 2000 groundwater elevations (257 wells used as calibration targets)
- Areas of gaining and losing streams (approximate)
- Approximate water budget quantities (order of magnitude comparison as no accurate estimates are available)
- Approximate calibration to transient groundwater levels measured between water years 1982 and 2003

Water Budget Modification. During the calibration process, it was anticipated that some adjustment to the water budget components computed using the previously described methodology would be necessary to obtain an acceptable degree of calibration. A water budget analysis performed on the raw input data provided by the root zone model, combined with simulated groundwater heads from model runs using that deep percolation data, suggested that the prescribed deep percolation rates in the northern (Red Bluff) and southern (Davis/Woodland) areas were too high. Deep percolation rates were reduced in these areas, resulting in a significant improvement in calibration residuals. To run the model is a transient mode, it was also necessary to make similar adjustments to the prescribed transient monthly deep percolation rates obtained from the root zone model. This was accomplished by computing the percent reduction in deep percolation that was required at each model node to obtain an acceptable steady-state calibration. It was then assumed that these same nodal reduction percentages were applicable to the monthly deep percolation estimates throughout the transient simulation period. While no rigorous transient calibration was performed, simulated groundwater levels over the 1982 though 2003 transient simulation period were compared to hydrographs of observed data at several locations across the model domain.

Steady-State Calibration to Year 2000 Groundwater Elevations. A graphical measure of the state of calibration is to develop a scattergram that plots the simulated versus the measured groundwater elevation at each target calibration well. A plot of this type is shown on Figure 8-5. A perfect fit between simulated and observed groundwater elevations would plot as a 45 degree line (slope = +1.0, Y-intercept=0). As can be seen on Figure 8-5, the simulated heads generated by the SACFEM model show good agreement between simulated and observed groundwater levels. This implies that the model is providing accurate estimates of the steady state groundwater elevations and flow directions that exist in the vicinity of the potential project sites evaluated under this conjunctive water management evaluation program.

Another quantitative measure of calibration that is commonly used is to calculate the root mean square error (RMS) divided by the range of observations. As a rule of thumb, a well calibrated regional model will have an RMS/range of less than 10 percent, and a well calibrated local scale mode will have an RMS/range of less than 5 percent. The RMS/range of the steady state calibration presented here is 4.6 percent, well below the 10 percent criterion.

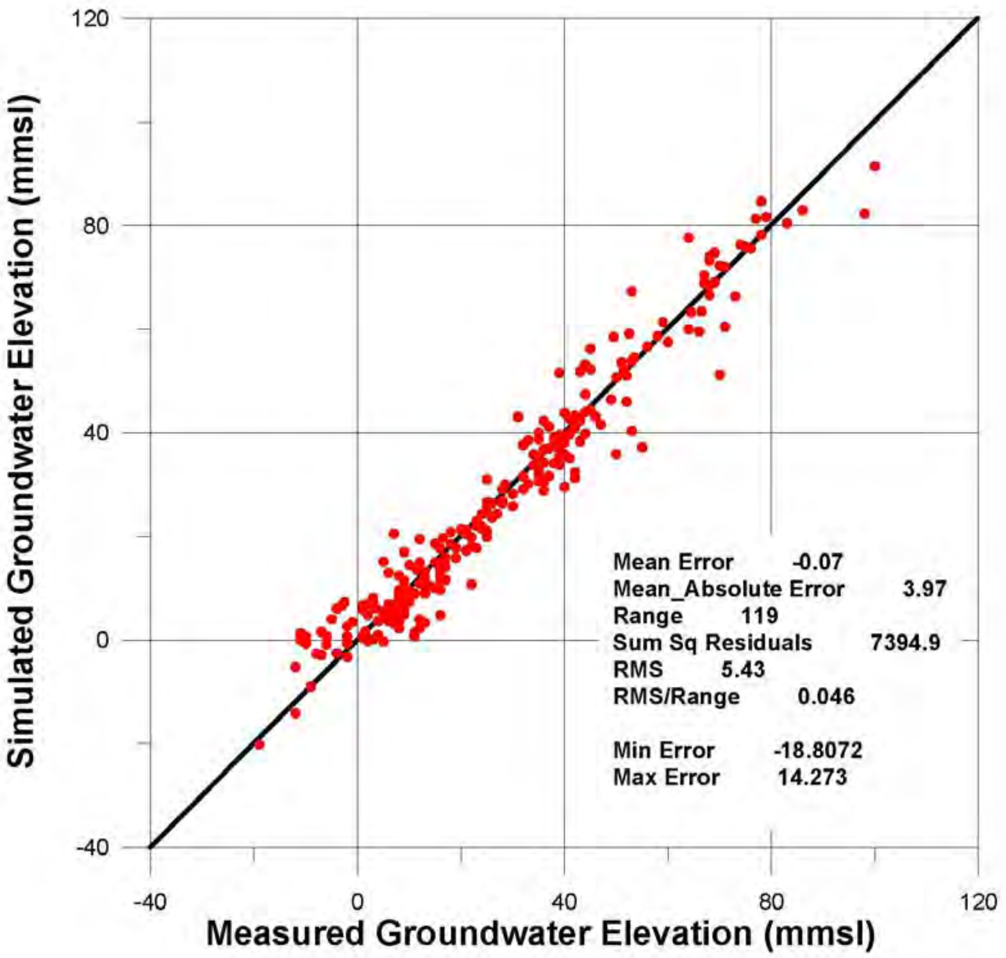

FIGURE 8-5
SACFEM CALIBRATION SCATTERGRAM
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

Calibrations to Gaining and Losing Stream Segments. In the Sacramento Valley, a further qualitative calibration target is the identification of stream segments that are gaining flow through groundwater discharge versus losing flow to groundwater recharge. While the exact distribution of stream reaches that gain or lose flow due to surface water/ groundwater interaction are not fully delineated, and this relationship changes over time with fluctuating groundwater levels and stream stages, a general pattern can be observed. The major trunk streams such as the Sacramento, Feather, and American Rivers tend to gain flow, especially in their lower reaches, while the smaller upper tributaries near the basin margin tend to lose flow to the groundwater system. The stream reaches predicted by the model to gain or lose flow to the groundwater aquifer are shown on Figure 8-6. The pattern predicted by the calibrated groundwater flow model is reasonably consistent with the generally accepted pattern described above. The distribution shown on Figure 8-6 should be considered an average condition with greater stream lengths gaining groundwater during wet periods with higher groundwater levels and greater stream lengths losing water to the aquifer system during dry periods with lower groundwater levels.

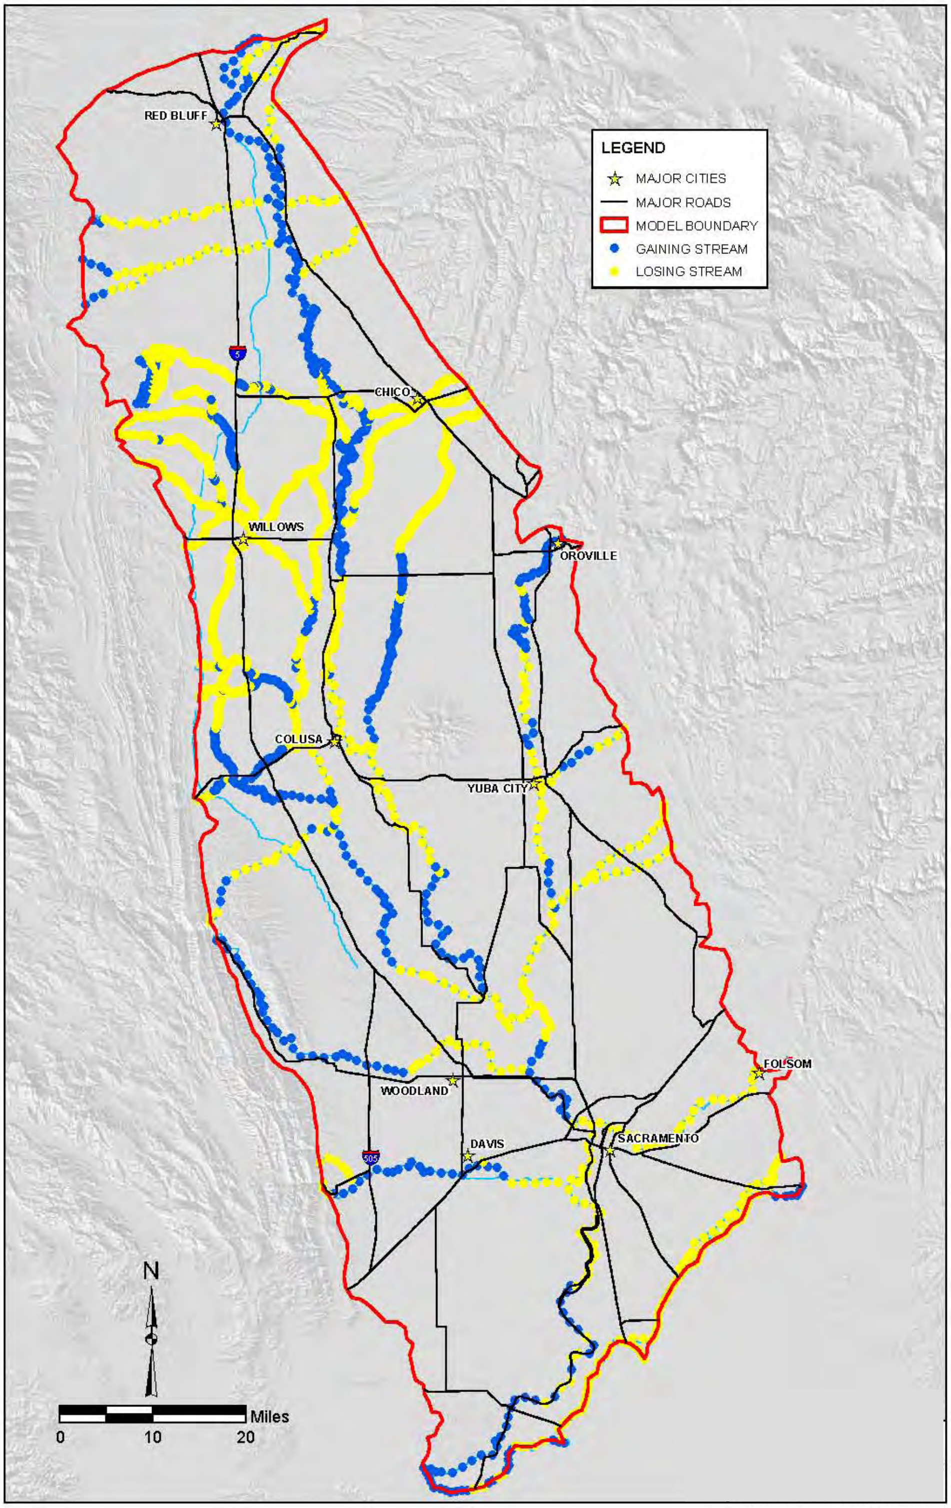

FIGURE 8-6
SIMULATED GAINING AND LOSING STREAM REACHES
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

Calibration to Steady-State Water Budget. The magnitude of the water budget components derived from the steady-state calibration run are summarized in Table 8-1. While exact comparative estimates are not available for most of these components, rough estimates are available. For example, the 2000 calibration simulation estimates a combined 2.5 million acre-feet (ac-ft) of groundwater pumping within the model domain, which agrees reasonably well with the generally accepted value of between 2.5 million and 3 million ac-ft of groundwater withdrawal in an average year. Similarly, while no independent estimates of the quantity of groundwater that discharges to the Sacramento River are available, the average simulated value of 975 cubic feet per second (cfs), which represents approximately 2 to 4 percent of mean annual flow measured at the Freeport gauge, seems reasonable.

TABLE 8-1
Average Annual or Year 2000 SACFEM Water Budget Summary
Sacramento Valley Conjunctive Water Management Technical Investigation Modeling Report

	ac-ft	cfs
Recharge		
Deep Percolation of Precipitation	1,398,461	1,932
Deep Percolation of Applied Water	865,131	1,195
Mountain Front Recharge	495,507	684
Seepage from Streams to Groundwater	816,848	1,128
Total Recharge	3,575,947	4,939
Discharge		
Agricultural Pumping	2,417,506	3,339
Urban Pumping	451,507	624
Groundwater Discharge to Streams	705,999	975
Total Discharge	3,575,012	4,938

Preliminary Transient Calibration. While the SACFEM model has not undergone a rigorous transient calibration, a comparison of simulated and observed groundwater elevations from Water Year 1982 through 2003 was performed to assess the performance of the model at simulating historic groundwater elevation trends. This step was necessary because the SACFEM model is being used to forecast the performance of various conjunctive water management projects during the 1982 through 2003 period, and it was necessary to determine the accuracy of the model at replicating the transient groundwater elevations that occurred over that period. The ability of the model to match observed transient heads is also an indication of the accuracy of the assumed transient water budget components being used in the model. The period 1982 though 2003 was used because it includes wet periods, such as the winter of 1983, and dry periods, such as the 1988 through 1992 drought. Using a climatic period of this type allows assessment of the effects of highly variable climatic conditions on conjunctive water management project operations and subsequent effects on groundwater levels and stream flows.

The accuracy of the model running in transient mode was assessed using two different methods. The first was to evaluate the ability of the SACFEM model to replicate the results of the final steady-state calibration run within a longer transient simulation. This was done by running the transient model using a monthly time step from water year 1982 though 2003, retrieving the simulated monthly head values for calendar year 2000, and averaging them to obtain a data set that should theoretically match the steady-state calibration data. The comparison of the simulated calendar year 2000 steady-state heads with the head values obtained by averaging the simulated monthly head values obtained from the transient simulation over the same period is shown on Figure 8-7. It is clear from this figure that the average calendar year 2000 heads computed from the results of the transient simulation almost exactly match the simulated steady-state heads obtained from the final calibration run. This suggests that after running the SACFEM model for 19 years (1982 though 2000) using estimates of the historic transient monthly water budget stresses, the model is still capable of providing a very accurate calibration to the year 2000 conditions.

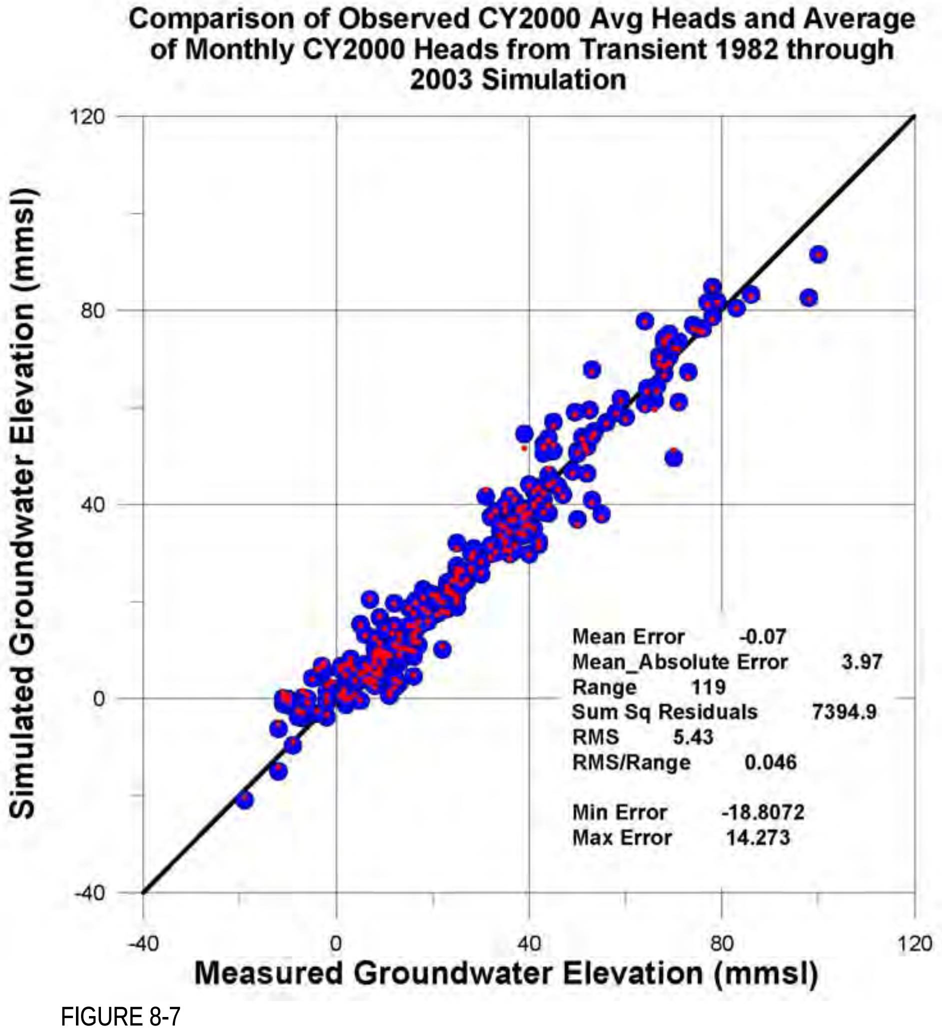

FIGURE 8-7
REPLICATION OF STEADY-STATE CALIBRATION HEADS WITHIN A 23 YEAR TRANSIENT SIMULATION
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

The second method used to assess the accuracy of the SACFEM model of simulating transient groundwater elevations was to compare simulated monthly groundwater elevations with measured groundwater elevations in monitoring wells over this same 1982 though 2003 period. These comparisons are shown on Figures 8-8 through 8-15. These results suggest that in most cases, the model provides a fairly accurate depiction of transient groundwater elevations throughout the time period evaluated. Several of the hydrographs show differences between the simulated and measured heads, but in each case the trends of both data sets are similar but displaced by several feet. It is likely that small adjustments in water budget fluxes or aquifer properties in those areas will improve agreement.

SECTION 9

Surface Water Model

Effective analysis of conjunctive management projects and operations requires simulation of both the surface and groundwater systems. As described above, conjunctive management operations for this project are closely related to surface reservoir operations and conditions throughout the CVP and SWP. Therefore a surface water model that includes CVP and SWP reservoir operations and conditions was developed to evaluate conjunctive management projects.

9.1 Modeling Approach

The best tool currently available for planning level analyses of the CVP/SWP system is the CalSim II model, developed jointly by DWR and Reclamation. CalSim II is a planning model designed to simulate operations of CVP and SWP reservoirs and water delivery system, flood control operating criteria, water delivery policies, instream flow and Delta outflow requirements, and hydroelectric power generation operations. CalSim II is the main systemwide hydrologic model being used by DWR and Reclamation to conduct planning and impact analyses of potential projects.

CalSim II is a simulation by optimization model. The model simulates operations by solving a mixed-integer linear program to maximize an objective function for each month of the simulation. CalSim II was developed to simulate the operation of the CVP and SWP for defined physical conditions and a set of regulatory requirements. The model presently simulates these conditions using 82 years of historical hydrology from water year 1922 through 2003. CalSim II simulates regulatory conditions specified in State Water Resources Control Board (SWRCB) Decision 1641 (D-1641); the Central Valley Project Improvement Act b(2), including non-discretionary and discretionary actions; and limited water transfer operations.

CalSim II is a complex optimization model that can give surprising, unintended results when used to simulate complex operations. Additionally, runtimes for CalSim II models are typically several hours, making it inappropriate for use in gaming sessions and for rapid evaluation of many different scenarios.

The approach used for this project is to rely on CalSim II to depict CVP/SWP operations and system conditions and then model incremental changes in CVP/SWP operations that reflect possible conjunctive management projects. The result of this approach is a surface water model of the CVP/SWP system that layers conjunctive management operations for use in gaming sessions to quickly investigate numerous scenarios and operations, and can be used to test sensitivities and tradeoffs associated with certain key assumptions. The surface water model was designed to be easily adapted for use with various CalSim II simulations.

9.2 System Baseline Assumptions

A CalSim II simulation of the existing level of development (approximately 2004), regulatory conditions, and resulting operation of the CVP and SWP is the basis for surface water modeling. This simulation was developed by the Common Assumptions Project to provide a generally accepted model baseline for use in CALFED surface storage investigations. Key assumptions for the baseline CalSim II simulation are provided in Appendix A.

The existing level of development was used, as opposed to a future level of development, because of the need for consistency in land use data used in the surface water groundwater models. Existing level of development GIS land use data were used in the development of the surface water budgets for the groundwater model. Existing level of development information is also less speculative as to how land use may change in the coming decades. Simulation of a future level of development would require assumptions on future land use and the spatial distribution of that land use throughout the Sacramento Valley.

9.2.1 Surface Water Model Operations

The surface water model simulates operations of conjunctive management projects and their interaction with CVP and SWP reservoirs to meet project objectives (satisfying presently unmet agricultural water demands and targeted environmental flows and durations) based on results of a CalSim II simulation of existing system operations. The following sections define and describe individual aspects of model operation. This section concludes with a description of how the individual pieces interact to simulate system operations with conjunctive management.

9.2.2 Environmental Objectives

The surface water model simulates conjunctive management operations to increase water supply within the Sacramento Valley. The additional water supply can be used to meet a combination of agricultural water demands and environmental flow objectives. Environmental flow objectives were developed by National Heritage Institute staff and documented in *Developing Ecologically Based Flow Targets for the Sacramento and Feather Rivers* (Cain and Monohan, 2008). Different flow objectives were developed for the Sacramento and Feather Rivers.

All flow objectives are simulated as all-or-nothing thresholds, meaning the model will release water to meet the flow objective only if the full target flow can be sustained for the specified duration. As discussed in the NHI report, environmental objectives are based on the magnitude and duration of flows required to replicate certain ecological and geomorphic processes.

Environmental objectives are specified and prioritized by water year type. The Sacramento River Water Year Type Index (Sacramento River Index), sometime referred to as the 40-30-30 Index, is used to classify each year as either wet, above normal, below normal, dry, or critical.

Geomorphic

Geomorphic releases are short-duration, high-flow events for the purpose of sediment transport, channel migration, and flood plain processes, such as inundation and fine sediment transport. Geomorphic releases are targeted from March through April and are only required to last several hours. The surface water model simulates geomorphic events lasting one day due to the ramping requirements when making these large releases from reservoirs. Table 9-1 presents geomorphic flow objectives for Sacramento and Feather Rivers.

TABLE 9-1
Geomorphic Flow Objectives for Sacramento and Feather Rivers
Sacramento Valley Conjunctive Water Management Technical Investigation Modeling Report

Sacramento River Index	Sacramento River (cfs)	Feather River (cfs)
Wet	105,000	50,000
Above Normal	85,000	35,000
Below Normal	65,000	20,000
Dry	35,000	10,000

No objective specified in critical year types.

Riparian Establishment

The purpose of riparian establishment flows is to recruit and grow cottonwoods in the riparian areas along the rivers. Riparian establishment flows are designed to assist in several phases of early cottonwood growth including seedbed preparation, seed germination, and seedling growth. These flows also create periodic large-scale disturbances of the riparian zone. Riparian establishment objectives (see Figure 9-1) are specified for the period of mid-April through mid-June to coincide with the cottonwood reproductive cycle. Riparian recruitment flows are large-magnitude flows for extended periods of time and are typically only possible during years of above average runoff. Therefore these objectives are only specified in years classified as wet or above normal by the Sacramento River Index.

Figure 9-1 illustrates the shape of the of riparian establishment objectives. The objective begins with a high-flow event held for a period of 5 days followed by a 60-day recession limb when the target each day is 5 percent less than the previous day’s target. Table 9-2 summarizes the objectives for both the Sacramento and Feather Rivers.

Spring Pulse

Spring pulse flows are designed to simulate a portion of the historic unimpaired runoff of the river to help create suitable flow conditions and temperatures for Chinook salmon migration. These flows also are designed to help maintain and recruit spawning habitat and avoid scour when eggs are in redds. Spring pulse flow targets are specified in all but critical year types, though the magnitude and duration of the target is reduced in years with less runoff. Tables 9-3 and 9-4 summarize the spring pulse objectives.

Flood Plain Inundation

Inundation of the Sutter and Yolo Flood Bypass channels is another environmental objective. It is assumed for this study that the weirs that currently block flow into the bypasses below certain river stages can be modified to allow inundation at lower river stages and flows. Inundation of the flood bypasses provides rearing habitat for juvenile salmonids. These inundation flows are targeted to correspond with outmigration of salmonids in the spring months and designed to last for 45 days. Flood plain inundation flows can be set for one of three different time-periods in the surface water model: February 15 to March 30, March 1 to April 15, or March 15 to April 30. Table 9-5 presents flood inundation objectives for Sacramento and Feather Rivers.

Note: No objective specified in critical year types

Cold Water Pool Management

The surface water model includes an environmental objective of increasing the flexibility of cold water pool management. This objective increases cold water pool volume in subsequent years by reducing summer reservoir releases (thereby increasing storage) in the current year by the volume of groundwater being pumped. This volume of water is then held in the reservoir through the winter and can increase cold water pool in following years. This operation occurs in years when fall reservoir storage is forecasted to be low. Low fall storage levels reduce the chance that any water stored will spill during the subsequent winter. However, operators may not be able to reduce summer releases in these years and still meet temperature control criteria in the current year. For example, summer releases from Lake Shasta in 2008 were typically controlled by temperature control criteria, not downstream irrigation demands. Therefore, it would not have been possible to offset reservoir releases with groundwater pumping. The surface water model is able to show the times and volumes of water potentially available to meet the cold water pool management objective, but a more thorough analysis with temperature models is needed to further evaluate the feasibility of this operation.

9.2.3 Agricultural Water Supply Objectives

The surface water model simulates the unmet agricultural demand within the Sacramento Valley based on hydrology, the underlying CalSim II simulation of CVP and SWP operations, and user input. Unmet agricultural demands are estimated to provide an understanding of the ability of conjunctive management to increase Sacramento Valley water supplies. Unmet agricultural demands are simulated differently for the Sacramento and the Feather River systems.

Sacramento River

Unmet demands of CVP contractors within the Tehama-Colusa Canal Authority (TCCA) are used to represent additional demands on the Sacramento River. Members of the TCCA, including contractors supplied from the Corning Canal, hold agricultural service contracts for approximately 320 TAF of contract supply from the CVP. Annual allocations to CVP contractors are simulated in CalSim II based on forecasted reservoir inflows, reservoir storage conditions, and the ability to deliver water. Simulated allocations range from 0 to 100 percent of full contract supply. When simulated allocations are less than 100 percent, it is assumed that the difference between simulated allocations and full contract supply is an unmet agricultural demand within the TCCA.

Figure 9-2 illustrates the annual unmet agricultural demand as a function of simulated allocations to the TCCA for each year of the study.

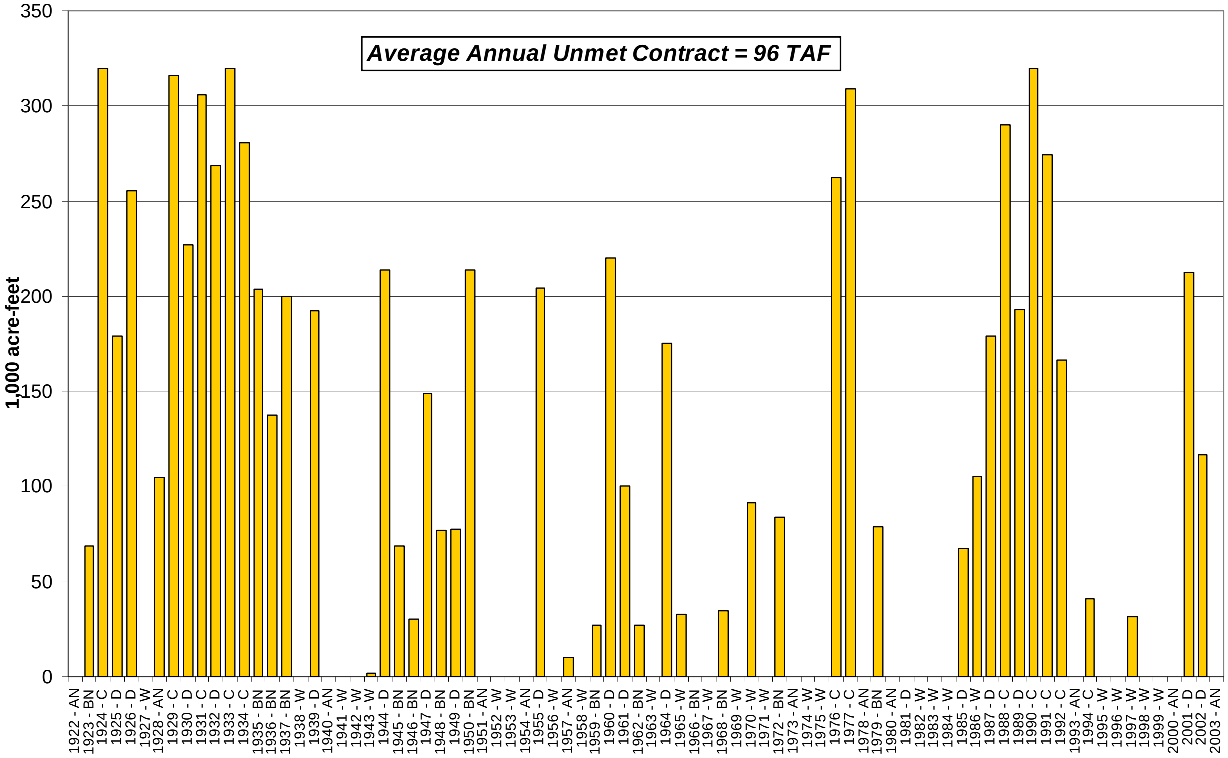

FIGURE 9-2
UNMET AGRICULTURAL DEMAND WITHIN TCCA
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION
MODELING REPORT

The annual unmet demand illustrated above is assumed to occur on a typical agricultural demand pattern during the irrigation season. The gaming model simulates conjunctive management operations and attempts to meet all or a portion of this demand when it occurs from reservoir release of project assets.

Feather River

The majority of SWP contractors on the Feather River system have reliable water supplies with the exception of a few small contractors. There are no existing SWP contractors with large, frequently unmet agricultural demands in the Butte Basin. Therefore a more general unmet agricultural demand is defined for the Feather River based on user input. Table 9-6 summarizes the assumed unmet agricultural demand that can be met from Feather River supplies in the surface water model.

TABLE 9-6
Assumed Unmet Agricultural Demand within the Feather River System
Sacramento Valley Conjunctive Water Management Technical Investigation Modeling Report

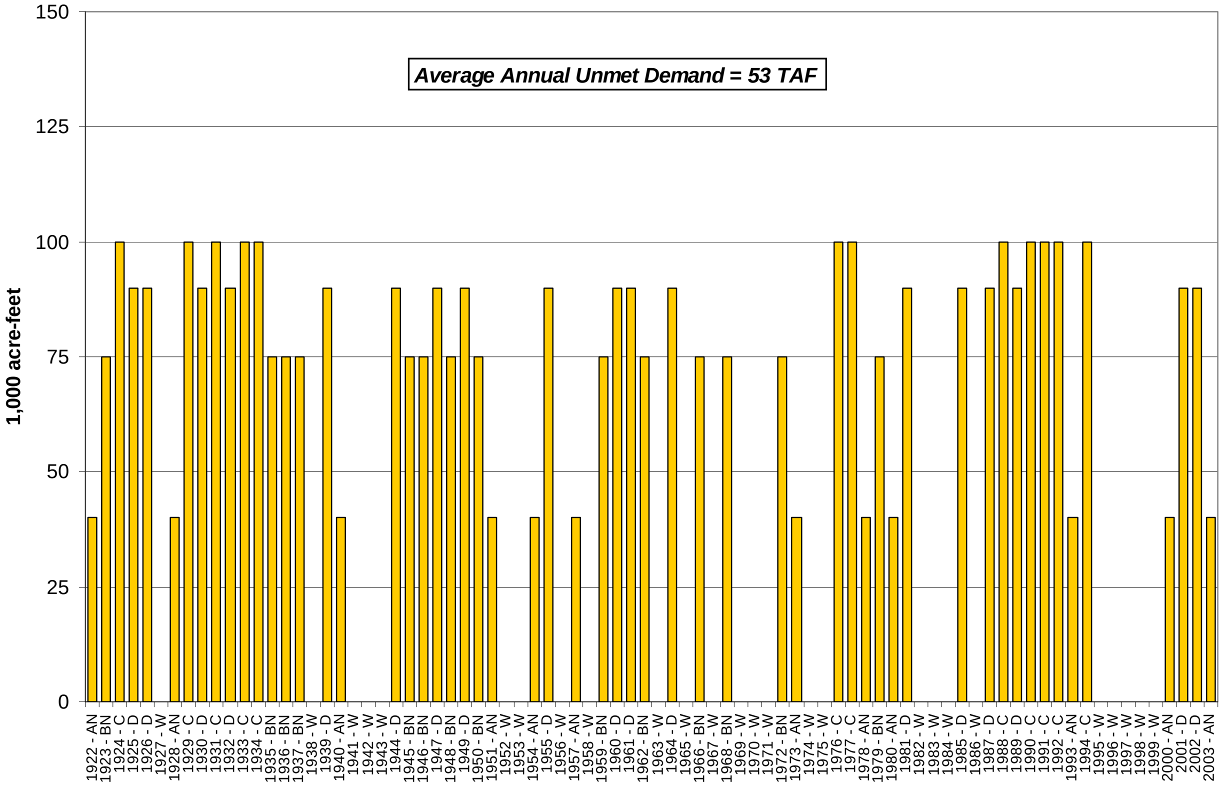

FIGURE 9-3
ASSUMED UNMET AGRICULTURAL DEMAND WITHIN FEATHER RIVER SYSTEM
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

9.2.4 Project Site Assumptions

Two project sites were selected for modeling. Project sites within GCID and the Butte Basin were simulated in the surface water model to determine the volume and timing of ground-water pumping and to better understand tradeoffs between groundwater pumping capacity and project benefits in the surface water system.

Each conjunctive management project site is defined in the model by several variables including maximum annual groundwater pumping capacity, monthly volumes of project pumping, and estimates of how pumping will affect stream-aquifer interactions. The estimated effects on stream-aquifer interaction were derived from iterative simulations between the surface and groundwater models.

The surface water model was developed to quickly evaluate a wide range of project pumping capacities and operations. Results of these sensitivity analyses (presented in later sections) led to evaluation of the following two different project pumping capacities or sizes: 1) 100 TAF in GCID and 50 TAF in Butte Basin, and 2) 200 TAF in GCID and 100 TAF in Butte Basin. Additionally, it was assumed that there would be no additional project pumping in years when surface water allocations are reduced in GCID or the Butte Basin. GCID's surface water allocations are reduced in years classified as "Shasta Critical" based on Sacramento River inflow into Shasta Reservoir. Feather River Settlement Contracts in the Butte Basin received reduced allocations under similar conditions on the Feather River.

Project Assets

Project assets are the volume of water that could potentially be made available through conjunctive management and the volume of additional water that could be released from CVP and SWP reservoirs to meet environmental flow targets or for additional agricultural water supply. Additional reservoir releases are possible because of the availability of groundwater pumping in the conjunctive management project, which serves as a "backstop" against drawing down reservoirs too far. Project assets are calculated each year considering reservoir storage conditions and available groundwater pumping capacity. A reservoir storage target table is used to determine how far operators may be willing to draw down reservoirs for different levels of available groundwater pumping capacity. Table 9-7 is an example for Shasta Reservoir that was a conjunctive management project in GCID with a maximum of 100 TAF of annual pumping capacity.

TABLE 9-7
Example Shasta Reservoir Storage and Project Assets
Sacramento Valley Conjunctive Water Management Technical Investigation Modeling Report

End of September Storage (TAF)	Project Asset (TAF)
Less than or equal to 2,400	0
Greater than 2,500	100

Table 9-7 shows that if end-of-September storage in Shasta Reservoir is forecasted to be less than 2,400 TAF, there are no project assets; therefore, no additional reservoir releases will be made. When forecasted end of September Shasta storage exceeds 2,500 TAF, additional reservoir releases up to the full 100 TAF of pumping capacity may be made to meet project objectives. The maximum project asset is the maximum annual pumping capacity because this represents the maximum backstop available to recover the reservoir in future years, if needed. The model interpolates if storage is between 2,400 and 2,500 TAF so that project operations do not draw Shasta Reservoir storage below 2,400 TAF. A conservative minimum end of September storage of 2,400 TAF was selected as a minimum to avoid any potential impacts.

Project assets also take into account any existing storage deficit, relative to baseline storage, in upstream reservoirs that may be carried over from project operations in previous years. Thus, the cumulative storage deficit over any series of years cannot exceed the annual groundwater pumping capacity of the conjunctive management project.

Water Cost

The surface water model compares environmental flow objectives with base flows that occur under existing system operations to determine additional reservoir releases necessary to meet each environmental objective. This additional release, calculated for the duration of the objective, is referred to as the water cost associated with meeting each environmental object. Water cost is expressed as a volume of water. Water cost for each objective is compared to available project assets to determine which objectives can be met. Figure 9-4 provides an example of water cost calculation for meeting a spring pulse objective.

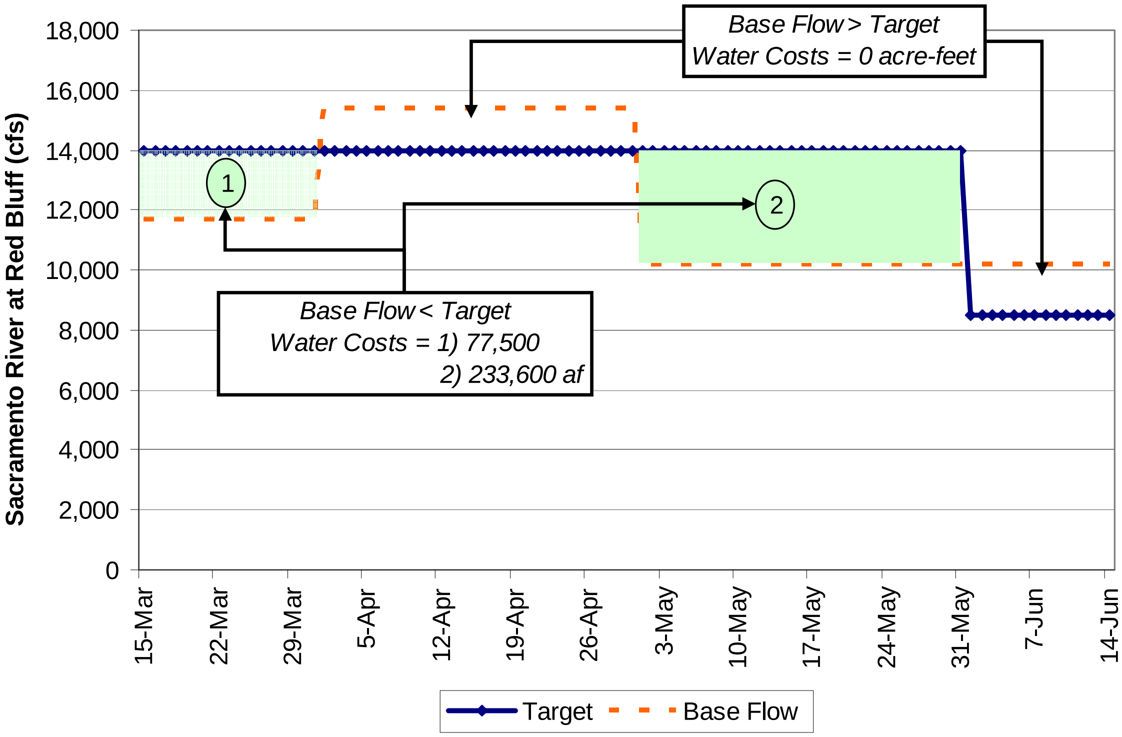

FIGURE 9-4
EXAMPLE WATER COST FOR MEETING SPRING PULSE OBJECTIVE
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION
MODELING REPORT

The water cost for meeting agricultural objectives is equal to the unmet agricultural demands for any year.

Prioritization

Environmental objectives are prioritized through a combination of user input and the frequency with which the various objectives are satisfied. Considering the frequency of when objectives have been satisfied places higher priority on objectives that have not been met in recent years relative to those that have. For example, if the spring pulse objective is typically the highest priority in an above normal year but was met in the previous year (either in the base condition or with a project release) it may be desirable to shift the highest priority to the flood plain inundation objective instead.

To implement this dynamic prioritization scheme that shifts the priority from one year to the next depending on year type and occurrence interval a user-specified relative priority value is combined with the number of years since an objective was last satisfied to determine the final priority of objectives each year.

Table 9-8 contains the relative priority matrix developed by the project team for use in the surface water model. Lower numbers are higher priorities.

TABLE 9-8
Relative Priority Matrix for Environmental Objectives
Sacramento Valley Conjunctive Water Management Technical Investigation Modeling Report

	Sacramento River			Both Rivers	Feather River		
Sacramento River Index	**Geomorphic**	**Riparian Recruitment**	**Spring Pulse**	**Flood Plain Inundation**	**Geomorphic**	**Riparian Recruitment**	**Spring Pulse**
Wet	10	2	10	10	10	2	10
Above Normal	15	6	2	4	15	5	2
Below Normal	2	99	1	3	2	99	1
Dry	5	99	2	90	5	99	2
Critical	80	99	1	90	80	99	1

Final priority is determined by subtracting the relative priority from the number of years since the objective was met and comparing the results for all objectives.

Table 9-9 provides an example prioritization calculation for a hypothetical wet year on the Feather River system.

TABLE 9-9
Example Prioritization of Environmental Objectives, Feather River, Wet Year
Sacramento Valley Conjunctive Water Management Technical Investigation Modeling Report

	Flood	Geo	Rip.	Spring
Years Since Met	6	1	4	25
Relative Priority	10	10	2	10
Final Priority	-4	-9	2	15

The objectives are prioritized by descending final priority scores, as follows: Spring Pulse, Riparian Recruitment, Flood Plain Inundation, and Geomorphic. In this example, because it had been 25 years since the spring objective had been met, Spring Pulse became the first priority objective, though its relative priority was lower than the Riparian Objective.

Decision Month

A decision must be made each spring to determine which objectives the model will attempt to meet that year. Several of the environmental objectives have variable start times and durations. To avoid always meeting the objective that starts earliest in the year or miss meeting an objective in hopes of satisfying a future objective, a user-specified decision month is used in the model. Project assets, water costs, and prioritization of environmental objectives are all determined during the decision month and results are used for operations that year. The decision month is used to determine what objectives the model will attempt to meet each year.

Agricultural Water Supply Objective

After determining which, if any, environmental objectives will be met from project assets the model calculates the remaining project assets available to meet any unmet agricultural demands. This operation wherein environmental objectives were met first and agricultural objectives second was used because environmental objectives are all-or-nothing thresholds, often with large water costs. In many years, all or a portion of project assets are available after making releases for environmental objectives. Simulations where agricultural water supply was prioritized first did not show significant increases in agricultural water supply deliveries, but significantly reduced the ability to meet environmental objectives. This analysis is presented in the section on sensitivity analysis.

Reservoir Release Logic

Figure 9-5 provides a flow chart of model decisions and operations for determining which objectives will be met from additional reservoir releases.

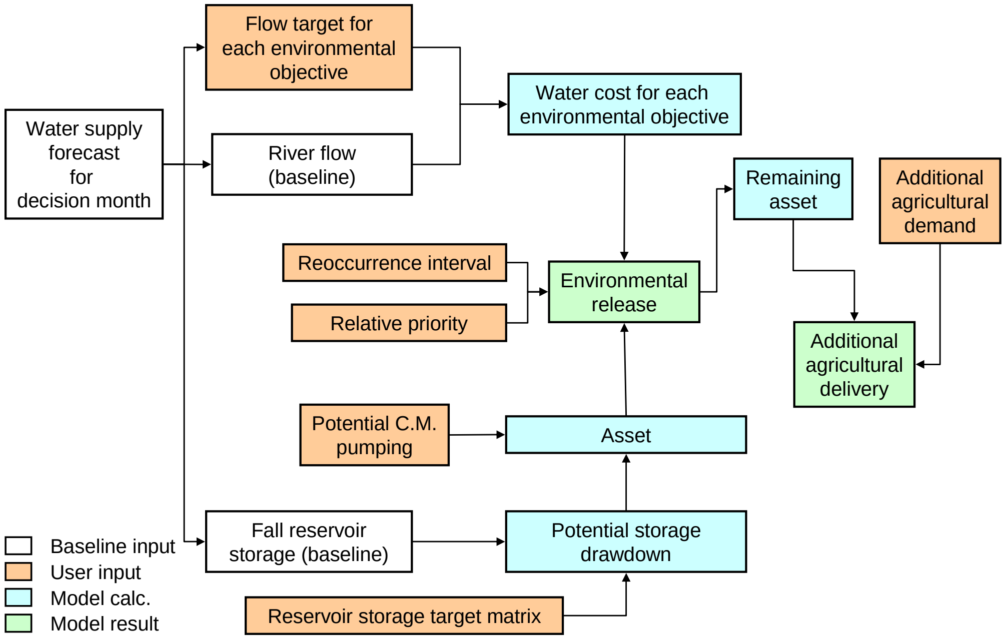

FIGURE 9-5
SURFACE WATER MODEL LOGIC FLOWCHART
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION
MODELING REPORT

The bottom of Figure 9-5 illustrates the steps associated with calculating project assets while the top illustrates the calculation of water costs and additional reservoir release. Assets and water costs are compared, according to the prioritized environmental objectives to determine any additional reservoir release for environmental objectives. Remaining assets and unmet agricultural demand are used to determine additional agricultural delivery from the reservoirs.

Groundwater Pumping Logic

Additional reservoir releases result in lower reservoir storage conditions relative to the baseline condition (without the conjunctive management project). Reservoir storage is refilled in the model from one of the following two sources: water that would have otherwise been released for flood control purposes or an increase in groundwater pumping to meet demands that otherwise would be met from the reservoir.

The surface water model simulates these operations by drawing down reservoir storages to make additional releases for project objectives and tracking the storage deficit relative to the baseline. In many instances storage deficits are refilled by water that would otherwise be released for flood control purposes (surplus surface water). Additional groundwater pumping is required when reservoirs are depleted prior to a series of dry years in which they do not fill. The surface water model uses fall reservoir trigger levels to determine when pumping is needed. These triggers are 2,400 TAF for Shasta Reservoir and 1,500 TAF for Lake Oroville. Therefore, if project operations result in reservoir storages below these levels pumping will occur to refill the minimum of any deficit caused by project operations or up to these levels.

Project pumping can be specified to occur over the summer season (May through August) the fall season (September through November) or a combination of both (May through November). Regardless of the selected season the total quantity of water to be pumped is spread evenly across the entire season to avoid turning pumps on and off and to reduce the number of groundwater production wells needed. Different seasons and pumping durations were selected to test the effects of pumping at different times and rates.

9.3 Surface and Groundwater Model Interaction

Evaluation of conjunctive management projects requires simulation of both surface water and aquifer systems. However, regional groundwater models with the needed level of refinement to adequately simulate pumping projects require run times that prohibit their use in gaming situations and for quickly evaluating multiple scenarios. Therefore, the surface water and groundwater model were used in an iterative fashion to simulate conjunctive management operations in both systems (see Figure 9-6).

An initial surface water model was developed to simulate project operations and develop the time series of groundwater pumping at each project site. Pumping time series were simulated in the groundwater model and results were reviewed, including changes in stream-aquifer interactions. These initial changes were used to develop response functions for use in the gaming model to quickly approximate changes in stream-aquifer interaction when simulating various conjunctive management operations. Response functions were used during the gaming sessions and when conducting tradeoff analyses to determine the final project scenarios. Pumping time series from the final project scenarios were then provided to the groundwater model for final simulation and resulting changes in stream-aquifer interactions associated with the pumping schedules were input back into the final surface water simulations.

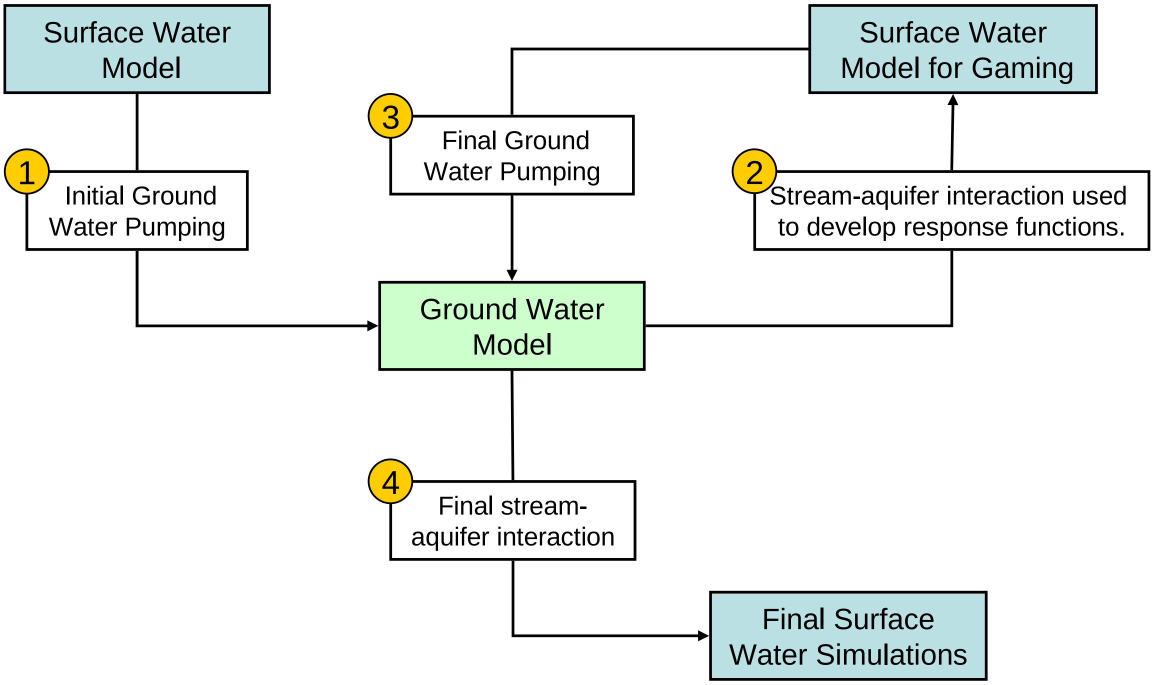

FIGURE 9-6
SURFACE WATER AND GROUNDWATER MODEL INTERACTION
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION
MODELING REPORT

SECTION 10

Level of Analysis

Technical analyses were performed at a planning level to help prove concepts and define conjunctive management projects and operations. Analyses were conducted for general projects, locations, and operations. More specific and refined analyses may be required as specific projects are defined. Most analysis was conducted in a comparative, rather than absolute, manner and results must be interpreted as such.

Additionally, mathematical modeling tools typically report results at a level of precision that exceeds their level of accuracy. For example, planning-level surface water models may provide estimates of water supply accurate to within a range of several thousand acre-feet, but results with a precision down to an acre-foot. Surface water model results presented in subsequent sections are generally rounded to the nearest 1,000 acre-feet. Groundwater draw down is reported in approximately 10-foot increments, and changes in stream-aquifer interaction are reported to the nearest cfs. Results are reported to these levels of precision for comparison with results from other scenarios. Planning-level modeling tools used in this analysis are not necessarily accurate to this level.

SECTION 11

Project Scenario Results

The following section presents results from four different project scenarios. All scenarios are based on two conjunctive management projects, one in GCID and the other in the Butte Basin. Surface water modeling results are presented first and include the ability to meet environmental and agricultural objectives, the resulting effects on reservoirs, and how reservoirs are refilled with the capture of surplus surface water and conjunctive management pumping.

Groundwater model results are presented after surface water model results. Groundwater model results include plots of peak aquifer drawdown and changes in stream-aquifer interaction. For each scenario, the groundwater model was used to evaluate two different well fields. The first well field option uses existing wells screened in the current aquifer producing zones. The second well field simulates all new wells pumping from the deep aquifer. Figures 11-1 through 11-4 illustrate these well fields for the two different project pumping capacities simulated in the four scenarios.

Plots of additional reservoir releases to meet flow requirements after accounting for changes in stream-aquifer interaction are presented after groundwater model results.

11.1 Scenario 1 – 100 TAF GCID, 50 TAF Butte Basin, Summer Pumping

Scenario 1 is defined by two conjunctive management projects with maximum seasonal groundwater pumping capacities of 100 TAF in GCID and 50 TAF in the Butte Basin. Environmental objectives and unmet agricultural demands are as presented in preceding sections. The pumping season spans 4 months of the irrigation season from May through August. The model first determines ability to meet environmental objectives and then uses remaining project assets to meet agricultural demands. Sensitivity to prioritization of environmental objectives and agricultural demands was evaluated and is explained in subsequent sections of this report.

The following series of plots summarize the annual operations with conjunctive management. The first series of plots summarize Sacramento River and Shasta Reservoir operations and the second series summarize Feather River and Oroville Reservoir operations. Plots are arranged in order of how operations occur each year. In winter and spring months, additional water is released from reservoirs to satisfy environmental objectives. During summer months additional water is released to meet agricultural demands. The result is that fall reservoir storage levels are lower than they would be under operations without conjunctive management projects, as shown on Figure 11-5. Reservoir storage space is typically refilled with surplus surface water during subsequent winter and spring periods. If reservoirs do not refill with surplus surface water and fall reservoir storage levels are forecasted to be low, reservoirs are refilled by pumping groundwater in conjunctive management projects and holding a similar volume of surface water in the reservoir.

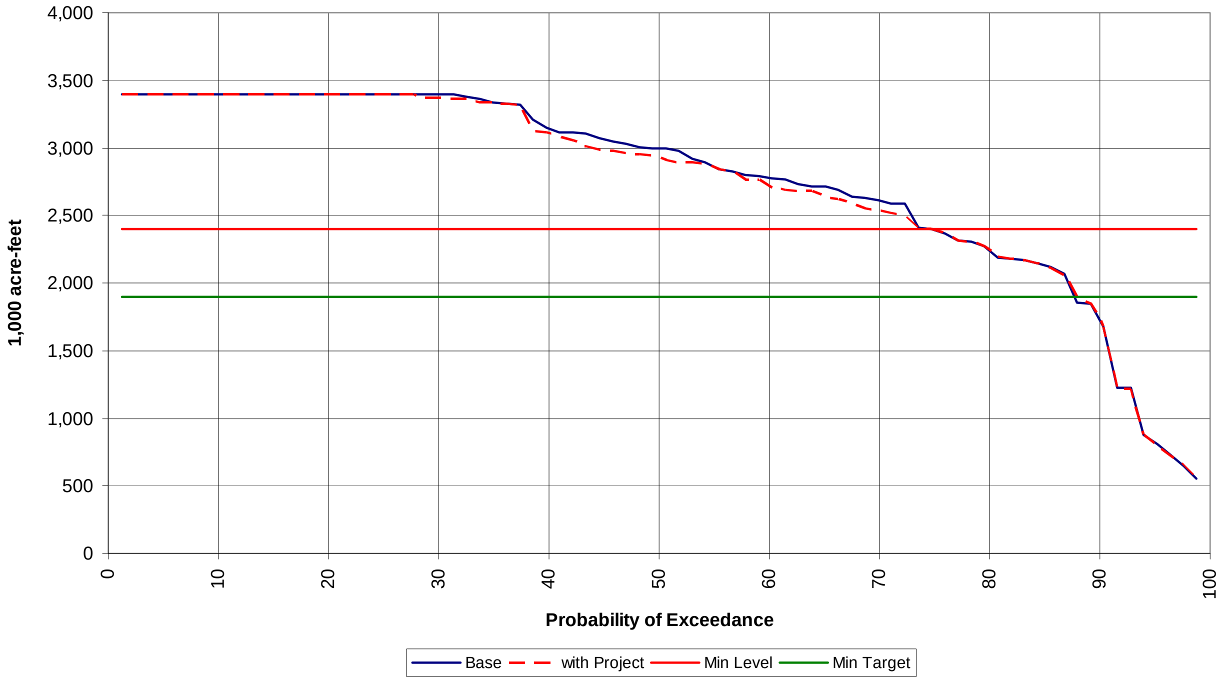

FIGURE 11-5
SHASTA RESERVOIR SEPTEMBER STORAGE EXCEEDANCE PROBABILITY WITH CONJUNCTIVE MANAGEMENT, SCENARIO 1
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

11.1.1 Shasta Reservoir and Sacramento River

Figure 11-6 illustrates annual volumes of water released to satisfy various environmental objectives on the Sacramento River. Color-coded bars and the legend refer to relative priority of objectives in each year. For example, in 1928 the red bar indicates that water was released to meet objective 4, the lowest priority objective. The type of objective, either geomorphic (Geo), riparian recruitment (Rip), spring pulse (Spring), or flood plain inundation (Flood) is labeled above the corresponding bar. Geomorphic objectives are met most frequently due to lower water costs associated with the short duration objective. Average annual release for environmental objectives is 13 TAF.

Figure 11-6 shows only years when environmental objectives are met through project release. Environmental objectives are also met at times under existing system operation. This information is summarized in Table 11-1. For the flood plain inundation objective, the project includes modifications to the Freemont Weir to allow inundation with less Sacramento River flow. The existing Fremont Weir crest limits inundation of the Yolo Bypass for flows less than approximately 62,000 cfs. The project assumes it is possible to modify the weir to allow inundation with flows of approximately 35,000 cfs. Therefore this objective can be met by the project; either under base condition flows between 35,000 and 62,000 cfs (base condition flows in excess of 62,000 cfs meet the objective in the base condition) or through additional reservoir release to create flows of approximately 35,000 cfs. Results presented in Table 11-1 show the flood plain objective is met in 20 years with the project, though there are only 2 years with releases for this objective illustrated on

Figure 11-6. This indicates that the objective was met with base condition flows between 35,000 and 62,000 cfs (without additional reservoir release) in 18 years.

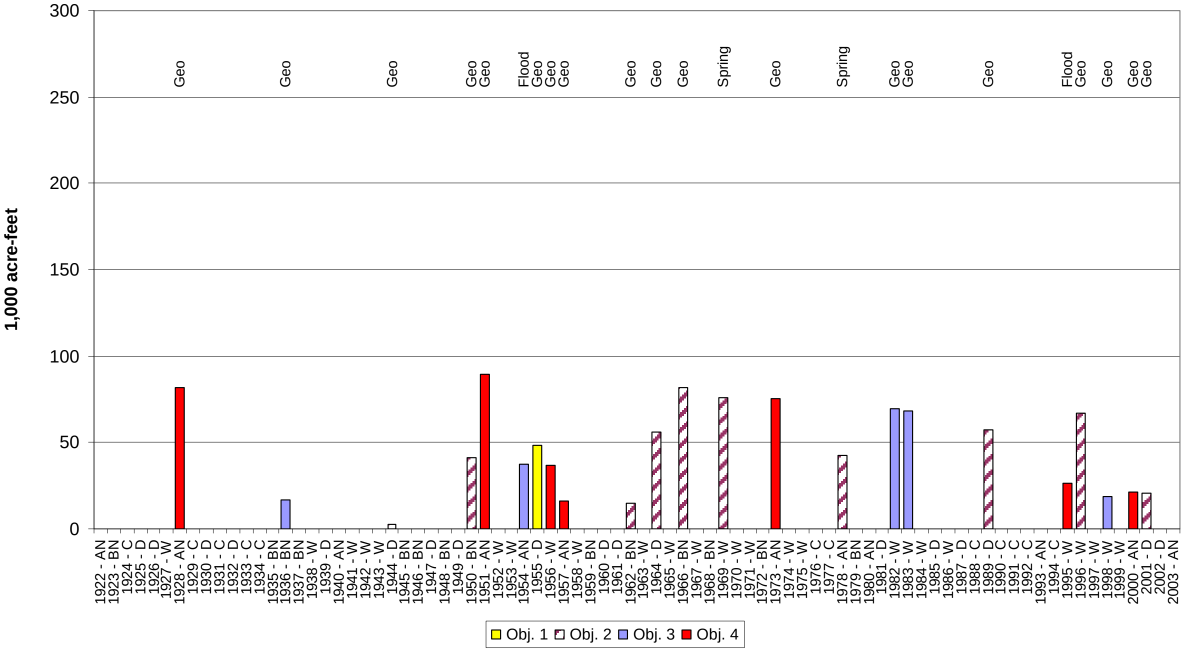

FIGURE 11-6
SACRAMENTO RIVER ENVIRONMENTAL OBJECTIVES MET WITH CONJUNCTIVE MANAGEMENT, SCENARIO 1
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION
MODELING REPORT

TABLE 11-1
Number of Years Sacramento River Environmental Objectives are Met, Scenario 1
Sacramento Valley Conjunctive Water Management Technical Investigation Modeling Report

Objective	Met with Base Conditions Flows	Met with Project Flows	Total
Spring Pulse	5	2	7
Riparian Recruitment	0	0	0
Geomorphic	25	18	43
Flood Plain Inundation	21	20	41

In some years, an objective may be met with base condition flows either before or after it is met with project releases during that same year. Results presented in Table 11-1 account for these occurrences and assume the objective is met in the base condition to prevent double counting in any year. For example, Figure 11-6 shows that releases were sufficient to meet the geomorphic objective in 19 of the 82 years analyzed. However, in 1 year (1956) the objective was met both under base conditions and then simulated to be met through project release. Results presented in Table 11-1 only show this objective being met during base condition flows to prevent potential double counting.

Figure 11-7 illustrates annual releases from Shasta Reservoir to meet additional agricultural demand in the TCCA service area. Dashed lines show unmet contract supply from CalSim II results and green bars illustrate the portion of unmet contract supply satisfied with conjunctive management operations. Additional agricultural releases are made in 24 of the 82 years simulated, or approximately 29 percent of the years. The average release in those years is 46 TAF, while the average annual agricultural delivery over the 82-year simulation period is 14 TAF.

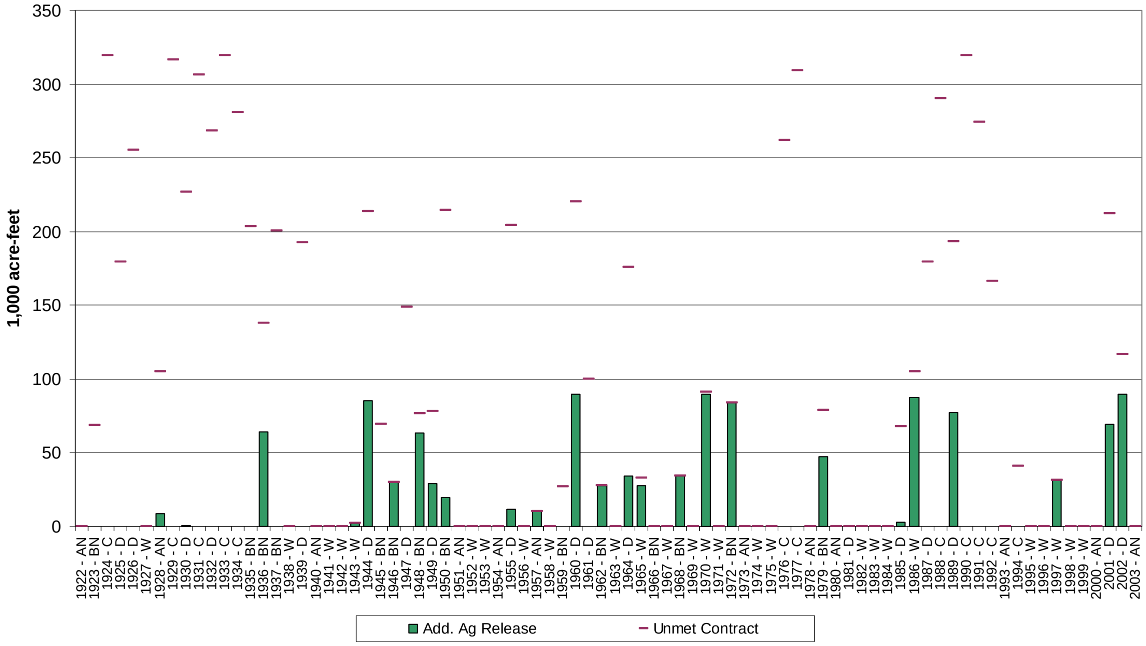

FIGURE 11-7
SACRAMENTO RIVER ADDITIONAL AG. DEMAND MET WITH CONJUNCTIVE MANAGEMENT, SCENARIO 1
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

Figure 11-7 illustrates that in many years when unmet contract supply for the TCCA is highest, there are no deliveries with conjunctive use. This is because in these years, project assets are typically low, either because fall reservoir storage is forecast to be low and no additional releases would be made or it is a Shasta Critical year and additional groundwater pumping for conjunctive management is assumed to be zero.

Additional reservoir releases for either environmental objectives or for additional agricultural delivery result in lower fall carryover storage in Lake Shasta. Figure 11-5 illustrates this with a probability of exceedance plot for end of September storage conditions. The solid blue line indicates fall storage conditions under base (without project) conditions. The red dashed line indicates conditions with conjunctive management. A solid red line at 2,400 TAF indicates the level when conjunctive management operations would not occur to limit the risk to cold water pool management in future years. Storage conditions below the solid green line at 1,900 TAF are when conjunctive management operations attempt to increase storage by pumping groundwater and holding water in Shasta above base levels.

Figure 11-5 illustrates that fall storage levels are lower in approximately 45 percent of the years and only when end of September storage is above 2,400 TAF. In wet years, when fall storage is at the flood control level of 3,400 TAF, releases in spring may refill in later months within the same year resulting in no change in fall storage conditions.

Figure 11-8 illustrates how storage deficits presented on Figure 11-5 are frequently refilled by the capture of surplus surface water. Surplus is water that would otherwise be released from the reservoir to maintain flood control storage and is not diverted downstream. This water is now stored in reservoir space created by making additional releases to meet agricultural and environmental objectives. Refill from surplus surface water occurs in 29 years with an average annual refill of 70 TAF in those years. Average annual refill with surplus surface water for the 82-year simulation is approximately 24 TAF.

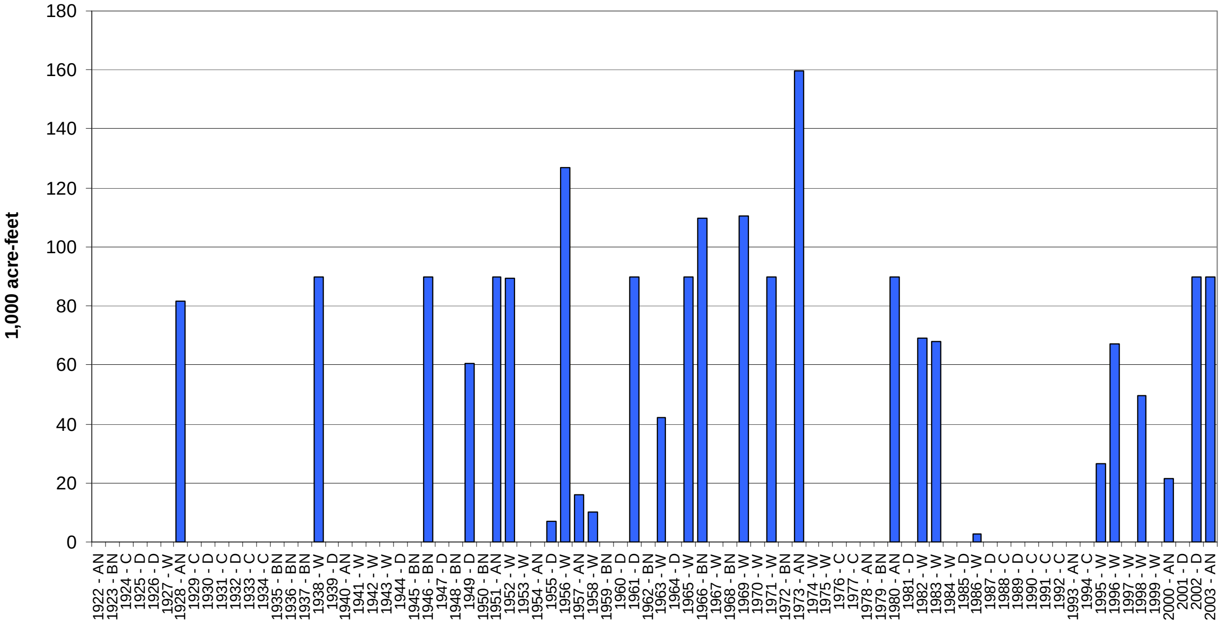

FIGURE 11-8
REFILL OF SHASTA RESERVOIR FROM SURPLUS SURFACE WATER, SCENARIO 1
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION
MODELING REPORT

In some years, following additional reservoir releases for agricultural and environmental objectives, there is no surplus surface water, and reservoir storage levels continue to decline putting future water supplies and cold water pool management at risk. In these years groundwater pumping in the conjunctive management projects is used to recover reservoir storage levels. Figure 11-9 illustrates this annual pumping. Conjunctive management pumping occurs in 4 of the 82 years simulated, or 5 percent of years. The average annual pumping in those years is 70 TAF. The average annual pumping for the entire 82-year simulation is approximately 3 TAF with a maximum annual pumping of nearly the full 100 TAF of capacity. Pumping typically occurs in drier year types when reservoirs do not refill with surplus surface water.

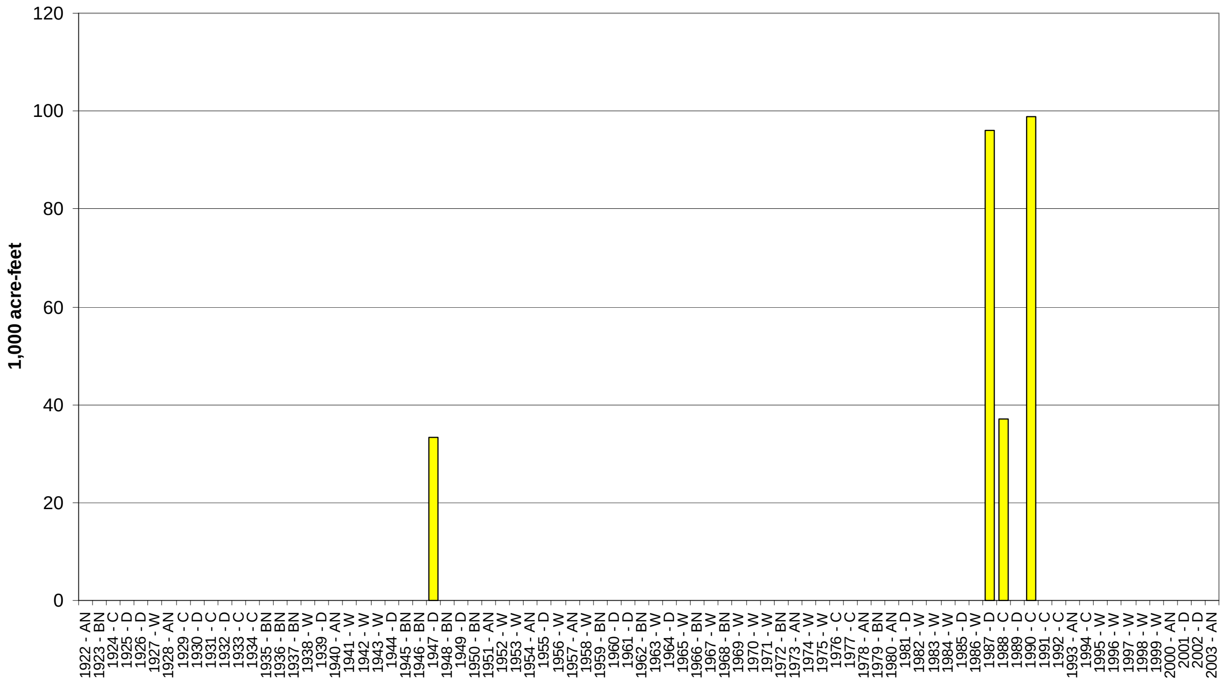

FIGURE 11-9
REFILL OF SHASTA RESERVOIR FROM CONJUNCTIVE MANAGEMENT PUMPING, SCENARIO 1
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

Over the 82-year simulation period, additional reservoir releases are made in 37 years, or 45 percent of the years. Reservoir refill is accomplished with surplus surface flows in 29 years and with project pumping in 4 years. The number of years with additional releases exceeds the number of years with refill because reservoir storage deficits do not have to be completely refilled before making additional releases, as long as the total reservoir storage deficit does not exceed the capacity of the project to refill the reservoir in a single year. Of the total average annual additional releases of 27 TAF (14 TAF for agriculture and 13 TAF for environmental objectives), 24 TAF is refilled from surplus surface water and 3 TAF from conjunctive management pumping.

11.1.2 Oroville Reservoir and Feather River

Figure 11-10 illustrates annual volumes of water released to meet environmental objectives on the Feather River. Hydrology and operations on the Feather River result in meeting different objectives in different years compared to the Sacramento River. Similar to the Sacramento River operations, the geomorphic objective is satisfied most frequently due to lower water cost associated with meeting the shorter duration objective. Average annual release for environmental objectives on the Feather River is 7 TAF.

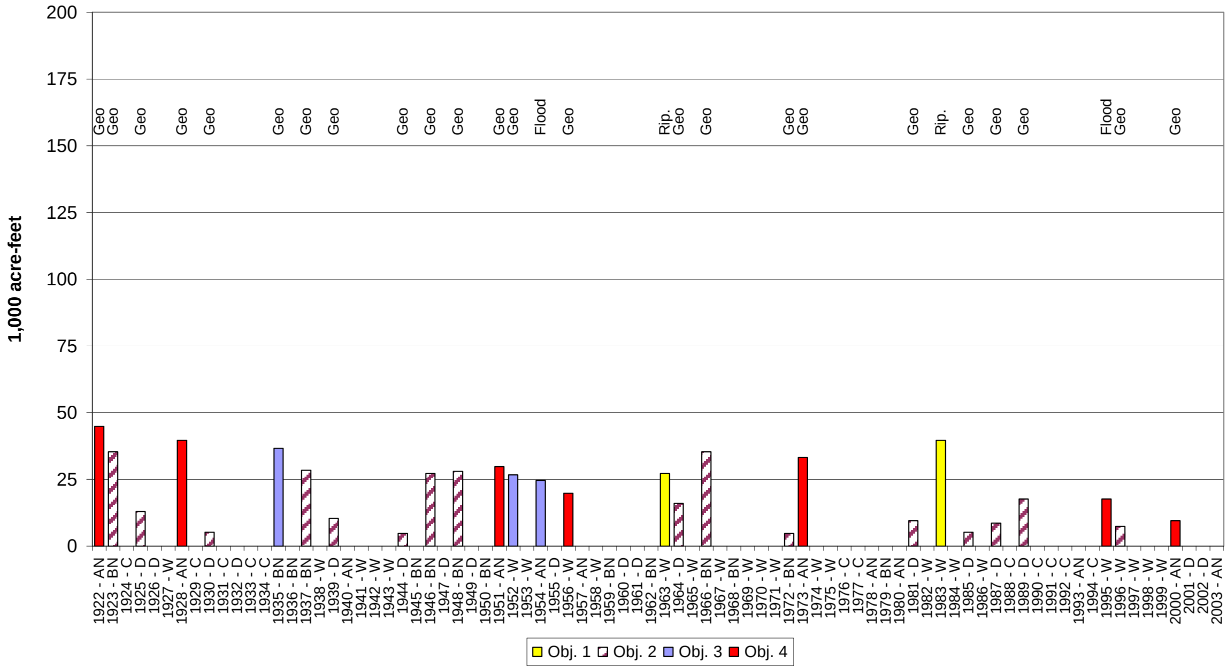

FIGURE 11-10
FEATHER RIVER ENVIRONMENTAL OBJECTIVES MET WITH CONJUNCTIVE MANAGEMENT, SCENARIO 1
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

Table 11-2 provides a summary of the number of times each objective is met by reservoir release and under base operations on the Feather River. Values reported in the table for the geomorphic objective only include years when the objective is not met under base operations. Therefore this value is less than the number of releases shown on Figure 11-7. The flood plain inundation objective can be met with the project under base condition flows with the modified weir, or with a combination of project releases and the modified weir.

TABLE 11-2
Number of Years Feather River Environmental Objectives are Met, Scenario 1
Sacramento Valley Conjunctive Water Management Technical Investigation Modeling Report

Objective	Met in Base	Met with Project	Total
Spring Pulse	3	0	3
Riparian Recruitment	1	2	3
Geomorphic	31	17	48
Flood Plain Inundation	21	20	41

Figure 11-11 illustrates additional agricultural deliveries possible with conjunctive management on the Feather River. Dashed lines relate to assumed unmet demands within the Feather River basin and correspond to the Sacramento Valley Index. Similar to operations on the Sacramento River, project assets do not allow additional releases for either environmental or agricultural objectives during drier year types when agricultural demands are higher. Additional agricultural releases are made in 30 of the 82 years simulated, or approximately 37 percent of the years. The average release in those years is 27 TAF, while the average annual agricultural delivery over the 82-year simulation period is 10 TAF.

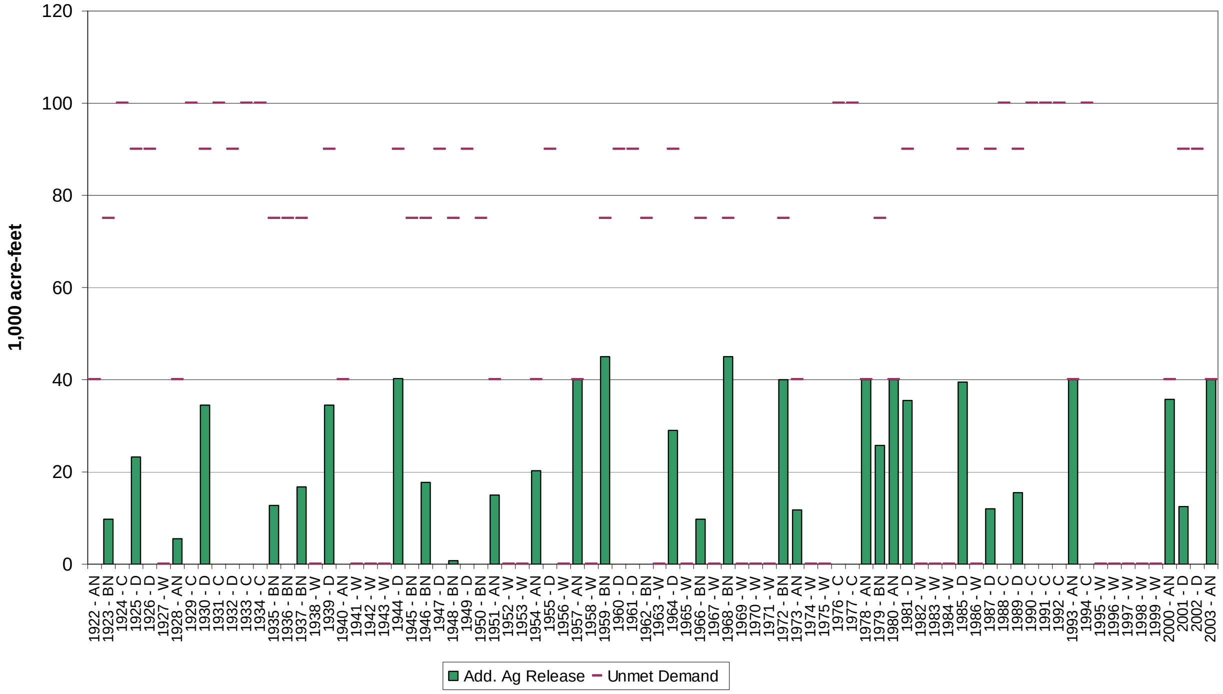

FIGURE 11-11
FEATHER RIVER ADDITIONAL AG. DEMAND MET WITH CONJUNCTIVE MANAGEMENT, SCENARIO 1
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION
MODELING REPORT

Figure 11-12 illustrates how conjunctive management operations result in slightly lower Oroville Reservoir fall storage conditions in approximately 60 percent of the years. Fall storage is not affected below the minimum level of 1,500 TAF. The solid green line at 1,200 TAF denotes target storage for cold water pool management when conjunctive management may be used to increase storage.

Figure 11-13 shows how storage space created in Oroville Reservoir through additional releases for agricultural and environmental objectives is frequently refilled with surplus surface water. Refill from surplus surface water occurs in 37 years with an average annual refill of 32 TAF in those years. The average annual refill with surplus for the 82-year simulation period is 14 TAF.

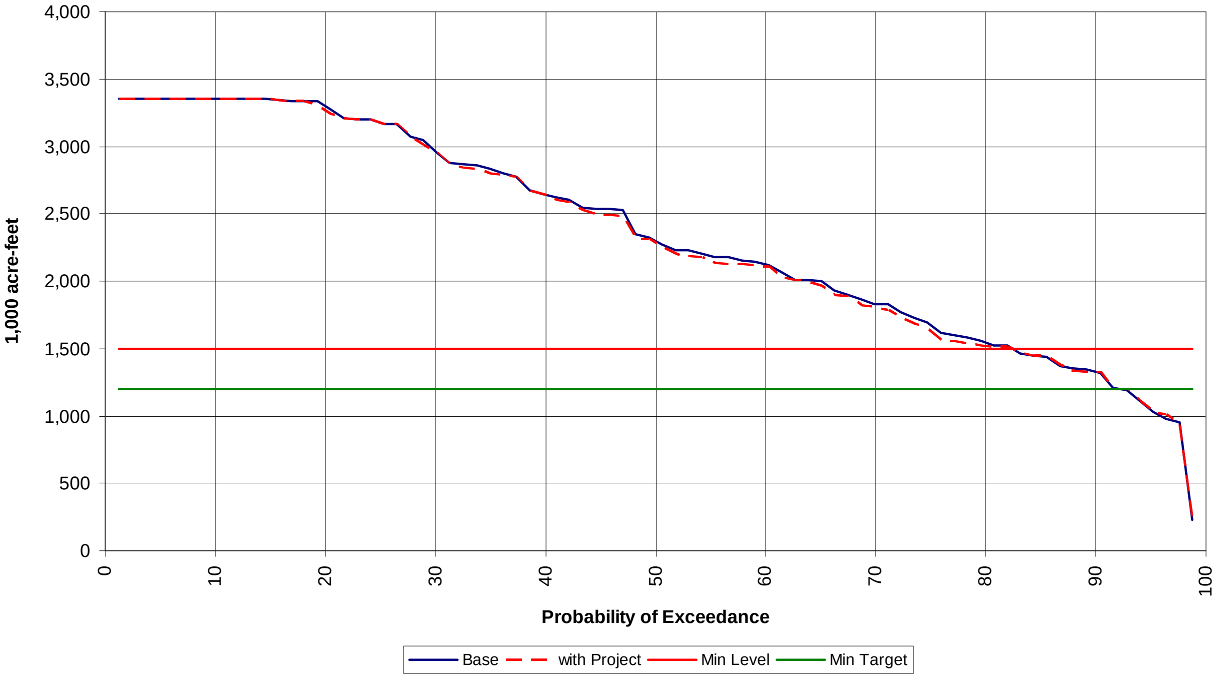

FIGURE 11-12
OROVILLE RESERVOIR SEPTEMBER STORAGE EXCEEDANCE PROBABILITY WITH CONJUNCTIVE MANAGEMENT, SCENARIO 1
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

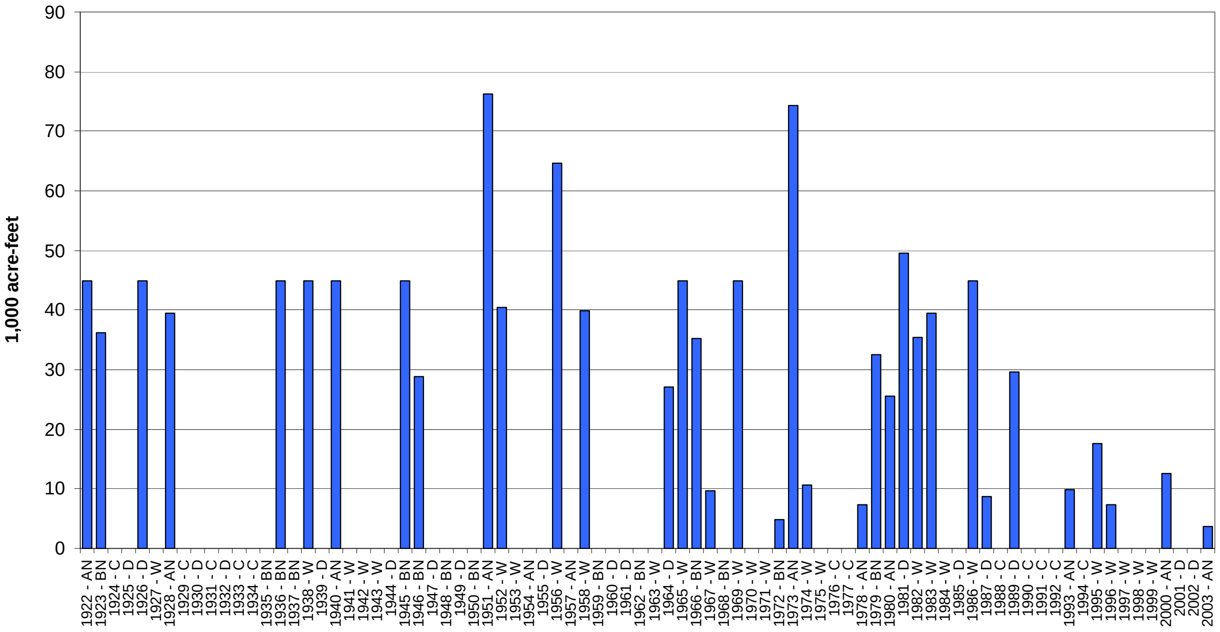

FIGURE 11-13
REFILL OF OROVILLE RESERVOIR FROM SURPLUS SURFACE WATER, SCENARIO 1
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

Figure 11-14 presents annual conjunctive management pumping in the Butte Basin project. Conjunctive management pumping occurs in 6 of the 82 years simulated or 7 percent of the years. The average annual pumping in those years is 44 TAF. The average annual pumping for the entire 82-year simulation is approximately 3 TAF with a maximum annual pumping of the full 50 TAF of pumping capacity.

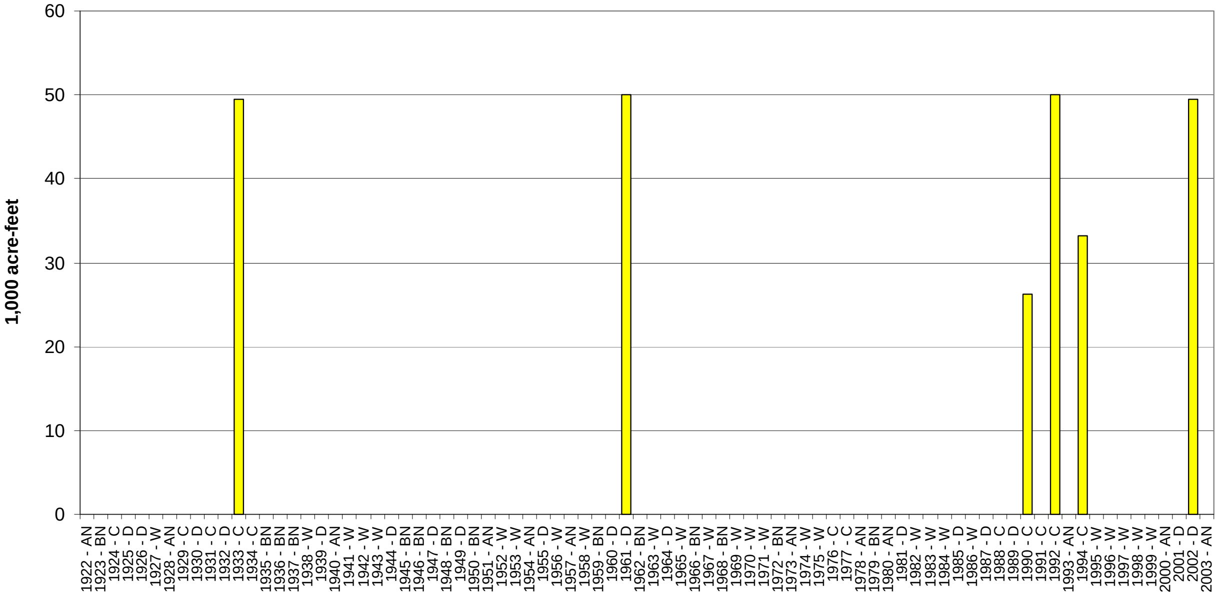

FIGURE 11-14
REFILL OF OROVILLE RESERVOIR FROM CONJUNCTIVE MANAGEMENT PUMPING, SCENARIO 1
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION
MODELING REPORT

Over the 82-year simulation period, additional reservoir releases are made in 37 years, or 45 percent of the years. Reservoir refill is accomplished with surplus surface flows in 37 years and with project pumping in 6 years. The number of years with refill exceeds the number of years with additional release because reservoir storage deficits may not completely refill in a single year, but instead refill over the course of several years. In summary, of total average annual additional releases of 17 TAF (10 TAF for agriculture and 7 TAF for environmental objectives), 14 TAF is refilled from surplus surface water and 3 TAF from conjunctive management pumping.

11.1.3 Groundwater Results

Existing Well Field

Monthly pumping for Scenario 1, illustrated on Figures 11-9 and Figure 11-14 for the GCID and Butte Basin projects, respectively, was simulated in the groundwater model for the existing well field shown on Figure 11-1. All discussions provided in this section referring to the existing well field reflect simulated drawdown in the regional aquifer. All discussions referring to the new well field reflect simulated drawdown in the deeper aquifer. Production would occur through existing wells screened in the regional aquifer at depths of 100 to

500 feet. Results of this simulation are summarized on Figures 11-15 through 11-17. Peak drawdown in groundwater levels associated with implementation of this scenario is presented on Figure 11-15. This figure depicts simulated drawdown in the pumped aquifer during August 1990. Maximum pumping rates under this alternative occur during 1990 and the drawdown distribution at the end of August represent the approximate maximum drawdown that will occur under this scenario. Figure 11-15 shows that the area of greatest drawdown occurs in the northern GCID area at a magnitude of 30 to 40 feet. Drawdown in the Butte Basin is negligible and is confined to the close vicinity of the production wells.

Simulated impacts to surface streams under Scenario 1 for an existing well field are summarized on Figures 11-16 and 11-17. These figures show that the greatest impact to surface streams will occur to the Sacramento River, between GCID and Wilkins Slough, and Butte Creek, with smaller impacts estimated to occur to surrounding streams. Figure 11-16 suggests that the peak cumulative impact to all surface water flows will be approximately 54 cfs in the summer of 1990, with a flow reduction of just more than 40 cfs forecasted to occur on the Sacramento River, and a flow reduction of approximately 13 cfs on Butte Creek. The peak impact to the Sacramento River will also occur in the late summer of 1990 while the peak impact on Butte Creek is forecasted to occur in early 1993. Peak impacts to stream flows on smaller tributary streams are less than about 6 cfs as shown on Figure 11-17.

The time of year in which impacts to rivers and streams are simulated to occur is a critical factor in assessing their significance. Typical flows in the Sacramento River at Wilkins Slough are on the order of 6,000 to 7,000 cfs in late summer and fall months with minimum flows for the historical period of 1980 through 2006 of 3,000 to 4,000 cfs. Therefore, the impacts reflected on Figure 10-16 represent a small percentage of total flow. Average summer and fall flows in the Feather River directly below Thermalito Afterbay are on the order of 2,000 to 3,000 cfs with minimum flows for the same historical period of approximately 1,000 cfs. Flows in Butte Creek near Chico average approximately 110 to 150 cfs with minimum flows of 50 cfs in some fall months. Therefore, simulated impacts to Butte Creek represent a larger percent of minimum or typical flows than impacts to the Sacramento or Feather Rivers.

Figure 11-16 illustrates stream flow reductions for the groundwater model simulation period. Reductions in the Sacramento River between GCID (Hamilton City) and Wilkins Slough show larger spikes during years with pumping in the GCID project and smaller increases during years with pumping in the Butte Basin project. Butte Creek reductions follow the opposite pattern with larger increases during years with pumping in the Butte Basin project and smaller increases in years with pumping in the GCID project. Reductions in all modeled streams show increases in years with pumping in either project. The annual cycle of increasing and decreasing reductions in all streams is due to the ephemeral nature of smaller streams. More reductions occur in winter months when smaller streams are simulated to be flowing and less reductions in summer when smaller streams are assumed to be dry.

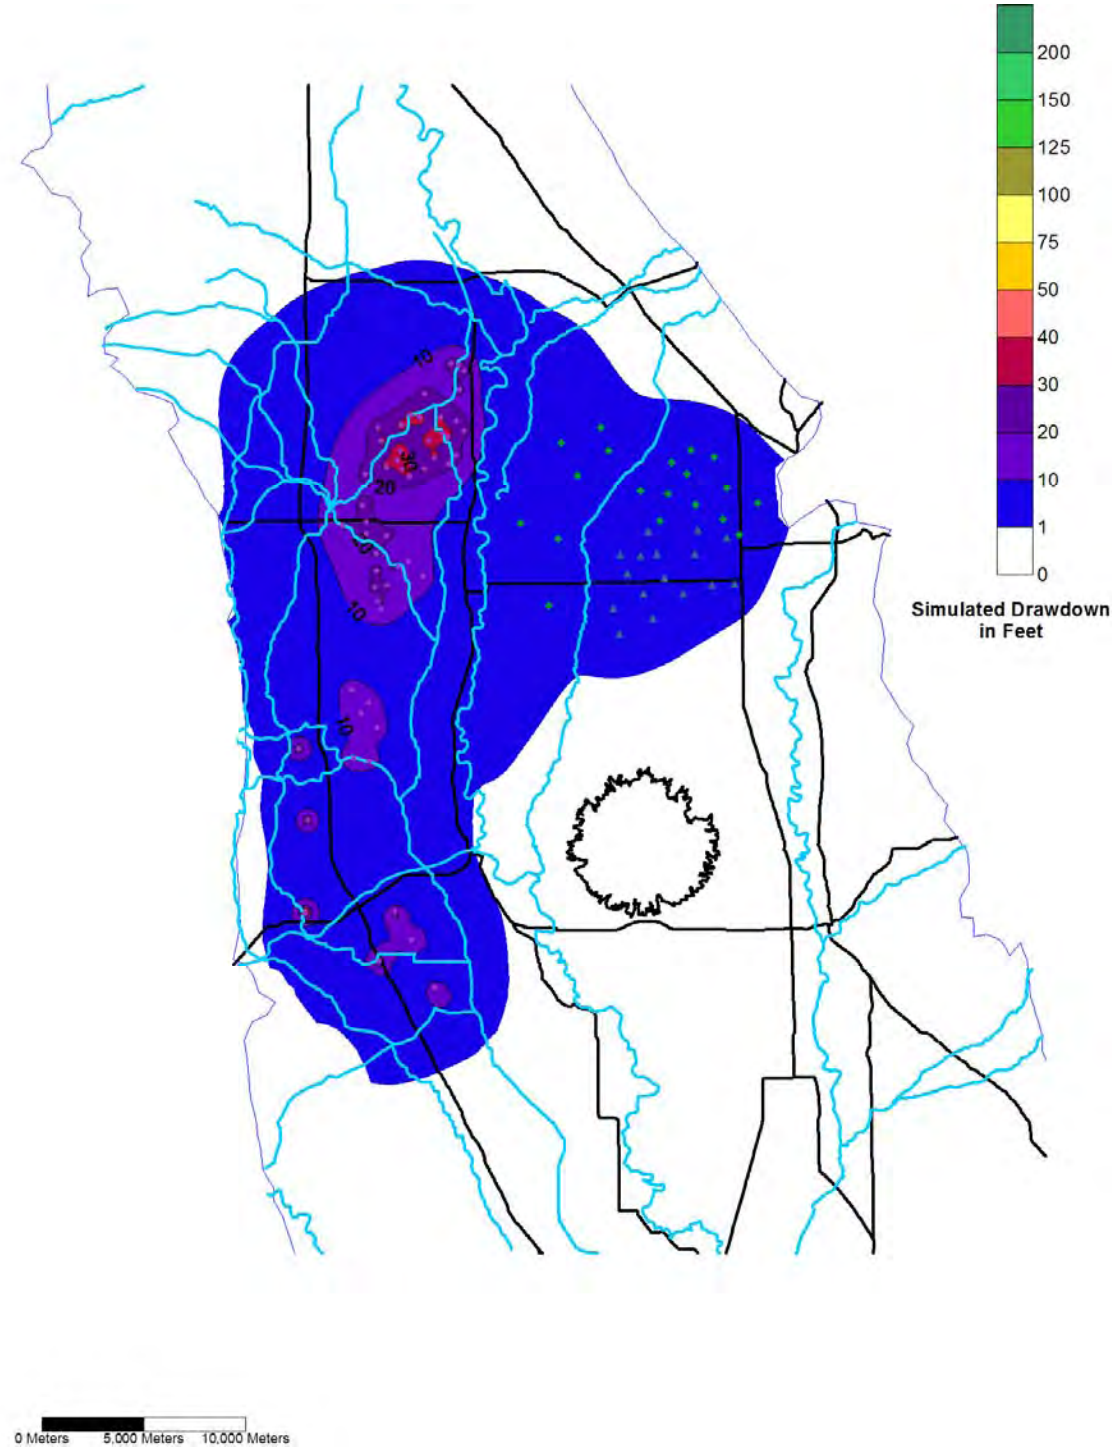

FIGURE 11-15

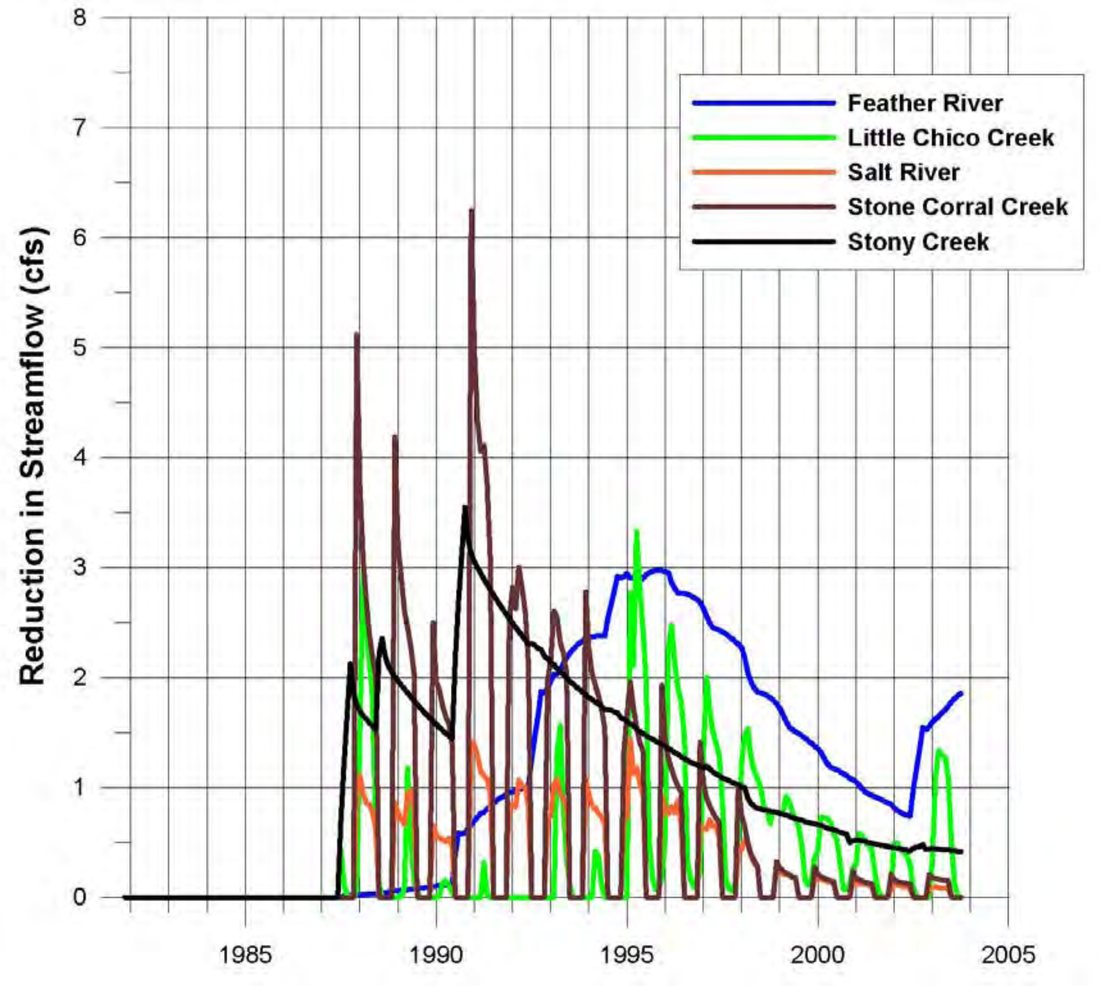

FIGURE 11-17
SIMULATED REDUCTION IN STREAMFLOW TO MINOR STREAMS, SCENARIO 1 - EXISTING WELL FIELD
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

Reservoir Release for Recharge

Stream reductions, due either to increased stream loss to aquifers or decreased aquifer flow into streams, may result in changes in upstream reservoir operations. The timing of when stream reductions occur and conditions in the surface water system determine if and how the surface water system may respond. For example, if stream reductions tend to occur in winter months of years with above average precipitation there may be little or no response required by upstream reservoirs to a decrease in stream flow. Alternatively, if stream reductions occur during fall months of years with below average precipitation, upstream reservoirs may be required to make additional releases to ensure compliance with flow or water quality requirements in the surface water system.

The surface water system is sometimes referred to as being in a “balanced” or “surplus” condition. Balanced conditions occur when upstream reservoirs are releasing water to meet specific downstream requirements for flow, diversions, water quality, or to support Delta exports. Surplus conditions typically occur when upstream reservoirs are releasing water for flood control purposes or tributary inflow below reservoirs results in surplus conditions. It is possible for parts of the system to be in balanced conditions while others are in surplus conditions. For example, if Shasta Reservoir is releasing water to maintain minimum required flow at the navigation control point (a location near Wilkins Slough) the system is in balance between Shasta and Wilkins Slough and reduction in Sacramento River flow or its tributaries upstream of Wilkins Slough may require additional release from Shasta. Simultaneously there may be surplus flow in the Sacramento River below Wilkins Slough or the Delta, and reduction in stream flow downstream of Wilkins Slough may require additional release from Shasta.

Time series of simulated streamflow reductions from the groundwater model were input back into the surface water model to determine system conditions at times when reductions occur. Depending on location and timing of reductions, upstream reservoirs may be required to make additional releases to compensate for streamflow reductions due to groundwater pumping. System conditions, either balanced or surplus, were determined from the CalSim II simulation of CVP/SWP operations. Additional releases from Shasta and Oroville were simulated and tracked in the surface water model. Figures 11-18 and 11-19 present annual additional releases from Shasta and Oroville, respectively, for Scenario 1 pumping from an existing well field.

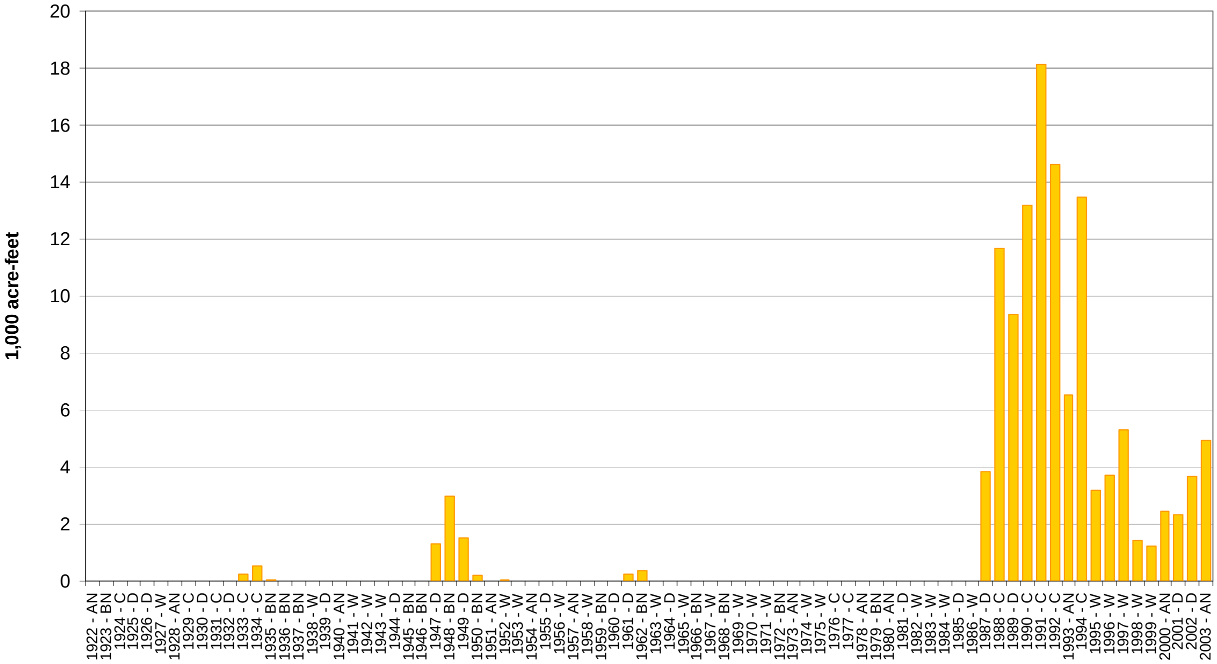

FIGURE 11-18

MODELING REPORT

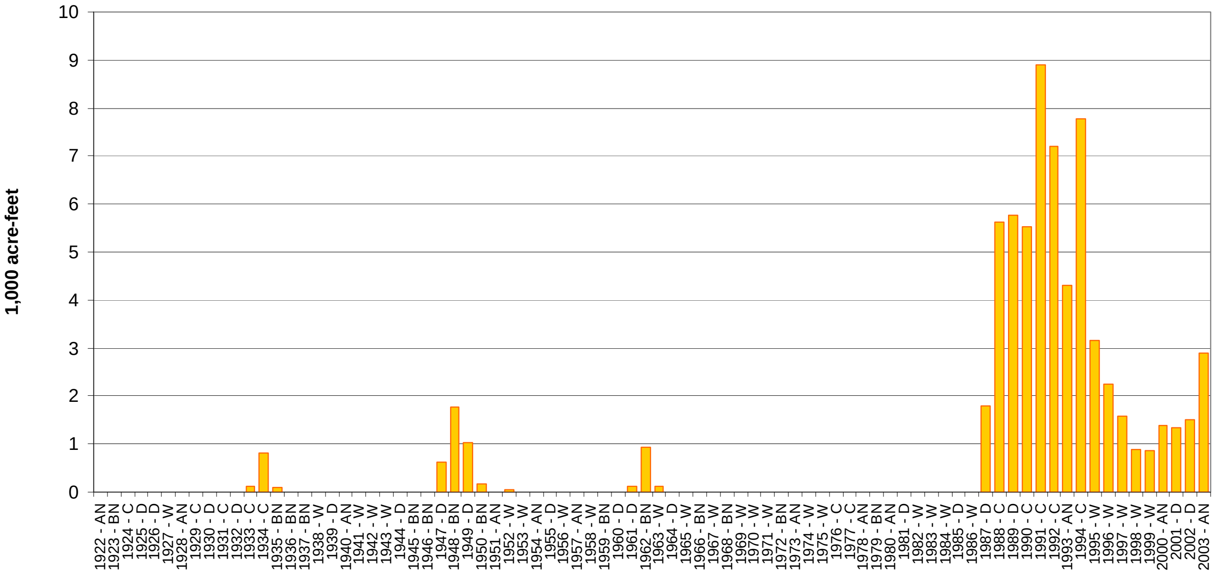

FIGURE 11-19
ANNUAL ADDITIONAL RELEASE FROM OROVILLE RESERVOIR TO COMPENSATE FOR CHANGE IN STREAM-AQUIFER INTERACTION, SCENARIO 1 - EXISTING WELL FIELD
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION
MODELING REPORT

Figures 11-18 and 11-19 also illustrate that in multiple years with higher levels of pumping, such as the simulation from 1987 through 1994, upstream reservoirs may have to release a small volume of additional water to compensate for increases in streamflow reductions. These results reflect the precision of both the groundwater and surface water models but not necessarily the accuracy of these models. Annual releases from Oroville Reservoir of 3 TAF in any year are far beyond the accuracy of planning level models. Results are presented to demonstrate potential effects and to illustrate concepts.

New Well Field

The same monthly pumping time series for Scenario 1 was also simulated in the well field shown on Figure 11-2. Production would occur through new wells screened in the deeper aquifer units at a depth of 900 to 1100 feet. Results of this simulation are summarized on Figures 11-20 through 11-22. Peak drawdown in groundwater levels associated with implementation of this alternative is presented on Figure 11-20. This figure depicts simulated drawdown in the pumped aquifer, during August 1990. The figure shows that the area of greatest drawdown occurs in the western GCID area at a magnitude of up to 100 feet. Drawdown in Butte Basin is the range of 10 to 20 feet.

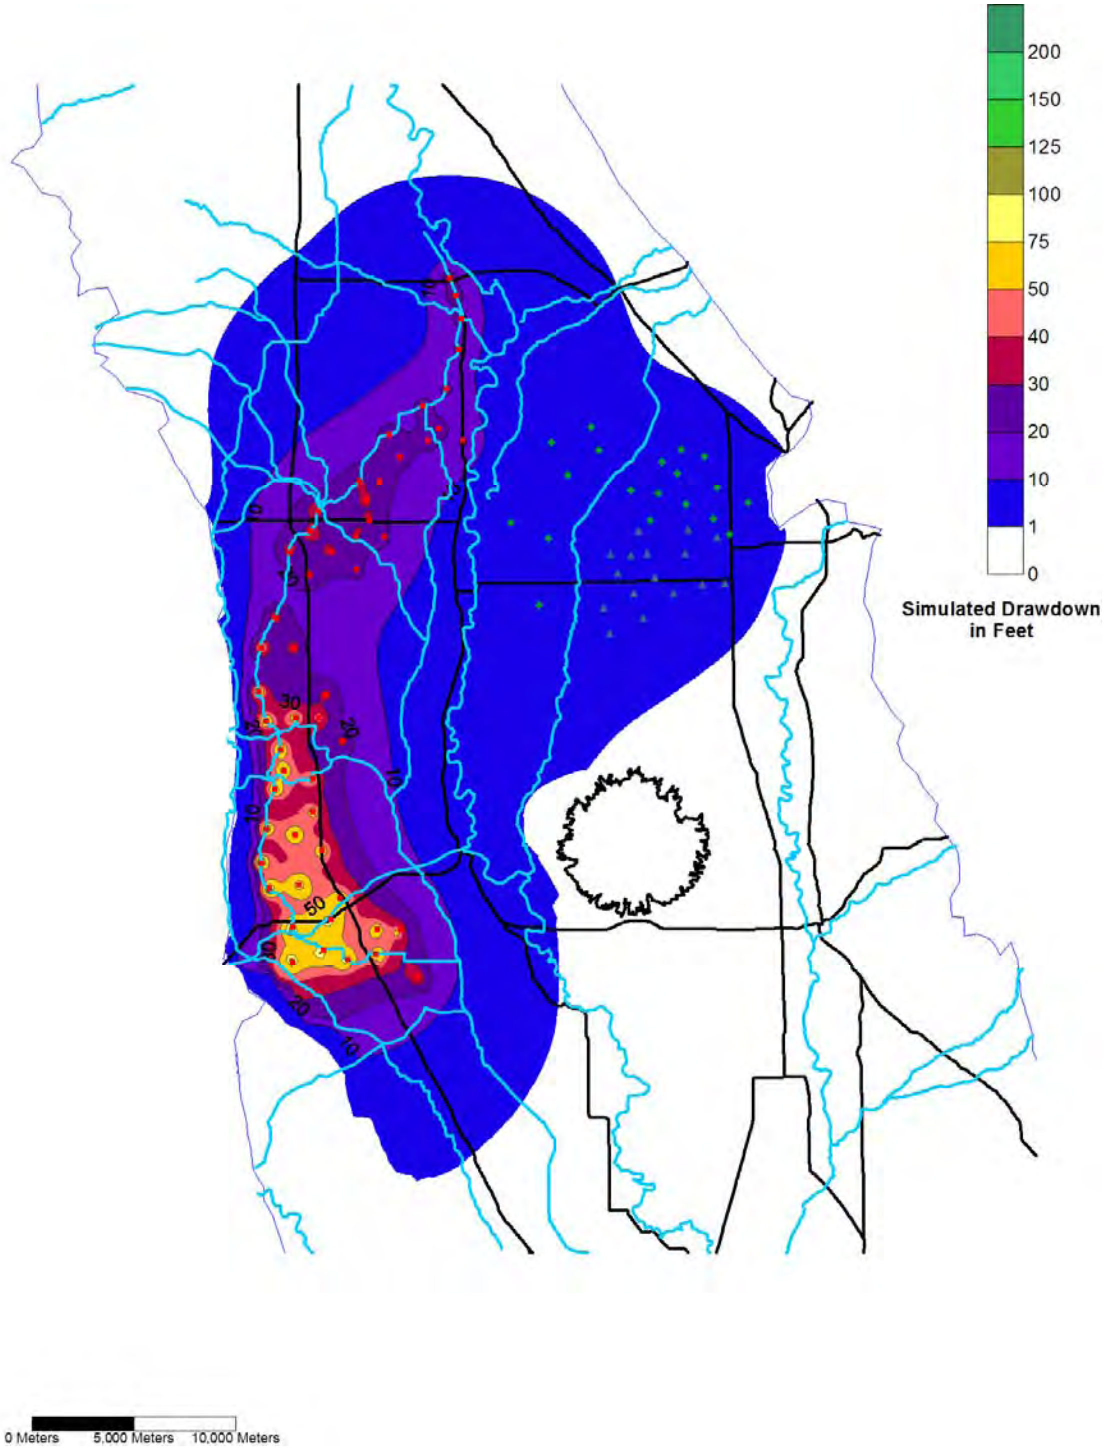

FIGURE 11-20
SIMULATED DRAWDOWN IN THE DEEP AQUIFER IN AUG 1990, SCENARIO 1 - NEW WELL FIELD
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

Simulated impacts to surface streams under Scenario 1 for a new well field are summarized on Figures 11-21 and 11-22. These figures show that the greatest impact to surface streams will occur to the Sacramento River, between GCID and Wilkins Slough, and Butte Creek, with smaller impacts estimated to occur to surrounding streams. Figure 11-21 suggests that the peak cumulative impact to all surface water flows will be a reduction of about 52 cfs in the late fall of 1990, while a flow reduction of just over 36 cfs is forecast to occur on the Sacramento River while a flow reduction of approximately 12 cfs is predicted on Butte Creek. The peak impact to the Sacramento River will also occur in the late fall of 1990, while two similar peak impacts occur on Butte Creek in early 1993 and the fall of 1994. Peak impacts to stream flows on smaller tributary streams peak at less than about 9 cfs as shown on Figure 11-22.

MODELING REPORT

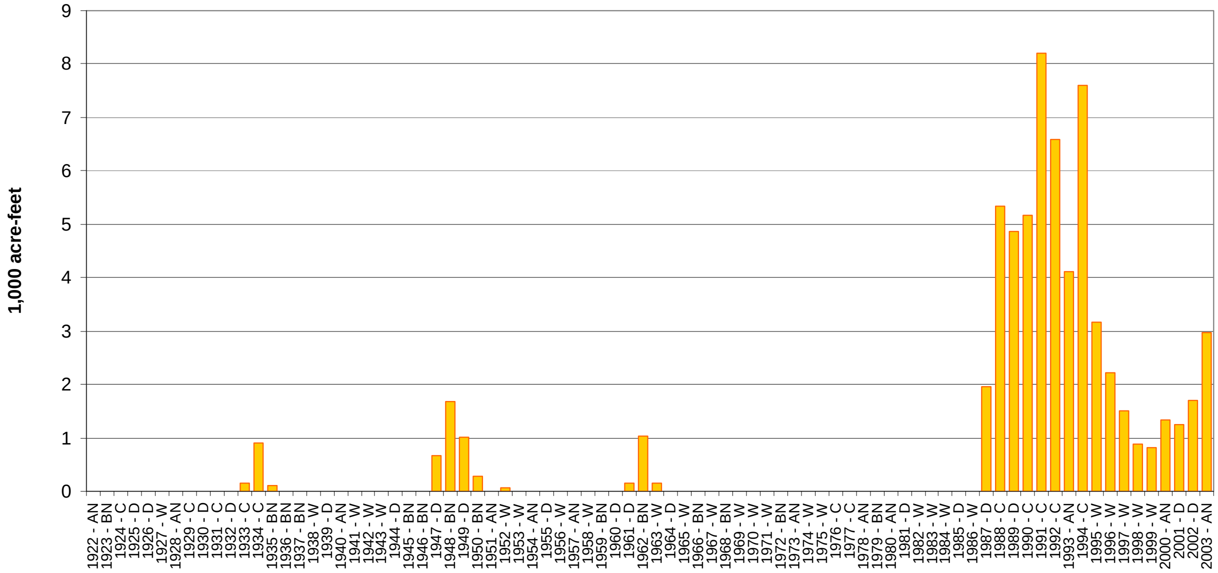

FIGURE 11-24
ANNUAL ADDITIONAL RELEASE FROM OROVILLE RESERVOIR TO COMPENSATE FOR CHANGE IN STREAM-AQUIFER INTERACTION, SCENARIO 1 - NEW WELL FIELD
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION
MODELING REPORT

Figures 11-23 and 11-24 illustrate peak annual reservoir releases to compensate for stream reductions may be slightly less for a new well field than for the existing well field, but annual releases are similar for either well field.

11.2 Scenario 2 – 200 TAF GCID, 100 TAF Butte Basin, Summer Pumping

Scenario 2 is defined by two conjunctive management projects with maximum seasonal pumping capacities of 200 TAF in GCID and 100 TAF in the Butte Basin. This scenario is the same as Scenario 1 but with twice the pumping capacity at each project.

11.2.1 Shasta Reservoir and Sacramento River

Figure 11-25 illustrates annual volumes of water released to satisfy various environmental objectives on the Sacramento River. The geomorphic objective is met most frequently due to lower water cost associated with the short duration, but the larger pumping capacity increases project assets and allows other objectives to be met more frequently than in Scenario 1. Additionally, in some years more than one objective may be met as indicated by stacked bars. Average annual release for environmental objectives under Scenario 2 is 45 TAF.

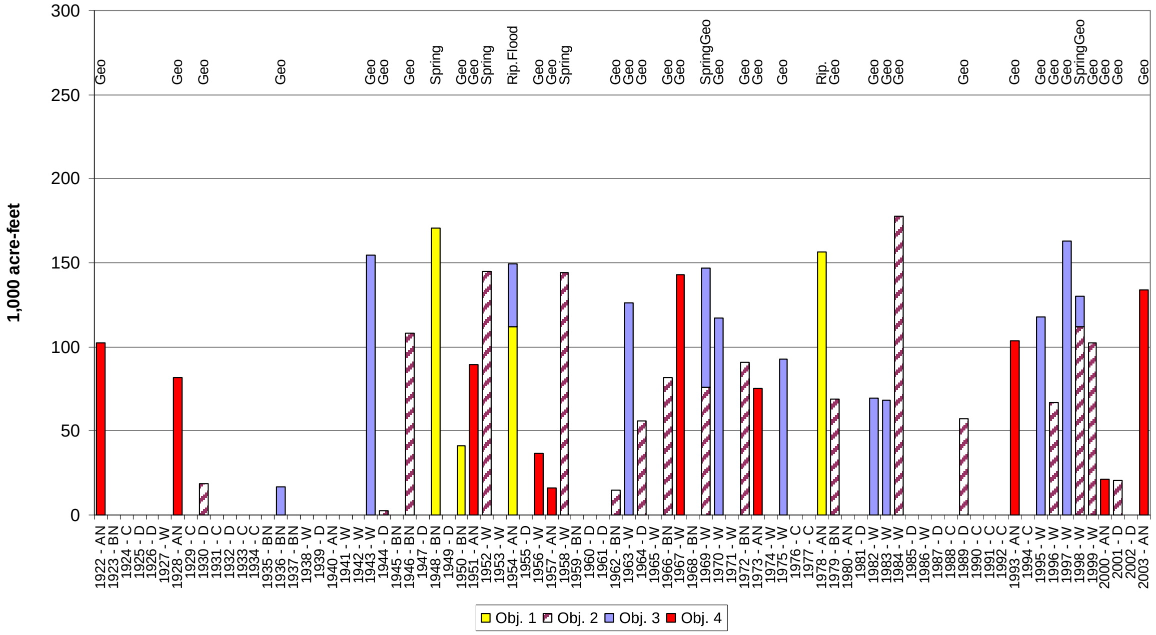

FIGURE 11-25
SACRAMENTO RIVER ENVIRONMENTAL OBJECTIVES MET WITH CONJUNCTIVE MANAGEMENT, SCENARIO 2
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

Figure 11-25 shows only years when environmental objectives are met through project release. Environmental objectives may also be met under the base operations of the system.

Table 11-3 provides a summary of the number of times each objective is met by reservoir release and under base operations on the Feather River. Values reported in the table for the geomorphic objective only include those years when the objective is not met under base operations. Therefore this value is less than the number of releases shown on Figure 11-25. The flood plain inundation objective can be met with the project under base condition flows with the modified weir, or with a combination of project releases and the modified weir.

TABLE 11-3
Number of Years Sacramento River Environmental Objectives are Met, Scenario 2
Sacramento Valley Conjunctive Water Management Technical Investigation Modeling Report

Objective	Met in Base	Met with Project	Total
Spring Pulse	5	5	10
Riparian Recruitment	0	2	2
Geomorphic	25	30	55
Flood Plain Inundation	21	20	41

Figure 11-26 illustrates annual release from Shasta to meet additional agricultural demand in the TCCA service area. Additional agricultural releases are made in 24 of the 82 years simulated, or approximately 29 percent of the years. The average release in those years is 75 TAF, while the average annual agricultural delivery over the 82-year simulation period is 22 TAF. Additional agricultural deliveries are made in many of the same years as in Scenario 1, but at higher volumes.

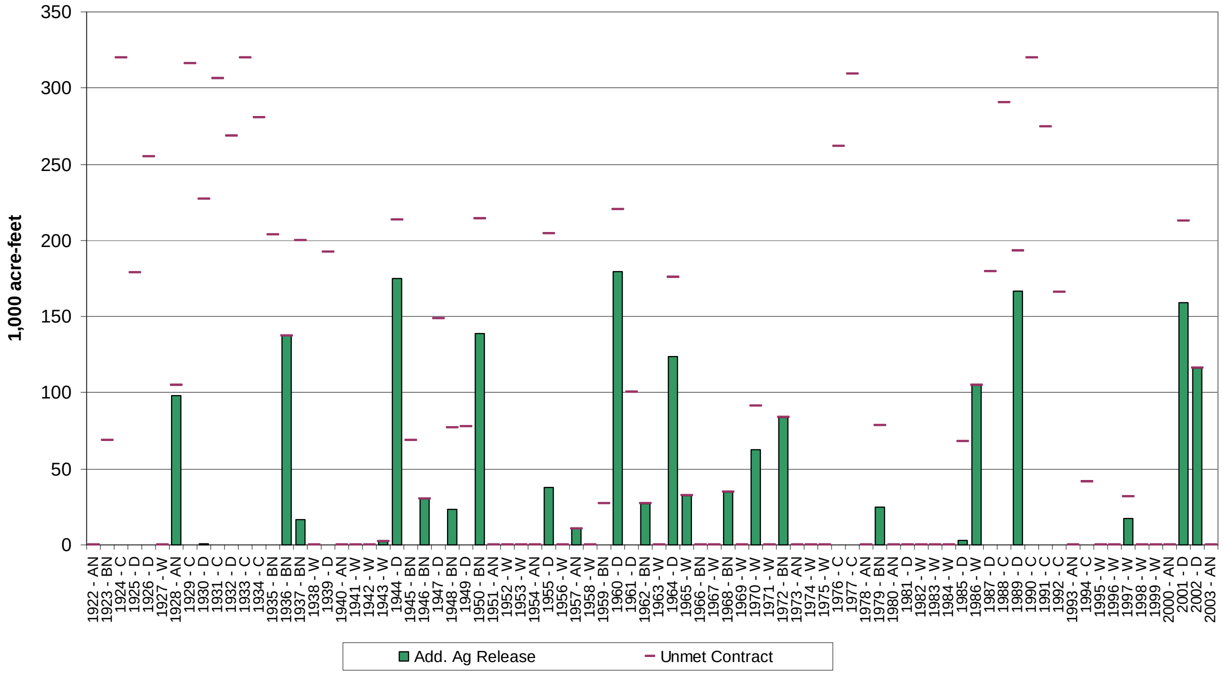

FIGURE 11-26
SACRAMENTO RIVER ADDITIONAL AG. DEMAND MET WITH CONJUNCTIVE MANAGEMENT, SCENARIO 2
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

Additional reservoir releases for either environmental objectives or for additional agricultural delivery result in lower fall carryover storage in Lake Shasta. Figure 11-27 illustrates that fall storage levels are lower in approximately 45 percent of the years and only when end of September storage is more than 2,400 TAF. During these years fall storages are lower compared to Scenario 1 because larger pumping capacity allows for more aggressive operation of the reservoir. Additionally, a small increase in fall storage below the 1,900 TAF target may also be possible.

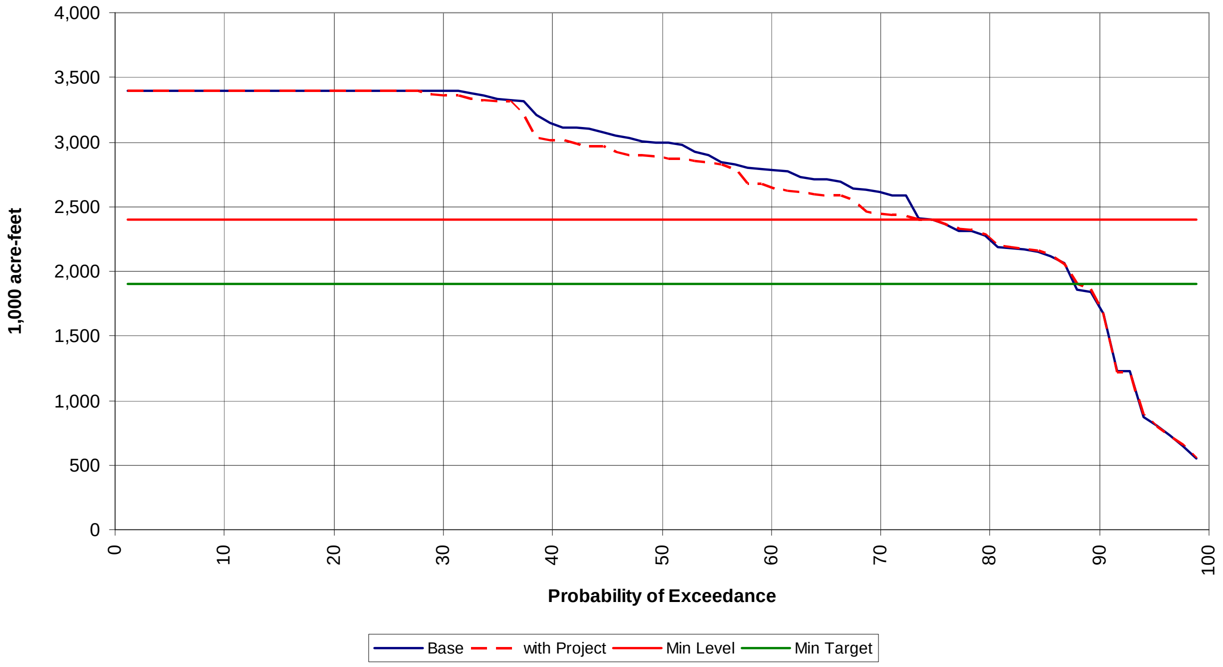

FIGURE 11-27
SHASTA RESERVOIR SEPTEMBER STORAGE EXCEEDANCE PROBABILITY WITH CONJUNCTIVE MANAGEMENT, SCENARIO 2
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

Figure 11-28 illustrates how storage deficits presented on Figure 11-27 are frequently refilled by capture of surplus surface water. Refill with surplus surface water occurs in 35 years with an average annual refill of 139 TAF in those years. Average annual refill with surplus surface water for the 82-year simulation is approximately 58 TAF.

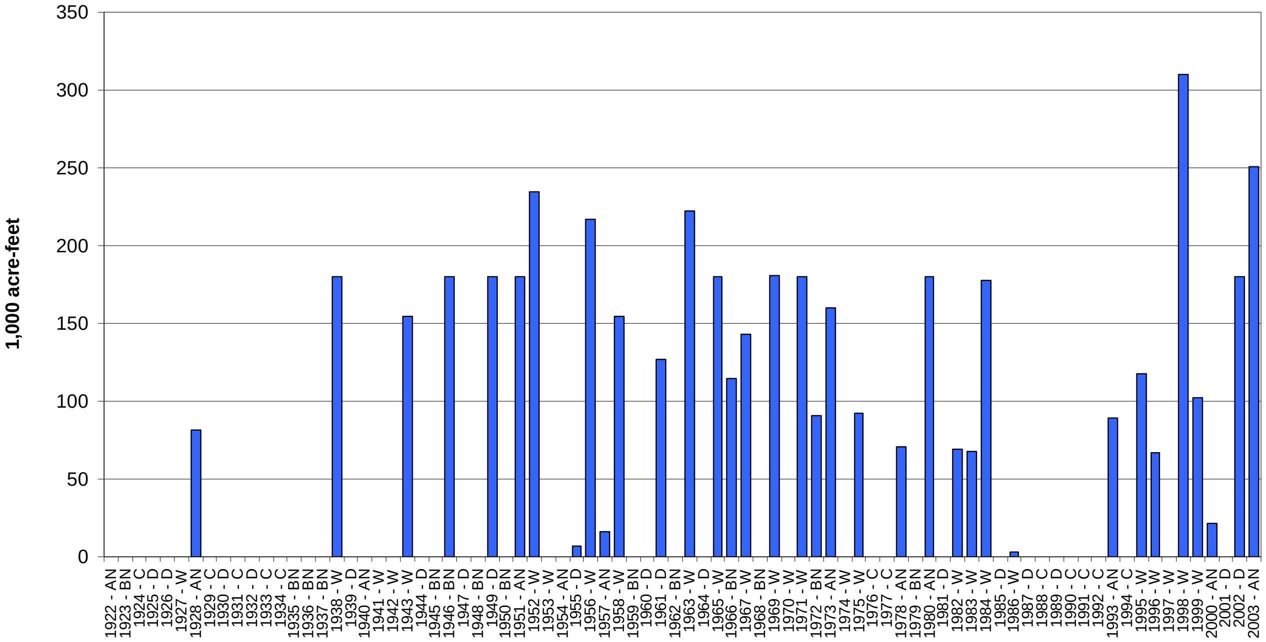

FIGURE 11-28
REFILL OF SHASTA RESERVOIR FROM SURPLUS SURFACE WATER, SCENARIO 2
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION
MODELING REPORT

Figure 11-29 illustrates annual conjunctive management groundwater pumping for Scenario 2. Conjunctive management pumping occurs in 6 of the 82 years simulated, or 7 percent of years. The average annual pumping in those years is 123 TAF. The average annual pumping for the entire 82-year simulation is approximately 9 TAF with a maximum annual pumping of nearly the full 200 TAF of capacity. Pumping typically occurs in drier year types when reservoirs do not refill with surplus surface water.

Over the 82-year simulation period, additional reservoir releases are made in 48 years, or 59 percent of the years. Reservoir refill is accomplished with surplus surface flows in 35 years and with project pumping in 6 years. The number of years with releases exceeds the number of years with refill because reservoir storage deficits do not have to be completely refilled before making additional releases, as long as the total reservoir storage deficit does not exceed the capacity of the project to refill the reservoir in a single year. In summary, of total average annual additional releases of 67 TAF (22 TAF for agriculture and 45 TAF for environmental objectives), 58 TAF is refilled from surplus surface water and 9 TAF from conjunctive management pumping.

11.2.2 Oroville Reservoir and Feather River

Figure 11-30 illustrates annual volumes of water released to meet environmental objectives on the Feather River. Similar to the Sacramento River operations, the geomorphic objective is satisfied most frequently, but increased groundwater pumping capacity allows for more aggressive reservoir operations allowing other objectives to also be satisfied. Average annual release for environmental objectives on the Feather River is 23 TAF.

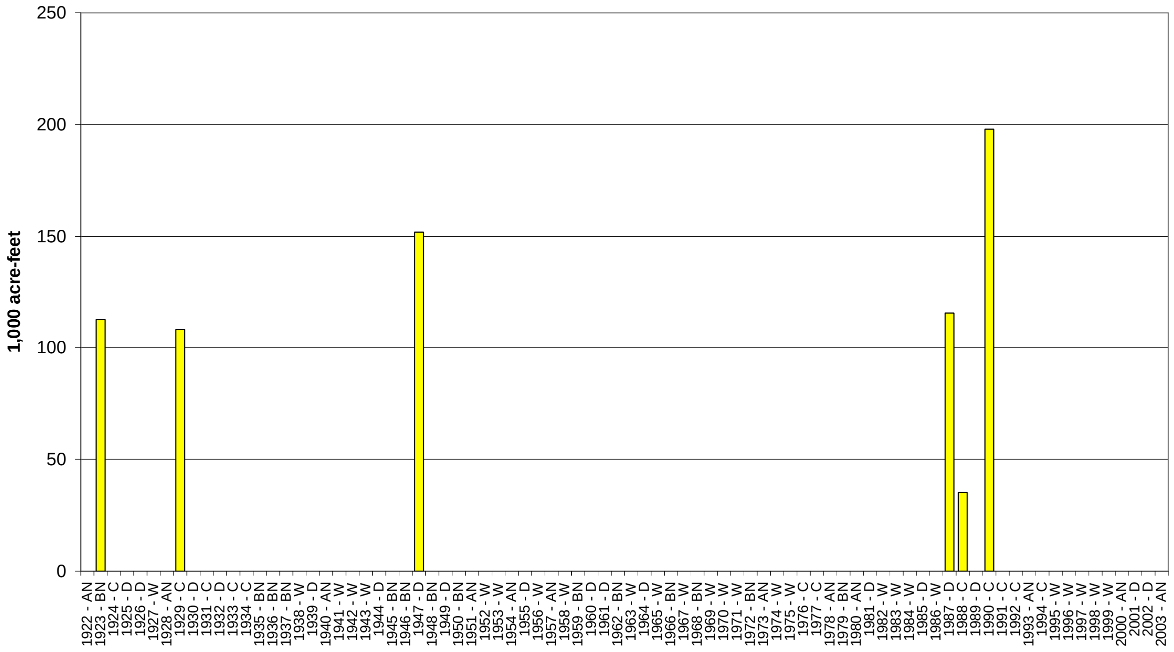

FIGURE 11-29

MODELING REPORT

Table 11-4 provides a summary of the number of times each objective is met by reservoir release and under base operations on the Feather River. Values reported in the table for the geomorphic objective only include those years when the objective is not met under base operations. Therefore this value is less than the number of releases shown on Figure 11-30. The flood plain inundation objective can be met with the project under base condition flows with the modified weir, or with a combination of project releases and the modified weir.

TABLE 11-4

Spring Pulse	3	1	4
Riparian Recruitment	1	8	9
Geomorphic	31	25	56
Flood Plain Inundation	21	20	41

Figure 11-31 illustrates additional agricultural deliveries under Scenario 2. Additional agricultural releases are made in 30 of the 82 years simulated, or approximately 37 percent of the years. The average annual release in those years is 52 TAF, while the average annual agricultural delivery over the 82-year simulation period is 20 TAF.

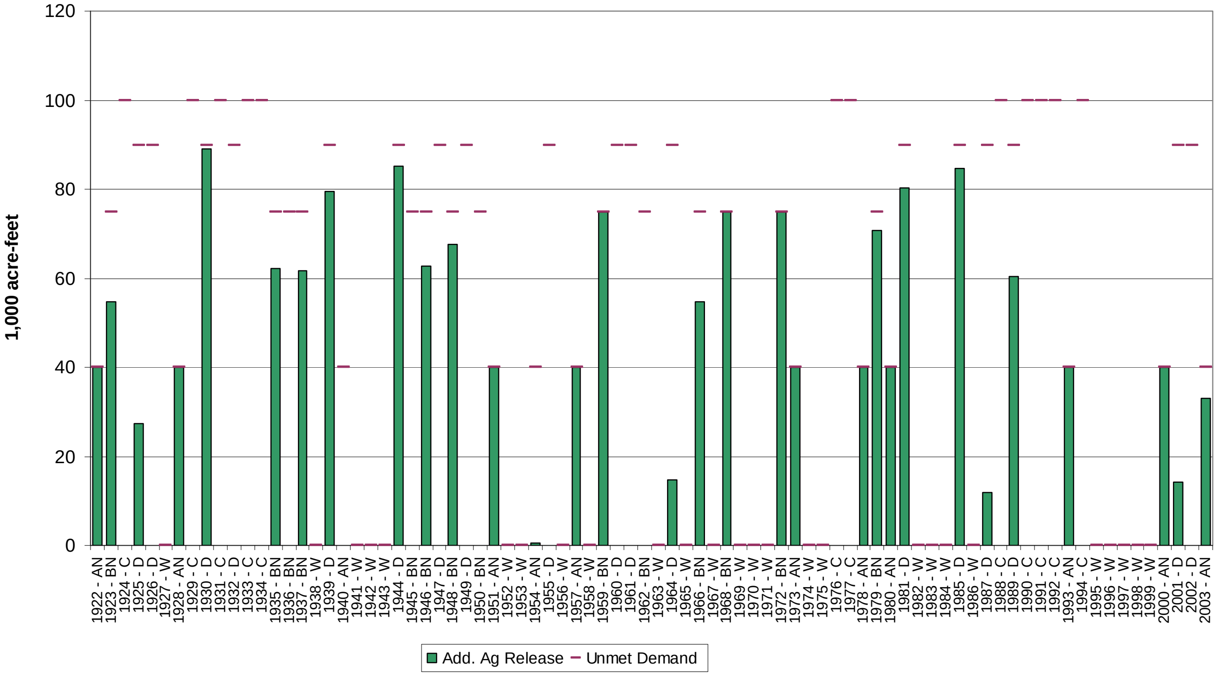

FIGURE 11-31
FEATHER RIVER ADDITIONAL AG. DEMAND MET WITH CONJUNCTIVE MANAGEMENT, SCENARIO 2
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION
MODELING REPORT

Figure 11-32 illustrates how conjunctive management operations result in lower Oroville fall storage conditions in approximately 60 percent of the years. Fall storage may be increased in a few years when it is below the minimum target level of 1,200 TAF.

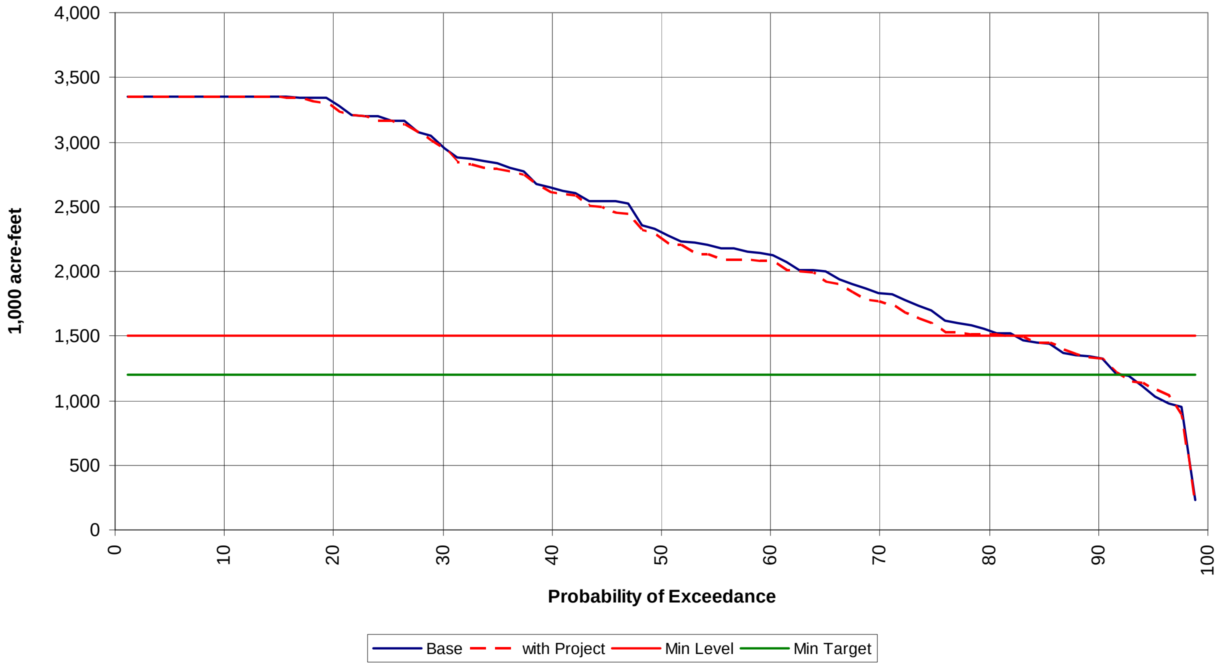

FIGURE 11-32
OROVILLE RESERVOIR SEPTEMBER STORAGE EXCEEDANCE PROBABILITY WITH CONJUNCTIVE MANAGEMENT, SCENARIO 2
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION
MODELING REPORT

Figure 11-33 shows how storage space created in Oroville Reservoir through additional releases for agricultural and environmental objectives is frequently refilled with surplus surface water. This occurs in 43 years with an average annual refill of 72 TAF in those years. Average annual refill with surplus for the 82-year simulation period is approximately 36 TAF.

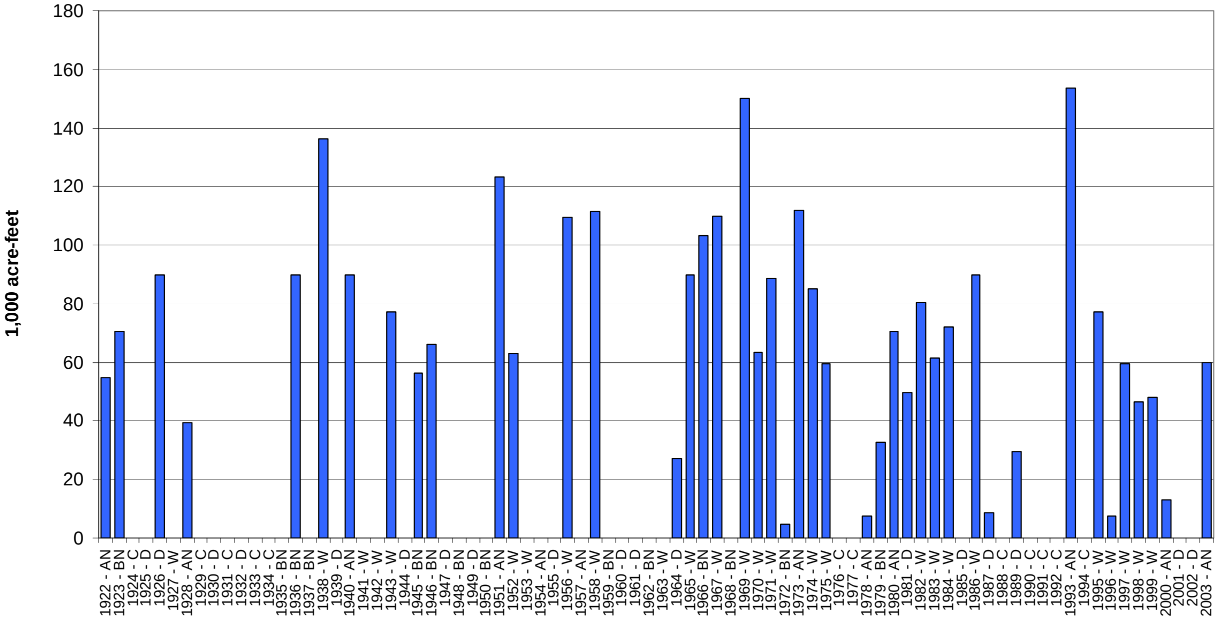

FIGURE 11-33
REFILL OF OROVILLE RESERVOIR FROM SURPLUS SURFACE WATER, SCENARIO 2
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION
MODELING REPORT

Figure 11-34 presents the annual conjunctive management pumping in the Butte Basin project for Scenario 2. Conjunctive management pumping occurs in 8 of the 82 years simulated or 10 percent of the years. The average annual pumping in those years is 75 TAF. The average annual pumping for the entire 82-year simulation is approximately 7 TAF with a maximum annual pumping of the full 100 TAF of pumping capacity.

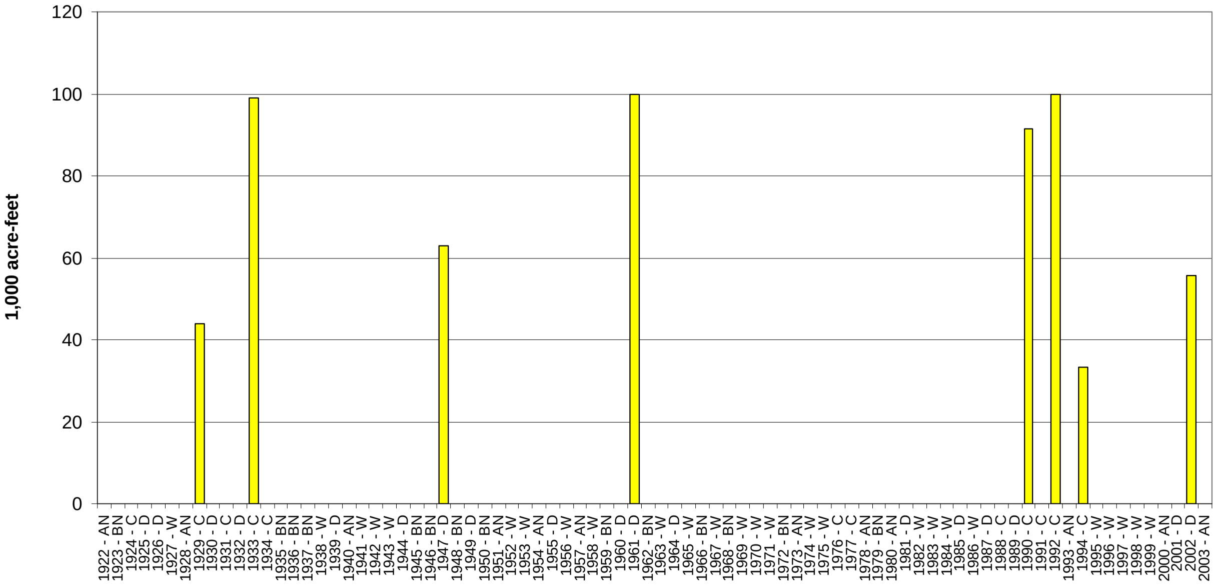

FIGURE 11-34
REFILL OF OROVILLE RESERVOIR FROM CONJUNCTIVE MANAGEMENT PUMPING, SCENARIO 2
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION
MODELING REPORT

Over the 82-year simulation period, additional reservoir releases are made in 51 years, or 62 percent of the years. Reservoir refill is accomplished with surplus surface flows in 43 years and with project pumping in 8 years. For Scenario 2 on the Feather River system, out of total additional releases of 43 TAF (23 TAF for agriculture and 20 TAF for environmental objectives), 36 TAF is refilled from surplus surface water and 7 TAF from conjunctive management pumping.

11.2.3 Groundwater Results

Existing Well Field

Results of pumping for Scenario 2 using the existing well field shown on Figure 11-3 are summarized on Figures 11-35 through 11-37. Peak drawdown in groundwater levels associated with implementation of this scenario is presented on Figure 11-35. This figure depicts simulated drawdown in the pumped aquifer, during August 1990. Maximum pumping rates under this alternative occur during 1990. Figure 11-35 shows that the area of greatest drawdown occurs in the northern GCID area at a magnitude of up to 100 feet.

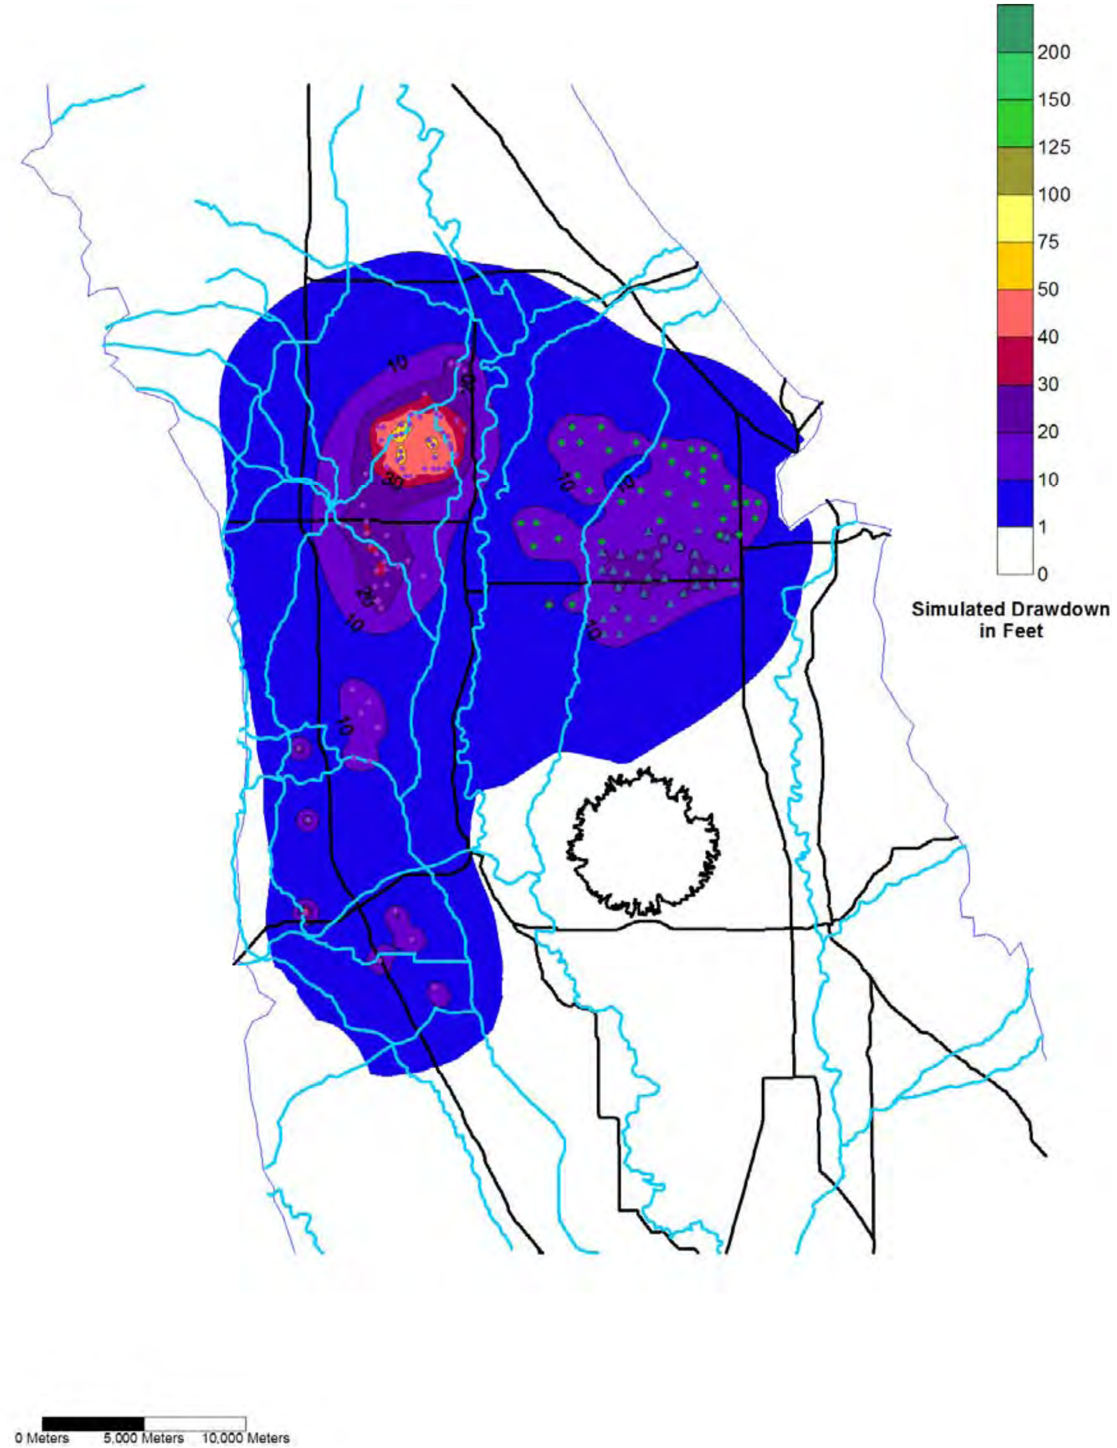

FIGURE 11-35
SIMULATED DRAWDOWN IN THE REGIONAL AQUIFER IN AUG 1990, SCENARIO 2 -EXISTING WELL FIELD
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

Simulated impacts to surface streams under Scenario 2 using an existing well field are summarized on Figures 11-36 and 11-37. These figures show that the greatest impact to surface streams will occur to the Sacramento River between GCID and Wilkins Slough and Butte Creek, with smaller impacts estimated to occur to surrounding streams. Figure 11-36 suggests that the peak cumulative impact to all surface water flows will be about 110 cfs in summer of 1990, while a peak impact of just over 70 cfs is predicted to occur on the Sacramento River and a peak impact of about 32 cfs is estimated to occur on Butte Creek. Peak impact to the Sacramento River will occur in late summer of 1990 while peak impact on Butte Creek is forecast to occur in early 1993. Peak impacts to stream flows on smaller tributary streams peak at less than about 11 cfs as shown on Figure 11-37.

SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

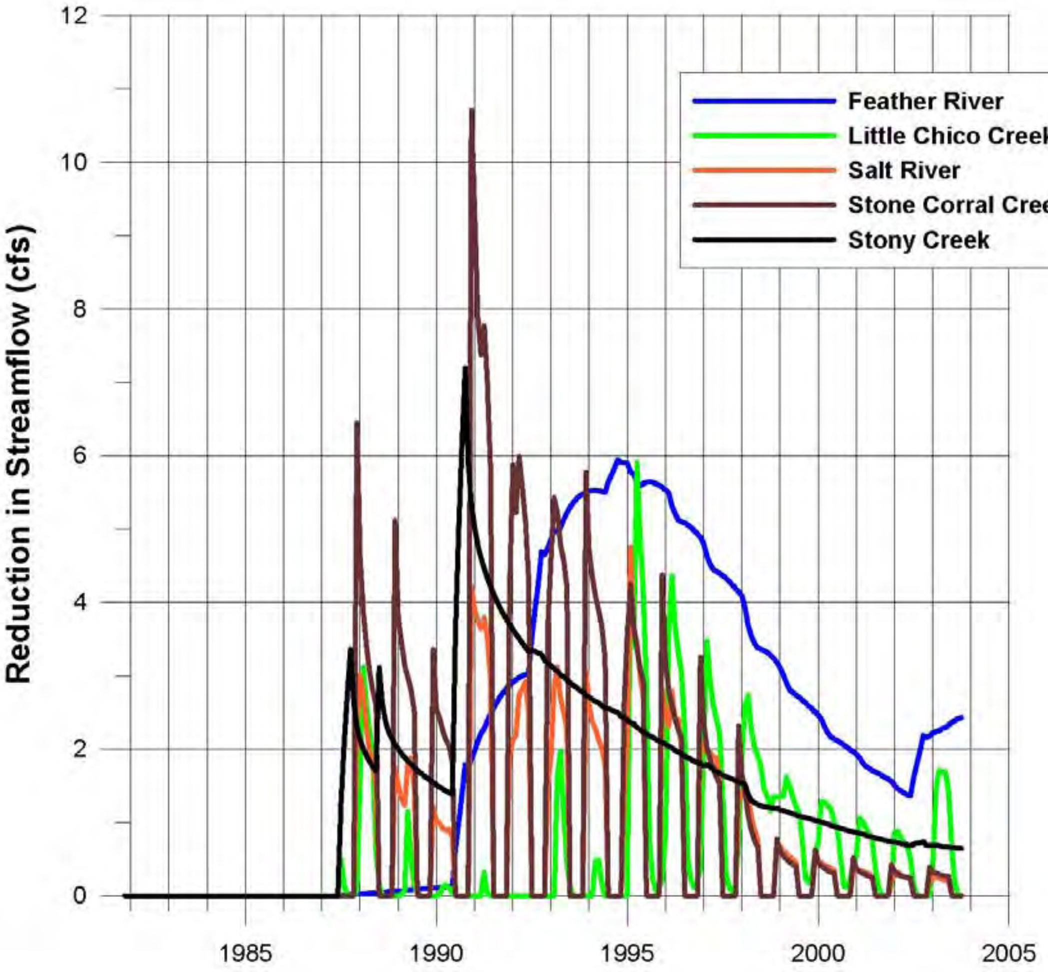

FIGURE 11-37
SIMULATED REDUCTION IN STREAMFLOW TO MINOR STREAMS, SCENARIO 2 - EXISTING WELL FIELD
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

11.2.4 Reservoir Release for Recharge

Streamflow reductions, due either to increased stream loss to aquifers or decreased aquifer flow into streams, may result in changes in upstream reservoir operations. Time series of simulated streamflow reductions from the groundwater model were input back into the surface water model to determine system conditions at times when reductions occur. Depending on location and timing of reductions, upstream reservoirs may be required to make additional releases to compensate for streamflow reductions due to groundwater pumping. System conditions, either balanced or surplus, were determined from the CalSim II simulation of CVP/SWP operations. Additional releases from Shasta and Oroville were simulated and tracked in the surface water model. Figures 11-38 and 11-39 present annual additional releases from Shasta and Oroville, respectively, for Scenario 2 pumping from an existing well field.

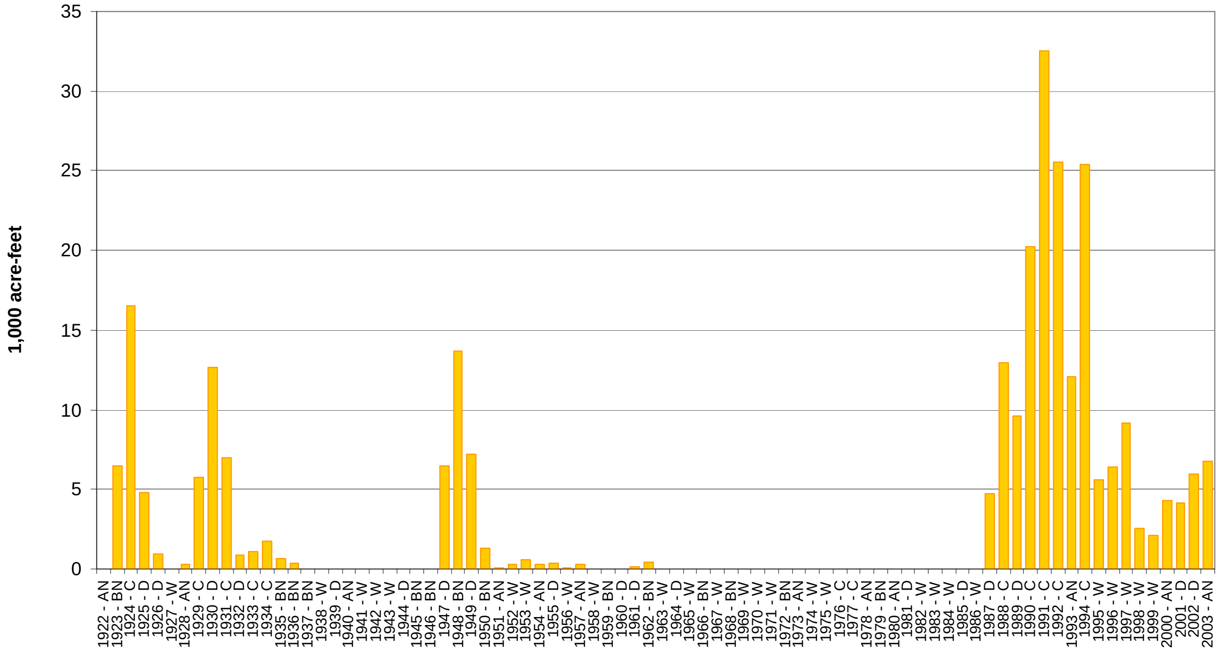

FIGURE 11-38

MODELING REPORT

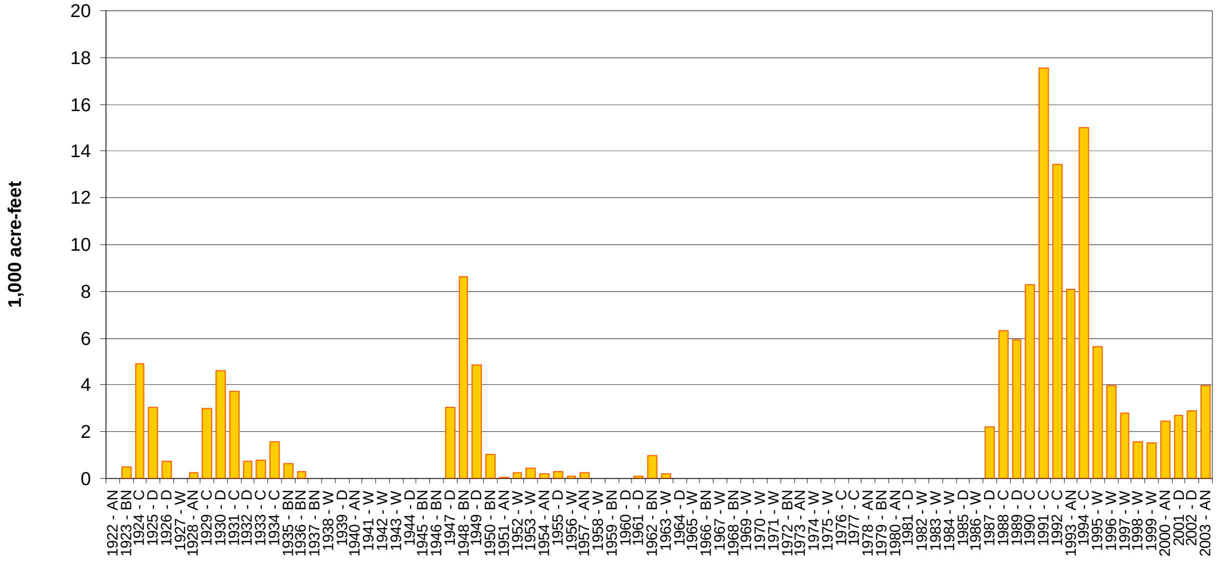

FIGURE 11-39
ANNUAL ADDITIONAL RELEASE FROM OROVILLE RESERVOIR TO COMPENSATE FOR CHANGE IN STREAM-AQUIFER INTERACTION, SCENARIO 2 - EXISTING WELL FIELD
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION
MODELING REPORT

Figures 11-38 and 11-39 illustrate that annual release from Shasta and Oroville to compensate for stream losses from conjunctive management pumping increase under Scenario 2 due to increased pumping frequency and quantity and the resulting increase in streamflow reductions.

New Well Field

Groundwater results for Scenario 2 using a new well field pumping from the deep aquifers are summarized on Figures 11-40 through 11-42. Peak drawdown in groundwater levels associated with implementation of this alternative is presented on Figure 11-40. This figure depicts simulated drawdown in the pumped aquifer during August 1990; the area of greatest drawdown occurs in the western GCID area at a magnitude of up to 200 feet.

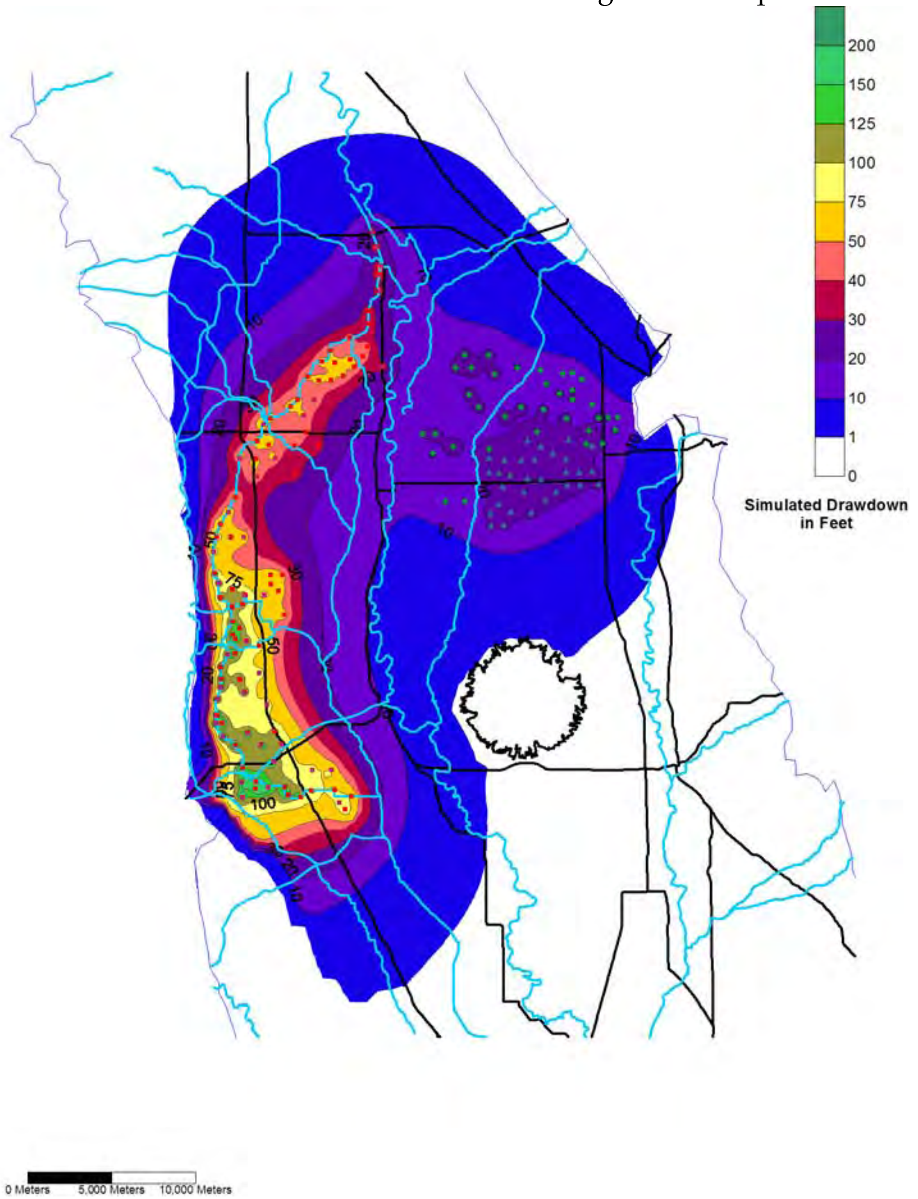

FIGURE 11-40
SIMULATED DRAWDOWN IN THE DEEP AQUIFER IN AUG 1990, SCENARIO 2 - NEW WELL FIELD
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION
MODELING REPORT

Simulated impacts to surface streams under Scenario 2 with a new well field are summarized on Figures 11-41 and 11-42. These figures show that the greatest impact to surface streams will occur to the Sacramento River, between GCID and Wilkins Slough, and Butte Creek, with smaller impacts estimated to occur to surrounding streams. Figure 11-41 suggests that the peak cumulative impact to all surface water flows will be about 105 cfs in the late fall of 1990, and that a peak flow reduction of just less than 70 cfs will occur on the Sacramento River while a peak flow reduction of about 27 cfs will occur on Butte Creek. Peak impact to the Sacramento River will also occur in late fall of 1990 while two similar peak impacts occur on Butte Creek in early 1993 and the fall of 1994. Impacts to stream flows on smaller tributary streams peak at less than about 15 cfs, as shown on Figure 11-41.

MODELING REPORT

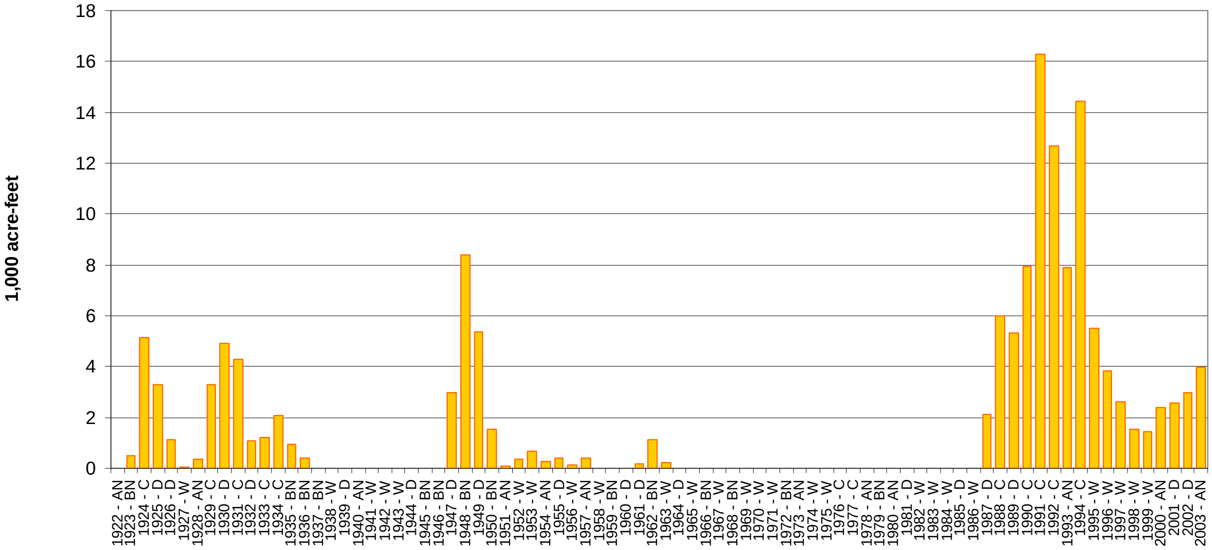

FIGURE 11-44
ANNUAL ADDITIONAL RELEASE FROM OROVILLE RESERVOIR TO COMPENSATE FOR CHANGE IN STREAM-AQUIFER INTERACTION, SCENARIO 2 - NEW WELL FIELD
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION
MODELING REPORT

Figures 11-43 and 11-44 show smaller peak reservoir releases to compensate for conjunctive management pumping for a new well field screen in the deep aquifer than for pumping existing wells. This reflects smaller streamflow reductions for a new well field at the higher pumping volumes simulated in Scenario 2.

11.3 Scenario 3 – 100 TAF GCID, 50 TAF Butte Basin, Fall Pumping

Scenario 3 has the same general reservoir release strategies and groundwater pumping capacities as Scenario 1. The difference is the season for conjunctive management pumping. Under Scenario 3 conjunctive management pumping for the purpose of recovering reservoir storage levels is conducted from September through November. Instead of offsetting irrigation season demands, this pumping is assumed to offset demands for rice straw decomposition and waterfowl habitat.

Shifting the conjunctive management pumping season may have several benefits. First, peak drawdown in the aquifers and resulting effects on nearby wells would occur outside of the primary pumping season for most existing wells. Second, a greater portion of aquifer recharge may occur during the winter rainy season when the surface water system is more likely to be in a surplus condition. Third, it may be easier to reduce fall reservoir releases to recover reservoir levels in the fall of dry years and still meet existing temperature control criteria on the Sacramento River.

A majority of results for Scenario 3 are the same as for Scenario 1 because spring and summer surface water operations do not change. The same environmental objectives are met, and the average annual releases for both environmental and agricultural objectives are the same. Reservoir refill for both Shasta and Oroville occurs with the same mix and timing of surplus surface water and groundwater pumping. There are minor differences in end of September storage in each reservoir under Scenario 3. These differences are in years when conjunctive management pumping occurs, but is not yet complete, by the end-of-September. Figures 11-45 and 11-46 illustrate this effect for both Shasta and Oroville.

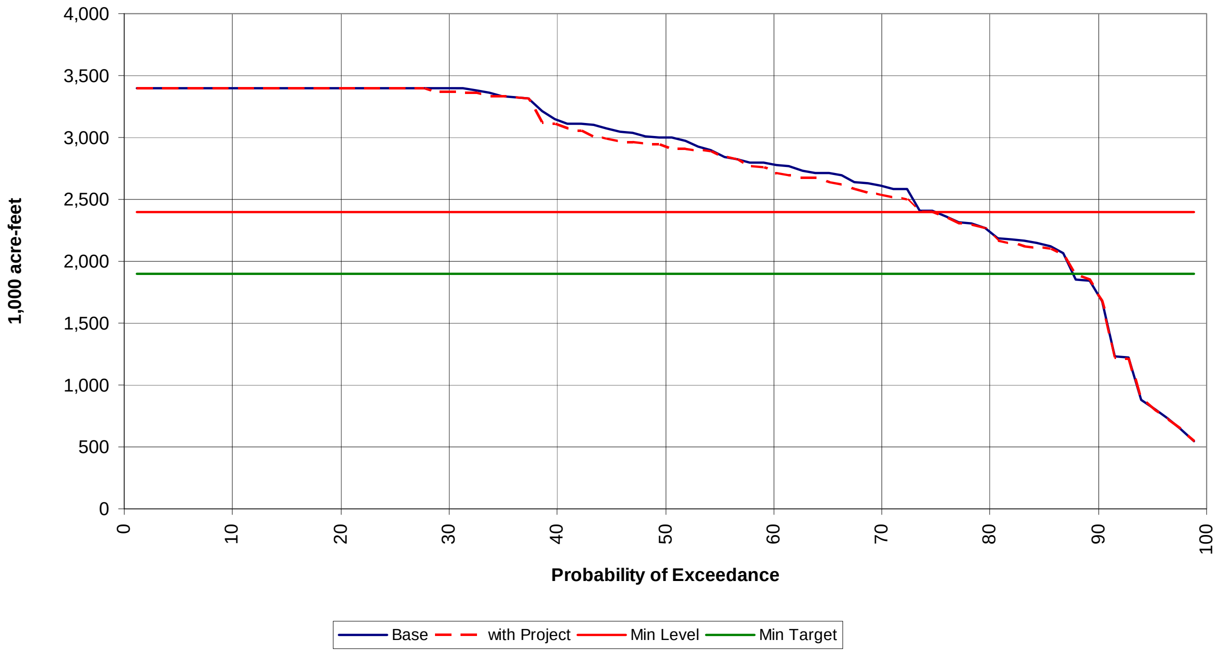

FIGURE 11-45
SHASTA RESERVOIR SEPTEMBER STORAGE EXCEEDANCE PROBABILITY WITH CONJUNCTIVE MANAGEMENT, SCENARIO 3
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

Figure 11-45 shows some minor differences between base conditions and Scenario 3 when end-of-September Shasta storage levels are below 2,400 TAF. In these years, conjunctive management pumping is occurring September through November so that the reservoir is recovered by the end of November and there is no risk to future water supplies or cold water pool.

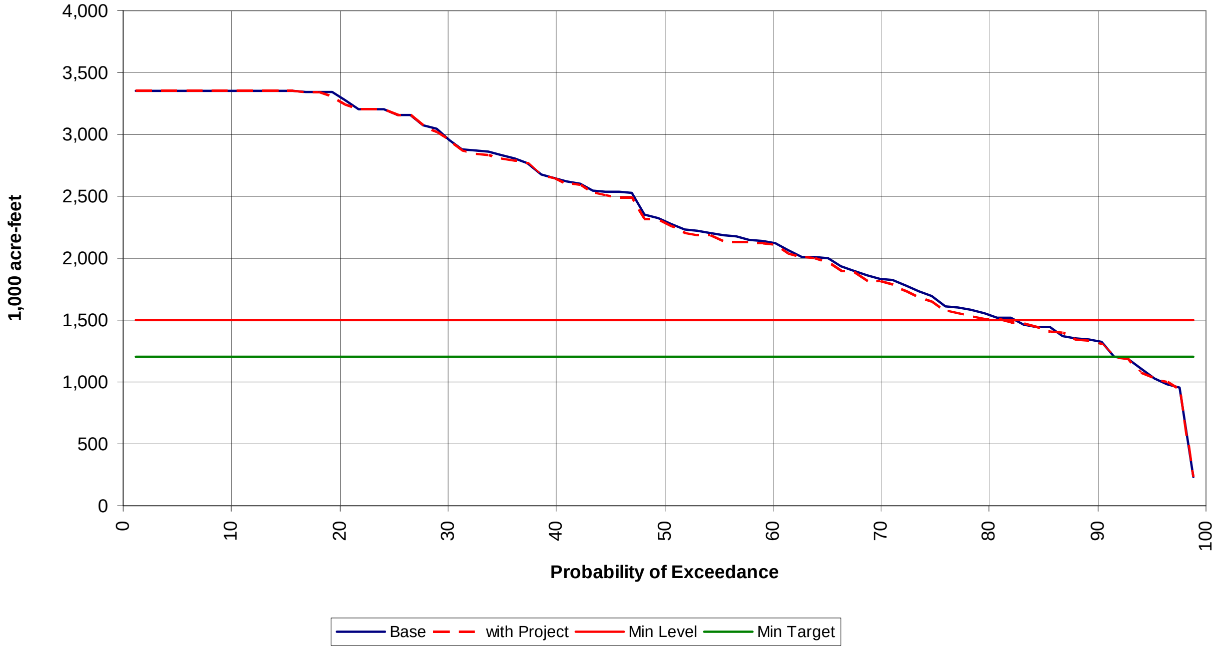

FIGURE 11-46
OROVILLE RESERVOIR SEPTEMBER STORAGE EXCEEDANCE PROBABILITY WITH CONJUNCTIVE MANAGEMENT, SCENARIO 3
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION
MODELING REPORT

Figure 11-46 illustrates a similar effect on Oroville Reservoir, but it is less clear due to the smaller difference between base and with project storages.

11.3.1 Groundwater Results

Existing Well Field

Results of pumping for Scenario 3 with an existing well field are summarized on Figures 11-47 through 11-49. Peak drawdown in groundwater levels associated with implementation of this alternative is presented on Figure 11-47. This figure depicts simulated drawdown in the pumped aquifer during November 1990. Maximum pumping rates under this alternative occur during 1990. Figure 11-47 shows that the area of greatest drawdown occurs in the northern GCID area at a magnitude of up to 50 feet.

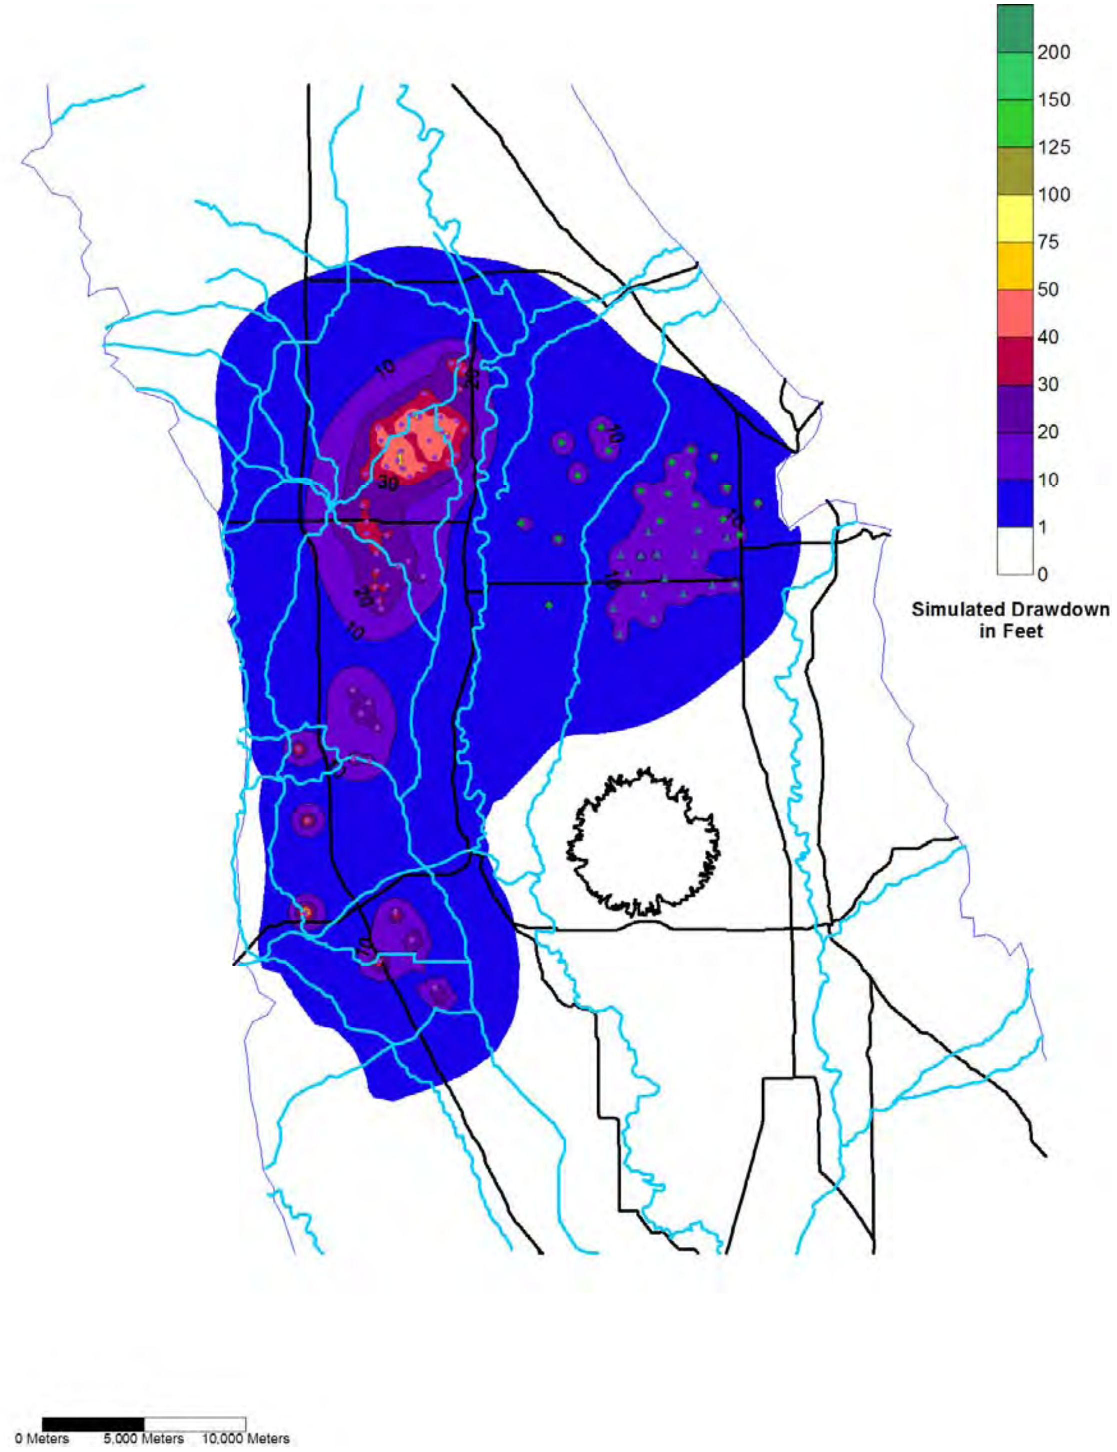

FIGURE 11-47
SIMULATED DRAWDOWN IN THE REGIONAL AQUIFER IN NOV 1990, SCENARIO 3 -EXISTING WELL FIELD
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION
MODELING REPORT

Simulated impacts to surface streams under Scenario 3 with an existing well field are summarized on Figures 11-48 and 11-49. These figures show that the greatest impact to surface streams will occur to the Sacramento River (between GCID and Wilkins Slough) and Butte Creek, with smaller impacts estimated to occur to surrounding streams. Figure 11-48 suggests that peak cumulative impact to all surface water flows will be approximately 80 cfs in the summer of 1990, with a flow reduction of approximately 50 cfs forecast to occur on the Sacramento River and a flow reduction of approximately 18 cfs on Butte Creek. Peak impact to the Sacramento River will also occur in late summer of 1990 while peak impact on Butte Creek is forecasted to occur in late 1994. Peak impacts to stream flows on smaller tributary streams peak at less than approximately 7 cfs, as shown on Figure 11-48.

Reservoir Release for Recharge

Streamflow reductions, due to either increased stream loss to aquifers or decreased aquifer flow into streams, may result in changes to upstream reservoir operations. Time series of simulated streamflow reductions from the groundwater model were input back into the surface water model to determine system conditions at times when reductions occur. Depending on location and timing of reductions, upstream reservoirs may be required to make additional releases to compensate for streamflow reductions due to groundwater pumping. System conditions, either balanced or surplus, were determined from the CalSim II simulation of CVP/SWP operations. Additional releases from Shasta and Oroville were simulated and tracked in the surface water model. Figures 11-50 and 11-51 present annual additional releases from Shasta and Oroville, respectively, for Scenario 3 pumping from an existing well field.

MODELING REPORT

Figures 11-50 and 11-51 show that peak annual releases are larger under Scenario 3 for the more condensed fall pumping season than under Scenario 1. General timing and volumes are similar between the two scenarios.

New Well Field

Results of Scenario 3 with a new well field are summarized on Figures 11-52 through 11-54. The peak drawdown in groundwater levels associated with the implementation of this alternative is presented on Figure 11-52. This figure depicts the simulated drawdown in the pumped aquifer, during November 1990. The maximum pumping rates under this alternative occur during 1990. It can be seen from the figure that the area of greatest drawdown occurs in the western GCID area at a magnitude of up to 125 feet.

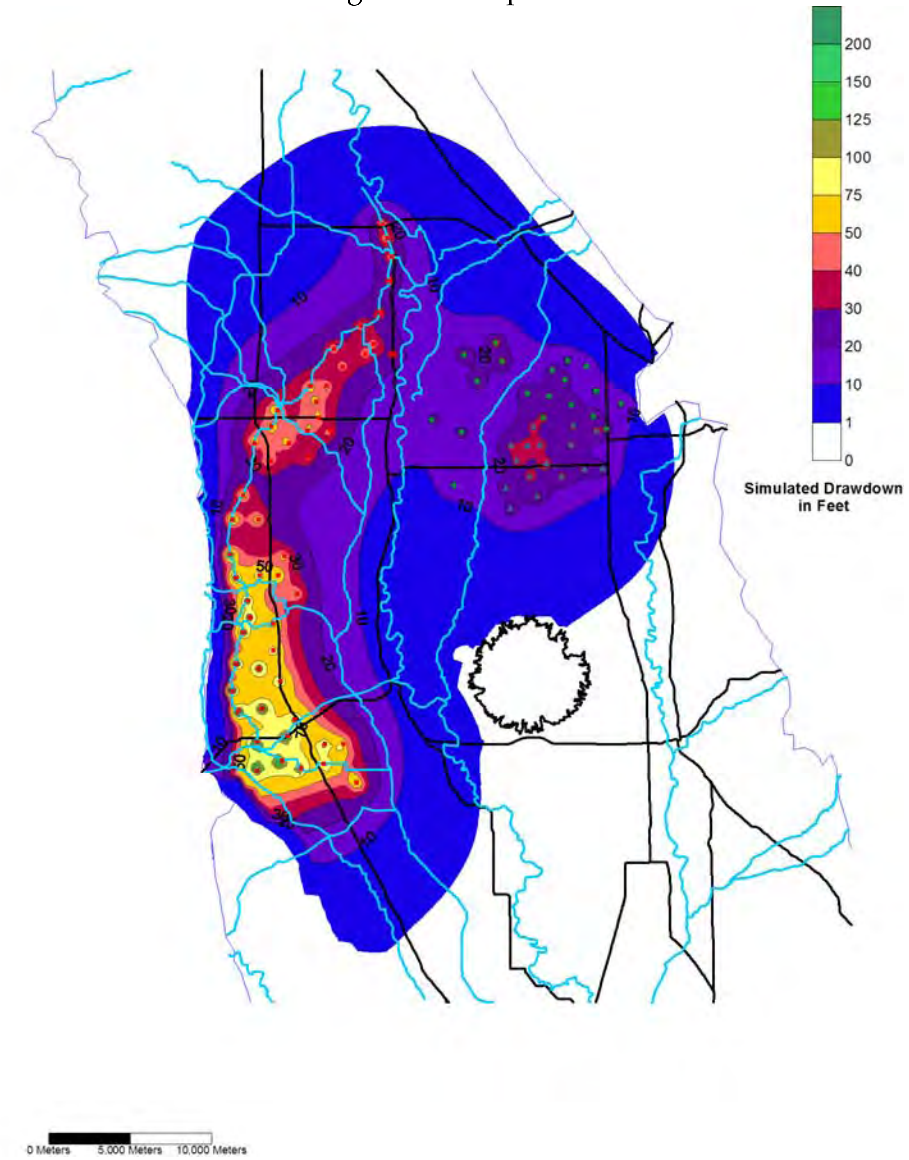

FIGURE 11-52
ANNUAL ADDITIONAL RELEASE FROM OROVILLE RESERVOIR TO COMPENSATE FOR CHANGE IN STREAM-AQUIFER INTERACTION, SCENARIO 3 - EXISTING WELL FIELD
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

Simulated impacts to surface streams under Scenario 3 with a new well field are summarized on Figures 11-53 and 11-54. These figures show that the greatest impact to surface streams will occur to the Sacramento River, between GCID and Wilkins Slough, and Butte Creek, with smaller impacts estimated to occur to surrounding streams. Figure 11-44 suggests that the peak cumulative impact to all surface water flows will be a reduction of about 90 cfs in December 1990, while a flow reductions of just more than 48 and 18 cfs is forecasted to occur on the Sacramento River and Butte Creek, respectively. Peak impact to the Sacramento River will also occur in December 1990 while peak impact predicted on Butte Creek will occur in December 1994. Peak impacts to stream flows on smaller tributary streams peak at less than about 10 cfs as shown on Figure 11-54.

MODELING REPORT

Figures 11-54 and 11-55 illustrate that maximum annual release from Shasta for a new well field is less than for the existing well field, while results are essentially the same on the Feather River.

11.4 Scenario 4 – 100 TAF GCID, 50 TAF Butte Basin, Summer and Fall Pumping

Scenario 4 has the same general reservoir release strategies and groundwater pumping capacities as Scenarios 1 and 3. The difference is again the season for conjunctive management pumping. Under Scenario 4 conjunctive management pumping is conducted in both the summer and fall from May through November. This pumping is used to offset both irrigation season demands and demand for rice straw decomposition water. Pumping over an extended period may provide benefits by reducing the quantity of water that must be pumped in any given month, thereby reducing the size and/or number of wells needed. Additionally, spreading pumping over a longer period may reduce drawdown and stream impacts.

Surface water results for Scenario 4 are similar to those presented for Scenario 1. The same environmental objectives are met, and the average annual releases for both environmental and agricultural objectives are the same. Reservoir refill for both Shasta and Oroville occurs with the same mix and timing of surplus surface water and groundwater pumping. Changes in end-of September storage in the reservoirs presented above for Scenario 3 are smaller in magnitude because under Scenario 4 the majority of conjunctive management pumping has occurred prior to the end of September. The minor differences seen under Scenario 4 are difficult to discern and are therefore not presented.

11.4.1 Existing Well Field

Results for Scenario 4 with an existing well field are summarized on Figures 11-57 through 11-58. Peak drawdown in groundwater levels associated with implementing this alternative is presented on Figure 11-57. This figure depicts simulated drawdown in the pumped aquifer, during November 1990. Maximum pumping rates under this alternative occur during 1990, and the drawdown distribution at the end of November represents approximately the maximum drawdown that will occur under this scenario. Figure 11-57 that the area of greatest drawdown occurs in northern GCID at a magnitude of less than 30 feet.

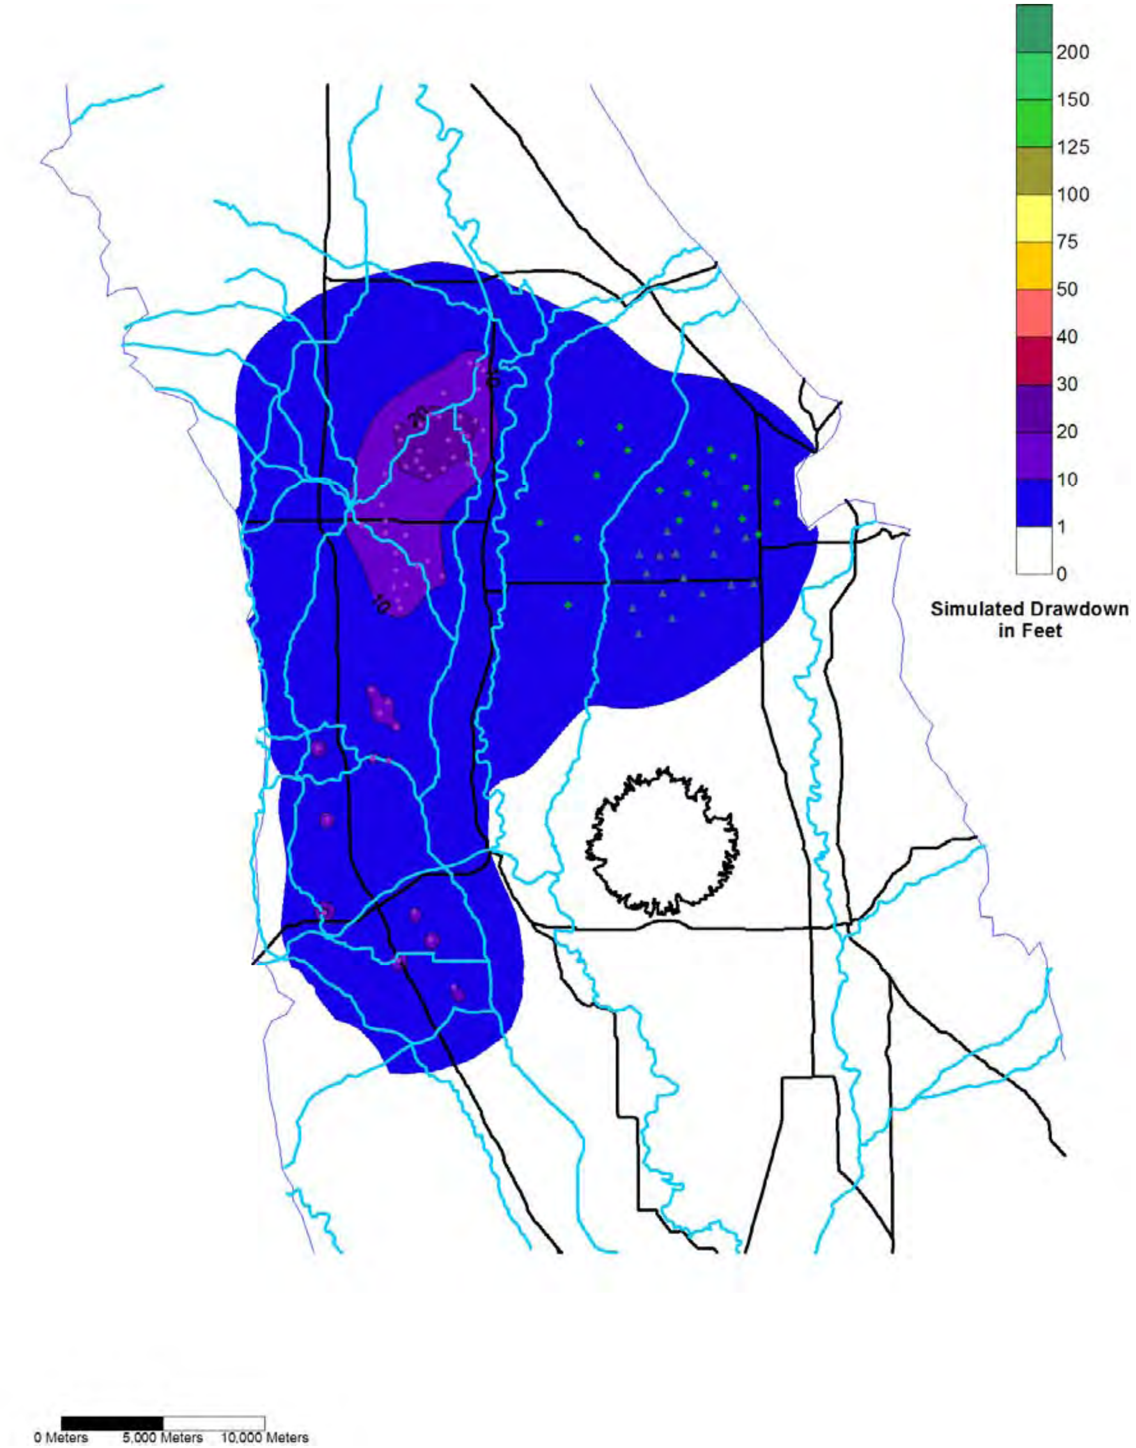

FIGURE 11-57
SIMULATED DRAWDOWN IN THE REGIONAL AQUIFER IN NOV 1990, SCENARIO 4 - EXISTING WELL FIELD
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

Simulated impacts to surface streams under Scenario 4 with an existing well field are summarized on Figures 11-58 and 11-59. These figures show that the greatest impact to surface streams will occur to the Sacramento River, between GCID and Wilkins Slough, and Butte Creek, with smaller impacts estimated to occur to surrounding streams. Figure 11-58 shows that the peak cumulative impact to all surface water flows will be approximately 64 cfs in December 1990, with a flow reduction of just less than 40 cfs forecasted to occur on the Sacramento River and a flow reduction of about 15 cfs on Butte Creek. Peak impact to the Sacramento River will also occur in December of 1990 while the peak impact on Butte Creek is forecast to occur in late 1995. Peak impacts to stream flows on smaller tributary streams peak at less than approximately 6 cfs, as shown on Figure 11-59.

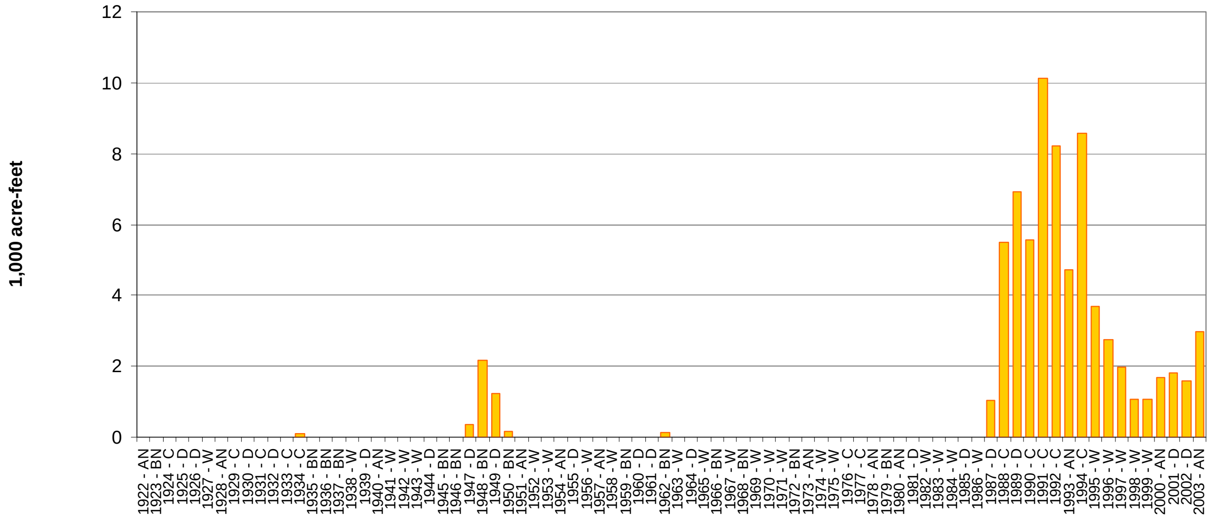

FIGURE 11-61
ANNUAL ADDITIONAL RELEASE FROM OROVILLE RESERVOIR TO COMPENSATE FOR CHANGE IN STREAM-AQUIFER INTERACTION, SCENARIO 4 - EXISTING WELL FIELD
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

Figures 11-60 and 11-61 indicate that the pattern and volume of additional reservoir release for Scenario 4 is similar to that for Scenarios 1 and 3 with the maximum annual release approximately between those two scenarios.

11.4.3 New Well Field

Results of simulation of pumping from a new well field under Scenario 4 are summarized on Figures 11-62 through 11-64. Peak drawdown in groundwater levels associated with implementation of this alternative is presented on Figure 11-62. This figure depicts simulated drawdown in the pumped aquifer during November 1990. Maximum pumping rates under this alternative occur during 1990, and the drawdown distribution at the end of November represents approximately the maximum drawdown that will occur under this alternative. It can be seen from the figure that the greatest drawdown occurs in the western GCID area at a magnitude of up to 50 feet.

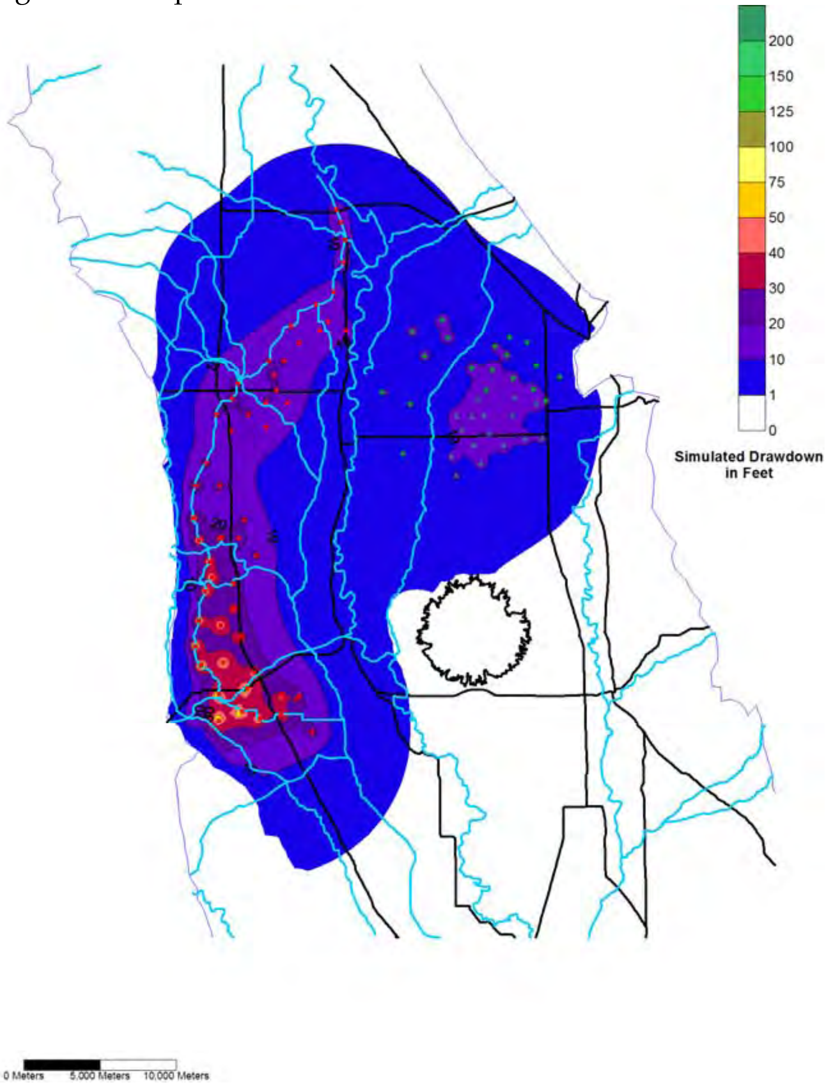

FIGURE 11-62
SIMULATED DRAWDOWN IN THE DEEP AQUIFER IN NOV 1990, SCENARIO 4 - NEW WELL FIELD
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

Simulated impacts to surface streams for Scenario 4 with a new well field are summarized on Figures 11-63 and 11-64. These figures show that the greatest impact to surface streams will occur to the Sacramento River, between GCID and Wilkins Slough, and Butte Creek, with smaller impacts estimated to occur to surrounding streams. Figure 11-63 shows that peak cumulative impact to all surface water flows will be a reduction of approximately 65 cfs in December 1990, while a flow reduction of just more than 33 cfs is forecasted to occur on the Sacramento River and a flow reduction of about 15 cfs is predicted on Butte Creek. Peak impact to the Sacramento River will also occur in December 1990 while peak impacts on Butte Creek occur in December 1995. Peak impacts to stream flows on smaller tributary streams peak at less than about 9 cfs, as shown on Figure 11-64.

SECTION 12

Sensitivity Analysis and Tradeoffs

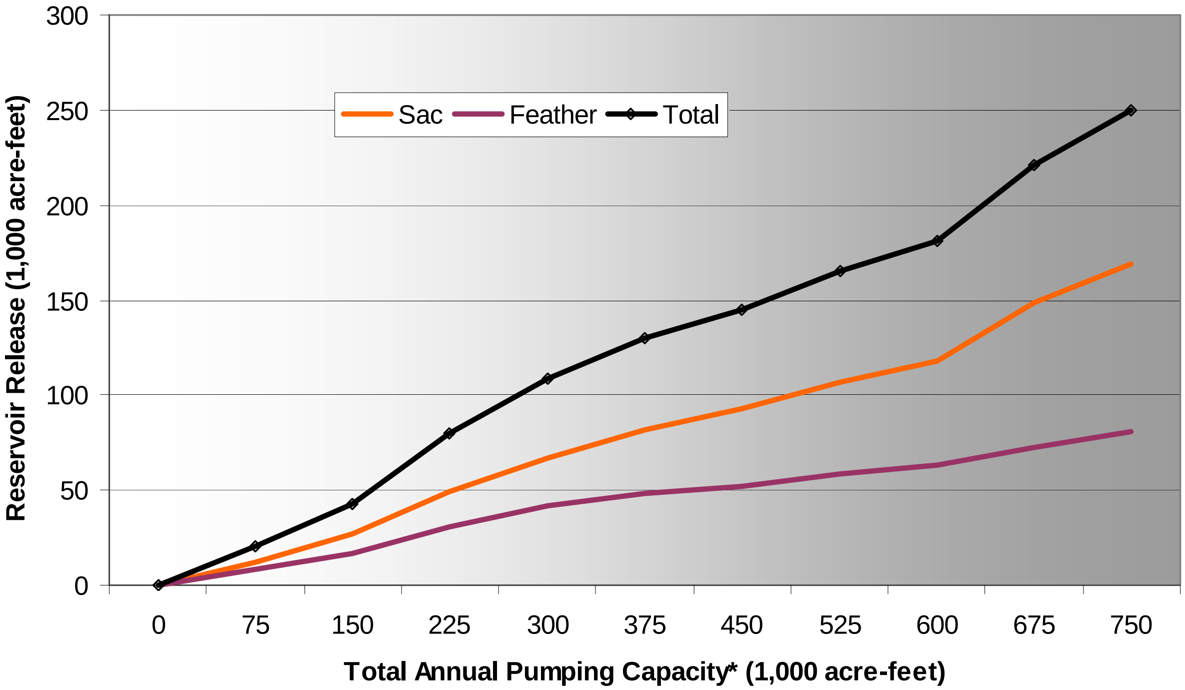
Simulation results presented in the previous section represent specific project sites and operations developed during the course of the analysis. Additional understanding of tradeoffs between certain key parameters and objectives can be gained from using the model in a sensitivity analysis mode in which or a limited number of parameters are varied while holding all other assumptions constant. This section presents results and conclusions for a limited set of model runs focused on better understanding key project inputs and assumptions.

Sensitivity analysis was conducted for several purposes. Sensitivity to parameters, such as project pumping capacity, was evaluated to assist in sizing potential projects. A range of environmental objectives were evaluated because considerable uncertainty exists in the development of objectives, and evaluating a range of possible objectives can help determine how much more or less conjunctive management could contribute to higher or lower flow targets. Evaluating various pumping periods and well field configurations was used to understand how aquifers respond to different pumping magnitudes and durations and the effects on stream-aquifer interactions.

12.1 Pumping Capacity

The surface water model was used to simulate a wide range of project pumping capacities and determine project benefits. Results of these simulations were one factor considered in determining final project capacities. The surface water model was used to simulate a range of pumping capacities to determine if certain capacities provided higher levels of project benefits. Project benefits were summarized as average annual reservoir release for both agricultural and environmental objectives.

Figure 12-1 illustrates that project benefits increase at different rates for different ranges of pumping capacities. For example, the incremental benefit of an additional 75 TAF of pumping capacity is greater when increasing pumping capacity from 150 to 225 TAF of total capacity than it is when increasing from 75 to 150 TAF, as illustrated by the steeper slope in the line. Benefits of incremental increases are smaller from 300 to 600 TAF (less steep line) and then increase again above 600 TAF. However, Figure 12-1, is shaded at the higher pumping capacities because projects of this size are not feasible and are not proposed for this project.

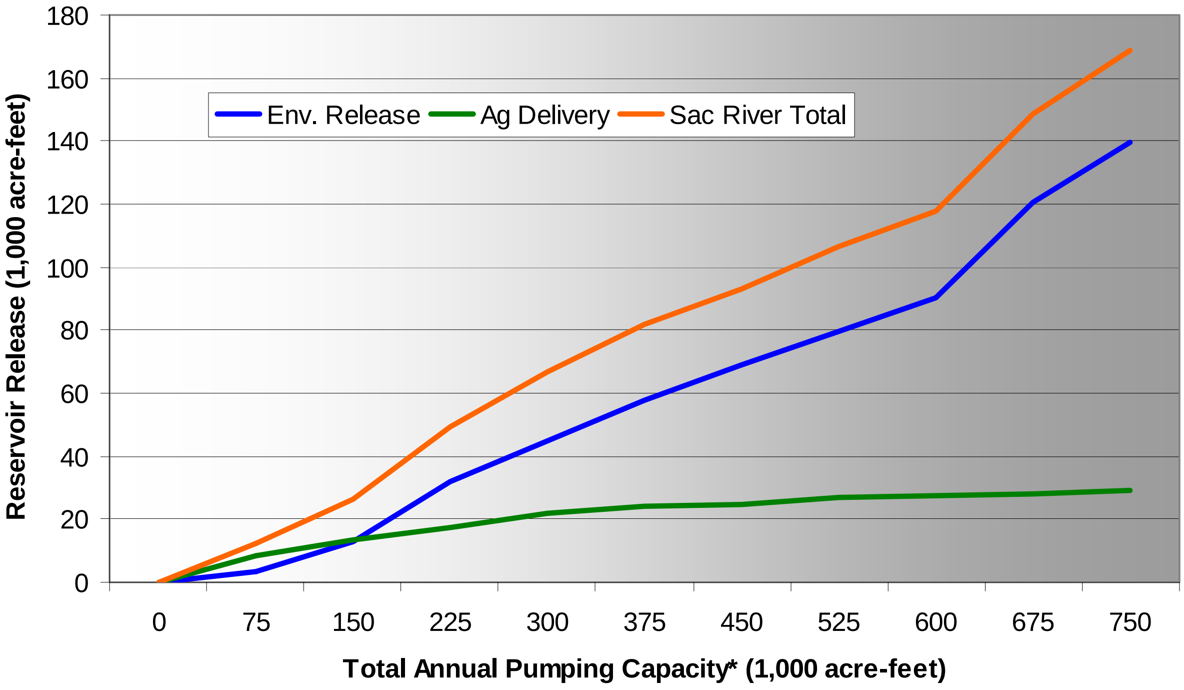


**Pumping capacity split 2:1 between GCID and Butte Basin*

FIGURE 12-1
TOTAL PROJECT BENEFITS FOR A RANGE OF PUMPING CAPACITIES
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION
MODELING REPORT

Figure 12-1 illustrates that projects between 75 and 150 TAF of pumping capacity have approximately the same marginal benefits when adding additional capacity. Figure 12-1 also illustrates that projects with 300 TAF may provide a good tradeoff at the upper end of the curve between pumping capacity and project benefits and that marginal benefits of increasing pumping capacity above 300 TAF are smaller than those realized by increasing from 150 to 300 TAF.

Project benefits presented on Figure 12-1 were compiled from reservoir releases to meet agricultural and environmental objectives. The model was set to first meet environmental objectives because of the all-or-nothing nature of those objectives. Figures 12-2 and 12-3 show the tradeoff between meeting agricultural and environmental objectives that occurs across a range of project pumping capacities.

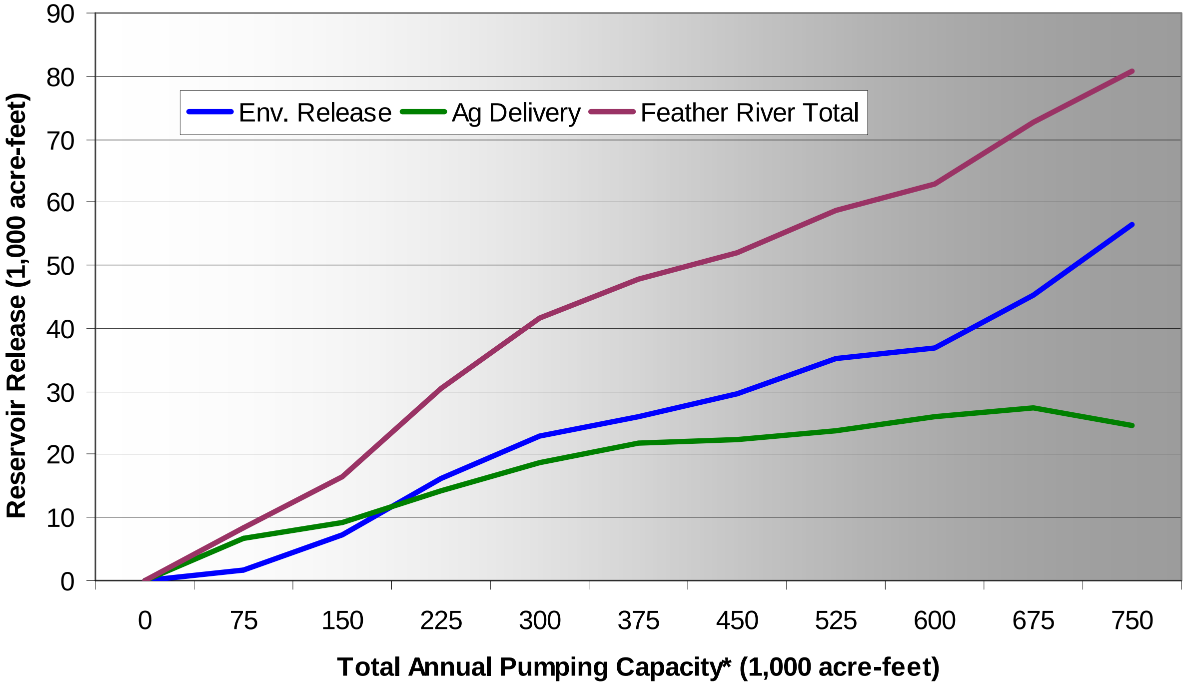


**Pumping capacity split 2:1 between GCID and Butte Basin*

FIGURE 12-2
SACRAMENTO RIVER AGRICULTURAL AND ENVIRONMENTAL PROJECT BENEFITS FOR A RANGE OF PUMPING CAPACITIES
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

Figure 12-2 provides additional detail on the split between project benefits for agricultural demand and environmental objectives on the Sacramento River. Projects with smaller pumping capacities do not provide as much water supply for environmental objectives. This occurs because water costs for meeting environmental objectives typically exceeds project assets for lower pumping capacity projects. The result is smaller pumping capacity projects supply a greater portion of total benefits to agricultural demands because agricultural objectives are not constrained by a minimum threshold. As pumping capacity, and therefore available project assets increase, a greater portion of total benefits are directed toward meeting environmental objectives. However, this does not necessarily come at the sake of meeting additional agricultural demand. A project with 300 TAF of pumping capacity is providing an average annual agricultural supply increase of approximately 20 TAF, and pumping capacity would need to be significantly increased to provide additional agricultural water supply, up to a maximum of approximately 30 TAF per year. Maximum agricultural benefit is also constrained by the restriction on project operations during Shasta critical years. In these years, there is significant unmet agricultural demand that conjunctive management projects cannot satisfy under assumptions made for this analysis.

Figure 12-3 shows same relationships between pumping capacity and agricultural, and environmental benefits presented for the Sacramento River on Figure 12-2 also exist on the Feather River.

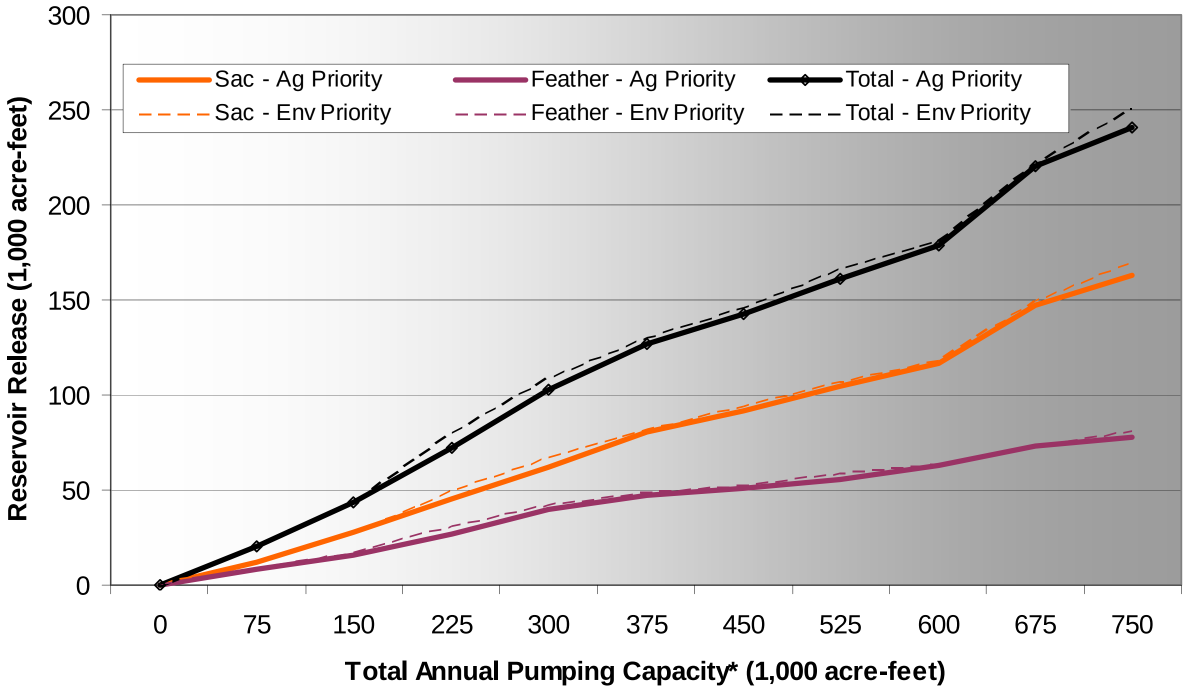


**Pumping capacity split 2:1 between GCID and Butte Basin*

FIGURE 12-3
FEATHER RIVER AGRICULTURAL AND ENVIRONMENTAL PROJECT BENEFITS FOR A RANGE OF PUMPING CAPACITIES
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

12.2 Prioritization of Objectives

The ability to direct additional water supply from conjunctive management toward meeting agricultural objectives first and environmental objectives second was also simulated. When environmental objectives are first priority, agricultural objectives are met more frequently for smaller capacity projects while environmental objectives are met more frequently for larger capacity projects. Figure 12-4 presents the same results as seen on Figure 12-1, with additional results that reflect when agricultural objectives are given first priority.



**Pumping capacity split 2:1 between GCID and Butte Basin*

FIGURE 12-4
TOTAL PROJECT BENEFITS FOR A RANGE OF PUMPING CAPACITIES WITH HIGHER PRIORITY TO AGRICULTURAL OBJECTIVES (AG PRIORITY) AND HIGHER PRIORITY TO ENVIRONMENTAL OBJECTIVES (ENV PRIORITY)
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

Figure 12-4 illustrates model results are insensitive to prioritization of objectives for lower pumping capacity projects. However, as pumping capacity increases and conjunctive management projects are able to meet additional environmental objectives, total project benefits decrease when meeting agricultural objectives first. Table 12-1 compares average annual benefits for each objective on each river system with different priorities and the number of environmental objectives met by conjunctive management projects.

TABLE 12-1
Comparison of Average Annual Benefits for 300 TAF Pumping Capacity Project with Different Prioritization of Objectives
Sacramento Valley Conjunctive Water Management Technical Investigation Modeling Report

	Sacramento River			**Feather River**		
	Env. First	**Ag First**	**Change**	**Env. First**	**Ag First**	**Change**
Ag Benefit (TAF)	22	26	+4	20	23	+3
Env Benefit (TAF)	45	36	-9	23	18	-5
Env Obj. Met (#)	57	50	-7	54	40	-14

Table 12-1 shows when prioritizing agricultural objectives first average annual agricultural benefits increase, but not by the same volume environmental benefits decrease. Therefore there is a reduction in the total project benefits when prioritizing agricultural benefits first, as illustrated on Figure 12-4.

12.3 Reservoir Drawdown Targets

A reservoir storage matrix is used in combination with project groundwater pumping capacity to determine project assets available to meet objectives each year. Results previously presented for Scenarios 1 through 4 assume a minimum end-of-September storage of 2,400 TAF for Shasta Reservoir and 1,500 TAF for Oroville Reservoir. Model sensitivity to these assumptions was evaluated to better understand risk to water supplies and cold water pool management in subsequent years.

Figure 12-5 illustrates effects of changes in minimum fall storage levels on end of September storage. A line at 1,900 TAF is shown because this is the minimum level specified in the biological opinion for winter run Chinook salmon and changes in storage below this level can have significant impacts on Reclamation's ability to manage cold water pool and meet existing temperature control criteria. Setting minimum fall storage levels less than 2,400 TAF can impact storage in subsequent years when storage goes below 1,900 TAF. Setting minimum storage levels above 2,400 TAF reduces project benefits.

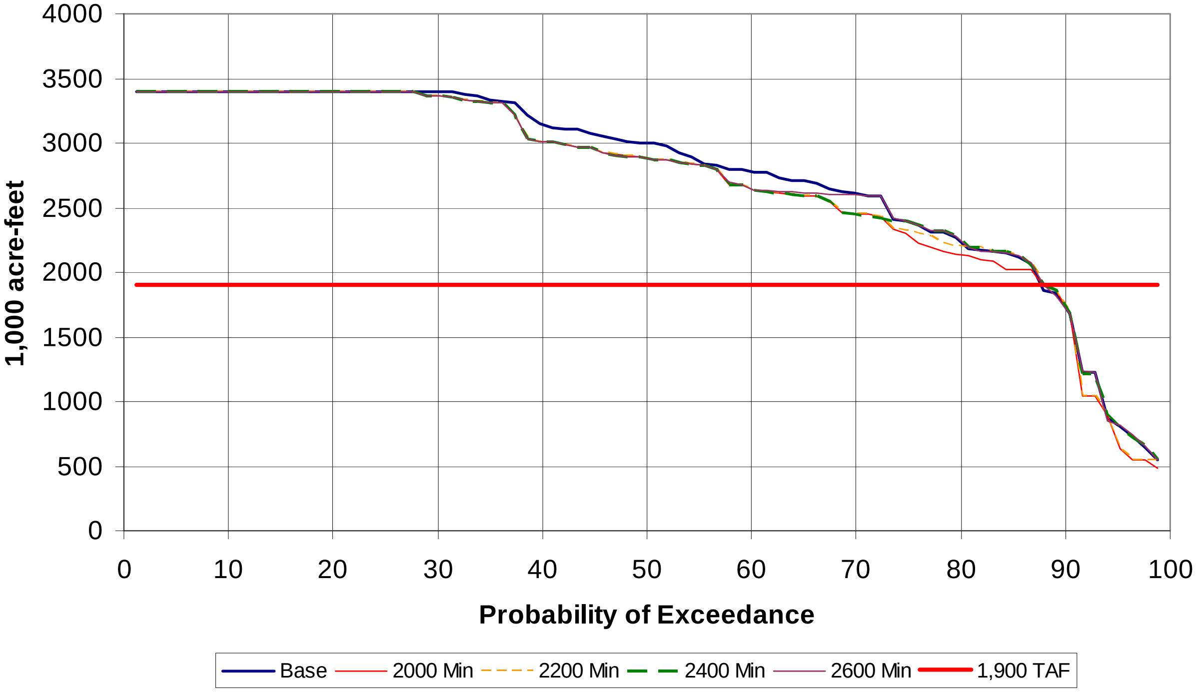


FIGURE 12-5
EXCEEDANCE PROBABILITY FOR END OF SEPTEMBER SHASTA STORAGE WITH SELECT MINIMUM STORAGE REQUIREMENTS
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

Figure 12-6 illustrates similar results for Oroville Reservoir. There is no specified target for fall storage in Oroville, but it is understood that hydropower operations are affected when storage goes below 1,000 TAF. Results are less clear because of the smaller differences between base and project conditions; however, more aggressive operation of Oroville with a lower fall storage level may put operations in future years at risk. Therefore, 1,500 TAF was selected as a balance between achieving conjunctive management project benefits and operational risks.

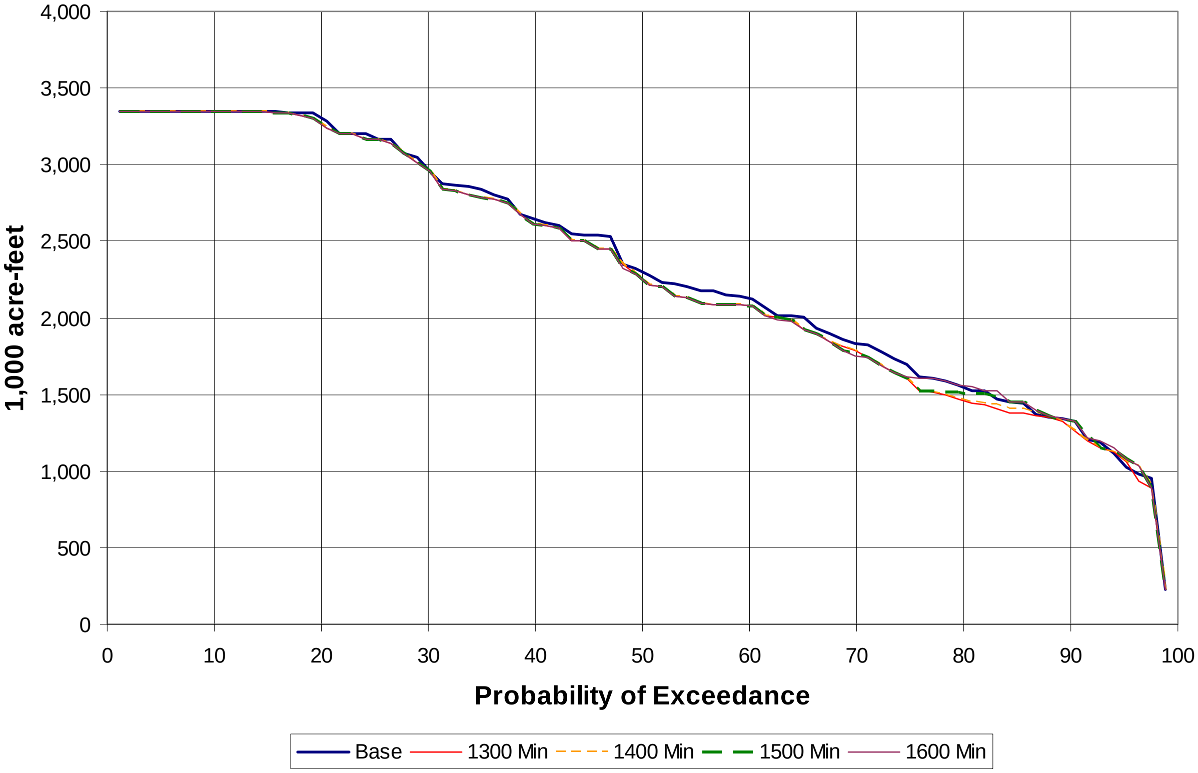

FIGURE 12-6
EXCEEDANCE PROBABILITY FOR SEPTEMBER OROVILLE STORAGE WITH SELECT MINIMUM STORAGE REQUIREMENTS
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

12.4 Environmental Objectives

Considerable uncertainty surrounds developing of environmental objectives; therefore, limited sensitivity analysis was performed to determine if changes in environmental objectives resulted in significant changes in project benefits. For example, if a 10 percent increase in flow targets specified for each objective resulted in no objectives being satisfied for a given scenario, the results from this scenario would be interpreted to contain significant uncertainty. Likewise, if project benefits are consistent across a range of environmental objectives, conjunctive management projects are likely to provide a level of environmental benefit, even if flow targets are slightly different than those simulated.

Figures 12-7 through 12-10 present simulation results of varying environmental targets (presented in Tables 9-1 through 9-5, by more or less than 10 percent. Figures 12-7 through 12-10 show the years that objectives are met, either in the base condition or through project release, and total number of years met. Results are aggregated for both river systems.

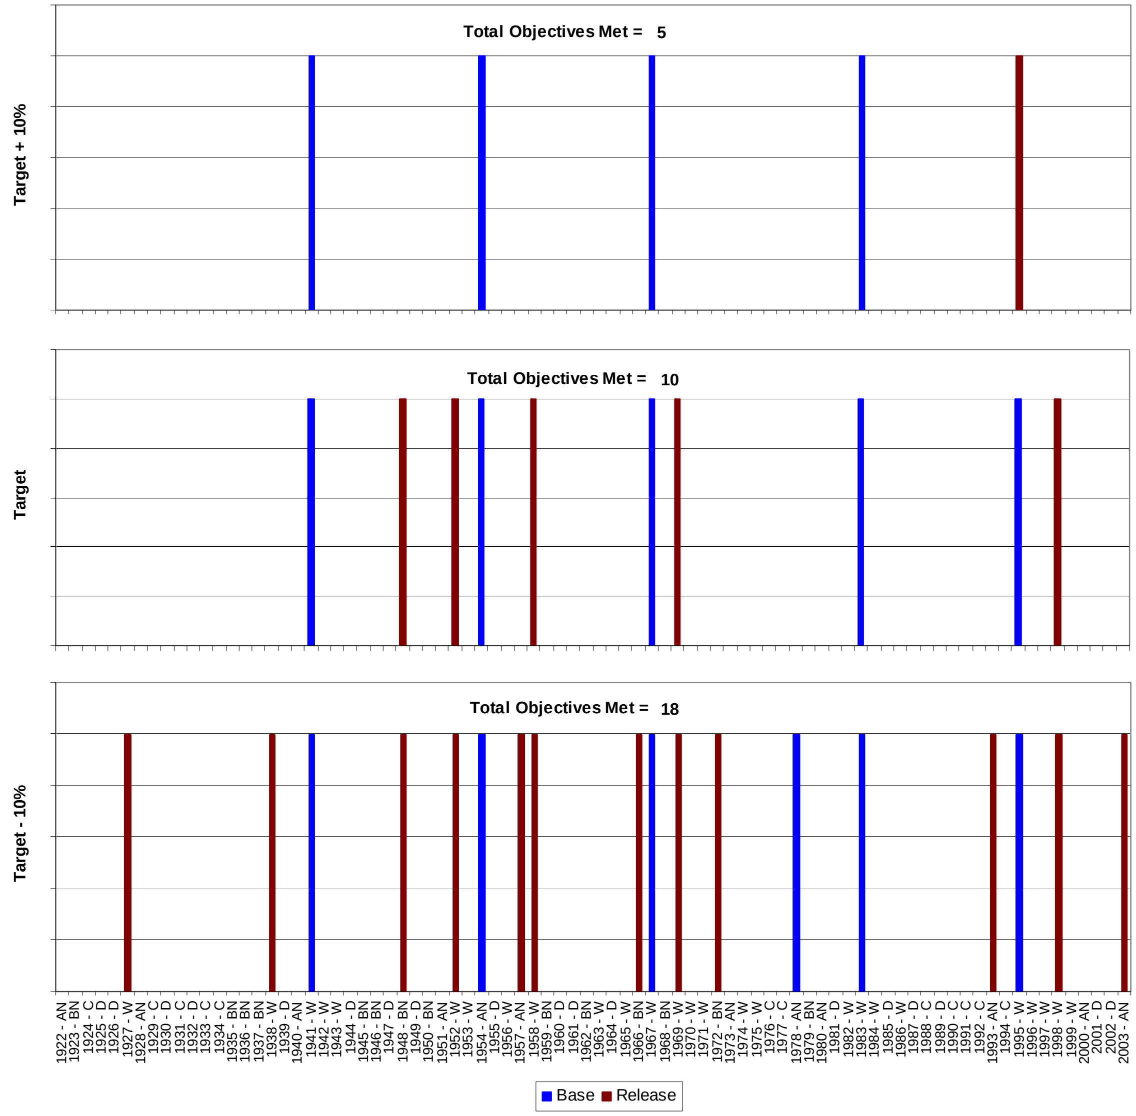

FIGURE 12-7
SENSITIVITY RESULTS FOR SPRING PULSE OBJECTIVE
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

Figure 12-7 shows that the larger water costs associated with meeting a larger spring pulse flow may decrease the ability of conjunctive management projects to satisfy the objective. Decreasing the flow target will increase the frequency of meeting the objective. The ability of conjunctive management projects to meet the spring pulse objective is sensitive to changes of more or less than 10 percent in the objective. Additionally, changes in the flow objective also change the frequency of meeting the objective with base operations.

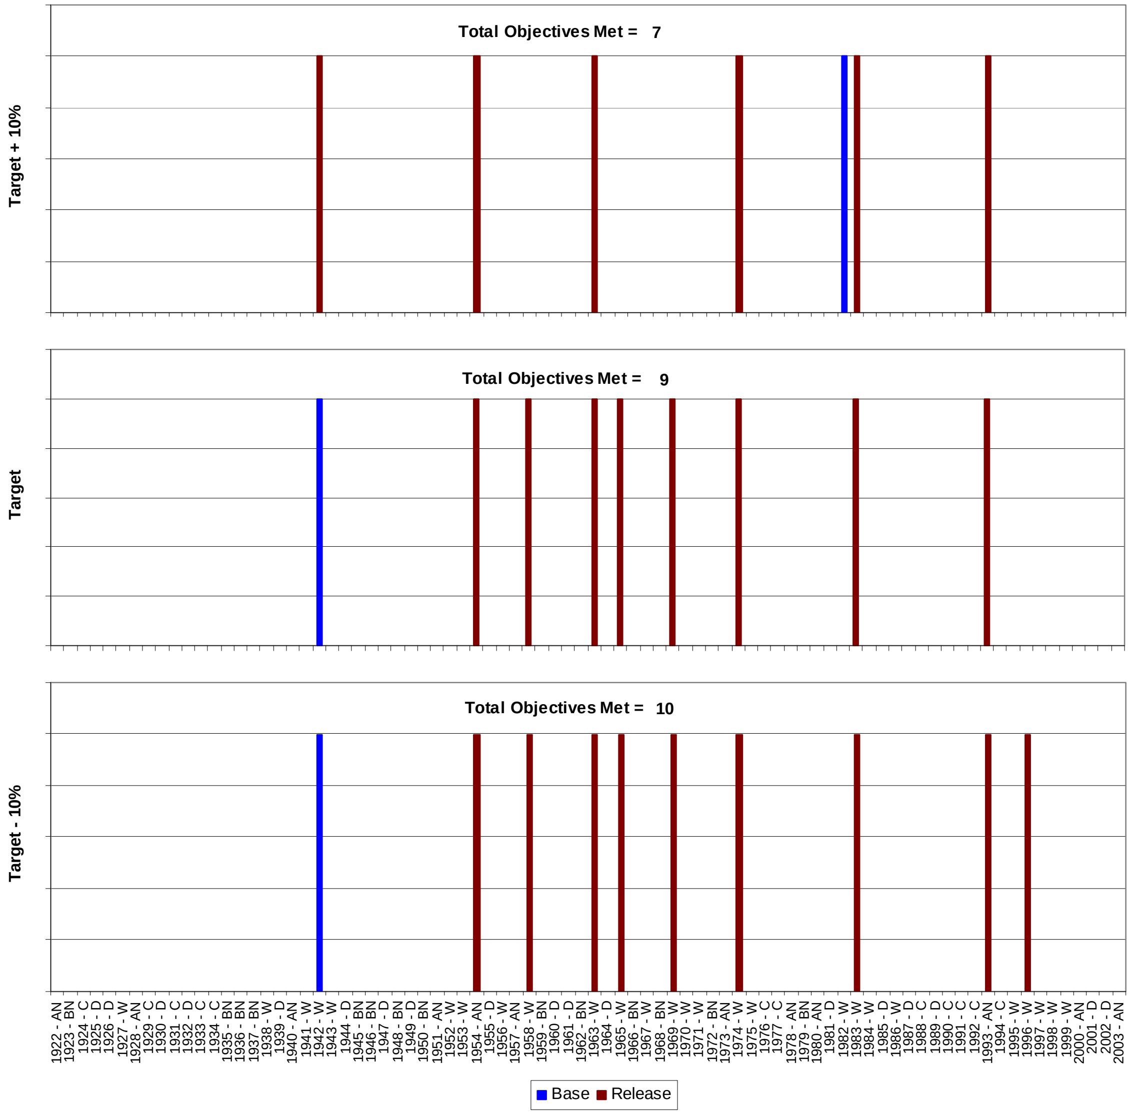

FIGURE 12-8
SENSITIVITY RESULTS FOR RIPARIAN RECRUITMENT OBJECTIVE
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION
MODELING REPORT

Figure 12-8 shows that riparian recruitment is less sensitive to changes in targets than the spring pulse objective. Changes in flow targets do not result in significant changes in the frequency of satisfying the objective.

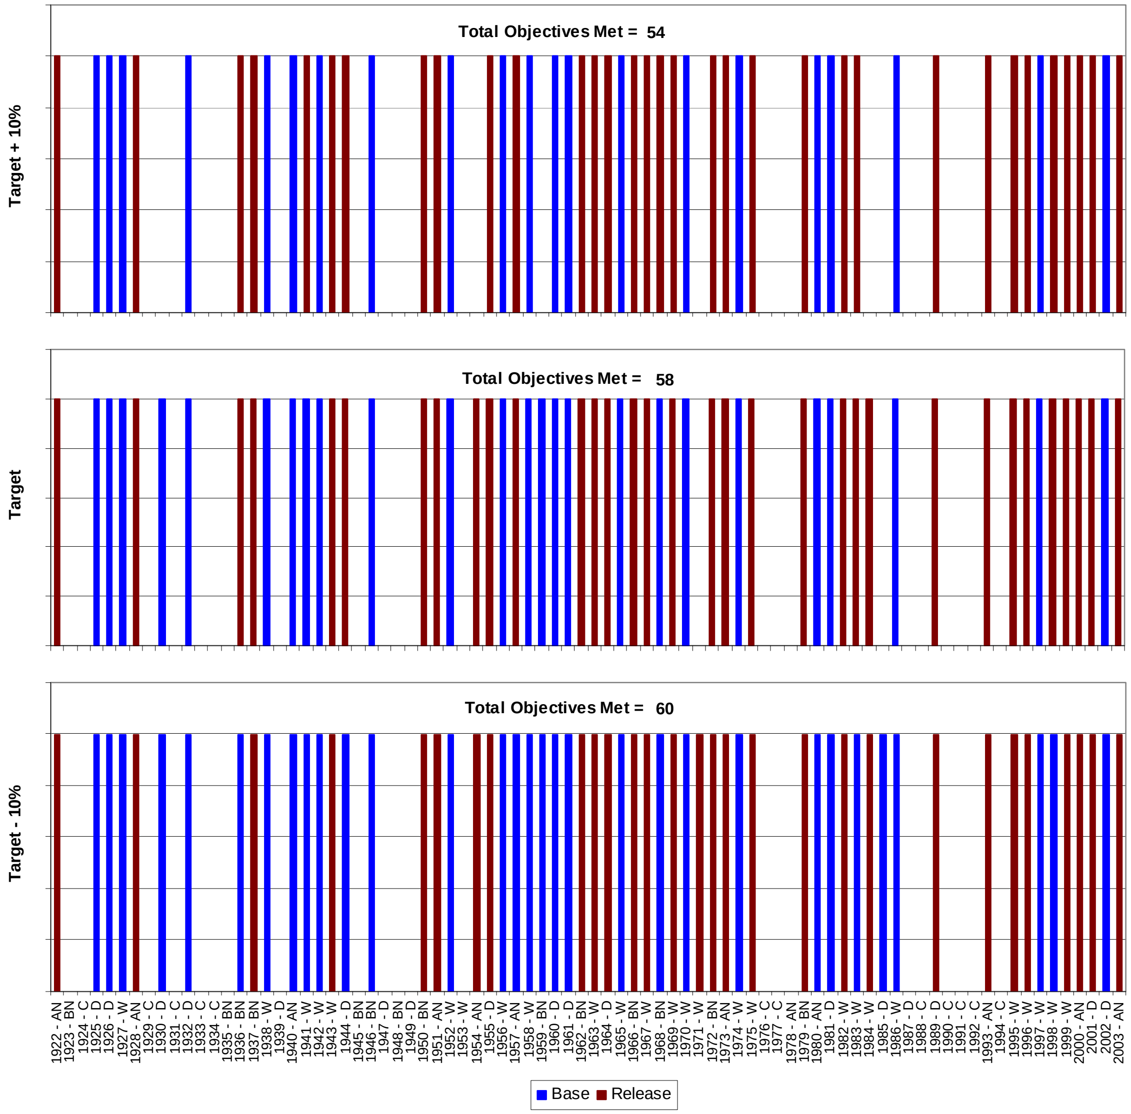

FIGURE 12-9
SENSITIVITY RESULTS FOR GEOMORPHIC OBJECTIVE
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

Figure 12-9 illustrates that the geomorphic objective is less sensitive to changes in targets than the spring pulse objective. Lower water cost of meeting a short duration objective results in being able to meet the objective, even when it is increased by 10 percent. Additionally, the objective is satisfied so frequently that reducing the flow target does not result in the objective being satisfied much more often.

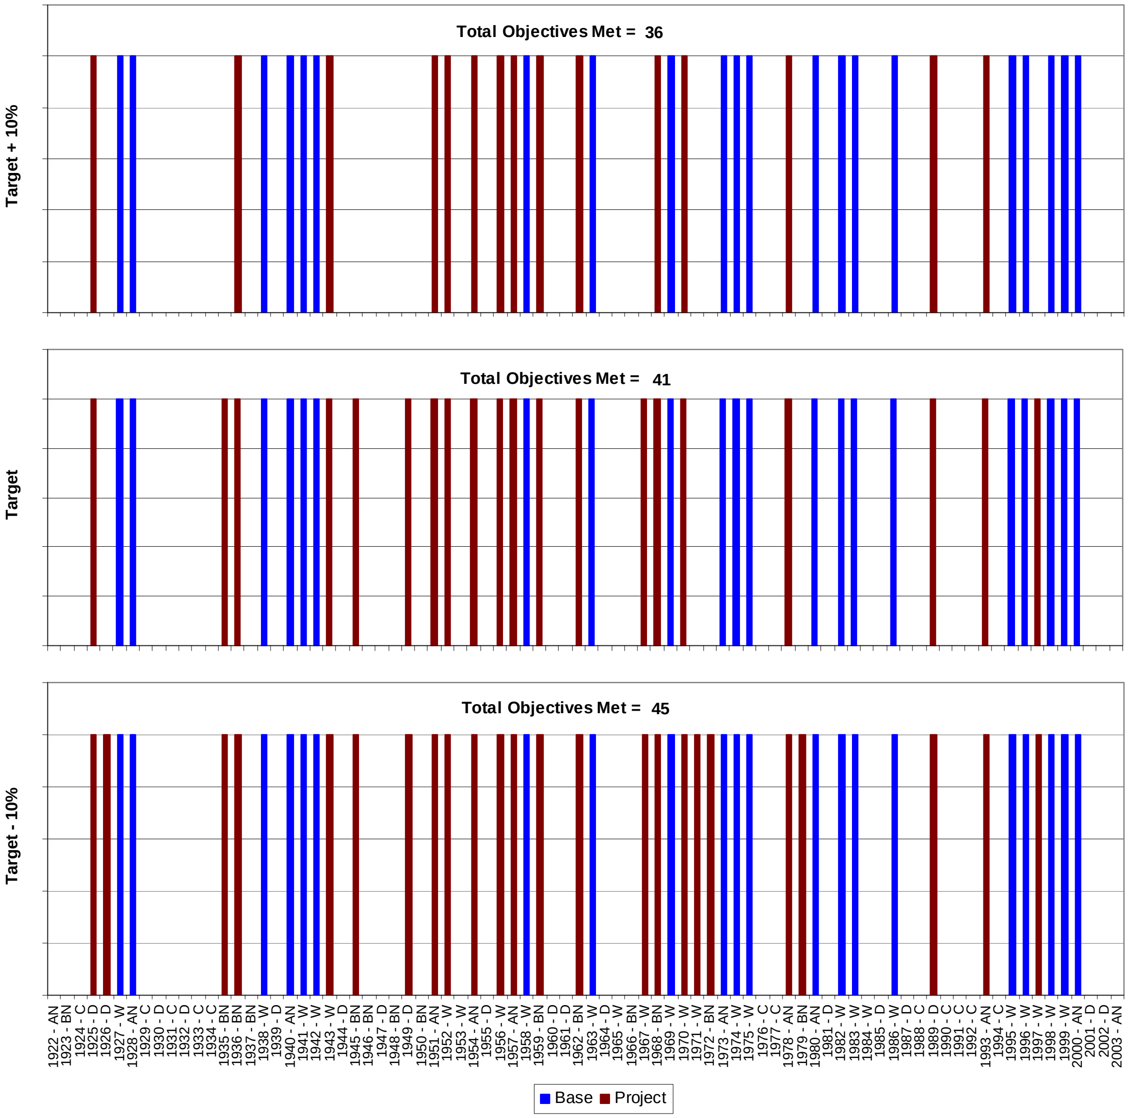

FIGURE 12-10
SENSITIVITY RESULTS FOR FLOOD PLAIN INUNDATION OBJECTIVE
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

Figure 12-10 illustrates that the flood plain inundation objective is also less sensitive to changes in the target than the spring pulse objective. Therefore, the conjunctive management project, including some form of weir modification, to allow inundation at lower river stages will allow the objective to be satisfied approximately 40 times if the flow target is within 10 percent of the target simulated in Scenarios 1 through 4.

SECTION 13

Systemwide Effects

This project focused operation of conjunctive management projects within the Sacramento Valley on developing water supply for uses within the Sacramento Valley. Developed water supply was split between environmental and agricultural objectives. However, water released to meet environmental objectives within the Sacramento Valley continues into the Sacramento-San Joaquin River Delta, where it may have additional environmental benefits or potentially be exported for delivery to CVP and SWP contractors south of the Delta.

13.1 Delta Salinity

Changes in Delta inflow, either increases from environmental releases or decreases when reservoirs or groundwater refill with surplus surface water, have the potential to change salinity conditions in the Delta. Formal simulation and analysis of expected changes is beyond the scope of modeling conducted to date. Generally, environmental releases will increase Delta inflow and improve salinity conditions, depending on how export operations respond to increased inflow. To the extent that environmental objectives can be met during drier periods those releases have potential to improve Delta salinity. Operations during wetter periods that either increased or decreased inflow may not result in large changes in Delta salinity. Overall, conjunctive management projects as described for this project will decrease average annual Delta inflow by the consumptive use of additional agricultural deliveries made possible by the project. Figures 13-1 and 13-2 present annual changes in inflow for Scenarios 1 and 2, respectively. Changes from Scenarios 3 and 4 are expected to be similar to those shown for Scenario 1.

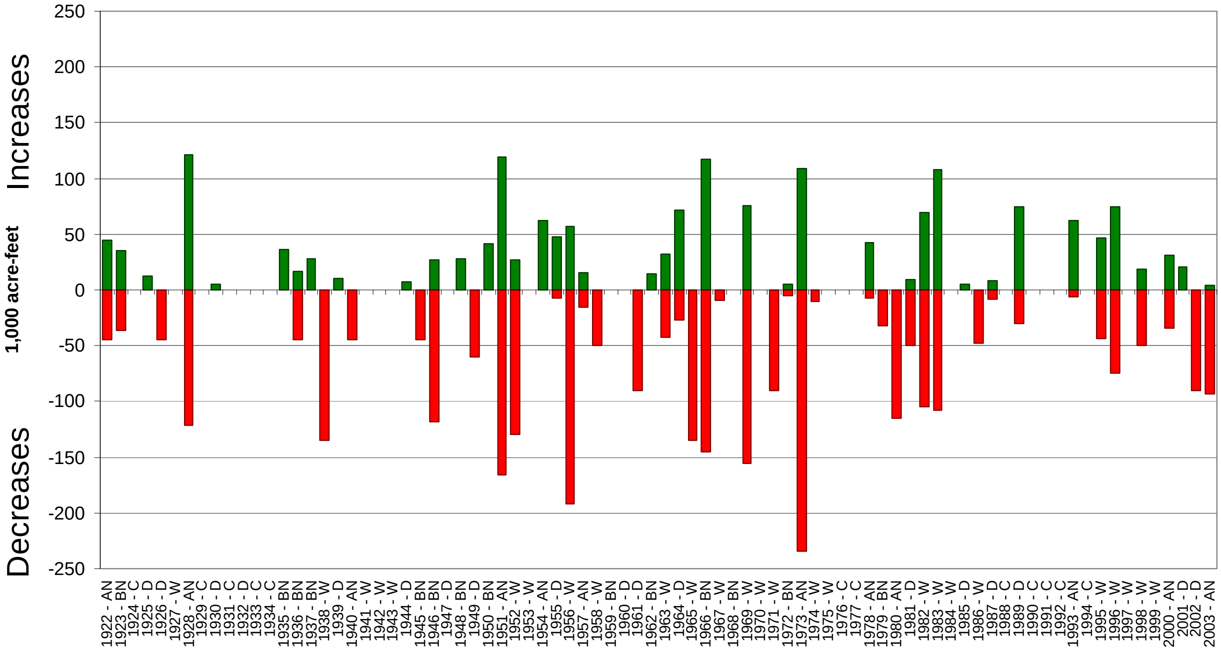

FIGURE 13-1
CHANGE IN ANNUAL DELTA INFLOW, SCENARIO 1
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

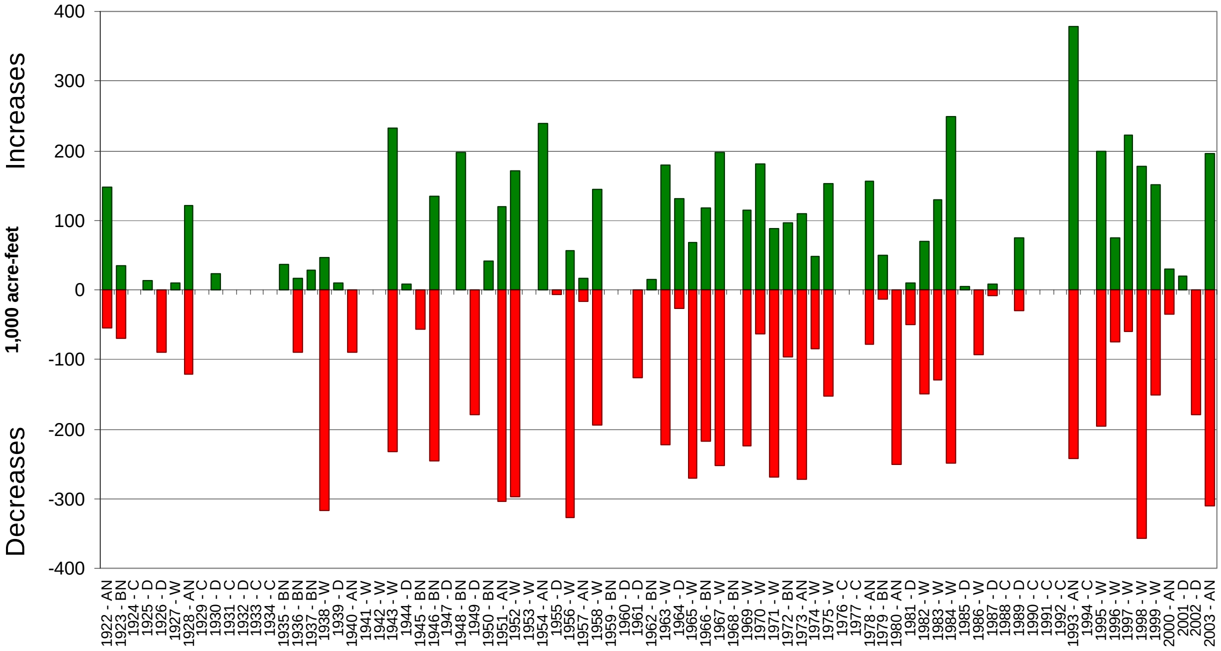

FIGURE 13-2
CHANGE IN ANNUAL DELTA INFLOW, SCENARIO 2
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

13.2 South of Delta Water Supply

A preliminary analysis of the ability to export simulated environmental releases was made using the underlying CalSim II operations. This analysis considers the constraints imposed by D-1641 Delta flow and salinity standards, CVPIA b(2) restrictions, the Vernalis Adaptive Management Plan (2000), and export pumping capacity constraints. Analysis did not include pumping restrictions for protecting Delta smelt as proposed in the recent OCAP Biological Opinion (U.S. Fish and Wildlife Service, 2008). Export restrictions for protection of Delta smelt may significantly reduce ability to export environmental releases because smelt restrictions limit export operations during winter and spring months when environmental releases are made. Additionally, it was assumed that there is demand for any additional water that could be exported.

Figures 13-3 and 13-4 illustrate annual time series of total potential export of environmental releases made from Shasta and Oroville for Scenarios 1 and 2. Results for Scenarios 3 and 4 are essentially the same as for Scenario 1, because the timing and volume of environmental release does not change.

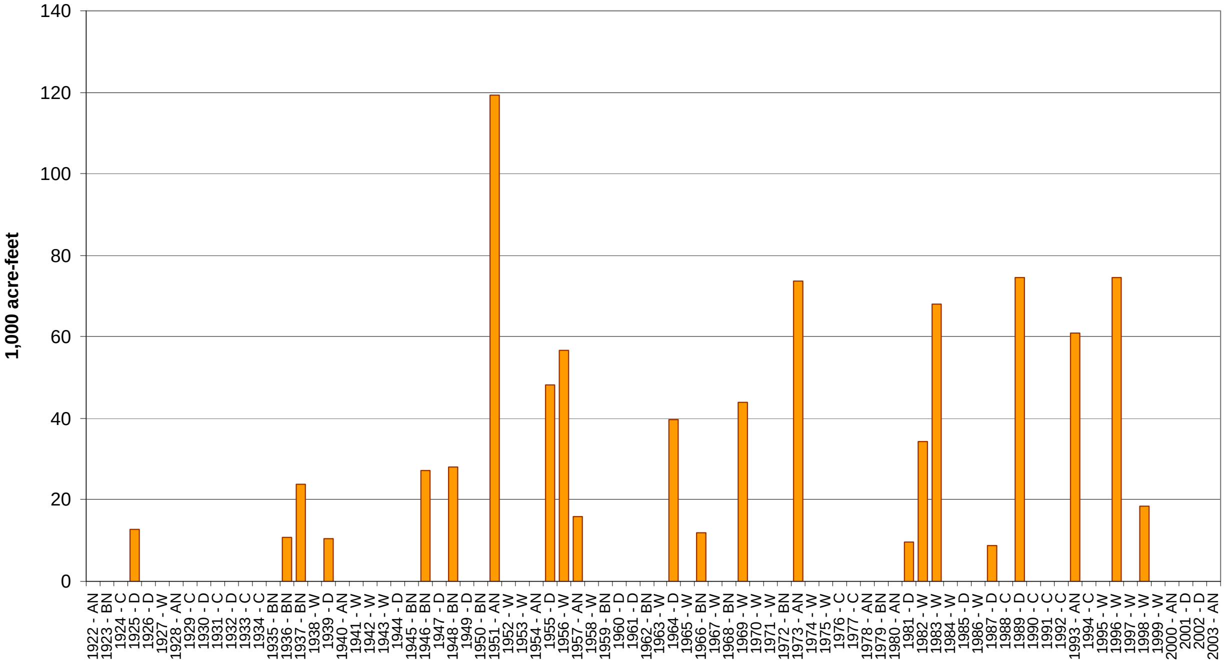

FIGURE 13-3
POTENTIAL EXPORT OF ENVIRONMENTAL RELEASES, SCENARIO 1
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

Figure 13-3 illustrates the volume and timing of additional export that may occur with conjunctive management projects. Average annual exports increase by approximately 11 of the 22 TAF from environmental releases on the Sacramento and Feather Rivers. The majority of additional exports occur when CVP and/or SWP San Luis Reservoir storage is full and would therefore provide additional Section 215 water for CVP contractors and Article 21 water for SWP contractors.

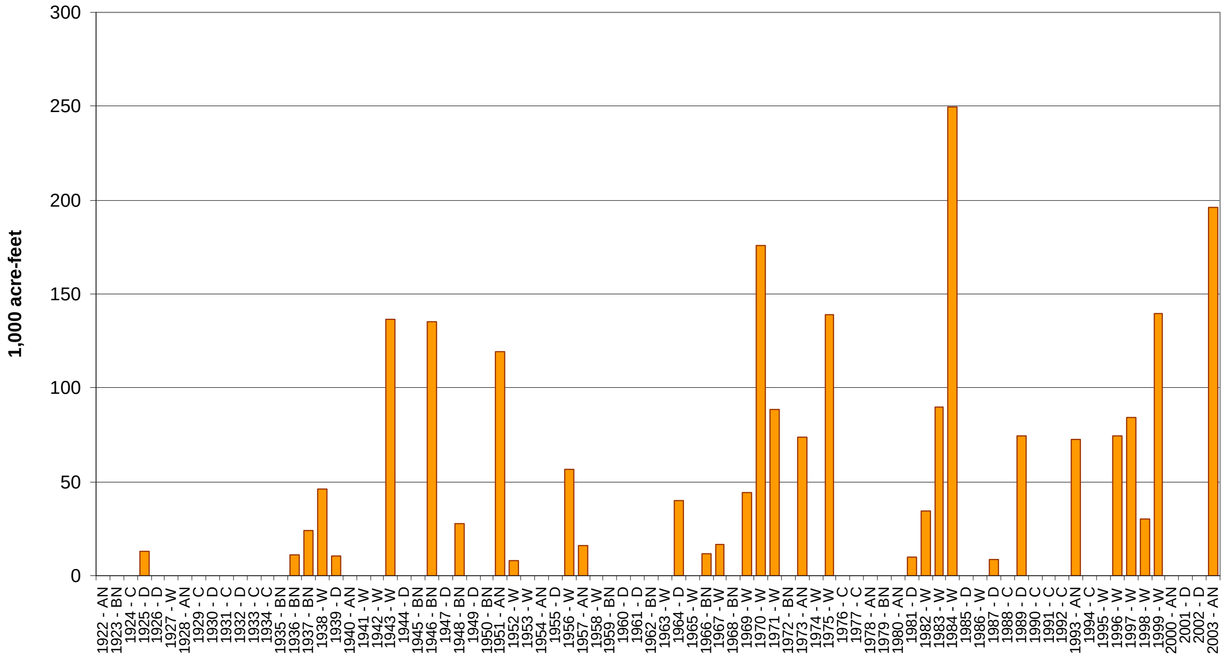

FIGURE 13-4
POTENTIAL EXPORT OF ENVIRONMENTAL RELEASES, SCENARIO 2
SACRAMENTO VALLEY CONJUNCTIVE WATER MANAGEMENT TECHNICAL INVESTIGATION MODELING REPORT

Figure 13-4 presents the same results for Scenario 2 with an average annual export of 28 of the 68 TAF of environmental releases. Exports with Scenario 2 may increase by up to 250 TAF in a given year. In these years with large increases, exports and may be limited by the ability to use or store the water south of the Delta.

13.3 Other Changes

Analysis conducted to date focused on operations on the main stem of the Sacramento and Feather Rivers, and CVP and SWP reservoirs on those rivers. In reality, the water system in California is operated as a whole and changes in one area, particularly large components of the system, such as Shasta and Oroville Reservoirs, will ripple into other areas. While not addressed in this report, it is understood that these changes would require additional analyses at a feasibility level.

SECTION 14

Model Limitations and Areas for Refinement

14.1 Groundwater Model

While SACFEM is a powerful tool designed specifically to evaluate effects of conjunctive water management pumping on surface water and groundwater resources, several areas for refinement remain. Due to constraints on available resources for this project, it was not possible to perform a rigorous transient calibration of the model to observed historic water level hydrographs across the valley. This effort would help improve the level of confidence that the model is accurately simulating transient patterns in groundwater levels seen historically. However, a preliminary assessment of the accuracy of SACFEM at matching a limited number of historic hydrographs was performed, and the model appears to generally replicate historically observed water levels quite well over the 22-year period of simulation (1982 through 2003).

Another area of potential refinement is to further evaluate behavior of smaller unregulated tributaries across the valley, specifically to better understand timing and magnitude of groundwater recharge that occurs from these surface water features. In the current analysis, it was assumed that unregulated streams were dry from June through October. While this assumption is reasonable, it is likely that behavior of these streams is more complex. Further, some of these tributary streams are used as conveyance facilities to deliver water within various water districts. This would result in streams being active over summer months, and potential sources of recharge to the groundwater system. An analysis of these stream characteristics could improve the accuracy of the simulation of recharge sources to the groundwater system, especially over the summer months.

Forecasts provided by modeling tools contain some degree of uncertainty, due to limitations of replicating a complex physical system with a more idealized mathematical representation of that system. Analyses described herein should be considered a planning level analysis that tests the general viability of conjunctive water management strategies presented, and provides a general estimate of benefits that may be realized by implementation of these projects. However, these evaluations will need to be significantly refined, both in specificity of infrastructure and operational protocols and response of the natural system to these operations, before a project of this type could be carried to the design phase.

14.2 Surface Water Model

Surface water modeling and analysis was conducted at a pre-feasibility, planning level and required numerous simplifying assumptions.

14.2.1 Forecast-based Operations

The surface water model uses perfect foresight in operating reservoirs and determining ability to meet environmental objectives. This results in an ideal operation of system reservoirs and decisions to meet project objectives. In reality, project operators must rely on imperfect forecasts of water supply and demands when making daily decisions. In actual operations, there would be instances in which environmental objectives would be met or missed due to changing conditions that cannot be forecasted.

One method to address this uncertainty in future analyses would be to implement forecast-based decision logic that may help to illuminate some of the challenges in implementing environmental objectives in real-world operations. For example, because environmental objectives are specified for spring months, a forecast of the water year type (e.g., wet or above normal) is needed to estimate the flow target. In actual operations these forecasts will be uncertain and operations will need to respond to actual hydrology.

14.2.2 Temperature and Power Analyses

Conjunctive management operations as described and simulated for this report may have impacts on the ability to meet temperature control criteria, and the generation and use of CVP and SWP hydropower. For example, in some years, making releases for environmental objectives in spring may create challenges in meeting temperature control criteria in the fall, depending on how water is released from reservoirs. Additionally, large releases for certain objectives may be constrained by power plant capacities and may occur at times when power is less valuable. A better understanding of these constraints and simulation of resulting effects is necessary in future phases of the project.

14.2.3 System Response

Analysis presented in this report focused on operation of only part of the CVP/SWP system. Shasta and Oroville Reservoirs and the Sacramento and Feather Rivers are part of a larger system that is operated in a coordinated manner. Simulation of only part of the system may underestimate benefits or impacts to other areas of the system. Preliminary analysis of systemwide effects based on how conjunctive management operations change, Delta inflows need to be refined and expanded to other areas of the system.

Accounting adjustments	Per May 2003 Interior Decision, no limit on responsibility for non-discretionary D-1641 requirements with 500 TAF target, no reset with the storage metric and no offset with the release and export metrics, 200 TAF target on costs from Oct-Jan	Same	Same

[a] A detailed description of the assumptions selection criteria and policy basis used is included in the Policy section of this Common Assumptions: Common Model Package (CACMP) report.

[b] The Sacramento Valley hydrology used in the Existing Conditions CALSIM II model reflects nominal 2005 land-use assumptions. The nominal 2005 land-use was determined by interpolation between the 1995 and projected 2020 land-use assumptions associated with Bulletin 160-98. The San Joaquin Valley hydrology reflects 2005 land-use assumptions developed by Reclamation to support Reclamation studies.

[c] The Sacramento Valley hydrology used in the Future No-action CALSIM II model reflects 2020 land-use assumptions associated with Bulletin 160-98. The San

TABLE A-1
CALSIM II Inputs
Common Assumptions: Common Model Package (Version 8D)
Sacramento Valley Conjunctive Water Management Technical Investigation Modeling Report

	Existing Condition Assumption	Future No Action Condition Assumption	Supplemental Future Condition (#1) Assumption

Joaquin Valley hydrology reflects draft 2030 land-use assumptions developed by Reclamation to support Reclamation studies.

[d] CVP contract amounts have been reviewed and updated according to existing and amended contracts as appropriate. Assumptions regarding CVP agricultural and municipal and industrial service contracts and Settlement Contract amounts are documented in Table 4 (North of Delta) and 6 (South of Delta) of Appendix B: CACMP Delivery Specifications.

[e] SWP contract amounts have been reviewed and updated as appropriate. Assumptions regarding SWP agricultural and M&I contract amounts are documented in Table 2 (North of Delta) and Table 3 (South of Delta) of Appendix B: CACMP Delivery Specifications.

[f] Water needs for federal refuges have been reviewed and updated as appropriate. Assumptions regarding firm Level 2 refuge water needs are documented in Table 4 (North of Delta) and 6 (South of Delta) of Appendix B: CACMP Delivery Specifications. As part of the Water Transfers technical memorandum (Appendix A: Characterization and Quantification), incremental Level 4 refuge water needs have been documented as part of the assumptions of future water transfers.

[g] Assumptions regarding American River water rights and CVP contracts are documented in Table 5 of Appendix B: CACMP Delivery Specifications.

[h] Sacramento Area Water Forum 2025 assumptions are defined in Sacramento Water Forum's EIR. PCWA CVP contract supply is modified to be diverted at the PCWA pump station. Assumptions regarding American River water rights and CVP contracts are documented in Table 4 of Appendix B: PFCMP Delivery Specifications.

[i] The new CALSIM II representation of the San Joaquin River has been included in this model package (CALSIM II San Joaquin River Model, Reclamation, 2005). Updates to the San Joaquin River representation have been included since the preliminary model release in August 2005. In addition, a dynamic groundwater simulation is currently being developed for San Joaquin River Valley, but is not yet implemented. Groundwater extraction/ recharge and stream-groundwater interaction are static assumptions and may not accurately reflect a response to simulated actions. These limitations should be considered in the analysis of results.

[j] The CACMP CALSIM II model representation for the Stanislaus River does not necessarily represent Reclamation's current or future operational policies.

[k] The Existing CVP contract is 140 TAF. The actual amount diverted is reduced due to supplies from the Los Vaqueros Project. The existing Los Vaqueros storage capacity is 100 TAF. Associated water rights for Delta excess flows are included.

[l] Table A and Article 21 deliveries into the San Francisco Bay Area Region–South and South Coast Region in the CACMP are a result of interaction between CALSIM II and LCPSIM. More information regarding LCPSIM is included in the following subsection of this document and the CALSIM-LCPSIM Integration technical memorandum (see Appendix C: Analytical Framework).

[m] The CCWD AIP is a new intake at Victoria Canal to operate as an alternate intake for Los Vaqueros Reservoir. This assumption is consistent with the future no-project condition defined by the Los Vaqueros Enlargement study team.

[n] This Phase 8 requirement is assumed to be met through Sacramento Valley Water Management Agreement Implementation.

TABLE A-1
CALSIM II Inputs
Common Assumptions: Common Model Package (Version 8D)
Sacramento Valley Conjunctive Water Management Technical Investigation Modeling Report

	Existing Condition Assumption	Future No Action Condition Assumption	Supplemental Future Condition (#1) Assumption

[o] Interim D-1644 is assumed to be implemented.

[p] Sacramento Area Water Forum Lower American River Flow Management Standard is not included in the CACMP. Reclamation has agreed in principle to the Flow Management Standard, but flow specifications are not yet available for modeling purposes.

[q] It is assumed that either VAMP, a functional equivalent, or D-1641 requirements would be in place in 2030.

[r] The CACMP CALSIM II model representation for the San Joaquin River does not explicitly implement the CALFED Salinity Management Plan.

Appendix C
Project Site Screening
Technical Memorandum

DRAFT TECHNICAL MEMORANDUM

DATE: October 18, 2007

TO: Sacramento Valley Conjunctive Management Project Team

FROM: NHI Technical Team

SUBJECT: DRAFT Candidate Site Screening Methodology

This memorandum is a draft summary of the methodology used to select sites for the Conjunctive Use IRWMP technical scenario development. The California Department of Water Resources and the U.S. Bureau of Reclamation (project donors) have awarded funds to Glenn Colusa Irrigation District and the Natural Heritage Institute to develop an Integrated Conjunctive Water Management Plan (ICWMP) for Northern California surface water and groundwater resources. A description of the criteria used to select sites for the Conjunctive Use IRWMP technical scenario development is summarized below. The evolution of knowledge for candidate sites considered is summarized for all technical meetings held between February 2007 and August 2007. Technical meeting notes and a draft technical memo developed by MBK are included as appendixes.

Objectives and Benefits

The three fundamental objectives driving the plan's development are:

- To improve local water supply reliability by enlarging the firm yield of the basin and enhancing water management flexibility.
- To enhance the ecosystems in the region's rivers. Healthy rivers are not just environmentally attractive, they also are central to ensuring reliable, sustainable water supplies. Water supply systems that work in concert with the environment are less likely to be encumbered by court orders, water rights hearings, and other restrictions that can have drastic effects on water supplies for farming and other economic uses.
- To allow for meeting water demands outside of the Sacramento River basin. The Sacramento River basin is already a source of much of the State's water supply. A plan that allows for well-managed and regulated water transfers is preferable to shortsighted decisions made when drought emergencies arise and water transfer revenues could help stabilize a challenged agricultural economy and provide regional economic benefits.

Methods

Conjunctive water management essentially involves the coordination of storage and withdrawal of water from surface reservoirs and groundwater aquifers to produce firm water supplies through wet and dry cycles. This general concept can be adapted in a variety of ways to increase operational flexibility both to enlarge the firm water supply and improve the environmental performance of the state and federal water projects. During the study, various reservoir reoperation scenarios will be developed and evaluated for Lakes Oroville and Shasta, the centerpieces of the State Water Project and Central Valley Projects, respectively. Additionally, the Stony Creek system will also be evaluated as another option for potential reservoir reoperation.

The region to be addressed in the integrated plan is comprised of all of the lands overlying the Lower Tuscan and interconnected groundwater formations within Butte, Glenn, Colusa and Tehama counties whose access to this groundwater could be hydrologically affected by development of the aquifer system at any location. The Sacramento Valley Conjunctive Management Technical Team (The team) began by looking for sites that fell into one of two conjunctive management operational modalities; Put-then-Take or Take-then-Put. A Put-then-Take modality involves storing surface water in a groundwater aquifer and extracting that water at a later date. This modality increases water storage space in reservoirs and increases the flexibility of water delivery quantity and timing. A Take-then-Put modality involves creating water storage space in the groundwater aquifer by extracting water that can later be refilled with surface water. Under this modality the groundwater banking operation would be given rights to surface water in storage that it can call at any time, whatever the hydrologic conditions, and require groundwater replenishment on a cycle that guarantees no interference with wells outside that water district. The goal of the site selection process was to identify at least one site for each operational modality that could be implemented through the State water project and one that could be implemented through the Central Valley project and which are sufficiently promising to warrant further analysis to develop specific operational conditions for conjunct management. The team developed screening criteria for each conjunctive management modality:

Put-then-Take Screening Criteria

1. Persistent or permanent cone(s) of depression with no seasonal recovery, (i.e. groundwater areas with available storage space) within
2. Dual use water districts that use both groundwater and surface water deliveries from the state or federal projects or within
3. Unincorporated groundwater usage areas adjacent to state or federal water districts so that the extension of the State Water Project (SWP) or Central Valley Project (CVP) into these areas is practical.

Take-then-Put Screening Criteria

1. Groundwater production areas within or adjacent to state of federal water districts areas, where groundwater extraction can be increased during drier than average years, and which are

2. A significant distance from surface water features of concern; rivers, wetlands, etc to avoid flow depletion effects, and where the dewatered aquifers

3. Can be actively recharged during wetter than average years from the state or federal reservoirs, without losing banked water, or which recover from annual infiltration.

Summary of technical meetings held on Feb 15th, 2007

At a project team meeting on February 15, 2007, nine preliminary sites were selected based on review of a Spring to Fall change groundwater contour map for 2006 made by DWR and the collective knowledge in the room regarding current operations. Five sites were selected as potential Put-then-Take sites, and four sites were selected as potential Take-then-Put sites.

a. Put-then-Take
   (1) Western Canal Water District
   (2) M & T Chico Ranch
   (3) Capay cone of depression
   (4) Cone of depression that is north of Richfield and west of Tehama
   (5) Yolo Zamora groundwater area
b. Take-then-Put
   (1) GCID—Stony Creek Fan partnership
   (2) Willow Creek Mutual Water District
   (3) Colusa County Water District
   (4) Olive Percy Davis Ranch

Summary of technical meeting held on June 19th, 2007 (See Appendix A)

For the June 19th, 2007 technical meeting MBK developed a brief description of each candidate site and how it might operate. This description was submitted to the project team in the form of a draft technical memorandum (Appendix B). For each site, current operations, current groundwater conditions, and the attributes of each water district were summarized in a table. These attributes included; general site information, operational concepts, aquifer characteristics, integration with surface water systems, infrastructure requirements, possible impacts and site screening criteria. There were several blanks in each attribute table, particularly for aquifer characteristics and potential impacts. These attributes required further research and development to be done during the full course of this study and would be used in future screening decisions. Based on each site's ability to meet the screening criteria they were either recommended to be retained for further analysis or to be dropped from the study. A brief summary of the nine sites considered is summarized below.

Put-Then-Take

WESTERN CANAL WATER DISTRICT - DURHAM CONE

Western Canal Water District (WD) extends surface water (SW) delivery system into the area overlying Durham cone of depression and operates a groundwater (GW) bank with Oroville providing the source water. One operation scenario would be to expand conjunctive management operations within Western Canal to increase surface water deliveries in wet years and reduce SW deliveries in dry years. Some of the augmented supply might be delivered to the refuges just west of Western Canal (Sac River Wildlife Refuge, Upper Butte Creek state reserve).

Groundwater levels fluctuate seasonally in response to agricultural and municipal pumping. The maximum measured fluctuation in the Chico-Durham area in 2006 was approximately 30 ft with an average value of approximately 20 ft. Hydrographs from individual wells indicate that groundwater levels fully recover over the winter months. Additionally, hydrographs indicate no long-term declining trends in groundwater levels exist in this area. It is likely that the aquifer in this area receives recharge from Big Chico Creek and other local streams. This site has the ability to contribute to Feather River flows and integrate with Oroville operations. It was proposed that we retain this site for further analysis.

ORLAND-ARTOIS WATER DISTRICT

Orland-Artois WD, a CVP Ag Service contractor, receives additional surface water from the Tehama-Colusa (TC) or Glen Colusa (GC) Canals, or directly from Stony Creek. Additional surface water reduces groundwater demand in current cone of depression. Water is returned to the system with additional groundwater pumping in dry years instead of Orland-Artois WD taking all or a portion of their CVP contract. (Note, the original discussion focused on this project with M&T Chico Ranch, but M&T is on east side of river while current cone of depression is on west side of the river, so a more likely project partner would be Orland-Artois WD.)

Groundwater levels fluctuate seasonally in response to agricultural pumping. The maximum measured fluctuation in the southern portion of Orland-Artois WD area in 2006 was approximately 25 ft, but appears to vary spatially due to localized pumping. Hydrographs from individual wells indicate that groundwater levels fully recover over the winter months. Additionally, hydrographs indicate no long-term declining trends in groundwater levels exist in this area. It is likely that the aquifer in this area receives recharge from streams tributary to Willow Creek. This site has the ability to contribute to Sacramento River flows and integrate with CVP operations. It was recommended that we retain this site for further analysis.

CAPAY RANCHO WATER DISTRICT

Capay Rancho WD would operate a groundwater bank by receiving surface water in wet years. Capay Rancho, a groundwater only district, is located over an existing cone of depression that may be utilized to store water. Methods for returning additional GW to the system in dry years are more complex, but may involve supplying water to areas in the TC Canal service area or GCID.

Groundwater levels fluctuate seasonally in response to agricultural pumping. The maximum measured fluctuation in the Capay WD area in 2006 was approximately 50 ft with an average value of approximately 25 ft. Hydrographs from individual wells indicate that groundwater levels fully recover over the winter months. Additionally, hydrographs indicate no long-term declining trends in groundwater levels exist in this area. It is likely that the aquifer in this area receives recharge from Stony Creek and other local streams. Note that this is right next to the Sac river, therefore may be problems with gw/sw interactions. Because there was no perceived ability to contribute to Sacramento River flows and integrate with CVP operations it was recommended that we drop this site from the study.

CORNING CANAL SERVICE AREA

A portion of the Corning Canal Service Area overlies an existing cone of depression north of Richfield and west of Tehama. The overlying districts that could operate the groundwater bank include Elder Creek, El Camino ID, Tehama Ranch, and Thomes Creek. The Corning Canal runs though these districts and typically has unutilized capacity. CVP contractors along the Corning Canal include Proberta (3.5 TAF/yr), Thomes Creek (6.4 TAF/yr), and Corning (23 TAF/yr) WDs. These WDs have recently been pumping additional GW instead of taking CVP contract water due to the relative costs of CVP water to groundwater.

Groundwater levels fluctuate seasonally in response to agricultural pumping. The maximum measured fluctuation in the Corning Canal Service Area in 2006 was in excess of 50 ft; but appears to vary spatially due to localized pumping. Hydrographs from individual wells indicate that groundwater levels fully recover over the winter months. Additionally, hydrographs indicate no long-term declining trends in groundwater levels exist in this area. It is likely that the aquifer in this area receives recharge from Thomes Creek, Elder Creek, and other local streams draining the western foothills. This site has the ability to contribute to Sacramento River flows and integrate with Shasta operations and it was recommended that we retain this site for further analysis.

YOLO-ZAMORA WATER DISTRICT

The Yolo-Zamora WD overlies an existing cone of depression and relies on groundwater for irrigation. Surface water could be supplied by extending the Tehama Colusa Canal or constructing a canal from the Sacramento River. This has been studied in the past but rejected as prohibitively expensive as a substitute for groundwater for irrigation. Returning water to the system may be challenging.

Unable to evaluate due to lack of data from the Central District at this time. Awaiting receipt of groundwater level data from DWR. The option of extending the Colusa Canal would be economically impractical to distribute surface water in normal and non-normal water years in addition it would be impractical to extract groundwater. There is currently no ability to contribute to Sacramento River flows and integrate with CVP operations it was recommended that this site be dropped from study.

Take-Then-Put

GLENN-COLUSA IRRIGATION DISTRICT - STONY CREEK FAN

Glenn-Colusa Irrigation District (GCID) could operate a groundwater bank in the Stony Creek Fan, banking CVP water in wet years and reducing CVP surface water deliveries in dry years. This operation may be similar to recent groundwater substitution transfers.

The northern portion of GCID represents an area known to have high aquifer transmissivity. The area is currently served by surface water. The area is underlain by the lower Tuscan Aquifer as well as shallower producing zones in the Tehama Formation. Groundwater levels in this area are shallow, generally less than 10 to 15 ft in the spring. Hydrographs suggest very little seasonal fluctuation in groundwater levels.

The southwestern portion of GCID is still relatively high, but less than that of the northern portion due to the proximity to the margin of the groundwater basin. Well yields in this area are more than sufficient to meet the demands of a take then put project. The area is currently served by surface water. Groundwater levels in this area are shallow, generally less than 5 to 15 ft in the spring. Hydrographs suggest extremely little seasonal fluctuation in groundwater levels. This sites ability to contribute to Sacramento River flows and integrate with CVP operations led to the recommendation that it be retained for further analysis.

WILLOW CREEK MUTUAL WATER DISTRICT

Willow Creek Mutual Water District (MWD) is a mixed groundwater and surface water district located between the GC Canal and the Sacramento River southeast of Willows. Willow Creek MWD is located in close proximity to the Sacramento National Wildlife Refuge. The District is small and does not have substantial agricultural areas. Groundwater characteristics were not evaluated due to proximity to the Sacramento National Wildlife Refuge. There is limited ability to contribute to Sacramento River flows and no clear way to integrate with CVP operations; therefore, it was recommended that it be dropped from the study.

COLUSA COUNTY WATER DISTRICT

Colusa County WD is a CVP Ag Service contractor that takes delivery from the southern reaches of the Tehama Colusa Canal. Some areas within the district are noted to receive both surface and GW. (Note, the original discussion included extracting the water from RD 108, but RD 108 is primarily supplied from surface water and borders the Sac River. I don't know that this is reasonable or necessary, though water banked under Colusa County WD may flow to RD 108.)

Wells to the east of I-5 indicate relatively shallow depth to water (<5 to 40 ft below ground surface [bgs]) in the spring of 2006. Depth to water increases to the west, in excess of 100 feet below ground surface along the western boundary of the water district. Wells in the eastern portion of the water district generally have higher seasonal fluctuations (up to 20 ft). Wells in the western portion of the district show little to no seasonal fluctuation in groundwater levels. Hydrographs further suggest that there is no long-term trend in groundwater levels since 2000. Aquifer transmissivity in this area decreases due to proximity to the margin of the groundwater basin. This site's ability to contribute to Sacramento River flows and integrate with Shasta operations led to the recommendation that it be retained for further study.

OLIVE PERCY DAVIS RANCH

The Olive Percy Davis Ranch (Ranch) has a Sacramento River Settlement Contract for water from the Sacramento River and CVP. The Ranch is located along the west bank of the river, east of Williams. The ranch has mixed water sources to include surface and groundwater.

Hydrographs in this area indicate that groundwater in this area is extremely shallow (up to 5 ft bgs) with very little seasonal fluctuation. Proximity to the Sacramento River could affect the implementability of a take then put project due to concerns regarding impacts on surface water resources. The aquifer in this area will likely yield large quantities of water to wells. This site has the ability to contribute to Sacramento River flows and integrate with Shasta operations. It is close in proximity to the Sacramento River and raises concerns over SW-GW interaction. Overall, it was recommended that this site be retained for further analysis.

Summary of technical meeting held on July 30, 2007 (See Appendix C)

In an attempt to identify viable put then take project sites in the northern valley, CH2MHill evaluated groundwater elevation data from the period 1970 though present. The objective of this analysis was to determine whether areas exists in the valley where cones of depression in the water table persist year-round such that they represent favorable sites where water could potentially be stored in the aquifer for later use during dry periods. The first step in the analysis was to evaluate spring-fall difference maps to look for seasonal cones of depression. Several areas with seasonal cones of depression exist, specifically the Chico-Durham area, the Capay area, and the area around the Corning Canal among others. Once areas with seasonal depressions were identified, longer term historic water level hydrographs covering the period 1970 to present were constructed for key wells defining the seasonal depressions. The results of this analysis indicated that the cones of depression were really only seasonal features, with almost complete recovery over the winter recharge period. The only exception was in some locations during the 1976-1977 and 1988-1992 drought periods. Some persistent cones of depression were suggested during these droughts but groundwater levels recovered as soon as normal rainfall returned to the valley. Overall, this groundwater level analysis suggests that no obvious locations for successful Put-then-Take scenarios exist in the northern Sacramento Valley.

Appendix A: Meeting Notes

Lower Tuscan Integrated Conjunctive Water Management Plan

Technical Team Meeting
June 19, 2007

Summary Notes

Following are brief notes from a meeting of the Lower Tuscan Technical Team at MBK Engineers on June 19th, 2007. The purpose of the meeting was to review progress on selection and screening of prospective conjunctive use sites, development of analytical tools and development of environmental flow targets.

Attendees:
Thad Bettner/GCID
Greg Thomas/NHI
Carrie Monohan/NHI
John Cain/NHI
Peter Lawson/CH2M HILL
Walter Bourez/MBK
Lee Bergfeld/MBK
Grant Davids/Davids Engineering

Site Selection and Screening

Peter presented well hydrographs from the nine candidate conjunctive management sites previously selected. He explained that while there are areas in the Sacramento Valley that experience seasonal depression of groundwater levels, these areas generally recover each year due to recharge from surrounding aquifers, precipitation, applied irrigation water, stream leakage and other sources. Contrary to initial assumption, there appear to be no areas in the valley where groundwater levels do not recover fully, except possibly in the very driest years or multi-year series. Thus finding conjunctive management sites where year-to-year groundwater banking is accomplished through initial cycles of “put” followed by “take” does not look promising. Instead, we are left with formulations where the take cycle occurs first, and recharge occurs primarily from natural sources, potentially including increased leakage from surface streams, or reduction of groundwater accretion to streams, induced by the lowering of groundwater levels.

With this sharpened perspective, it appears that promising conjunctive management sites would be irrigated areas where:

1) Surface water supplies are reliable (meaning appreciable entitlement in dry years) and form a substantial portion or all of the total irrigation water supply.

2) Underlying groundwater aquifers are productive and economically developed

3) Interaction between groundwater and surface streams, especially the Sacramento River and Feather River does not exist or is highly damped.

Given these attributes, the basic operational scenario would be to pump groundwater and forego use of an equivalent amount of surface water. The surface water could be withdrawn from storage on a schedule designed to meet environmental needs, or other needs. Another option would be to reoperate surface reservoirs to draw them down further and, if they did not refill, rely on groundwater to fill the resulting shortage. Additional yield would be produced by groundwater refilling from natural recharge or surface reservoirs refilling from water that otherwise would be released for flood control purposes.

A significant concern is the extent to which groundwater pumping affects streamflow, and when the effects occur. Effects occurring during balanced conditions would need to be addressed.

We discussed the need to revisit selection of the candidate conjunctive management sites given the additional considerations defined above, and to better document the selection criteria and process. However, no decisions were made.

Model Development

MBK demonstrated the current version of the conjunctive operations spreadsheet model, clarifying that it is still a work in progress. The basic simulation approach is to use outputs from selected CALSIM runs and impose the conjunctive operation on the CALSIM simulated conditions. The basic functionality of the model is complete, and remaining work will focus on adding data integrity and hydrogeologic characterization of the candidate sites.

The model is set up so that each of the nine sites is represented. They can be evaluated independently or in combination, although rules will be needed to establish priorities among sites for combined runs. Independent runs will be made first, and then combined runs explored.

Environmental Flows

NHI has made substantial progress toward establishing environmental flow objectives for the Sacramento River, drawing substantially on ongoing efforts by others, notably The Nature Conservancy and Stillwater Sciences. The objectives address flows for Freemont Cottonwoods, sustaining geomorphic processes, and floodplain inundation. Recognizing that the environmental flow needs may far exceed the additional supplies and timing modifications possible through conjunctive management, next steps will focus on prioritization among the Sacramento River flow objectives, and developing similar objectives for the Feather.

It was acknowledged that the existing Delta export pumping schedules pose significant constraints to reduction of Sacramento River summer flows; however, analysis of modified export schedules (such as might be possible with an isolated facility and additional south of Delta storage) are far beyond the scope of the current investigation.

Action Items

1) **Peter** to check with DWR and validate that there are no areas within the Sacramento Valley with persistent cones of depression where put-then-take operation might work.
2) **Peter** will review the nine sites identified initially, and advise the group as to whether and how site selection should be revisited, considering today's discussion and what is learned from DWR (see #1 above).
3) **Grant** will provide water balance information to Lee for GCID, Orland-Artois, and the Orland Unit.

Next Meeting

1) Next meeting is scheduled for Monday, July 30, 9:00 am at MBK.
2) Peter and Grant will meet at CH2M HILL in Redding on July 19 to discuss site selection.

Appendix B:

MBK ENGINEERS

DRAFT TECHNICAL MEMORANDUM

DATE: June 16, 2007

TO: Sacramento Valley Conjunctive Management Project Team

FROM: MBK and CH2M Hill Technical Team

SUBJECT: DRAFT Candidate Site Screening

This memorandum is a summary of nine potential project sites developed during a project team meeting at MBK Engineers on February 15, 2007. A brief description of how each site would operate and the current groundwater conditions is followed by a table listing site attributes relevant for conjunctive management and integration with the surface water system. The last section of each table summarizes the screening criteria used to rate the site to include ability to meet project objectives, volume of water that may be developed, and relative cost of developing the site. Information in the table was developed using existing data, tools, planning factors, and professional judgment to objectively evaluate all sites by consistent standards. The objective of this analysis is to screen the full list of sites and identify a maximum of six sites to carry forward in the study.

The tables are blank for several attributes, particularly for aquifer characteristics and potential impacts. These attributes will be researched and developed during the course of the study and used in future screening decisions. For example, aquifer characteristics will be determined during the next phase when water budgets are calculated for each project site. Aquifer characteristics and preliminary surface water modeling results will be used to further screen sites, and these sites may then be evaluated for possible impacts.

Western Canal Water District - Durham Cone

Project Operations

Western Canal Water District (WD) extends surface water (SW) delivery system into area overlying Durham cone of depression and operates a groundwater (GW) bank with Oroville providing the source water. An alternative operation would be to expand conjunctive management operations within Western Canal to increase surface water deliveries in wet years and reduce SW deliveries in dry years.

Current Groundwater Conditions

Groundwater levels fluctuate seasonally in response to agricultural and municipal pumping. The maximum measured fluctuation in the Chico-Durham area in 2006 was approximately 30 ft with an average value of approximately 20 ft. Hydrographs from individual wells indicate that groundwater levels fully recover over the winter months. Additionally, hydrographs indicate no long-term declining trends in groundwater levels exist in this area. It is likely that the aquifer in this area receives recharge from Big Chico Creek and other local streams.

Table 1: Western Canal-Durham Cone Site Attributes

General Site Information	
Project Location:	Western Canal WD and northeast of Western Canal WD near Durham
Current Water Source:	GW
Approximate Area:	? acres over Durham cone; Western Canal = 58,800 ag acres
Existing Project Contracts:	Western Canal – 145 TAF/yr Settlement, 150 TAF/yr Project
Operational Concepts	
Type of Operation:	Put-then-take
Supply (wet years):	Supply SW thru Western Canal to GW users
Return (dry years):	Pump additional GW in Western Canal to reduce SWP diversions from Feather River and Oroville
Aquifer Characteristics	
GW Recharge Concept:	In-lieu
Existing GW Levels:	Seasonally depressed
Storage Capacity:	
Loss Rates:	
Stream-GW Interaction:	Butte Creek
GW Quality:	Localized high Ca, NO3, and TDS in the Chico Area
Integration with SW System	
Existing:	Western Canal with SWP; Durham area is not integrated
With Project:	SWP
Reservoir:	Oroville
Infrastructure Requirements	
Supply Water:	Extend Western Canal canals to include lifts, distribution system in current GW only area
Return Water:	Additional wells in Western Canal
Possible Impacts	
Surface Water:	

Surrounding GW Levels:	
Subsidence:	
Sensitive Habitats:	
Site Screening Criteria	
Meets Project Objectives:	Ability to contribute to Feather River flows and integrate with Oroville operations
Est. Water Developed:	Existing ag demands and contracts > 250 TAF/yr
Relative Cost:	Low in Western Canal only; high to include Durham area
Site Status:	**Retain for further analysis**

Orland-Artois Water District

Project Operations

Orland-Artois WD, a CVP Ag Service contractor, receives additional surface water from the Tehama-Colusa (TC) or Glen Colusa (GC) Canals, or directly from Stony Creek. Additional surface water reduces groundwater demand in current cone of depression. Water is returned to the system with additional groundwater pumping in dry years instead of Orland-Artois WD taking all or a portion of their CVP contract. (*Note, the original discussion focused on this project with M&T Chico Ranch, but M&T is on east side of river while current cone of depression is on west side of the river, so a more likely project partner would be Orland-Artois WD.)*

Current Groundwater Conditions

Groundwater levels fluctuate seasonally in response to agricultural pumping. The maximum measured fluctuation in the southern portion of Orland-Artois WD area in 2006 was approximately 25 ft, but appears to vary spatially due to localized pumping. Hydrographs from individual wells indicate that groundwater levels fully recover over the winter months. Additionally, hydrographs indicate no long-term declining trends in groundwater levels exist in this area. It is likely that the aquifer in this area receives recharge from streams tributary to Willow Creek.

Table 2: Orland-Artois WD Site Attributes

General Site Information	
Project Location:	Between TC and GC Canals south of Stony Creek
Current Water Source:	GW and mixed within Orland-Artois WD
Approximate Area:	? acres in cone; Orland Artois WD = 25,000 ag acres
Existing Project Contracts:	Orland-Artois WD – 53 TAF/yr CVP Ag service
Operational Concepts	
Type of Operation:	Put-then-take
Supply (wet years):	Additional SW thru TC Canal, Stony Creek, or uphill from GC Canal
Return (dry years):	Pump additional GW to reduce surface water diversions and back water into Shasta and/or Stony Creek System

Aquifer Characteristics	
GW Recharge Concept:	In-lieu and natural recharge from Stony Creek
Existing GW Levels:	Seasonally depressed
Storage Capacity:	
Loss Rates:	
Stream-GW Interaction:	Stony Creek and Sacramento River
GW Quality:	High nitrates occur in Arbuckle, Knights Landing, and Willows. Localized areas have high manganese, fluoride, magnesium, sodium, iron, ASAR, chloride, TDS, ammonia, and phosphorus.
Integration with SW System	
Existing:	CVP with Orland-Artois WD
With Project:	Possibly expand integration with CVP thru TC or GC canals
Reservoirs:	Shasta (Folsom) and/or Stony Creek system
Infrastructure Requirements	
Supply Water:	Distribution system, extend canals and possibly lift water from GC canal
Return Water:	Additional wells within Orland-Artois WD; minimal to return water to GC Canal
Possible Impacts	
Surface Water:	
Surrounding GW Levels:	
Subsidence:	
Sensitive Habitats:	
Site Screening Criteria	
Meets Project Objectives:	Ability to contribute to Sacramento River flows and integrate with CVP operations
Est. Water Developed:	Existing ag demands and contracts > 50 TAF/yr
Relative Cost:	Medium
Site Status:	**Retain for further analysis**

Capay Rancho Water District

Project Operations

Capay Rancho WD would operate a groundwater bank by receiving surface water in wet years. Capay Rancho, a groundwater only district, is located over an existing cone of depression that may be utilized to store water. Methods for returning additional GW to the system in dry years are more complex, but may involve supplying water to areas in the TC Canal service area or GCID.

Current Groundwater Conditions

Groundwater levels fluctuate seasonally in response to agricultural pumping. The maximum measured fluctuation in the Capay WD area in 2006 was approximately 50 ft with an average value of approximately 25 ft. Hydrographs from individual wells indicate that groundwater levels fully recover over the winter months. Additionally, hydrographs indicate no long-term declining trends in groundwater levels exist in this area. It is likely that the aquifer in this area receives recharge from Stony Creek and other local streams.

Table 3: Capay Rancho WD Site Attributes

General Site Information	
Project Location:	Between TC Canal and Sacramento River, north of Stony Creek
Current Water Source:	GW
Approximate Area:	? acres overlying cone; Capay Rancho WD = 7,700 ag acres
Existing Project Contracts:	None
Operational Concepts	
Type of Operation:	Put-then-take
Supply (wet years):	Provide surface water thru TC Canal, Stony Creek, or pump up from Sacramento River or head of GC Canal
Return (dry years):	Pump additional GW, possibly into GC Canal to reduce surface water diversions and back water into Shasta
Aquifer Characteristics	
GW Recharge Concept:	In-lieu and natural recharge in Stony Creek
Existing GW Levels:	Seasonally depressed
Storage Capacity:	
Loss Rates:	
Stream-GW Interaction:	Project borders Sacramento River, near Stony Creek
GW Quality:	The Corning Subbasin has locally high calcium.
Integration with SW System	
Existing:	None
With Project:	CVP thru TC or GC Canals
Reservoirs:	Shasta (Folsom) and/or Stony Creek system
Infrastructure Requirements	
Supply Water:	Distribution system to take surface water from nearby canals; possibly lift from Sacramento River, Stony Creek, or GC Canal
Return Water:	Conveyance to pump GW into GC or TC Canals?
Possible Impacts	
Surface Water:	
Surrounding GW Levels:	
Subsidence:	
Sensitive Habitats:	
Site Screening Criteria	
Meets Project Objectives:	Currently no ability to contribute to Sacramento River flows and integrate with CVP operations
Est. Water Developed:	Small ag area (demands) and no existing contracts
Relative Cost:	Medium

Site Status:	**Drop from study**

Corning Canal Service Area

Project Operations

A portion of the Corning Canal Service Area overlies an existing cone of depression north of Richfield and west of Tehama. The overlying districts that could operate the groundwater bank include Elder Creek, El Camino ID, Tehama Ranch, and Thomes Creek. The Corning Canal runs though these districts and typically has unutilized capacity. CVP contractors along the Corning Canal include Proberta (3.5 TAF/yr), Thomes Creek (6.4 TAF/yr), and Corning (23 TAF/yr) WDs. These WDs have recently been pumping additional GW instead of taking CVP contract water due to the relative costs of CVP water to groundwater.

Current Groundwater Conditions

Groundwater levels fluctuate seasonally in response to agricultural pumping. The maximum measured fluctuation in the Corning Canal Service Area in 2006 was in excess of 50 ft; but appears to vary spatially due to localized pumping. Hydrographs from individual wells indicate that groundwater levels fully recover over the winter months. Additionally, hydrographs indicate no long-term declining trends in groundwater levels exist in this area. It is likely that the aquifer in this area receives recharge from Thomes Creek, Elder Creek, and other local streams draining the western foothills.

Table 4: Corning Canal Service Area Site Attributes

General Site Information	
Project Location:	Corning Canal service area
Current Water Source:	Mixed
Approximate Area:	? acres overlying cone of depression
Existing Project Contracts:	Corning Canal contracts total 32.9 TAF/yr
Operational Concepts	
Type of Operation:	Put-then-take
Supply (wet years):	Supply SW thru Corning Canal and possibly TC Canal
Return (dry years):	Pump additional GW to reduce surface water diversions and back water into Shasta
Aquifer Characteristics	
GW Recharge Concept:	In-lieu
Existing GW Levels:	
Storage Capacity:	
Loss Rates:	
Stream-GW Interaction:	Sacramento River and Thomes Creek
GW Quality:	Impairments in the Red Bluff Subbasin include high magnesium, TDS, calcium, ASAR, and phosphorus.

Integration with SW System	
Existing:	CVP Ag service contractors currently integrated
With Project:	Potential to integrate additional areas with CVP
Reservoirs:	Shasta (Folsom)
Infrastructure Requirements	
Supply Water:	Minimal in Corning Canal area; significant in existing GW only areas
Return Water:	Additional wells and conveyance?
Possible Impacts	
Surface Water:	
Surrounding GW Levels:	
Subsidence:	
Sensitive Habitats:	
Site Screening Criteria	
Meets Project Objectives:	Ability to contribute to Sacramento River flows and integrate with Shasta operations
Est. Water Developed:	Existing ag demands and contracts > 30 TAF/yr
Relative Cost:	Low Corning Canal area only; High to include other areas
Site Status:	**Retain for further analysis**

Yolo-Zamora Water District

Project Operations

The Yolo-Zamora WD overlies an existing cone of depression and relies on groundwater for irrigation. Surface water could be supplied by extending the Tehama Colusa Canal or constructing a canal from the Sacramento River. This has been studied in the past but rejected as too expensive as a substitute for groundwater for irrigation. Returning water to the system may be challenging.

Current Groundwater Conditions

Unable to evaluate due to lack of data from the Central District at this time. Awaiting receipt of groundwater level data from DWR.

Table 5: Yolo-Zamora WD Site Attributes

General Site Information	
Project Location:	Between southern end of Colusa Basin Drain (CBD) and north of Cache Creek
Current Water Source:	GW
Approximate Area:	? acres overlying cone; Yolo-Zamora WD = 19,000 ag acres
Existing Project Contracts:	None

Operational Concepts	
Type of Operation:	Put-then-take
Supply (wet years):	Surface water thru TC Canal or possibly from Colusa Basin Drain
Return (dry years):	Challenging to return water to system
Aquifer Characteristics	
GW Recharge Concept:	In-lieu
Existing GW Levels:	Depressed
Storage Capacity:	
Loss Rates:	
Stream-GW Interaction:	Sacramento River and Cache Creek
GW Quality:	Localized areas of the Colusa Subbasin have high manganese, fluoride, magnesium, sodium, iron, ASAR, chloride, TDS, ammonia, and phosphorus.
Integration with SW System	
Existing:	None
With Project:	Possibly with CVP
Reservoirs:	Shasta (Folsom)
Infrastructure Requirements	
Supply Water:	Extend TC Canal or CBD; distribution system within Yolo-Zamora WD
Return Water:	Unknown
Possible Impacts	
Surface Water:	
Surrounding GW Levels:	
Subsidence:	
Sensitive Habitats:	
Site Screening Criteria	
Meets Project Objectives:	Currently no ability to contribute to Sacramento River flows and integrate with CVP operations
Est. Water Developed:	Significant ag area (demands) but no existing contracts
Relative Cost:	High
Site Status:	**Drop from study**

Glenn-Colusa Irrigation District - Stony Creek Fan

Project Operations

Glenn-Colusa Irrigation District (GCID) could operate a groundwater bank in the Stony Creek Fan, banking CVP water in wet years and reducing CVP surface water deliveries in dry years. This operation may be similar to recent groundwater substitution transfers.

Current Groundwater Conditions

The northern portion of GCID represents an area known to have high aquifer transmissivity. The area is currently served by surface water. The area is underlain by the lower Tuscan Aquifer as well as shallower producing zones in the Tehama Formation. Groundwater levels in this area are shallow, generally less than 10 to 15 ft in the spring. Hydrographs suggest very little seasonal fluctuation in groundwater levels.

The southwestern portion of GCID is still relatively high, but less than that of the northern portion due to the proximity to the margin of the groundwater basin. Well yields in this area are more than sufficient to meet the demands of a take then put project. The area is currently served by surface water. Groundwater levels in this area are shallow, generally less than 5 to 15 ft in the spring. Hydrographs suggest extremely little seasonal fluctuation in groundwater levels.

Table 6: GCID-Stony Creek Fan Site Attributes

General Site Information	
Project Location:	Northern portion of GCID
Current Water Source:	Primarily surface water
Approximate Area:	Estimate area within GCID overlying Stony Creek Fan
Existing Project Contracts:	GCID - 825 TAF/yr Settlement Contract
Operational Concepts	
Type of Operation:	Take-then-put
Supply (wet years):	In normal and wet years area takes existing surface water supply
Return (dry years):	Water returned to system by additional GW pumping to reduce surface water deliveries and back water into Shasta
Aquifer Characteristics	
GW Recharge Concept:	Natural
Existing GW Levels:	Shallow and stable
Storage Capacity:	
Loss Rates:	
Stream-GW Interaction:	Sacramento River
GW Quality:	Localized areas of the Colusa Subbasin have high manganese, fluoride, magnesium, sodium, iron, ASAR, chloride, TDS, ammonia, and phosphorus.
Integration with SW System	
Existing:	CVP thru GCID
With Project:	No change
Reservoirs:	Shasta (Folsom); potentially Stony Creek System
Infrastructure Requirements	
Supply Water:	None
Return Water:	Additional wells
Possible Impacts	
Surface Water:	

Surrounding GW Levels:	
Subsidence:	
Sensitive Habitats:	
Site Screening Criteria	
Meets Project Objectives:	Ability to contribute to Sacramento River flows and integrate with CVP operations
Est. Water Developed:	Existing ag demands and contracts > 800 TAF/yr
Relative Cost:	Low
Site Status:	**Retain for further analysis**

Willow Creek Mutual Water District

Project Operations

Willow Creek Mutual Water District (MWD) is a mixed groundwater and surface water district located between the GC Canal and the Sacramento River southeast of Willows. Willow Creek MWD is located in close proximity to the Sacramento National Wildlife Refuge. The District is small and does not have substantial agricultural areas.

Current Groundwater Conditions

Groundwater characteristics were not evaluated due to proximity to the Sacramento National Wildlife Refuge.

Table 7: Willow Creek MWD Site Attributes

General Site Information	
Project Location:	West of Willow Creek, east of Sacramento NWR and north of Delevan NWR
Current Water Source:	Mixed
Approximate Area:	Willow Creek MWD = 7,100 acres total, 2,900 ag
Existing Project Contracts:	None
Operational Concepts	
Type of Operation:	Take-then-put
Supply (wet years):	
Return (dry years):	
Aquifer Characteristics	
GW Recharge Concept:	
Existing GW Levels:	Shallow and stable
Storage Capacity:	
Loss Rates:	
Stream-GW Interaction:	Sacramento River
GW Quality:	Localized areas of the Colusa Subbasin have high manganese, fluoride, magnesium, sodium, iron, ASAR, chloride, TDS, ammonia,

	and phosphorus.
Integration with SW System	
Existing:	
With Project:	
Reservoirs:	
Infrastructure Requirements	
Supply Water:	
Return Water:	
Possible Impacts	
Surface Water:	
Surrounding GW Levels:	
Subsidence:	
Sensitive Habitats:	
Site Screening Criteria	
Meets Project Objectives:	Currently no ability to contribute to Sacramento River flows and integrate with CVP operations
Est. Water Developed:	Small ag area (demands) and no existing contracts
Relative Cost:	Not evaluated
Site Status:	**Drop from study**

Colusa County Water District

Project Operations

Colusa County WD is a CVP Ag Service contractor that takes delivery from the southern reaches of the Tehama Colusa Canal. Some areas within the district are noted to receive both surface and GW. (*Note, the original discussion included extracting the water from RD 108, but RD 108 is primarily supplied from surface water and borders the Sac River. I don't know that this is reasonable or necessary, though water banked under Colusa County WD may flow to RD 108.)*

Current Groundwater Conditions

Wells to the east of I-5 indicate relatively shallow depth to water (<5 to 40 ft below ground surface [bgs]) in the spring of 2006. Depth to water increases to the west, in excess of 100 feet below ground surface along the western boundary of the water district. Wells in the eastern portion of the water district generally have higher seasonal fluctuations (up to 20 ft). Wells in the western portion of the district show little to no seasonal fluctuation in groundwater levels. Hydrographs further suggest that there is no long-term trend in groundwater levels since 2000. Aquifer transmissivity in this area decreases due to proximity to the margin of the groundwater basin.

Table 8: Colusa County WD Site Attributes

General Site Information

Project Location:	Southern reaches of TC Canal, west of RD 108
Current Water Source:	Mixed
Approximate Area:	Colusa County WD = 38,000 ag acres
Existing Project Contracts:	Colusa County WD - 68 TAF/yr
Operational Concepts	
Type of Operation:	Take-then-put
Supply (wet years):	Supply additional surface water through TC Canal
Return (dry years):	Pump additional groundwater to reduce surface water deliveries and back water into Shasta
Aquifer Characteristics	
GW Recharge Concept:	In-lieu
Existing GW Levels:	Stable since 2000. Depth increases from east-west (<5 ft bgs to >100 ft bgs).
Storage Capacity:	
Loss Rates:	
Stream-GW Interaction:	Local streams
GW Quality:	Localized areas of the Colusa Subbasin have high manganese, fluoride, magnesium, sodium, iron, ASAR, chloride, TDS, ammonia, and phosphorus.
Integration with SW System	
Existing:	CVP
With Project:	Expanded integration with CVP
Reservoirs:	Shasta (Folsom)
Infrastructure Requirements	
Supply Water:	Minimal
Return Water:	Minimal
Possible Impacts	
Surface Water:	
Surrounding GW Levels:	
Subsidence:	
Sensitive Habitats:	
Site Screening Criteria

Olive Percy Davis Ranch

Project Operations

The Olive Percy Davis Ranch (Ranch) has a Sacramento River Settlement Contract for water from the Sacramento River and CVP. The Ranch is located along the west bank of the river, east of Williams. The ranch has mixed water sources to include surface and groundwater.

Current Groundwater Conditions

Hydrographs in this area indicate that groundwater in this area is extremely shallow (up to 5 ft bgs) with very little seasonal fluctuation. Proximity to the Sacramento River could affect the implementability of a take then put project due to concerns regarding impacts on surface water resources. The aquifer in this area will likely yield large quantities of water to wells.

Table 9: Olive Percy Ranch Site Attributes

General Site Information	
Project Location:	Between town of Williams and Sacramento River
Current Water Source:	Mixed
Approximate Area:	Ranch = 6,900 ag acres (9,110 per contract)
Existing Project Contracts:	Ranch = 31.8 TAF/yr Settlement Contract
Operational Concepts	
Type of Operation:	Take-then-put
Supply (wet years):	Supply additional surface water from Sacramento River
Return (dry years):	Pump additional groundwater to reduce surface water deliveries and back water into Shasta
Aquifer Characteristics	
GW Recharge Concept:	In-lieu
Existing GW Levels:	
Storage Capacity:	
Loss Rates:	
Stream-GW Interaction:	Sacramento River
GW Quality:	Localized areas of the Colusa Subbasin have high manganese, fluoride, magnesium, sodium, iron, ASAR, chloride, TDS, ammonia, and phosphorus.
Integration with SW System	
Existing:	CVP
With Project:	Expanded integration with CVP
Reservoirs:	Shasta (Folsom)
Infrastructure Requirements	
Supply Water:	Potentially expand SW distribution system
Return Water:	Additional pumps?

Possible Impacts	
Surface Water:	Possible impacts to Sacramento River flows from increased GW pumping
Surrounding GW Levels:	
Subsidence:	
Sensitive Habitats:	
Site Screening Criteria	
Meets Project Objectives:	Ability to contribute to Sacramento River flows and integrate with Shasta operations; close proximity to Sacramento River raises concerns over SW-GW interaction and impacts
Est. Water Developed:	Existing ag demands and contracts > 30 TAF/yr
Relative Cost:	Inexpensive
Site Status:	**Retain for further analysis**

summary of site screening

A summary of the nine proposed sites and their respective status is provided in the following table.

Table 10: Summary of Site Status

Site Name	Status
Western Canal WD – Durham	**Retain**
Orland Artois WD	**Retain**
Capay Rancho WD	Drop
Corning Canal Service Area	**Retain**
Yolo-Zamora WD	Drop
GCID – Stony Creek Fan	**Retain**
Willow Creek MWD	Drop
Colusa County WD	**Retain**
Olive Percy Davis Ranch	**Retain**

The six sites that are retained will be carried forward for additional analysis to include calculation of water budgets, determination of aquifer characteristics, and preliminary surface water modeling.

Lower Tuscan Integrated Conjunctive Water Management Plan

Technical Team Meeting
July 30, 2007

Summary Notes

Following are brief notes from a meeting of the Lower Tuscan Technical Team at MBK Engineers on July 30, 2007. These are not intended as meeting minutes, rather as a summary of key points, decisions and action items. The primary purposes of the meeting were to: 1) resolve issues related to project site selection and 2) reach consensus on the technical approach for the groundwater analysis. Environmental flows for the Feather River were also discussed. The full meeting agenda is attached.

Attendees:
Thad Bettner/GCID
Carrie Monohan/NHI
John Cain/NHI
Peter Lawson/CH2M HILL
Walter Bourez/MBK
Lee Bergfeld/MBK
Grant Davids/Davids Engineering
Maurice Hall/DWR

1. Revisit Potential "Put-then-Take" Sites

Peter reviewed the rationale that had been used to identify particular geographic areas for investigation of put-then-take (P-T) conjunctive operations. While there are areas in the Valley where cones of depression develop seasonally, those cones generally refill each year by natural recharge and therefore do not offer opportunity for inter-annual storage as is needed for conjunctive operations. Additionally, to the extent that groundwater levels in these areas do not recover completely, this tends to occur in dry years when there would be little surface water available for recharge.

Groundwater hydrographs were reviewed for three areas where seasonal cones of depression occur:

- Chico-Durham
- Capay
- Corning

Some long-term downward decline in groundwater levels is evident in some wells, but there are no persistent inter-annual cones of depression in these areas.

The Yolo-Zamora area was also discussed. Lee explained that while this area does have a local cone of depression that might be conducive to groundwater storage, there are two major shortcomings associated with this site. One is that it does not have an existing surface water supply to forego use of in dry years (and a new surface water supply would most likely be a CVP water service contract which would not provide a reliable dry year supply). The second is the need for extensive infrastructure improvements involving extension of the Tehama-Colusa Canal and construction of a completely new water distribution system.

The conclusion of the review was that there are no areas where a P-T strategy appears workable at this time on an appreciable scale. Therefore the investigation will proceed focusing on "take-then-put" (T-P) strategies, recognizing that natural recharge will play a significant role in refilling groundwater extracted for project purposes.

The degree of rigor and level of documentation needed in our screening process was discussed. It was agreed that our objective is not to conduct an exhaustive assessment of all possible conjunctive management sites in the Sac Valley, but to identify 2 or 3 most promising sites based on available information and professional judgment, and move ahead with characterization of those sites and development of our analytical tools. We also agreed that given the more detailed modeling approach we have adopted (see below), we should not conduct intermediate analyses of several sites (as originally planned) as a means of selecting the final 2 or 3.

The primary qualifications for candidate T-P sites (as discussed at our last meeting) are places where:

4) Surface water supplies are reliable (meaning appreciable entitlement in dry years) and form a substantial portion or all of the total irrigation water supply.

5) Underlying groundwater aquifers are productive and economically developed

6) Interaction between groundwater and surface streams, especially the Sacramento River and Feather River does not exist or is highly damped.

Additionally, sites that have potential to produce large quantities of groundwater are desirable.

The following three locales were discussed as having these basic attributes, and will receive primary attention as we move ahead with T-P analyses.

- Western Canal WD (potentially including the Chico-Dayton area)
- Stony Creek Fan-Northern GCID
- Central GCID

It was agreed that Carrie would spearhead documentation of our site screening and selection process. Our documentation needs to be clear that elimination of sites for our purposes at this time does not mean that those sites would not be attractive for other purposes or at other times.

2. Analytical Approaches and Tools

The ongoing Delta Vision process and its possible implications to our project were discussed at some length. It was acknowledged that it is as likely that future Delta operations will change, perhaps appreciably, as they are to remain the same. However, it was also acknowledged there is no reliable way to anticipate possible future Delta changes nor related changes to CVP and SWP reservoir operations. We agreed to continue the planned course of analysis within the context of existing Delta operating parameters. The tools and knowledge we are developing may be instructive for planning broader operational changes, but this is outside the scope of our current effort.

The three model improvement approaches formulated by CH2M HILL and MBK were discussed and a decision was made to pursue modifications to the existing superposition model (Option 3). This begins with MBK providing spatially distributed hydrologic time series to CH2M HILL for incorporation into the model. The model will be calibrated to historical groundwater levels.

The need to acknowledge and understand the nature of error and uncertainty in our analysis was discussed. Peter mentioned that sensitivity analyses could be conducted to assist in this process. We will need to track this and design appropriate analyses when we are further along.

Grant will review project budgets to identify where the necessary additional $40,000 can be found and review the necessary adjustments with GCID, NHI and DWR.

3. Environmental Flows

John and Carrie reiterated NHI’s basic approach of seeking operational changes that move toward pre-project flow regimes. This approach, rather than a species-specific approach, is thought to be most effective and defensible. Hydrographs for the Feather River were discussed. (This discussion occurred in conjunction with discussion of Item 2.)

Specific rules and priorities by month are needed to incorporate the environmental flows into the analysis. John and Carrie will work on this next.

4. Schedule

Peter, Lee and Walter will establish milestones and develop a proposed schedule for completion of technical tasks to be reviewed by the Team.

5. Summary of Action Items

- Carrie will initiate draft documentation of our site screening and selection processes drawing on the assistance of other team members as needed. A draft will be distributed before our next meeting.
- Lee to transfer hydrologic data to Peter ASAP.
- Grant to review project budgets and initiate task order revisions to CH2M HILL and MBK, in coordination with GCID, NHI and DWR, ASAP.
- John and Carrie to coordinate with Walter in expressing environmental flows in a form conducive to modeling.
- Peter, Lee and Walter will establish milestones and develop a proposed schedule for completion of technical tasks to be reviewed by the Team, ASAP.

6. Next Meeting

The next meeting was set for September 13 at 10:00 a.m. at MBK

Appendix D
Estimating Ecologically Based Flow Targets for the Sacramento and Feather Rivers

Estimating Ecologically Based Flow Targets for the Sacramento and Feather Rivers

THE NATURAL HERITAGE INSTITUTE

John Cain

Carrie Monohan

April 2008

PREFACE

This report was prepared as part of a collaborative investigation by the Glenn Colusa Irrigation District (GCID) and the Natural Heritage Institute (NHI) to explore opportunities to expand water supplies in the Sacramento Valley through conjunctive management of surface water and groundwater supplies. These expanded supplies could contribute toward achieving three primary objectives: (1) improve local in-basin water supply reliability for farms, cities, and the environment; (2) contribute to improvement of statewide water supply reliability; and (3) enhance ecosystems in the rivers in the Sacramento Valley. The investigation was funded by the California Department of Water Resources and Bureau of Reclamation.

The Scope of Work of the federal and state grants includes a task to define a range of environmental flows to restore in stream and riparian ecosystem processes to the maximum extent compatible with the protection of the interests of the riparian landowners in the floodplain improvements. Flows shall be defined for both the Sacramento River below Shasta and Keswick dams, and the Feather River below Oroville and Thermalito dams, in terms of magnitude, duration, frequency, seasonality and reach. This will be defined in a manner to avoid any uncompensated risks to affected landowners. The range may include various assumptions about levee setbacks in the floodplains. Flood-routing models will be used to estimate the potentially inundated area and system capacity to carry environmental flows.

This report was prepared by the NHI in partial fulfillment of the above-defined task. It postulates hypothetical environmental flow regimes for the Sacramento and Feather Rivers that are significantly different from those that presently exist. It is not yet known to what extent the flows can be achieved through conjunctive water management or, potentially, by other means that are outside the scope of this investigation, while other existing and future water demands are satisfied. Also, the risks that the recommended flows may pose to affected landowners are not addressed in the report, but will be addressed in subsequent work. NHI has prepared this report for the purposes of this planning investigation only. To the extent this report is used or referenced for other purposes, it will be subject to review, modification, and acceptance by the larger number of entities and stakeholders necessarily involved in crafting water management policies, projects and practices in the Sacramento Valley and downstream affected areas.

Conceptual Models for Geomorphic, Riparian, and Salmonid Objectives

1. EXECUTIVE SUMMARY

This study identifies an environmental flow regime for the Sacramento and the Feather Rivers in order to:

- Test the feasibility of reoperating terminal reservoirs in the Sacramento River Basin without diverting additional water away from agriculture,
- Develop a comprehensive hypothesis regarding the range of flows that may be necessary to restore ecological processes to the Sacramento River, and
- Use the environmental flow targets to inform and guide conjunctive use scenarios.

The development of environmental flow regimes is as much an art as a science, but we attempted, to the extent possible, to use established methods to develop a transparent and replicable approach for identifying and environmental flow regime. We conducted a detailed literature review of various methods and approaches previously utilized to develop environmental flow recommendations, and employ a version of the holistic approach practiced in South Africa and Australia (King et. al. 2000) to identify an environmental flow regime for the Sacramento and Feather Rivers. This approach relies heavily on hydrological evaluations, previous studies and modeling efforts analysis of historical hydrology, and expert opinion to estimate environmental flow requirements.

Our approach consists of five basic steps:

1. Identify specific environmental objectives (i.e,. target species, aquatic and riparian communities, and desired ecological conditions that are flow dependent).
2. Approximate the timing, magnitude, frequency, and duration (TMDF) of flows necessary to support achieve environmental objectives.
3. Compare and analyze existing and historical hydrology to understand natural hydrologic patterns and how they have been altered.
4. Identify obvious gaps between flows necessary to achieve objectives and existing flows.
5. Modify the existing hydrograph into an environmental flow hydrograph based on an understanding of natural hydrology and the flows necessary to achieve key objectives.

These five steps will ultimately need to be followed by an adaptive management research program to test and refine an improved environmental flow regime over time.

We designed the environmental hydrograph to achieve the following three types of objectives

- Geomorphic Functionality: Bed mobility, channel migration, and floodplain inundation.

- Riparian Habitat Sustainability: Recruitment and maintenance of Fremont Cottonwood.
- Chinook Salmon: Improved habitat, particularly rearing habitat, for all runs.

We relied on field data, modeling results, and studies , particularly the recent Nature Conservancy Study of the Sacramento River, to identify the minimum flows and critical thresholds to achieve each of our objectives. We then analyzed historical and existing hydrology to understand how the objectives may have been achieved under pre-dam conditions and to evaluate how existing hydrology may fall short of meeting those objectives.

A sharp reduction in the magnitude and duration of the late winter and early spring hydrograph and a corresponding reduction of inundated floodplain habitat is the most obvious and significant change in the hydrograph on both the Sacramento and Feather Rivers. The reduction in late winter and spring flows reduces the frequency of geomorphic and riparian flows and substantially reduces the extent and frequency of occurrence of inundated floodplain rearing habitat for salmonids. Restoring spring flows alone, however, will not be sufficient to dramatically increase the amount of floodplain habitat. Modifications of the levees and bypass system will also be necessary to enable high flows to inundate historical floodplains. We evaluate the amount of flow necessary to inundate the Yolo and Sutter Bypasses assuming modification of the weirs controlling flows into those bypasses in the interest of identifying water efficient strategies for creating large areas of inundated floodplain habitat.

The last chapter identifies an environmental flow regime for the Sacramento and Feather Rivers. An increase in late winter and early spring flow is the primary component of the environmental flow regime, but a corresponding reduction in summer base flows is also recommended. Reduced summer flows are primarily needed to free-up water needed to restore the spring hydrograph but may also provide ecological benefits by better approximating the natural hydrograph. Reducing summer base flows could, however, increase summer temperatures and harm salmonids including the endangered winter-run Chinook salmon. On the other hand, cool water temperatures in the upper Sacramento River are largely controlled by the volume of cold water storage behind Shasta Dam and the environmental flow regime identified here does not involve modifying coldwater pool management.

The summer temperature issue is one of several key uncertainties that must be addressed before any significant modifications to the flow regime can be refined and implemented for environmental purposes. Articulating a hypothetical environmental flow regime is the first step in identifying and addressing constraints and uncertainties associated with improving environmental flow regimes on regulated rivers. To that end, NHI welcomes comments and criticisms so that we can improve upon this report as we learn more about the rivers and the people who depend upon them for their livelihood.

2. INTRODUCTION

This study identifies environmental flow targets for the Sacramento River and the Feather River. The purpose of developing environmental flow targets is to:

- Test the feasibility of reoperating terminal reservoirs in the Sacramento River Basin without diverting additional water away from agriculture,
- Develop a comprehensive hypothesis regarding the range of flows that may be necessary to restore ecological processes to the Sacramento River, and
- Use the environmental flow targets to inform and guide conjunctive use scenarios.

Our thesis is that reservoirs operated today for a limited set of water supply and flood control objectives could be reoperated to achieve newly defined ecological objectives without compromising existing objectives. This opportunity was recognized by the authors of CALFED's Strategic Plan for Ecosystem Restoration:

> "There is underutilized potential to modify reservoir operations rules to create more dynamic, natural high-flow regimes in regulated rivers without seriously impinging the water storage purposes for which the reservoir was constructed. Water release operating rules could be changed to ensure greater variability of flow, provide adequate spring flows for riparian vegetation establishment, simulate effects of natural floods in scouring riverbeds and creating point bars, and increase the frequency and duration of overflow onto adjacent floodplains."

Clearly defining this new set of ecological objectives and estimating the flows necessary to achieve them is the first step toward evaluating the feasibility of restoring these flows. The biological and physical processes that support natural riverine functions are complex and the task of defining environmental flow regimes is enormously difficult. For the purpose of defining an environmental flow regime and assessing the feasibility of attaining it, we have identified a simplified but broad set of water intensive ecological objectives that best capture the full range and magnitude of environmental flow requirements in the Sacramento Basin. These objectives include:

- Geomorphic Processes: sediment transport, channel geomorphology, floodplain inundation.
- Riparian vegetation: cottonwood recruitment and maintenance flows
- Chinook and Steelhead: stream temperatures and adequate flow for various life stages.

This study focuses on the magnitude and timing of flows necessary to replicate key ecological and geomorphic processes, and considers the flows necessary to provide suitable conditions for various life stages of Chinook salmon and steelhead. This study does not identify specific population targets for salmonid restoration, nor does it address important non-flow objectives such as habitat area required for restoration of target species or augmentation of coarse sediment supplies necessary to restore full geomorphic structure and function. Rather this study focuses on magnitude, pattern, and quantity of water necessary to restore ecological functions assuming that adequate physical habitat exists or will be created to complement a suitable environmental flow regime. The rationale of this focus is to identify a hypothetical environmental flow regime for the purpose of evaluating whether it is possible to reestablish ecological and geomorphic flows on the rivers of the Sacramento Basin without reducing water supply deliveries to existing water users.

This report would not have been possible without the foundational analysis conducted by the Nature Conservancy and their consulting team, but it differs substantially from the Sacramento River Ecological Flows Study (SREFS) developed by the Nature Conservancy with funding from the CALFED Bay-Delta Program. The SREFS compiled information on the state of the Sacramento River ecosystem and developed a decision support tool to predict how changes in the flow regime of the Sacramento River might affect key attributes and species of the riverine ecosystem. The SREFS did not, however, attempt to develop an environmental flow prescription for the river and did not address ecological conditions or flow requirements for the Feather River. The SREFS decision support tool could be used to test and refine the flow regime developed for this report, but the SREFS did not and will not propose an environmental flow regime. We relied heavily on the information developed for the SREFS to generate the environmental flow regime described in this report.

Our study relies heavily on analysis of historical hydrology and the habitat it created to provide a reference point for identifying ecosystem restoration goals, but we recognize that it is not possible to restore historic conditions in highly altered systems such as the Sacramento River. Historical hydrologic analysis is useful for identifying patterns in the timing, magnitude, duration, and frequency of flows that may be important for maintaining native species, but it is less useful in developing specific flow prescriptions, because physical habitat has been so profoundly changed by dams and levees. We recognize that it is not possible to fully restore historical hydrology or habitat conditions in the Sacramento Valley, but ecosystem restoration will require reestablishment of a minimum threshold of both hydrologic and physical habitat conditions.

Although this study identifies hypothetical restoration flow regimes for the Sacramento and Feather Rivers, we recognize that the most reliable method for developing a restoration flow regime is through a long-term adaptive management program including a series of trials that test the effectiveness of various flow prescriptions. The hypothetical flow regime serves as a reasonable starting point for evaluating the economic feasibility of reoperating reservoirs and a long-term adaptive management program. The assumptions and uncertainties associated with the hypothetical flow regime are important to acknowledge and understand. To cost effectively achieve restoration, managers will ultimately need to test these assumptions and limit the uncertainties through an adaptive management program consisting of a combination of modeling, pilot flow studies, model calibration, and long-term implementation.

3. METHOD FOR DEVELOPING ENVIRONMENTAL FLOW RECOMMENDATIONS FOR THE SACRAMENTO AND FEATHER RIVERS

We conducted a detailed literature review of various methods and approaches previously utilized to develop environmental flow recommendations, which is described in further detail in Appendix A. We have employed a version of the holistic approach practiced in South Africa and Australia (King et. al. 2000) to identify an environmental flow regime for the Sacramento River. This approach relies heavily on hydrological evaluations, previous studies, and expert opinion to estimate environmental flow requirements and develop a long-term adaptive management plan for implementing and refining an environmental flow regime over time. The results of the holistic approach provide a framework for increasing knowledge regarding the relationship between flow and environmental objectives and refining water management practices over time. The output of the holistic method envisioned here provides not only an estimate of environmental flow requirements, but more importantly, an explicit identification of key assumptions and uncertainties that need to be tested overtime to more accurately describe the flow requirements necessary to achieve environmental objectives.

We made two important assumptions in generally applying this method to the Sacramento River.

- Similarities in both the restoration objectives and the hydrologic, geomorphic, and ecological conditions on the Sacramento River will result in relatively similar prescriptions for environmental management flows. We believe this assumption is well supported by the environmental conditions and historical alteration of this river.

- The flow necessary to achieve restoration objectives may vary greatly depending on non-flow restoration actions such as improving spawning habitat, reconstructing degraded channel, removing levees to restore floodplain habitat, modifying and screening water diversions, reducing polluted run-off, managing ocean harvest, and other factors. In general, non-flow restoration actions will reduce the amount of water necessary to achieve restoration objectives.

The holistic approach applied in this study consists of the following 6-step process to identify an environmental flow regime:

1. Identify specific environmental objectives (i.e,. target species, aquatic and riparian communities, and desired ecological conditions that are flow dependent).
2. Approximate the timing, magnitude, frequency, and duration (TMDF) of flows necessary to support target species, communities and desired ecological processes.
3. Compare existing vs. historical hydrology to understand natural hydrologic patterns and how they have been altered.

4. Identify obvious gaps between objective flow requirements and existing flows.
5. Develop an environmental flow hydrograph to achieve ecological objectives based upon a clear understanding of historical and existing hydrologic patterns, and identify key hypotheses and uncertainties regarding the relationship between flow patterns and environmental objectives.
6. Design an adaptive management program to further test and refine environmental flows.

1) Identify specific environmental objectives (i.e,. target species, aquatic and riparian communities, and desired ecological conditions that are flow dependent).

Well-articulated target ecological conditions and desired species and communities are necessary for establishing environmental flows. Despite the correctly vogue concept of restoring ecosystem processes and avoiding species specific approaches, there is no getting around the fact that key species need specific hydrologic conditions at specific times. This analysis will include both aquatic and riparian communities and the flow parameters necessary to sustain these communities such as floodplain inundation, appropriate water temperature, or creation of structural habitat through geomorphic processes. These specific environmental objectives may vary by region, sub-basin, and reach of the river.

2) Approximate the timing, magnitude, frequency, and duration (TMDF) of flows necessary to support target species, communities and desired ecological processes.

An environmental flow regime encompasses the adequate timing, magnitude, duration, and frequency of flows necessary to support target species and facilitate specific ecological processes encompassed in the stated environmental objectives. Where we understand the life cycle timing of various target species, it is relatively easy to identify the approximate timing and duration of flows necessary to support different life stages of target species. Estimating the required flow magnitude is far more difficult but can be informed by field data, results of numerical models, and general relationships described in the literature. Most short lived target species require adequate flows each year to reproduce, while longer lived species can sustain their populations with a lower frequency of flow conditions conducive to reproduction. For example, riparian forest species may only require recruitment flows every five to ten years to establish new seedlings.

Estimating the magnitude of flows necessary to support or optimize conditions for target species and processes is by far the most difficult element of the environmental hydrograph to approximate. Environmental engineers and biologists have developed relatively elaborate methods for determining ideal flow regimes such as physical habitat simulation (PHABSIM) and Instream Incremental Flow Methodology (IFIM) to identify optimum flow magnitudes based on known habitat preferences of target species, measured habitat conditions (velocity and depth) at various flows, and numerical models that predict habitat conditions at a range of flows. Numerical models that describe the width, depth, and velocity of the rivers at various discharges are useful for predicting river stage and temperature at various locations, factors that are important considerations for habitat or facilitating geomorphic and hydrologic processes. As discussed above, these models tend to focus on the needs of specific species and can sometimes produce results that are inconsistent with both holistic ecological process restoration and common sense. Furthermore, these models are often not calibrated, particularly at higher flows relevant to riparian recruitment, geomorphic processes, and spring outmigration temperatures. Nevertheless, we utilized the results of these models as a guide combined with other information to develop our environmental flow management hypothesis.

Where possible, we relied on actual data and measurements to estimate the flows necessary to achieve suitable conditions to support biological, riparian, and geomorphic objectives for temperature, floodplain inundation, and bed mobilization. In particular, we relied on USGS temperature gauges to characterize the relationship between temperature and flow. Similarly, we relied on previous studies of the rivers to characterize flows necessary to mobilize bed material and inundate the floodplain.

3) Compare existing vs. historical hydrology to understand natural hydrologic patterns and how they have been altered.

Analyses of historical hydrologic data is useful for describing natural patterns and identifying potential links between hydrology and the requirements necessary to maintain species and precipitate key processes. An analysis of historical patterns can provide clues about the timing, magnitude, duration, and frequency of flows under which target species have evolved. Identification of major changes between historical and hydrologic patterns combined with the life history requirements of various species can help generate hypotheses about how flow regulation may be limiting target species. We will use the an analysis similar to the Index of Hydrologic Alteration approach (Richter et al. 1996) and the Hydrograph Component Analysis (HCA) (Trush et al. 2000) to evaluate changes in flow patterns. The analysis similar to the IHA provides a quick statistical overview of how several important hydrologic attributes have changed. The analysis similar to the Hydrograph Component Analysis (HCA) method developed by McBain and Trush provides a detailed graphical analysis of historical and existing hydrologic conditions. While valid and useful, the statistical analysis in the IHA method is not substitute for visually comparing and evaluating key components of the pre- and post-dam hydrographs. Similarly, visual comparisons of pre- and post-alteration hydrographs don’t always reveal important changes identified by the IHA method.

4) Identify obvious gaps between objective flow requirements and existing flows.

An analysis of historical flow patterns combined with an approximation of the TMDF of flows necessary to achieve objectives compared with the regulated flow regime can help illustrate obvious gaps between regulated flows and flows that may be necessary to achieve environmental objectives. We will plot TMDF flow requirements developed in Step 2 as an annual hydrograph and compare it with average regulated and historical conditions.

5) Develop an environmental flow hydrograph to achieve ecological objectives based upon a clear understanding of historical and existing hydrologic patterns, and identify key hypotheses and uncertainties regarding the relationship between flow patterns and environmental objectives.

This project identifies hypothetical restoration flow regimes but recognizes that the most reliable method for developing a restoration flow regime is through a long-term adaptive management program including a series of trials that test the effectiveness of various flow prescriptions. The purpose of developing the hypothetical flow regime is to develop a comprehensive hypothesis regarding the range of flows that may be necessary to restore ecological processes to the Sacramento River. However, the assumptions and uncertainties associated with the hypothetical flow regime are as important as the flow regime itself.

6) Design an adaptive management program to further test and refine environmental flows.

To cost effectively achieve restoration, managers will ultimately need to test these assumptions and limit the uncertainties through an adaptive management program consisting of a combination of numerical modeling, pilot flow studies, model calibration, and long-term restoration implementation.

4. IDENTIFY ENVIRONMENTAL OBJECTIVES AND UNDERLYING CONCEPTUAL MODELS

4.1. Environmental Objectives

The geomorphic, riparian, and salmonid objectives considered in this report are summarized below. A more detailed description of the objectives, background information, and the underlying conceptual models is included in Appendix B.

Geomorphic Objectives

- Sediment Transport: bed mobilization and bed scour
- Channel Migration
- Floodplain Processes: inundation and fine sediment deposition

Riparian Objectives

- Fremont cottonwood seedbed preparation
- Fremont cottonwood seed germination
- Fremont cottonwood seedling growth
- Periodic large-scale disturbance of the riparian zone
- Riparian stand structure and diversity

Chinook Objectives

- Chinnook salmon: suitable flow conditions and temperatures for all life stages.
- Provide inundated floodplain habitat for rearing juveniles during the later winter and early spring.
- Maintain and recruit spawning habitat, but avoid scouring gravels while eggs or alevon are present

We purposely did not identify population targets for salmonids. The extent and magnitude of restoration actions depends on the size of the population fish managers are attempting to restore. More fish require presumably require more habitat particularly for spawning and rearing. Creating more habitat may require both physical changes in channel conditions and increased flows. .

Appendix B describes the underlying assumptions and rationale (conceptual model) for environmental flow requirements. It describes the science of how and why river flows are necessary to achieve the objectives listed above, and identifies some of the challenges associated with developing environmental flow prescriptions.

5. ENVIRONMENTAL FLOW THRESHOLDS AND REQUIREMENTS

5.1 Geomorphic Thresholds

Flow requirements broadly fall into two categories: threshold and targets. Thresholds are flow prescriptions that only achieve their objective if the threshold is reached or exceeded. For example, bed mobility flows must be high enough to mobilize the bed. If they are below the threshold, the bed does not mobilize and no progress toward the objective occurs. In actuality, however, bed mobilization may occur at different flows in different reaches making it difficult if not impossible to name a single threshold number. Targets are flow requirements that are desirable but not essential to achieve. Benefits still accrue when there is progress toward the target even though the target is not actually reached. For example, a flow release to meet a target of 5,000 cfs to achieve an optimal water temperature for twenty four hours a day will still provide temperature benefits even if the release only achieves 4,000 cfs and optimal water temperatures eighteen hours per day. At some point, however, there is a minimum threshold or minimum flow below which temperatures are lethal or flows are insufficient to support fish.

This paper focuses on thresholds for key ecological and geomorphic objectives that generally require high flow thresholds, but also identifies flow targets to sustain salmon. We have not attempted to define minimum flow thresholds for salmon, but rather have identified more generous targets based on historical base flow conditions. We identify the basis for these thresholds and targets in this section and compile them into a environmental hydrograph in the final chapter of this report.

For each threshold, we have estimated the magnitude, duration, frequency, and timing of flows necessary to achieve a desired outcome and have organized table X and the following text accordingly.

5.1.1. Bed Mobilization:

Magnitude: There is limited information regarding the magnitude of flows required to initiate bed mobilization on the Sacramento River, but less information regarding flows necessary to precipitate full-scale bed mobilization. Under natural conditions the gravel bedded reaches of the Sacramento River were theoretically mobilized by peak flows exceeding the 1.5 to 2 year recurrence interval of the annual instantaneous peak (Leopold et al 1964), which is approximately 80,000 cfs to 120,000 cfs. For comparison, the post dam Q1.5 and 2.0 recurrence interval flow is approximately 65,000 and 80,000 cfs respectively. The Department of Water Resources estimated that the threshold for spawning gravel mobilization immediately below Keswick Dam was 50,000 cfs (CDWR 1981), but this is considered to be a minimum because it was based on observations of gravel that was artificially deposited below the dam *(Stillwater,*

> *2006).*[1] DWR added 13,300 yd^3 of gravel below Keswick Dam in 1978 and 1979, and estimated that 85% of it was eroded by high flows of 36,000 and 50,000 cfs during the winter of 1980 (CDWR 1981). Latter, Koll Buer of the USBR measured mobility and transport downstream of Keswick with "flower box" samplers – boxes placed into the channel bed before a high flow event. Buer's measurements indicate that gravel transport begins at 24,000 cfs but did not provide information about when larger gravels and the entire bed begin to mobilize. The coarser riffles downstream of Keswick (small boulders and large cobbles) are probably armored due to years of erosion from sediment free water released from Shasta Dam. These armored riffles appear not to change and thus probably remain immobile even at flows exceeding 100,000 cfs (K. Buer, personal communication in Kondolf, 2000).

There are not empirical studies or observations regarding bed mobility on the Feather River. Historical flow data is the only information available to estimate the discharge necessary to mobilize the bed on the Feather River. The 1.5 to 2 year recurrence interval of the annual instantaneous peak prior to the construction of Oroville Dam was 33,000 to 50,000 cfs respectively.

> *Frequency:* Relatively frequent bed mobilization is necessary to prevent vegetation establishment and encroachment on gravel bars. Willows can become well established and resistant to scour in three to four years (cite). Therefore, bed mobilization flows are necessary at a greater frequency then every three to four years to prevent vegetation establishment.
>
> *Duration:* The duration of peak flows may vary depending on the objective. A short duration may be enough to clean gravels on a spawning riffle while a longer duration flow may be necessary to maintain overall transport of gravels. Because coarse sediment inputs are limited by the upstream dam and riffles already show signs of armoring, long duration peak flows may actually degrade riffles. For this reason and to both reduce flood hazards and economize water, a short duration bed mobilization flow of approximately 12 hours at the recommended peak flow and then ramping down thereafter consistent with historical patterns may be optimal.
>
> *Timing:* Ideally, bed mobility flows should occur after fall run fry have emerged from the gravel and before swallows begin nesting on stream banks in late march. We therefore recommend a 30 day target window between February 20 and March 20.

---

[1] These gravels may have mobilized at lower flows because of their unnatural position relative to the high flows or because they were not integrated into the gravel/cobble matrix of the natural bed

5.1.2 Bed Scour

Less is known about the bed scour process, flows exceeding the natural 5–10 year recurrence interval are probably necessary to precipitate bed scour (Trush et al. 2000). The pre-dam Q5 and Q10 recurrence interval on the Sacramento are 150,000 and 200,000 cfs respectively. During the post dam era, flows of 150,000 cfs or more occurred roughly once every 10 years. On the Feather River, the pre-dam Q5 and Q10 were 104,000 and 144,000 respectively. Flows of this magnitude have only occurred twice in the forty years since Oroville Dam was constructed. Because of the lack of information regarding bed scour and the probable flooding impacts of these flows, it is exceptionally difficult to develop and achieve a bed scour flow recommendation.

5.1.3 Bank Erosion and Channel Migration

Magnitude

Stillwater reports that there is general disagreement on the exact magnitude of flow to initiate substantial bank erosion, but claims there is growing evidence that flows between 20,000 and 25,000 cfs will erode some banks while flows above 50,000 to 60,000 cfs are likely to cause widespread bank erosion (Stillwater, 2007). Meander migration modeling analysis for the Sacramento River assumed that 15,000 cfs was the lower threshold for meander migration (Larsen, 2007). Total bank erosion and channel migration, however, is dependent on both the duration and magnitude of flows, which together produce a cumulative streampower in any given year. Analysis of cross section surveys (Buer, 1994a) over more than ten years shows that rates of bank erosion are closely correlated with cumulative annual stream power (Larsen, et al., unpublished in Stillwater, 2006). Bank erosion.

On the Feather River, there is very little information regarding flows necessary to initiate bank erosion and channel migration. The pre-dam Q1.5 on the Feather River (35,000 cfs) is approximately forty four percent of the pre-dam Q 1.5 on the Sacramento River (80,000) cfs. If channel migration flows on the Feather were similarly proportioned channel migration flows on the Sacramento (50,000 – 60,000 cfs), then one could expect significant and wide spread bank erosion on the Feather River at flows between 20,000 and 25,000 cfs. Instantaneous peak flows of this magnitude reoccur every 2.5 years on average, and large areas of channel revetment along the Feather River indicate that the unprotected bank is subject to erosion under the current flow regime.

Duration

The stream power relationship between magnitude and duration make it difficult to identify a specific threshold. Without modeling analysis, it is difficult to assess whether two weeks at 30,000 cfs could result in as much bank erosion as two days at 60,000 cfs.

Frequency

Bank erosion and channel migration are important for maintaining general riparian habitat, nesting habitat for bank swallows, and turbidity for juvenile fish cover. We are uncertain how often migration and erosion should occur but suspect that some bank erosion every year is a reasonable target. Slight but annual bank erosion may be beneficial for maintaining optimal bank swallow habitat. More significant and annual erosion events may be necessary for producing turbid water conditions. Moderate but less frequent bank erosion, every (2-4) years, may be adequate for generating new riparian habitat.

Timing
Erosive flows during the bank swallow nesting period, which generally begins in late March, can actually disrupt bank swallows. Therefore, it may be most beneficial to bank swallows to achieve bank erosion objectives prior to late march.

5.1.4 Floodplain Inundation and Rearing Habitat Flows

The occurrence of inundated floodplain habitat has been substantially altered by both levees and dams. Dams have reduced the frequency of high flows sufficient to inundate floodplains, while levees have prevented high flows, even very high flows, from inundating floodplains particularly in the lower reaches of the river below Colusa. It is not reasonable to reestablish inundated floodplains by overtopping levees, because it would require extremely, even unnaturally, high flows and would cause widespread flood damage.

Adequate duration of flooding in the designated flood bypasses generally occurs in the wet years and sometimes in normal wet years creating excellent conditions for salmon and splittail. But overtopping the weirs and flooding the bypasses in normal dry and dry years would require prohibitive amounts of water to achieve in normal dry and dry years. For efficiency sake, it is probably only realistic to achieve prolonged (30-60 days) floodplain inundation in normal dry and dry years by notching (or removing) the upstream weirs to allow a small amount of water to pass (3,000-5,000 cfs) and installing inflatable weirs in the low flow channels of the bypasses to back-up water.

Strategically breaching levees and flood control weirs to inundate flood bypasses and other undeveloped land is a much more prudent and achievable approach for creating inundated habitat. Although there may be many places to create inundated flood plain habitat with strategic levee modifications, we have focused on identifying flows that would create inundated habitat in the Yolo and Sutter Bypasses if modifications are made to the weirs that control flow onto the bypass. The area of inundation under a given flow is determined by topography and drainage. We assume changes in the topography and drainage of the bypasses (i.e. berms or inflatable wiers) to maximize the area of inundation at lower flows and minimize the potential for stranding. While it might be possible to create large areas of habitat at low flows, more flows may be necessary to optimize temperatures on the flood plain and conveyance of nutrients from the floodplain to the Delta.

Magnitude
We evaluated two questions associated with magnitude: the magnitude of flow necessary in the Sacramento or Feather Rivers necessary to inundate the bypasses and the magnitude of flow in the bypasses necessary to create large areas of suitable floodplain

habitat. It may be possible to inundate large areas of the bypass with relatively little flow by installing flow barriers in the bypass to back-up water onto the floodplain. While this may be suitable for creating large areas of inundation, it might not create the right residence time and temperature for optimal habitat. Habitat characteristics such as velocity, depth, temperature, residence time, primary productivity are negatively correlated with flow, while Diptera, an important food resource, was positively correlated with flow (Sommer et al, 2004).

According to DWR modeling analysis, large areas of the bypass become inundated with as little as 5,000 cfs flowing through the bypass (figure 5.1) (Harrell, B., 2008). Flows in excess of 25,000 cfs in the Sacramento River, however, may be necessary before it is possible to get 5,000 cfs down the bypass.

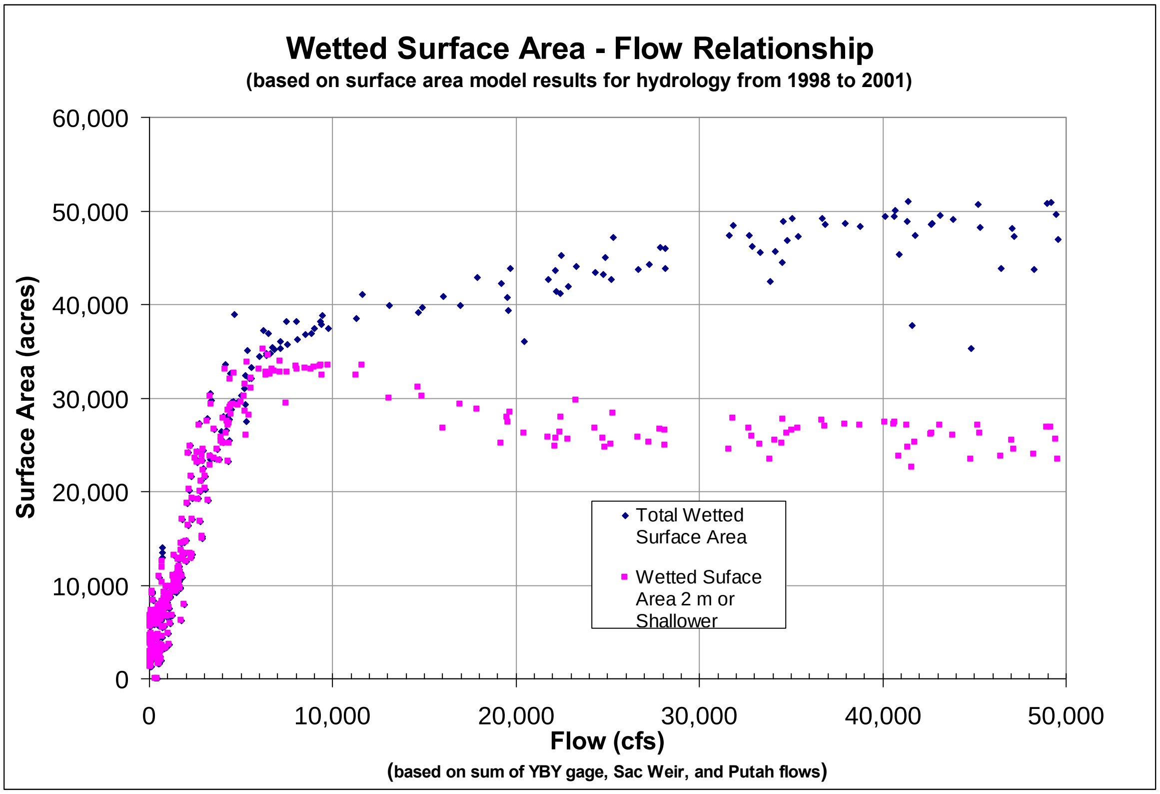

Figure 5.1: Wetter surface area-flow relationship for flows in the Yolo bypass (cite)

To estimate the amount of flow necessary to inundate the Sutter and Yolo Bypasses, we referred to USGS topographic maps to determine ground elevations at Tisdale and Freemont weirs which currently control flows onto the bypass, and then used stage discharge relationships for nearby gauges to estimate the amount of flow necessary to achieve a stage equal to the ground elevation at the weir – an overbank flow assuming the weir did not exist or was operable (table 5.1). The overbank flow, however, is not enough to push substantial amount of water down the bypasses. We therefore assumed that a minimum of 5,000 to 10,000 cfs above the overbank flow was necessary to create substantial inundated floodplain in the bypass.

Table 5.2 identifies flow recommendations for various year types at four key sites: Tisdale Weir, Freemont Weir, and Verona Gauge on the Sacramento River and Nicolaus Gauge on the Feather River. Tisdale Weir spills into the Sutter Bypass and then flows back into the Sacramento River near Freemont Weir. The sum of Freemont and Nicolaus should equal Verona. Note, however, that table 5.1 flows at Verona are lower then the sum of Freemont and Nicolaus. This is because large amounts of the Sutter Bypass (ground elevation of 25 feet) will flood with backwater from the Sacramento at flows above 27,000 cfs at Freemont Weir. In other words, if Freemont or Verona is greater then 30,000 cfs, then large amounts of the Sutter Bypass are flooded irregardless of flows in the Feather River or at Tisdale Weir.

Table 5.1: Overbank flows in the Yolo or Sutter Bypass assuming levees or weirs along the Sacramento and Feather Rivers are breached or removed

Gauge or Weir	Ground Elevation	Overbank Flow	Notes
Nicolaus Gauge (Feather)	30	10,500	
Freemont Weir	25	27,000	Approximate based on Verona Gauge
Freemont with Excavation	13	15,000	Invert of the Toe Drain
Tisdale Weir	40	25,000	Approximate
Sacramento Wier (I Street Bridge)	15	49,000	
Sac Weir with Excavation	10	31,000	Sac Weir with excavation
Right Bank at Verona	25	42,000	Remove right bank levee

Table 5.2: Recommended flows to create inundated floodplain habitat in the Yolo and Sutter Bypasses for various year types.

	Year Type				
	C	D	BN	AN	W
Nicolaus (Feather)			12,000	15,000	20,000
Freemont Wier		25,000	30,000	37,500	45,000
Tisdale Weir		25,000	30,000	35,000	40,000
Verona		25,000	35,000	45,000	55,000

Duration and Timing

Provide floodplain inundation flows for 30 – 60 days between February 15 and April 30 into Sutter and Yolo Bypasses to provide rearing habitat for salmon and splittail and spawning habitat for splittail. Where possible, time releases to coincide with and extend duration of high releases on the Yuba and Sacramento.

Frequency

Ideally, it would be possible to inundate the bypass in every year to enhance foodweb productivity and improve rearing habitat for every year class of salmon. It may be possible to do this while economizing on water by inundating relatively small areas in dry years and very large areas in wet years with no inundation in critical dry years.

5.2 Riparian Flow Requirements

A sequence of hydrologic, geomorphic, and biologic phenomena is necessary to recruit cottonwood seedlings to the riparian forest. Under natural flow regimes, moderate 5- to 10-year flood events precipitate channel migration and the creation of point bars suitable for cottonwood seedling establishment (McBain and Trush 2000, Trush et al. 2000). Analysis of hydrologic data, dendrochronologic data, historic channel mapping, and aerial photography riparian recruitment appears to occur approximately once per decade in the post-regulation period (Roberts, 2003). But recruitment may now be limited to larger, less frequent events due to greater hydrologic modification in recent years. Recruitment did result from the recent large flood events of 1983-1986, and 1995-1997, (Roberts, 2003) but willows dominate while cottonwood recruitment is spatially limited.

In order to maintain or re-establish woody riparian vegetation using a process-based restoration approach, managed flows need to mimic natural hydrographs in the following key ways (Stillwater, 2007):

- High flow peaks, which should mimic to some degree the characteristics of peak flows associated with winter peak rain events in the unimpaired hydrograph are necessary to control vegetation encroachment by herbaceous and weedy species and prepare seedbeds prior to seedling recruitment flows in wet years (scouring or encroachment prevention flows) and seedbed preparation flows.
- High spring snow-melt peak flows with relatively gradual recession rates during wet years to moisten the seedbeds and induce seed germination on geomorphic surfaces suitable for long-term establishment (recruitment flows for seedling initiation).
- Summer and fall base flows are needed to ensure that new seedling cohorts and older cohorts of saplings and mature trees have adequate soil moisture for summer growth and survival during the annual dry season (seedling establishment and maintenance flows).

In regulated rivers it may also be necessary to limit unnaturally high summer flows. Summer base flows higher than spring flows may give a competitive advantage to non-native species that reproduce by seed during the summer months. Establishment of non-natives could impede later recruitment of natives such as cottonwood (cite).

5.2.4 Site Preparation

Large flows scour away herbaceous plants and/or deposit fine sediments on floodplains, preparing new seed beds for pioneer riparian species (Mahoney and Rood 1998). The magnitude of flows necessary to scour or deposit seed beds is presumably much larger then the amount of water necessary to inundate these sites. For this analysis, we assume that flows sufficient to mobilize the bed (80-100k cfs on the Sacramento and 35,000-50,000 on the Feather) are sufficient and that seedling establishment flows will only occur in wetter years after bed mobilization generally occurs.

5.2.5 Seedling establishment:

In order to assure long-term survival, seedlings must become established in a zone that is high enough on the bars and banks to avoid scour from peak flows, but low enough to avoid desiccation during low flows in summer and fall. Rood and Mahoney (2000) developed a recruitment box model that placed this zone at 2.5 to 4 feet above mean low (MLW) water for the St. Mary River in Alberta Canada. Roberts (2003) calibrated the recruitment box model on the Sacramento placing the recruitment zone at 3-6 feet above MLW and developed a stage discharge relationship at three representative sites to determine that recruitment zone is inundated at flows between 23,000 and 30,000 cfs. Roberts recruitment zone, however, is based on the artificially high summer flows in the Sacramento River. Under natural summer flow conditions the recruitment zone, and flows necessary to inundate it, may be somewhat lower.

Little to no information exists regarding seedling establishment elevation for the Feather River. Furthermore, it is difficult to identify a suitable recruitment zone at some distance from the mean low water, because mean low water levels in the summer are two to three times higher then pre-dam, natural levels. The stage discharge relationship for the Feather River at Nicolaus combined with topographic maps indicate that the Feather River overflows its banks at Nicolaus at approximately 12,500 cfs. The banks further upstream are higher and can convey more flow before overtopping. Since cottonwoods generally become established on the banks and gravel bars of alluvial rivers, it is reasonable to assume that the recruitment zone is below the stage of the bankfull discharge. The seedling establishment flow on the Sacramento (23,000 – 30,000 cfs) is twenty seven to thirty seven percent of the bankfull discharge (Q1.5 to Q2) on the Sacramento. Assuming a similar proportional relationship on the Feather River, flows in the range of 9,500 to 18,000 would be suitable for seedling establishment. Analysis of historical flow data (section seven of this report) indicate that flows in this range were common during April and May when germination is most likely to occur.

Post-germination decline of river stage, which is presumed to control adjacent groundwater levels, should not exceed approximately one inch per day (Mahoney and Rood 1998, Busch et al. 1992). This is the rate at which seedling root growth (0.16–0.47 inches/day; Reichenbacher 1984, Horton et al. 1960) can maintain contact with the capillary fringe of a receding water table in a sandy substrate. Cottonwood root growth and seedling establishment rates are higher in these soils than in coarser textured soils, which are more porous (Kocsis et al. 1991). In reaches with gravelly substrates, slower draw-down rates are necessary to support seedling establishment.

Information necessary to design a gentle recession limb is limited. Stage discharge data from gauging stations may not be representative of Cotonwood recruitment sites, because they are generally sited at geomorphically stable and simple sites while cottonwood recruitment often occurs on complex and dynamic sites. Kondolf and Stillwater (Kondolf, 2007) measured stage discharge relationships at several representative gravel bars along the Sacramento River and determined that stage drops 0.1 meter (.34 feet) per 1000 cfs at flows ranging from 7,000 to 15,000 cfs, but cautioned against extrapolating this relationship to flows outside the observed range. Within this range, however, a discharge decline of 250 cfs per day would yield a stage decline of one inch per day.

To estimate a suitable recession rate flow schedule, we assumed that cottonwood seedlings would become established six feet above the mean low water and then calculated that it would take 72 days to drop river stage six feet at a rate of one inch per day. On this basis, we recommend a 72 day recession period from the establishment flow to the summer base flow. The actual recession flow required may vary substantially depending where seedlings become established relative to the mean summer flows.

5.2.6 Recruitment stage:

After the second year, growth rates level. Despite extensive root development during this stage, cottonwoods are still somewhat susceptible to drought stress. Yearly flows must be sufficient to maintain groundwater levels within 10 to 20 feet of ground surface elevations (JSA and MEI 2002). Groundwater extraction and reduced flows can reduce groundwater levels and induce drought stress in cottonwood saplings (Jones & Stokes 1998. Acute draw down and corresponding drought stress is primarily a problem in arid river ecosystems and will probably not be a problem on the Sacramento River where summer flows are artificially high.

5.3 Chinook Flow Requirements

Adult Upstream Migration

If salmon migration is motivated by major storms, early freshets or pulses after the first rain, and most of the large flows from storm events are trapped behind dams, reservoir operators can simulate pulse events by releasing water from the reservoir. However, "There is [a] concern that pulse flow releases in mid October to attract salmon may cause the fish to enter the rivers earlier than normal, which may expose them to high water temperatures when the pulse flows cease." (CMARP). Therefore, if flows are increased during this mid-fall period, it is important to continue to maintain adequate flows for migrating adults and subsequent spawning.

Spawning

In order to provide quality areas of spawning habitat, adequate flows need to be released from dams into the tributaries during the spawning period. Due to channel alteration from gravel mining, artificial gravel habitat construction and enhancement may be necessary. Over the long run, periodic high flows are necessary to mobilize gravels and flush-out fine sediments. However, large peak flow events that occur in channels that have been excessively incised and leveed cause excessive gravel mobilization, which can disrupt spawning and cause egg mortality (CMARP). Therefore, these flows should be released after mid-February so they reduce mortality to incubating salmon eggs (McBain and Trush, 2000). Increased flows may also be needed to decrease water temperatures in late October and early November to prompt earlier spawning, expand the area with suitable temperatures for spawning and incubation, to increase egg viability, and to reduce the probability of superimposition of redds. If flows are increased during this mid-fall period, it is important to continue to maintain adequate flows for spawning and to prevent dewatering of redds.

Egg Development and Emergence

Dewatering of redds is a known mortality factor effecting development of alevins. (Becker et al., 1982, 1983 in Healey, 1991). Dewatering of redds can be minimized below dams by careful flow regulation.

Adequate base flows during the incubation and emergence period combined with periodic flushing flows outside the period should reduce the mortality factor of eggs and alevins. Instream flows, at or above spawning flows, should be maintained throughout the incubation and emergence period to avoid dewatering redds. Siltation and capping from fine sediments could be minimized with small reservoir releases timed to coincide with rainfall induced local run-off. These releases would help convey fine sediments out of the spawning reach.

Rearing and Outmigration

We hypothesize that increasing rearing habitat will improve growth rates and successful smolt outmgration and may also reduce mortality from diversions and predation, because larger fish are less vulnerable to these sources of mortality. Based on robust results from research in the Yolo Bypass, it appears providing seasonally inundated floodplain habitat is perhaps the best way to ensure adequate growth before outmigration to the Delta and Ocean. If nothing else, providing seasonally inundated floodplain habitat will provide better habitat for the young that migrate or are washed out of the gravel bedded reaches early. We describe the flow regimes necessary to create inundated floodplain in section 6.3 above.

In addition to inundated floodplain habitat, seasonally inundated off-channel habitats may also provide valuable rearing habitats for juvenile salmon. Kondolf and Stillwater (Kondolf, 2007) determined that secondary scour channels on gravel bars along the upper Sacramento River become inundated and connected to the mainstem at flows above 12,500 cfs. They also determined that these same secondary channels become disconnected and desiccated at flows below 8,500 cfs. To assist juvenile rearing, it may therefore be advantageous to maintain flows between 8,500 and 12,500 cfs or greater during winter and spring when fish are rearing. To prevent establishment of non-native, resident predator fish populations that thrive in shallow or warm water habitats, however, it may be beneficial to maintain flows below 8,500 cfs during the summer months. Preventing inundation and connectivity of the off-channel habitats during summer months could also reduce temperatures by significantly reducing wetted perimeter and surface area. Lower temperatures should favor native fish over exotic fish populations.

6. EVALUATION OF EXISTING AND HISTORIC FLOW REGIMES

To identify specific hydrograph component alterations between historical and current conditions which may limit the attainment of environmental objectives an analysis of existing and historical hydrologic patterns was conducted using daily flow data from USGS gages at multiple locations on the Sacramento and Feather Rivers. We used two approaches to compare existing and historical hydrologic patterns, a statistical approach similar to IHA whereby specific hydrograph components were graphed using box plots for different year types and a visual approach similar to HCA whereby median hydrographs for historical and current conditions were compared.

We evaluated pre- and post-project hydrology using statistical methods similar to IHA and HCA methods to generate hypotheses regarding the causal links between historical hydrograph components and ecological conditions relevant to our restoration objectives. The Index of Hydrologic Alteration (IHA) method (Richter et al. 1996) provides a statistical overview of how several important hydrologic attributes change between historical and regulated conditions. The Hydrograph Component Analysis (HCA) method developed by McBain and Trush provides a detailed graphical analysis of historical and existing hydrologic conditions. Instead of using a formal IHA and HCA analysis the fundamental principals of these methods were used to conduct an analysis based on first principles.

To conduct this analysis USGS daily discharge data was organized into water year types based on the Sacramento Four Rivers Index. The water year data was divided into pre project or post project data sets. The project id defined by the construction of a dam in the headwaters of the river under consideration. For the Sacramento River the project is Shasta Dam which was constructed in 1945. For the Feather River the project is defined by Oroville Reservoir which was constructed in 1968. Hydrograph components for each water year were compared for pre and post project periods using box plots. This statistical approach was coupled with a visual comparison of the pre and post project median flows hydrographs. The pre project period was further defined by the 25th and 75th percentile hydrographs. The 25th and 75th percentile captured the natural range of variability around the median hydrograph during the pre project period for each year type. When the current hydrograph was outside of this acceptable range of variability then a significant discrepancy between the historic and current flow regimes could be identified.

The hydrograph components that were considered for the statistical analysis were: 1) summer baseflow, 2) winter peaks, 3) winter baseflows and 4) spring peaks(Figure 5). A useful way to describe streamflow hydrology and relate it to geomorphic, riparian, and biological ecosystem components is by quantifying these hydrograph components. Kondolf et. al. 2000 described these four primary components of the annual hydrograph in the following way:

(1) Summer base flows extending from July through Spetember/October

(2) Large magnitude, short duration winter floods during December through April

(3) Sustained high winter base flows intermittent between high flow events

(4) Spring snowmelt flood and recession limb of long duration, but typically moderate magnitude

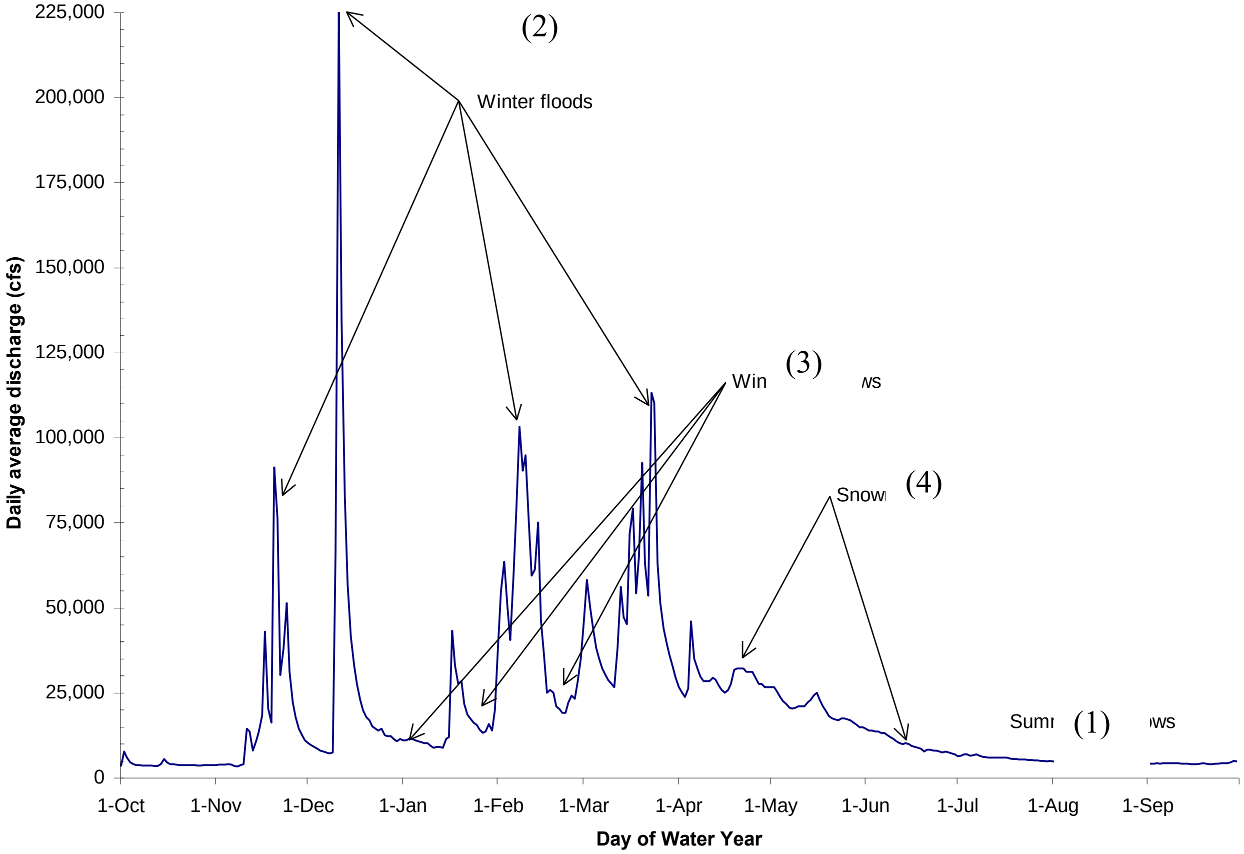

Figure 6.1: Sacramento River hydrograph components illustrated in the 1938 hydrograph for the Sacramento River above Bend Bridge, near Red Bluff gauging station. Modified from Kondolf et al. 2000.

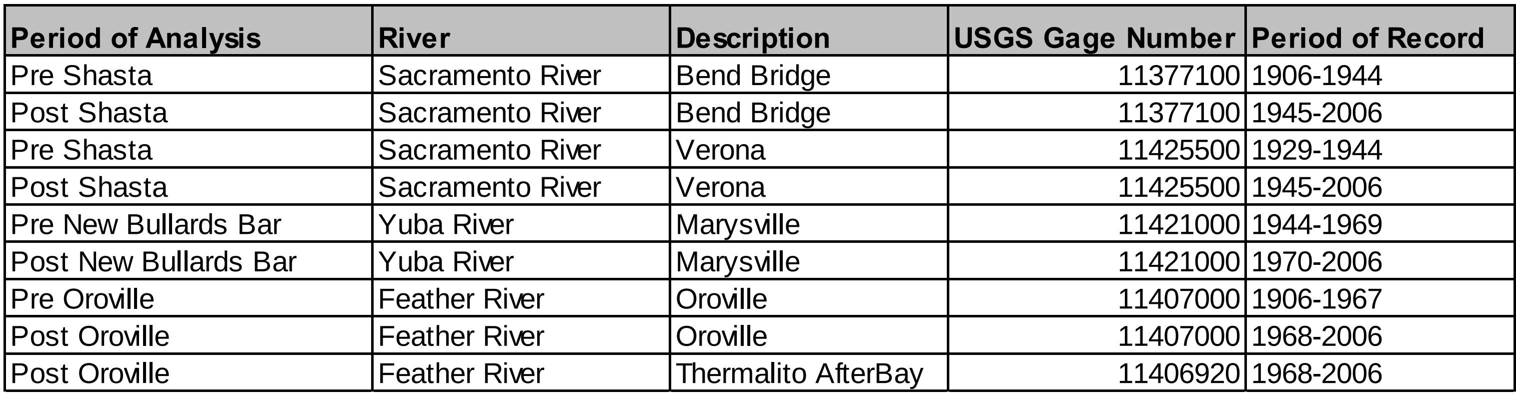
a. Methods

Data Source

We analyzed hydrologic data for periods before and after dams were constructed on the Sacramento and Feather Rivers. Table 4 shows the gauges analyzed their period of record, and the pre and post-dam analysis periods. We divided data into five year types based on the Sacramento Basin Index: wet, above normal, below normal, dry, and critical.



Period of Analysis	River	Description	USGS Gage Number	Period of Record
Pre Shasta	Sacramento River	Bend Bridge	11377100	1906-1944
Post Shasta	Sacramento River	Bend Bridge	11377100	1945-2006
Pre Shasta	Sacramento River	Verona	11425500	1929-1944
Post Shasta	Sacramento River	Verona	11425500	1945-2006
Pre New Bullards Bar	Yuba River	Marysville	11421000	1944-1969
Post New Bullards Bar	Yuba River	Marysville	11421000	1970-2006
Pre Oroville	Feather River	Oroville	11407000	1906-1967
Post Oroville	Feather River	Oroville	11407000	1968-2006
Post Oroville	Feather River	Thermalito AfterBay	11406920	1968-2006

Table 6.1: USGS gauges used for hydrologic analysis, the period of analysis, location, description and the period of record.

Hydrographs

For each year type we compared post-dam median flows to pre-dam median flows. Median flows bounded by the 25th and 75th percentiles represent the natural range of variability during the pre-dam period for each water year type. Hydrographs provide a visual tool to identify portions of the current hydrograph that are outside of the historic range of variability. When the current hydrograph is outside of the natural range of variability we would expect the greatest potential loss of environmental flow benefits.

Box Plots

Box plots were used to statistically compare hydrograph components including summer baseflows, winter floods, winter baseflows, and spring peak flows. The lower edge of the boxes represent the 25th percentile and the upper end represents the 75th percentile, with the whiskers at the maximum and minimum values. The various components of the hydrograph were computed as follows.

- **Summer baseflows** were computed as average August discharge. Summer baseflows begin following the spring snowmelt recession in July and August and last through autumn when the first rainfall events occur.
- **Winter floods** were computed as the maximum daily average discharge over the course of the entire water year.
- **Winter baseflows** were computed as the median flow for February and March.
- **Spring peak flows** were computed as peak flows in April and June.

Flood Frequency Analysis

We conducted the food frequency analysis for a range of reoccurrence intervals for pre and post project periods using the peak instantaneous flow records at USGS. The flood frequency analysis enables further quantification of storm events and their geomorphic potential.

b. Results

The analysis utilized 100 years of daily flow data from the Bend Bridge gage near Red Bluff on the Sacramento River (11377100). This gage was selected for the analysis because it has a long period of record 1906-2006, and best characterizes flow conditions where salmon concentrate. The Bend Bridge gage is at the upstream end of what is considered the most valuable habitat in the Sacramento River. However, flows at Bend Bridge are not fully representative of downstream conditions, particularly in the irrigation season because irrigation diversions operate downstream. Four major diversions are listed below:

- The Glenn-Colusa Irrigation District (GCID) diversion, located just upstream of Hamilton City at RM 206, began diverting summer flows for irrigation around the turn of the century, and has a diversion capacity of about 3,000 cfs.
- The Anderson-Cottonwood Irrigation District (ACID) diversion, located on the north side of the City of Redding downstream of Shasta Dam, began diverting for irrigation during the summer months, around 1917.
- The Red Bluff diversion and Tehama-Colusa Canal at Red Bluff was built in 1964, and diverts during the summer months for irrigation.
- The Trinity River Division of the Central Valley Project was completed in 1963, and typically diverted over 1,000,000 acre-ft/yr of Trinity River flows into the Sacramento River basin just below Shasta Dam between 1963 and 2000. Due to new flow requirements for the Trinity River, substantially less flow is now diverted into the Sacramento River.

The hydrograph at Bend Bridge reflects operations at Shasta Reservoir in timing and magnitude, but it is only by looking at the hydrograph from a downstream gage that we can evaluate the impacts of diversions operations and the degree of hydrograph recovery from tributary inputs. It is for this reason that we used the eighty year record, from 1926-2006) daily discharge data at the USGS gage at Verona (11425500). Major tributary inputs to the Sacramento below Bend Bridge include Mill Creek, Deer Creek and the Feather River. The Feather River flow regime exhibits similar characteristics to the Sacarmento below Red Buff because of the operation of Oroville Dam. The major tributary to the Feather is the Yuba River which also displays similar characteristics due to the operation of Bullards Bar. For this reason a hydrograph comparison for the Feather (11407000, 11406920) and Yuba River (11421000) was also conducted.

5.2.1 Sacramento River at Bend Bridge

Hydrologic Changes
The hydrographs and box plots for pre and post Shasta at Bend Bridge (Figures 6 and 7) illustrate significant differences in all hydrograph components.

- Summer base flows are significantly higher post Shasta for all water year types. The average summer base flow pre-Shasta was 3,000-4,000 cfs which is significantly less than the current average of 10,000-12,000 cfs. These artificially high summer flows are driven by summer water supply demands for agriculture and power.

- Spring peak flow events are significantly reduced in the post Shasta era for below normal, above normal and wet year types and there is a truncated spring and early summer recession limb, particularly in wet years. The reduction in spring peak flows hampers cottonwood recruitment, seed establishment and germination.

- Winter peak flows are significantly reduced in the post Shasta era. The magnitude and duration of winter peak flows are responsible for channel forming flows. Channel forming flows effect cottonwood recruitment and off channel habitat formation critical to Chinook Salmon rearing and survival.

- In addition to significantly altered hydrograph components there is also a general decline in hydrologic variability in the post Shasta era.

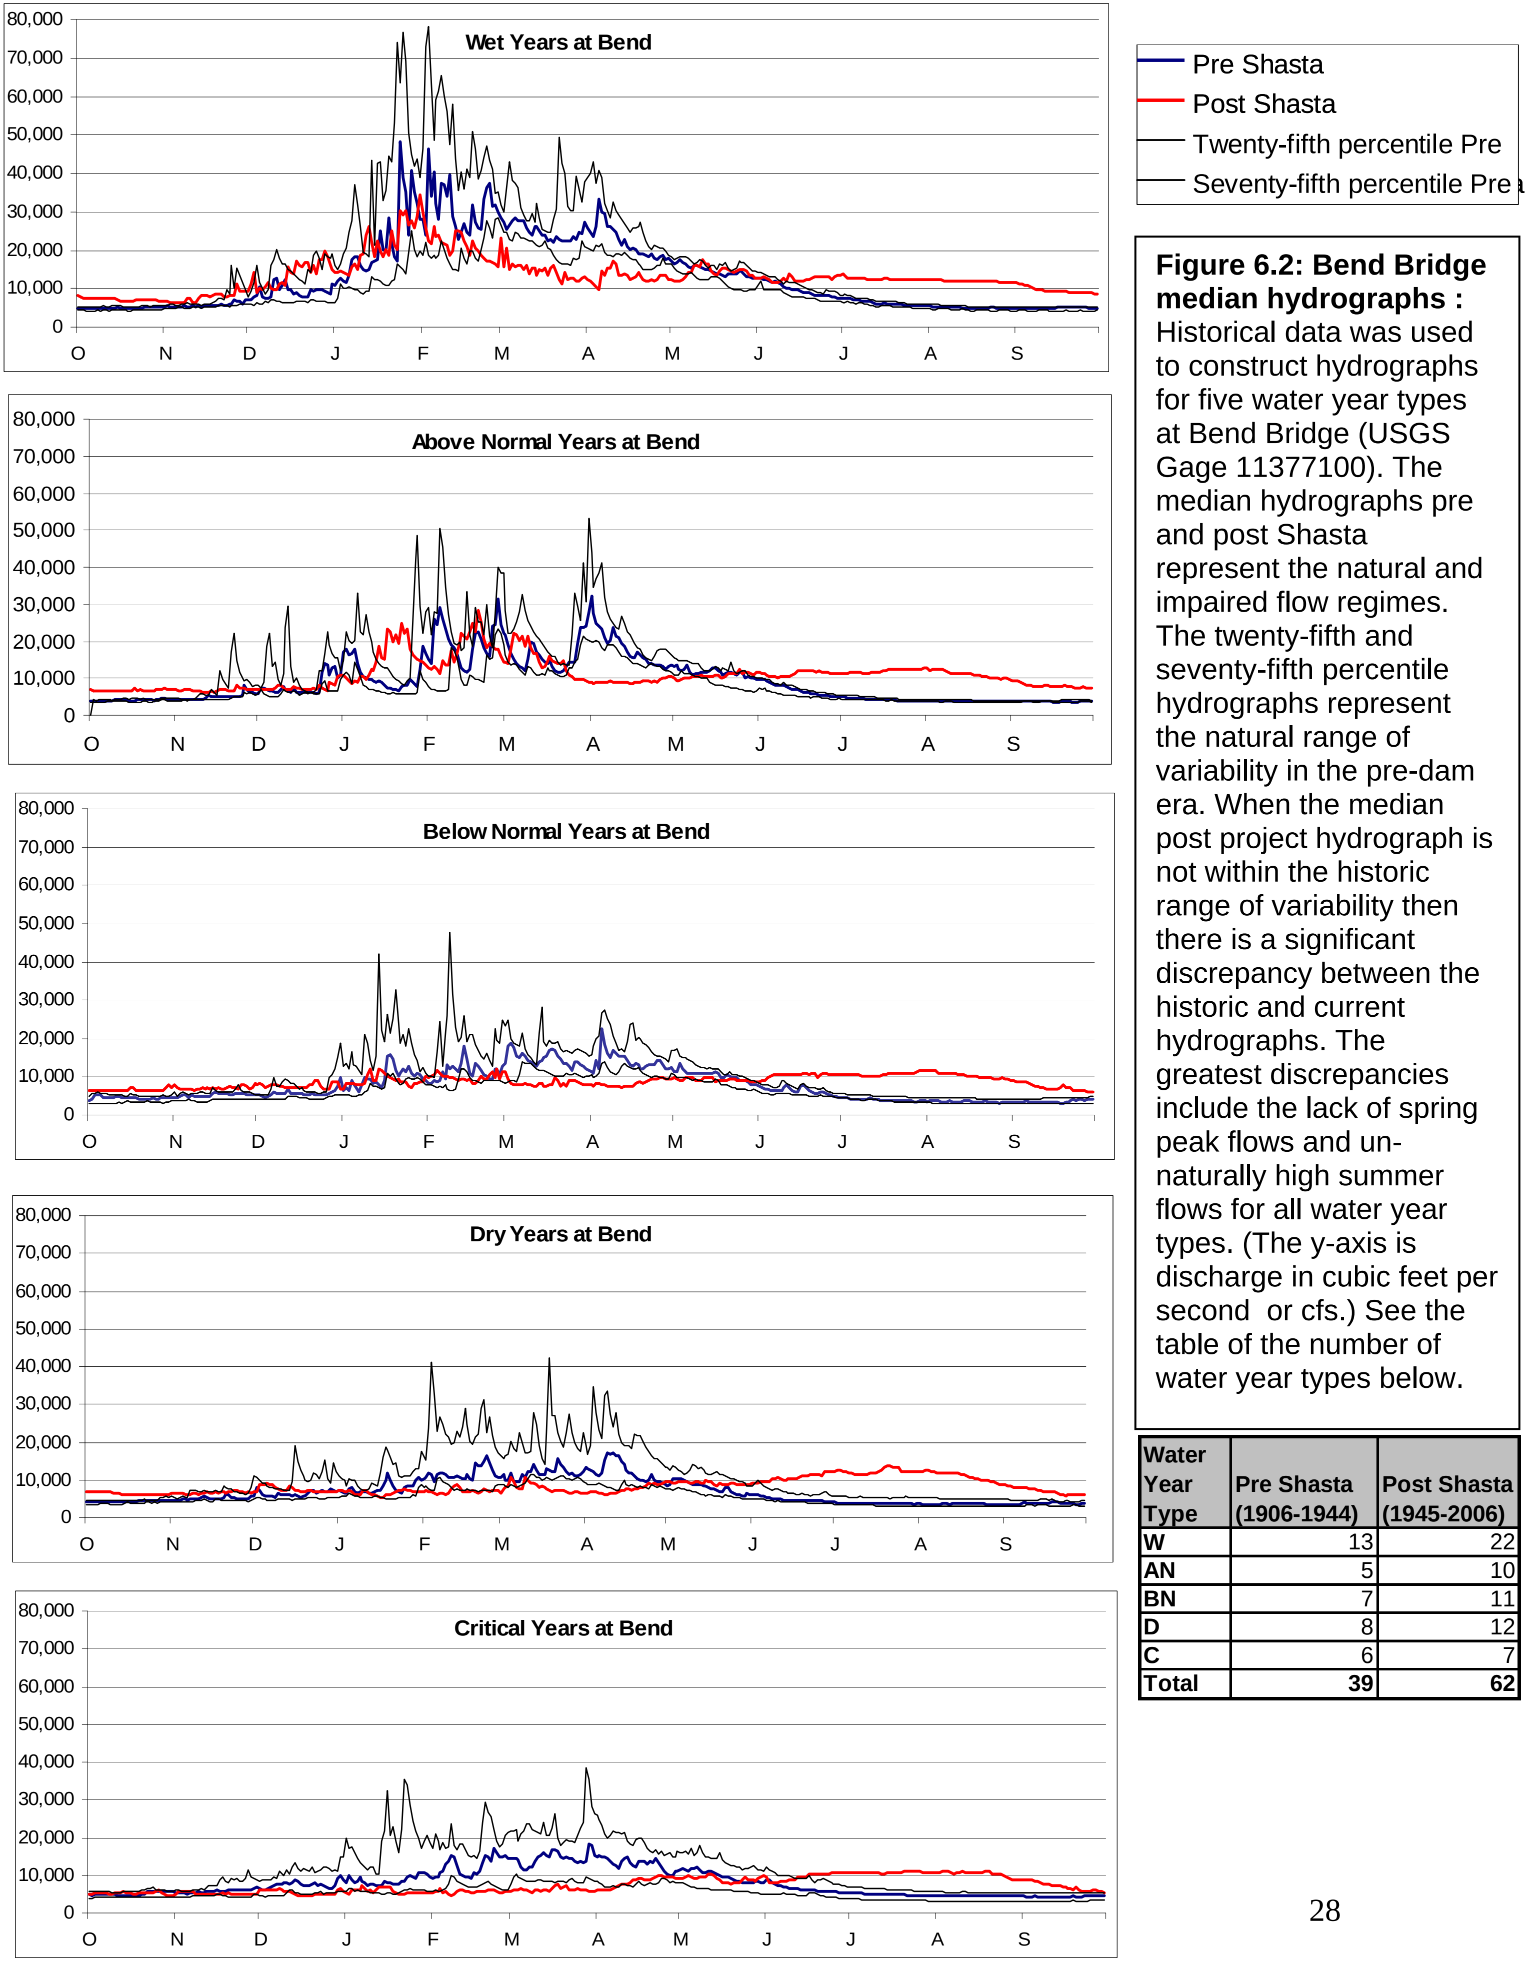


Figure 6.2: Bend Bridge median hydrographs : Historical data was used to construct hydrographs for five water year types at Bend Bridge (USGS Gage 11377100). The median hydrographs pre and post Shasta represent the natural and impaired flow regimes. The twenty-fifth and seventy-fifth percentile hydrographs represent the natural range of variability in the pre-dam era. When the median post project hydrograph is not within the historic range of variability then there is a significant discrepancy between the historic and current hydrographs. The greatest discrepancies include the lack of spring peak flows and un-naturally high summer flows for all water year types. (The y-axis is discharge in cubic feet per second or cfs.) See the table of the number of water year types below.

Water Year Type	Pre Shasta (1906-1944)	Post Shasta (1945-2006)
W	13	22
AN	5	10
BN	7	11
D	8	12
C	6	7
Total	**39**	**62**

Figure 6.3: Sacramento River Box Plots at Bend Bridge. Box plots display the median and the range of variability for each hydrograph component. Summer baseflows are represented by the average August discharge for each water year type. Winter floods are represented by the maximum daily average discharge for each water year type. Winter base flows are represented by the median discharge in February and March for each water year type. Spring peak flows are represented by peak average daily discharge value in April-June for each water year type. The top of the box plot is the 75th percentile and the bottom of the box is the 25th percentile. The 25th percentile means that 75% of the data is above this point. The wiskers represent the maximum and minimum values. The dark line inside the box is the median value, or 50th percentile. When the boxes do not over lap then there is a very highly significant difference between the data sets.

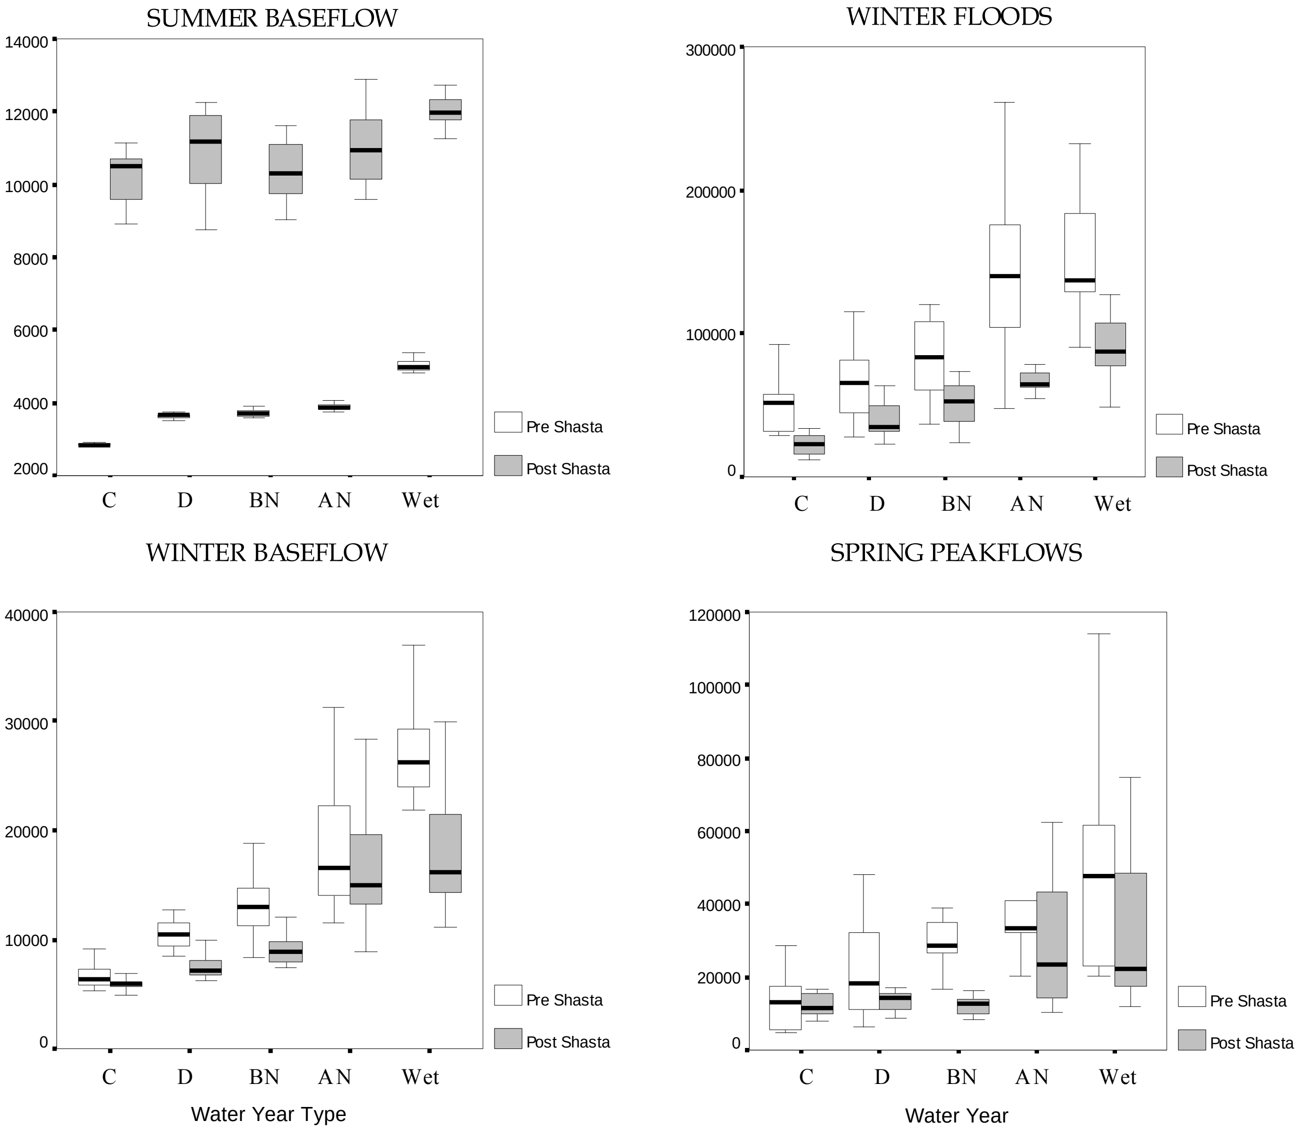

Figure 6.4: Flood frequency analysis at Bend Bridge Pre and Post-Shasta. The flood frequency analysis displays the magnitude of flows expected to occur in a 1.5, 2, 2.5, 5, 10, 20….year flood. The two year flood event in the pre Shasta era is ~100,000 cfs. Bed mobility is expected at the 1.5 year flood (Q1.5) or 82,795cfs.

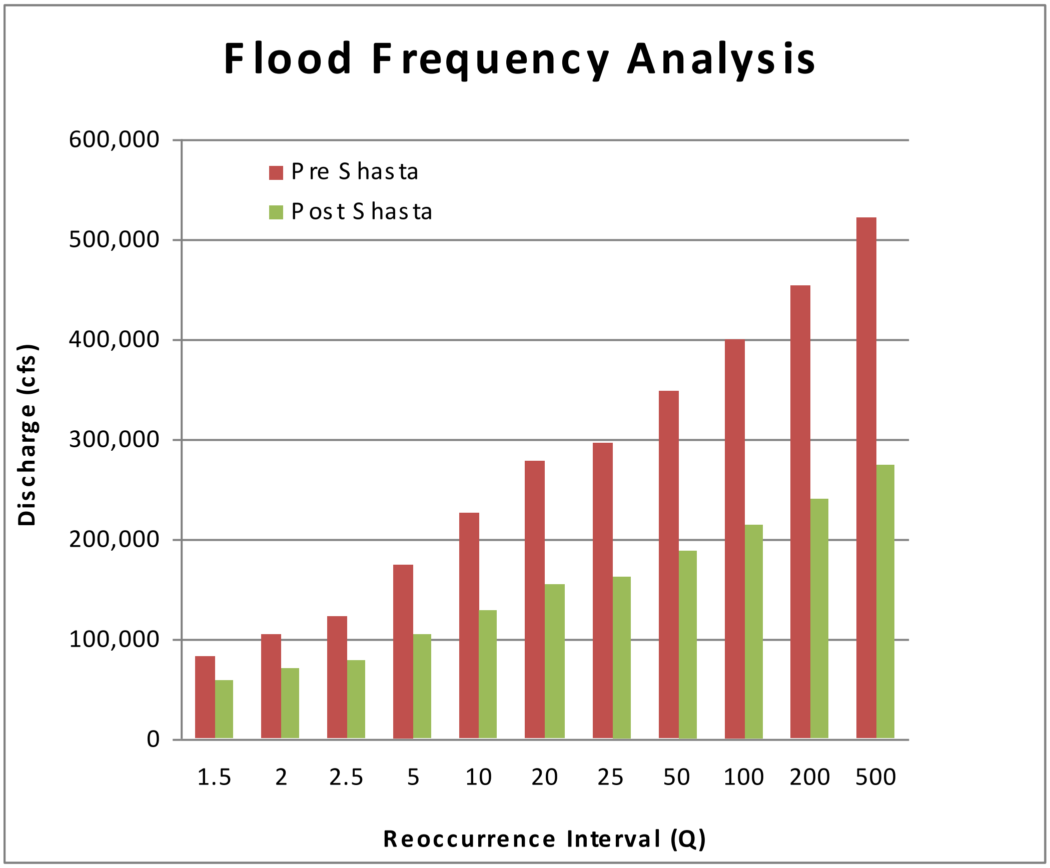

Table 6.2: Sacramento River Flood Frequency

6.2.1 Feather and Yuba Rivers

Introduction

Oroville Dam and Reservoir on the Feather River were completed in 1968 and have a storage capacity of 3.5 million acre feet (maf). It is managed for water supply, hydropower, and flood control. The average annual yield of the upstream Feather River basin at Oroville is about 4.2 maf. Due to several diversions in the upper watershed, average annual inflow into Oroville Reservoir is approximately 4.0 maf, but varies annually depending on precipitation. From 1979 to 1999, annual inflows ranged from a minimum of 1.7 maf to as high as 10 maf . Most of the water released from the dam, except during flood spills, is routed through the Thermalito diversion pool and afterbay and therefore bypass a 7 mile stretch below the dam known as the low flow channel. A minimum flow of 700-800 cfs is released into the low flow channel to maintain habitat for salmonids.

We evaluated change in hydrology that resulted from construction and operation of Oroville Dam. We compared pre and post dam hydrology at the USGS gauge below Oroville. In order to account for the water in the post-dam period that is discharged into the Thermalito diversion pool and bypasses the Oroville gauge, we summed daily values from the Thermalito (11406920) and Oroville (11407000) gauges to calculate the average daily flow for the river below the low flow channel.

Minimum instream flows below Thermalito Afterbay range from 1,000 cfs in the late spring and summer to 1,200 -1,700 cfs during the fall winter months. Minimum flows for the low flow channel are between 700 and 800 cfs all year. Minimum flows are slightly higher during the fall and winter to provide flow for spawning and incubating salmonids. Minimum flows in the summer are necessary to maintain cool temperatures for over summering juveniles and adult salmonids.

Most irrigation releases are made directly into irrigation canals, so relatively little water is conveyed to irrigators via the Feather River channel. Most irrigation water is released from Oroville Reservoir into Thermolito Diversion Pool, Forebay, and Afterbay where it is subsequently diverted into irrigation canals. Thus, it is possible to substantially meet summer irrigation demands without conveying water through the Feather River Channel.

The Feather River is joined downstream by a major tributary, the Yuba River. The hydrology of the Yuba River was modified early in the 19th century, but the first big storage reservoir, Bullards Bar, was not constructed until 1968. As a result, the hydrology of both the Yuba and Feather River were substantially altered at the same time by large reservoirs constructed in the late 1960s.

Hydrologic Changes

The construction and operation of Oroville dam and reservoir have significantly altered the hydrograph of the Feather River downstream of Oroville. Figures 10 and 11 depict the hydrologic patterns during different year types before and after 1968 when Oroville

Dam was completed. Figure 12 and Table 6 show changes in peak flow magnitude and duration. The most significant changes to the hydrograph are:

- Very significant reductions in spring flows during all year types, particularly during April and May. Storage of spring run-off and snow melt behind Oroville Dam has virtually eliminated any spring flows above a base flow of approximately 2,000 cfs.
- Increases in summer flows by 150-200% in all year types during July, August, and September.
- Reduction in the frequency and magnitude of peak flows, such as Q1.5[2] or channel forming flow by an order of magnitude. Substantially less reduction in the magnitude of the 5 year recurrence interval event (Table 6)
- Reduction in the frequency of short duration fall and winter flow pulses.

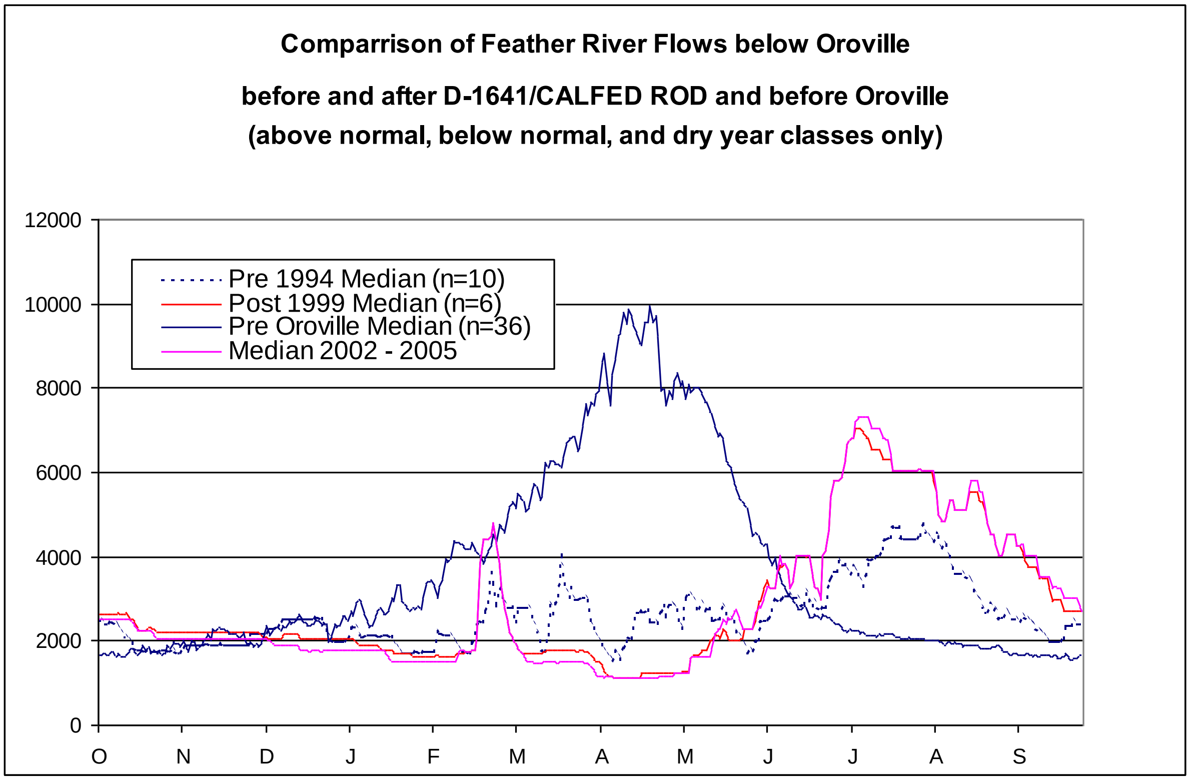
These hydrograph modifications are a result of Oroville Reservoir's water supply, flood management, and hydropower operations. Oroville Reservoir captures high flows in the winter and spring for use during the summer months. Stored water is released to meet minimum instream flows, irrigation demand in the Feather River region between April 1 and October 31, generate hydropower primarily in the summer, and meet water quality and export water demands in the Delta. Large volumes of stored water are periodically released during the winter months to create reservoir space for flood management purposes.

Most of the increases in summer flow in the Feather River channel are the result of Oroville releases to meet water quality and export demands in the Delta. As a unit of the State Water Project, Oroville is specifically operated to meet water quality and export demands in the Delta. An analysis of pre-1995 and post 1995 hydrology shows that Feather River flows changed significantly after the 1995 Water Quality Control Plan tightened restrictions on the timing of Delta diversions. After implementation of the plan, spring flow in the Feather River has been further diminished while summer flow has been further increased.

---

[2] The instantaneous peak annual flow with a recurrence interval of 1.5 years.

Figure 6.5: Influence of Sacramento-San Joaquin Delta Regulations on Feather River Hydrograph. The blue line of pre Oroville median flows represents the most natural hydrograph. In 1995 the Water Quality Control Plan tightened restrictions on the timing of Delta diversions. The pre 1994 hydrograph compared to the post 1999 illustrates how the hydrograph shifted spring flows to summer releases to meet Delta requirements.



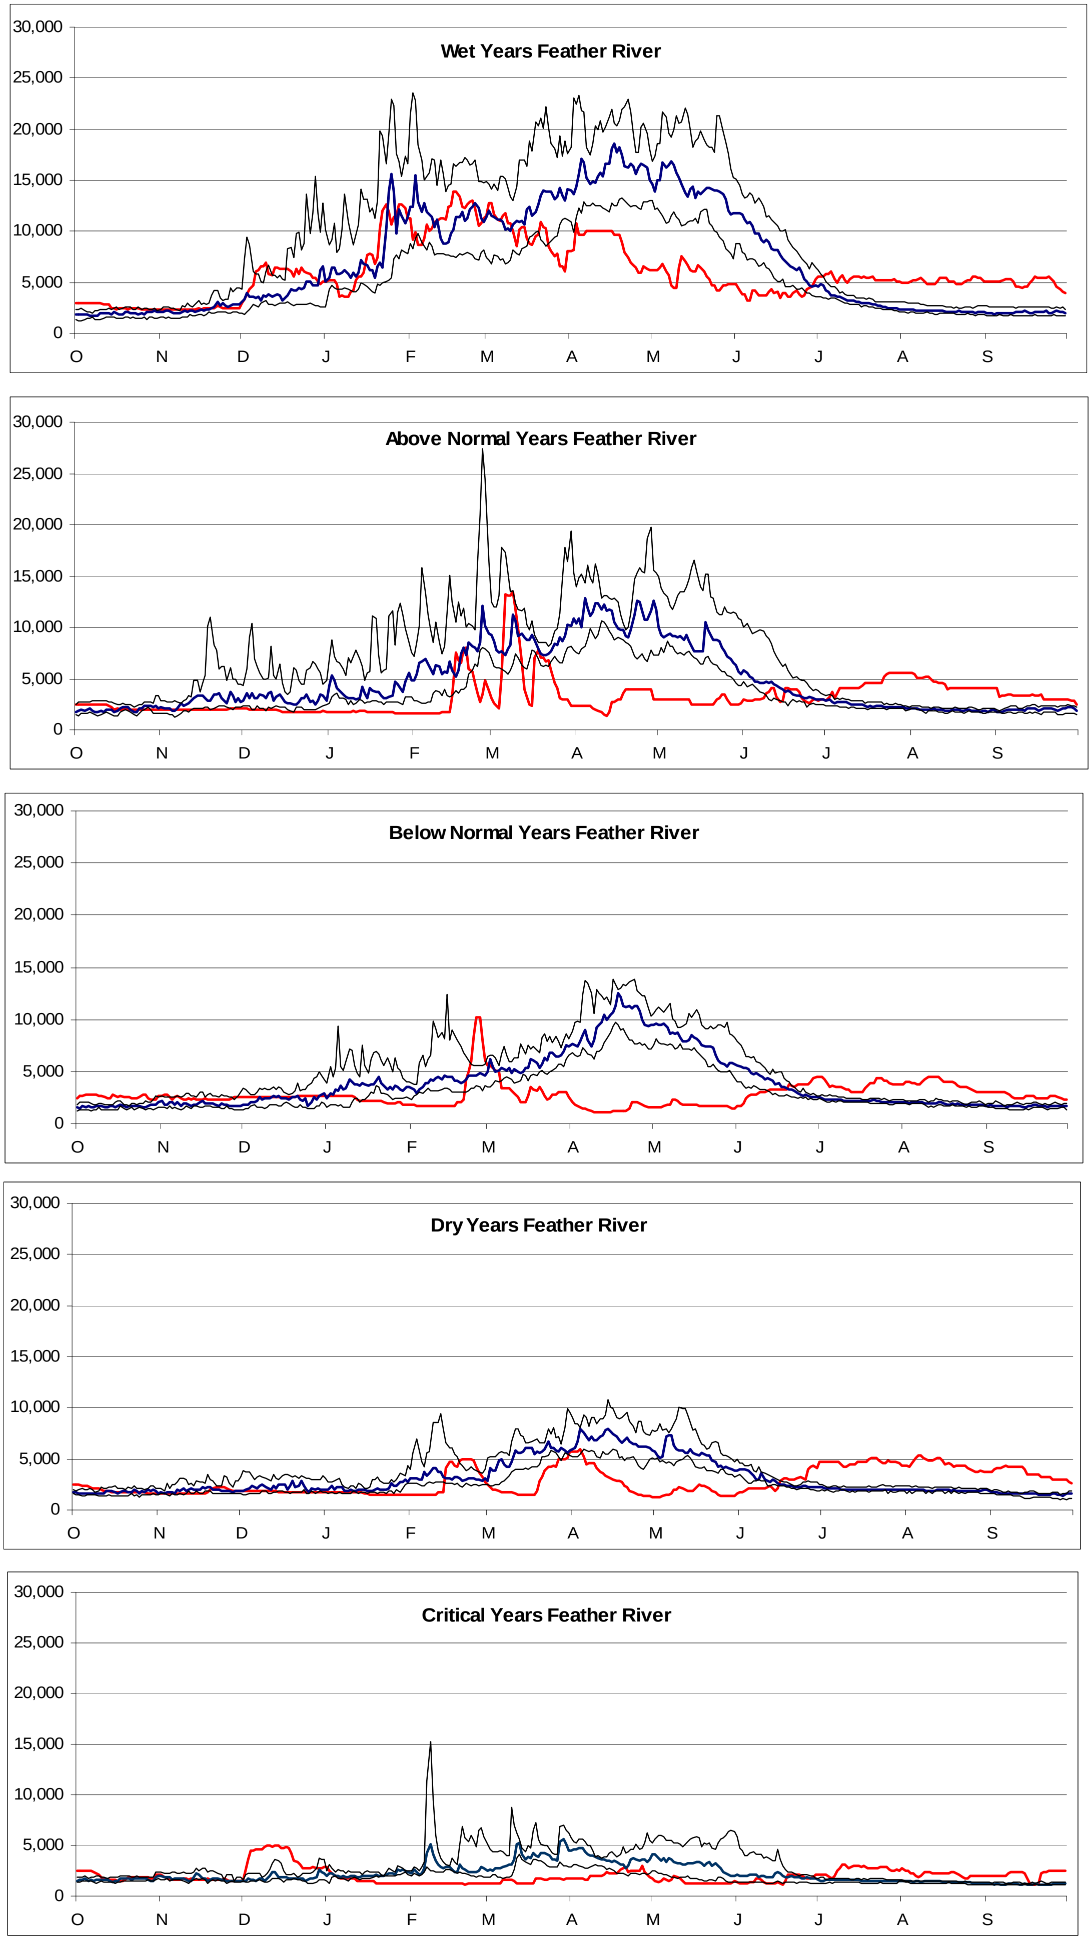


Figure 6.6: Feather River median hydrographs : Historical data was used to construct hydrographs for five water year types on the Feather River (USGS Gage11407000 and 11406920). The median hydrographs pre and post Oroville represent the natural and impaired flow regimes. The twenty-fifth and seventy-fifth percentile hydrographs represent the natural range of variability in the pre-dam era. When the median post project hydrograph is not within the historic range of variability then there is a significant discrepancy between the historic and current hydrographs. The greatest discrepancies include the lack of spring peak flows and un-naturally high summer flows for all water year types. (The y-axis is discharge in cubic feet per second or cfs.) The hydrographs post Oroville (1968-2006) are the sum of the Oroville (11407000) and Thermolito Afterbay gages (11406920). See the table of the number of water year types below.

6.3 Sacramento River at Verona

Analysis of the Sacramento and Feather Rivers at gauges near the large dams only tells part of the story. The Verona gauge is downstream of the confluence of the Sacramento and Feather River, and measures run-off from numerous large tributaries not measured by the gauges at Oroville and Bend Bridge. Several of these tributaries do not have large storage reservoirs and thus continue to exhibit relatively natural hydrographs. Figure 14 shows the hydrographs from Mill and Deer Creek which are characterized by large, gently receding spring flows. As a group, these less regulated tributaries tend to dampen the effect of Shasta, Oroville, and New Bullards Bar, but only to a limited extent.

Figures 16 shows hydrologic patterns for four periods: before Shasta, after Shasta but before Oroville Dam, after Oroville Dam, and after the implementation of the 1995 water quality control plan that established stringent limits on the timing of water exports from the Delta. The hydrology from all four periods shows a clear and consistent trend: progressively less spring flow and continuously increasing summer time flows. The decrease in spring flows and increase in summer flows is particularly striking after 2000 when the water quality control plan was in full effect in the Delta. Due to stringent export restrictions in the spring, the state water project, which operates Oroville Reservoir and controls the Harvey O'Banks pumping plant in the Delta, has apparently shifted operations to minimize spring time releases from Shasta and favor summer time releases so that it can deliver water to the Delta when pumping restrictions are less severe.

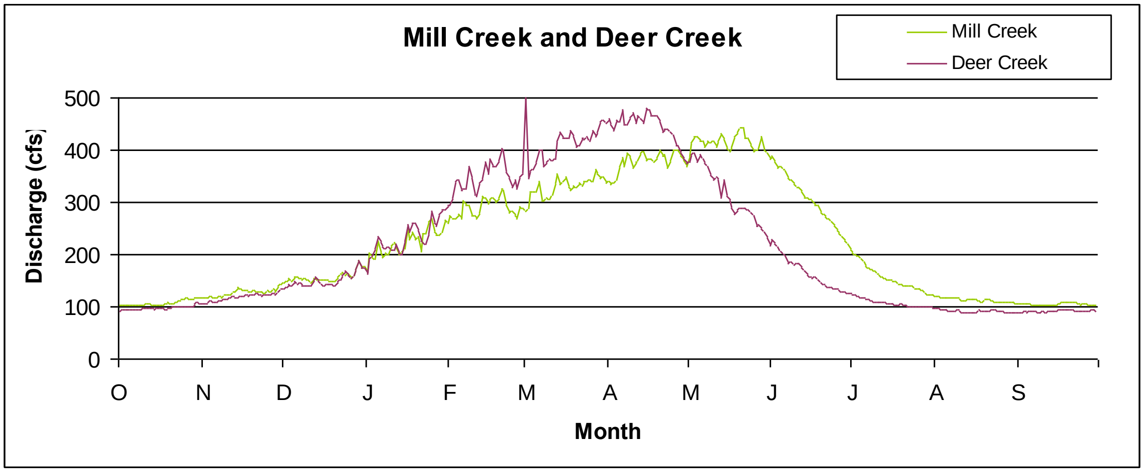

Figure 6.10: Median hydrographs for Mill and Deer Creek.

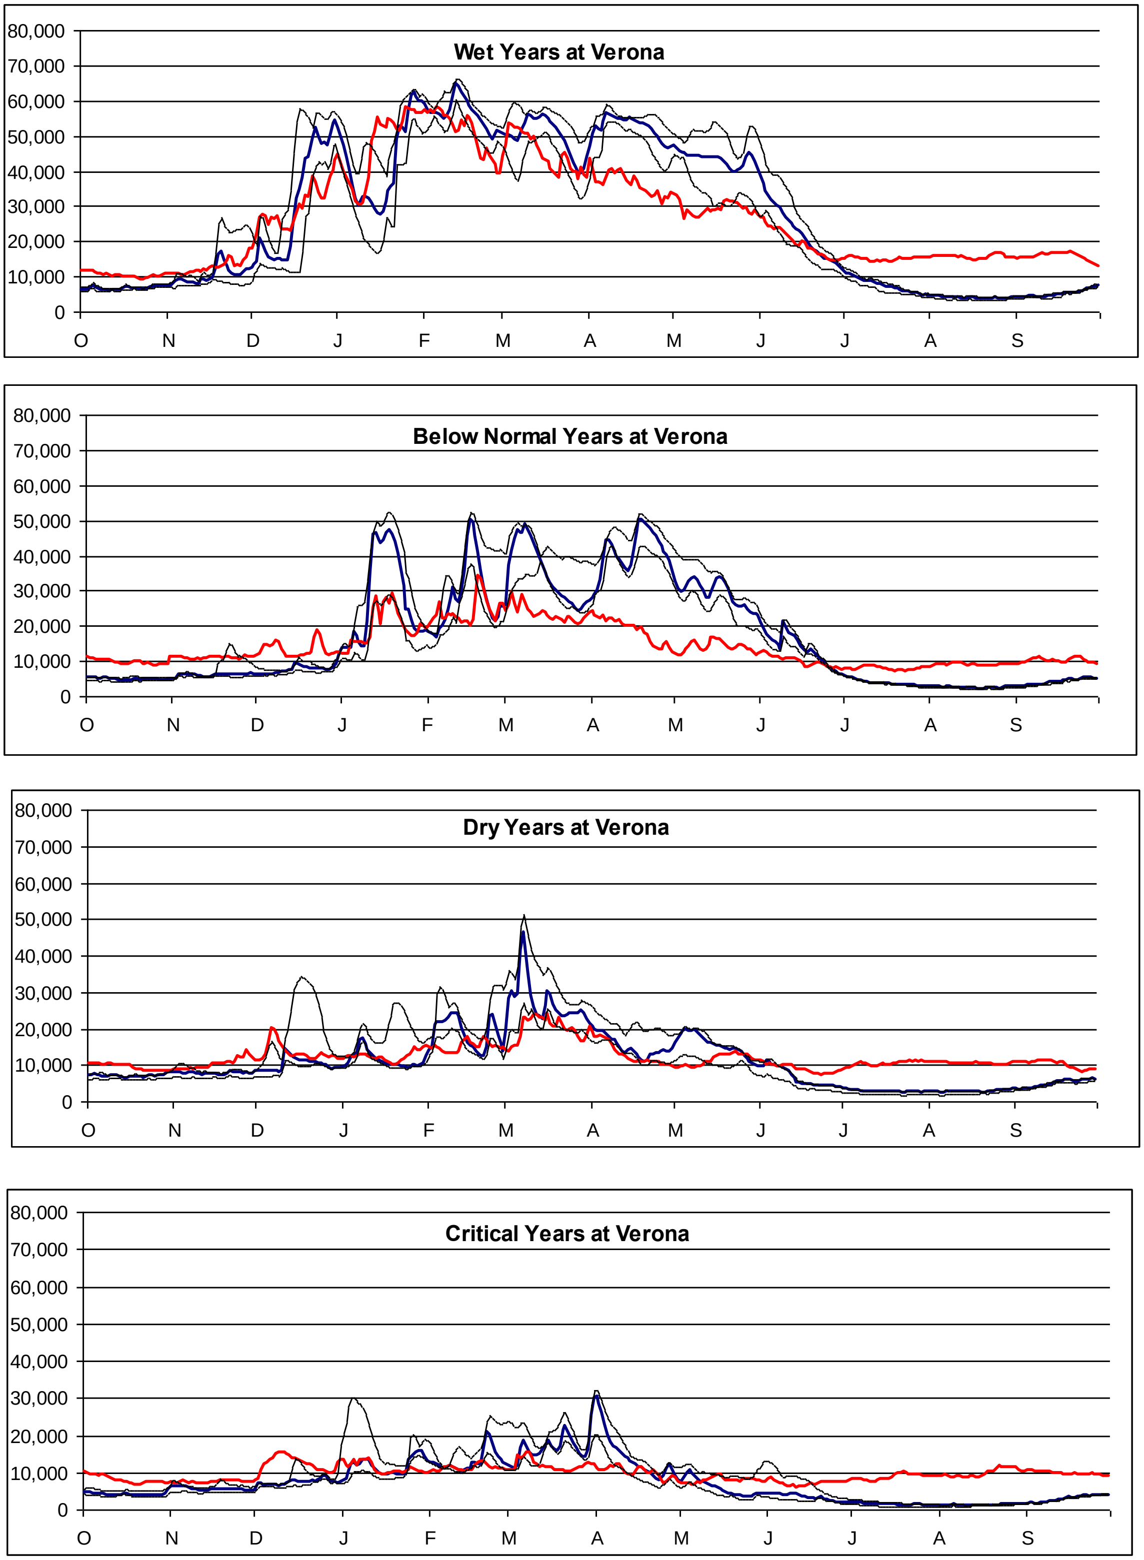

Figure 6.11: Verona median hydrographs : Historical data was used to construct hydrographs for different water year types at Verona (USGS Gage 11425500). The median hydrographs pre and post Shasta represent the natural and impaired flow regimes. The twenty-fifth and seventy-fifth percentile hydrographs represent the natural range of variability in the pre-dam era. When the median post project hydrograph is not within the historic range of variability then there is a significant discrepancy between the historic and current hydrographs. The greatest discrepancies include the lack of spring peak flows and un-naturally high summer flows for all water year types. (The y-axis is discharge in cubic feet per second or cfs.) There is no median hydrograph for an Above Normal Year type because there was only one year of this type between 1929 and 1944. See the table of the number of water year types below.

W	4	22
AN	1	10
BN	3	11
D	4	12
C	3	7
Total	15	62

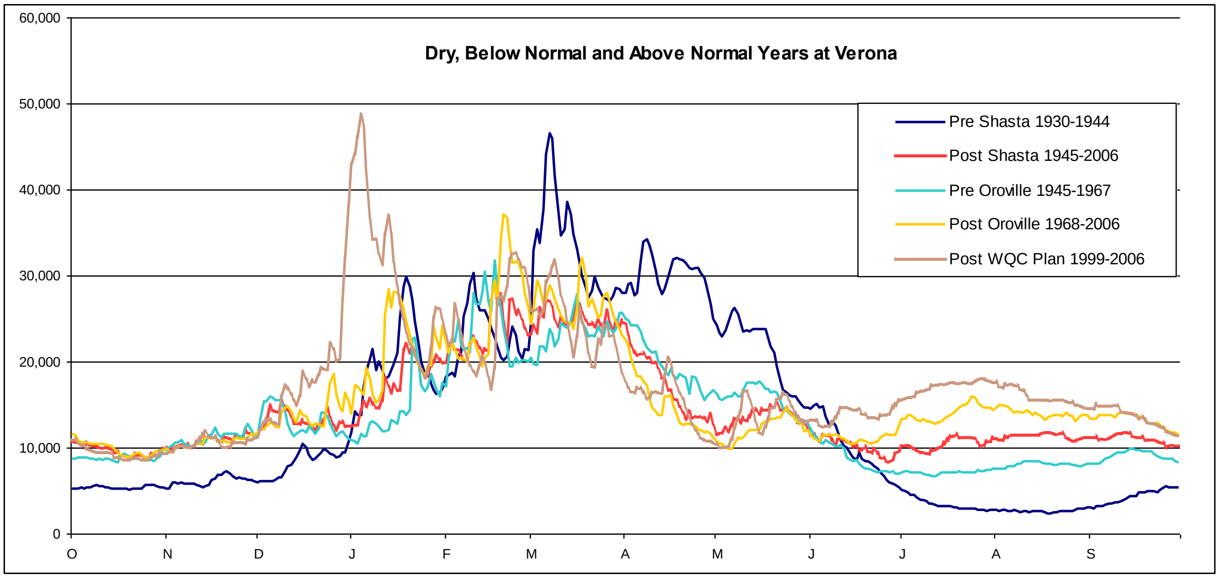

Figure 6.12: Median hydrographs for different time periods indicate a progression towards increased summer flows and decreased spring peaks. The increased regulation of the Sacramento and Feather Rivers with Shasta in 1945, Oroville in 1968 and the implementation of the Water Quality Control Plan in 1999 all had the effect of releasing increased flows during the summer when demands are high and as a consequence eliminated spring peak flows.

Summary of Results
From the hydrograph comparisons of current hydrographs to pre project, or natural hydrographs, a consistent trend immerges for all sites. This trend is the result of reservoir operations where by water is stored until periods of peak demand arise. In the Sacramento River basin peak demands occur in the summer months which means that reservoirs hold water through the spring, eliminating peak spring flows and augmenting summer base flows well above pre project levels. In this way reservoirs alter the timing and magnitude of the spring and summer hydrographs. In addition the presence large reservoirs in the headwaters dampen winter floods in all but the wettest of years. Loss of these geomorphic and riparian flows impacts riparian vegetation and Chinook Salmon habitat.

7.0 IDENTIFY OBVIOUS GAPS BETWEEN OBJECTIVES FLOW REQUIREMENTS AND EXISTING FLOWS

7.1 Gaps in Riparian Vegetation Objectives

Bed Mobilization

The frequency and size of large flows capable of mobilizing the bed have been reduced, but large flows occur in more than half of the years on the Sacramento River. The size of the Q1.5 has been reduced by twenty fiver percent. The pre-dam Q1.5 of 87,000 cfs now has a recurrence interval of every 2.5 years instead of every 1.5 years. While this is a significant reduction, it is a relatively small reduction in comparison to hydrologic alteration on other rivers such as the Feather or San Joaquin Rivers. The abundance of active riffles in the Sacramento River meander belt suggests that the river still periodically mobilizes its bed. Lack of bed mobility in the upper reach below Keswick Dam may be more a result of armoring due to coarse sediment trapping upstream then it is a result of reduced flows.

On the Feather River, the frequency and magnitude of peak flows has been reduced more substantially. The historical instantaneous Q1.5 – 2 has of 33,000 – 50,000 has been reduced by an order of magnitude to 3,000 – 5,000 cfs. The Q2.5, however, is 25,000 cfs. Under the post dam regime, several 4-5 years can pass without exceeding a bed mobilizing flow. This enable riparian vegetation to become established on gravel bars leading to long term stabilization and degradation of the channel.

Bed Scour

The frequency of very large, bed scouring events has been reduced substantially. The pre-dam Q5 of 160,000 cfs now has a twenty-year recurrence interval rather then a five-year recurrence interval. Similarly, the pre-dam ten-year flow now has a one hundred year recurrence interval. The physical processes and ecological function of these large events is not well understood. It is possible that smaller flows substantially scour the bed, rearrange the channel, and form new channel habitat. If so, the reduction in very large flows may not be as important. On the other hand, these very large events may be very important for creating and maintaining important habitats such as oxbow lakes and other off-channel habitats.

Bank Erosion and Channel Migration

We did not conduct an assessment of changes in stream power, but figure 5.2 illustrates that the occurrence of flows exceeding 15,000 or 20,000 cfs in dry, critical dry, and below normal years has been reduce substantially. Larson (2007) identified 15,000 cfs as the lower threshold for bank migration. Median flows frequently reached 15,000 cfs in these drier year types during the pre-dam period, but in the post-dam period median flows seldom rise above 10,000 cfs. During the wettest forty percent of years, wet and normal wet years, median flows frequently exceed 20,000 cfs and thus maintain some level of bank erosion and channel migration processes. Reduction in the frequency and duration of erosive events may have substantial impacts on the colonization and succession of riparian habitat over time. It definitely has habitat implications for bank swallow, a listed species that nests on recently eroded stream banks. Reduced bank erosion almost certainly lowers the suspended sediment levels and could therefore have significant impacts on instream fish habitat for juvenile salmon or Delta smelt that appear to prefer or concentrate in turbid waters (citation?). Although the reduction in the frequency or duration of bank erosion events may have significantly ecological impacts, it may be less important then the widespread presence of bank revetments along the Sacramento Rivers (Larson, 2007).

Inundated Floodplain and off-channel habitat during late winter and spring

The lack of prolonged flows of sufficient magnitude to inundate floodplain and off-channel habitats during the late winter and early spring months is perhaps the most significant ecological change to the Sacramento and Feather Rivers. Large, prolonged flows still occur in wet and normal wet years, but they are largely disconnected from the floodplains due to levees that prevent inundation of the vast historic floodplain of the lower Sacramento River. Large areas of the Sutter and Yolo Bypass become inundated in wet and normal wet years, but little or no floodplains become inundated for any length of time in the drier sixty percent of the years. This is a result of both levees and flow alteration, but flow alteration alone is sufficient to preclude floodplain inundation in the drier years.

Loss of shallow water habitats in secondary channels and floodplains not only reduces the amount of rearing habitat, it also may reduce foodweb productivity in the spring months when juvenile fish are rearing and moving downstream to the Delta. Increase connectivity between shallow water habitats and open water can substantially increase aquatic productivity in estuaries (Cloern, 2008).

Inundated off-channel habitat such as high flow channels can also provide rearing habitat for salmon (Peterson and Reid, 1984), but regulated spring flows are generally insufficient to inundate these habitats for prolonged periods (30-60) days. A recent study of these habitats in the Sacramento River determined that a large proportion of secondary channels between Red Bluff and Colusa become fully connected to the river at flows above 12,000 cfs (Kondolf, 2007). Regulated flows seldom exceed 10,000 cfs in the drier year types (dry and below normal) during late winter and spring when salmon are most likely to require spawning habitat. Even in normal wet years, median April flows are generally below 10,000 cfs.

7.2 Gaps in Riparian Vegetation Objectives

Peak spring flows are conspicuously absent under current conditions. On both the Sacramento and Feather River, median summer flows are significantly greater then median spring flows in all but wet years. As a result, any seeds that might germinate during the cottonwood seed release period in April and May are at risk of mortality from prolonged inundation throughout the summer months. If seeds to become established, they are less likely to grow deep roots during their first growing season due to high groundwater levels and therefore may be more vulnerable to desiccation mortality when water levels do drop.

In addition to the overall decapitation of the spring hydrograph, rapid flow declines during the spring months create a hostile environment for establishment of Fremont cottonwoods. Changes in the rate of the spring snowmelt recession are not obvious from the composite hydrographs depicted in figure 6 because they are of average spring flows over several years. The recession rate is more directly controlled by reservoir release operations in specific wet and above normal years. Our evaluation of hydrographs for individual years indicates that the recession rates are often characterized by abrupt changes in flow during the seed germination period on both the Sacramento and Feather rivers as illustrated in figures 6.1 and 6.2. Abrupt changes in reservoir releases during germination and initial seedling establishment period can limit recruitment by abruptly desiccating recently germinated seedlings before their roots reach the water table or by scouring and inundating newly established seedlings with high summer flows shortly after germination.

Even in wet years, median flows do not reach the documented threshold of 23,000 cfs on the Sacramento necessary to recruit riparian vegetation in a zone that is not vulnerable to subsequent channel scour. Similarly, the Feather River only reaches the assumed threshold of 8,000 -10,000 in median wet years. While it is true that the median numbers depicted in figure 6 obscure the variability that actually occurs in various years, figure 6 clearly illustrates how dramatically the critical spring and summer hydrograph has been altered in non-wet years. Even in wet years, the hydrographs are often not suitable due to the rapid fluctuation in flows (figures 6.1 and 6.2).

Figure 7.1: Annual hydrograph for Sacramento River at Bend Bridge illustrating abrupt flow decline in mid April during cottonwood germination period.

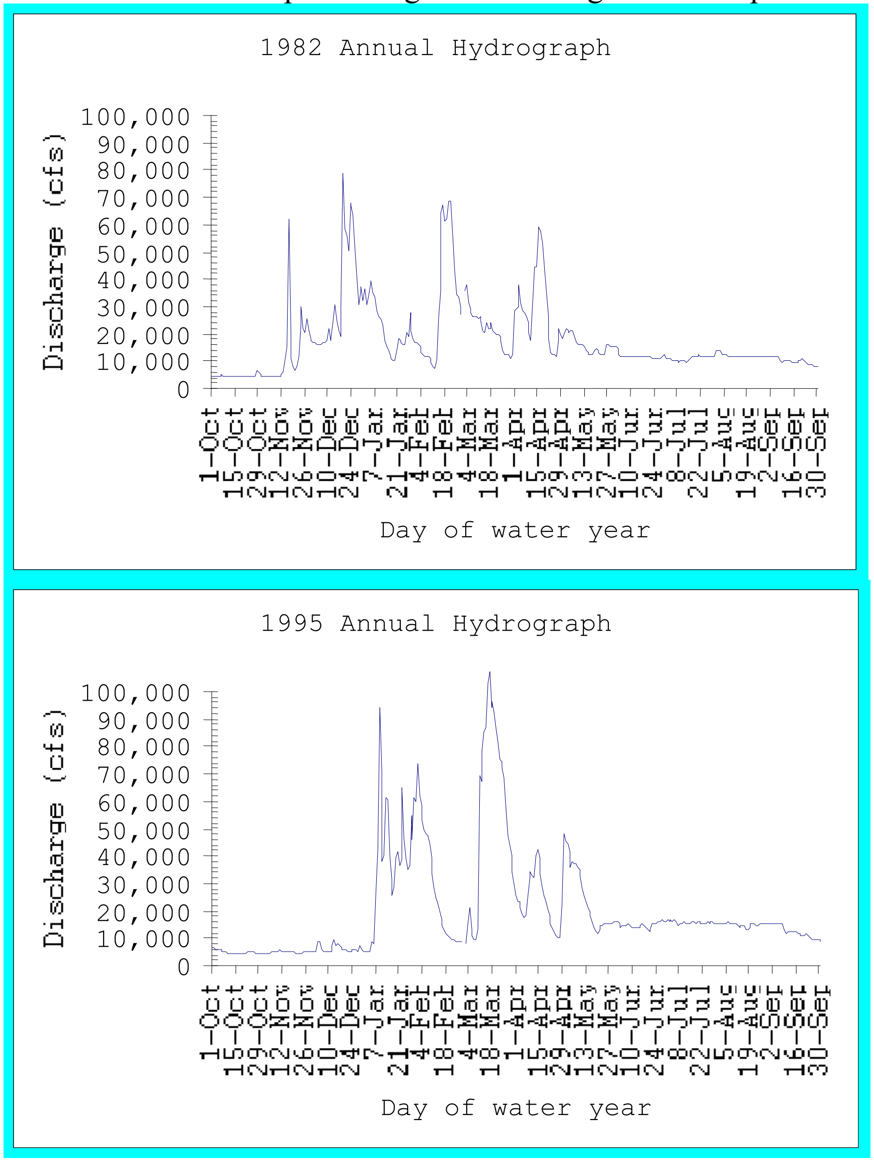

Figure 7.2: Annual hydrograph for Feather River at (sum of Oroville and Thermolito gauges) illustrating abrupt flow decline in mid April during cottonwood germination period.

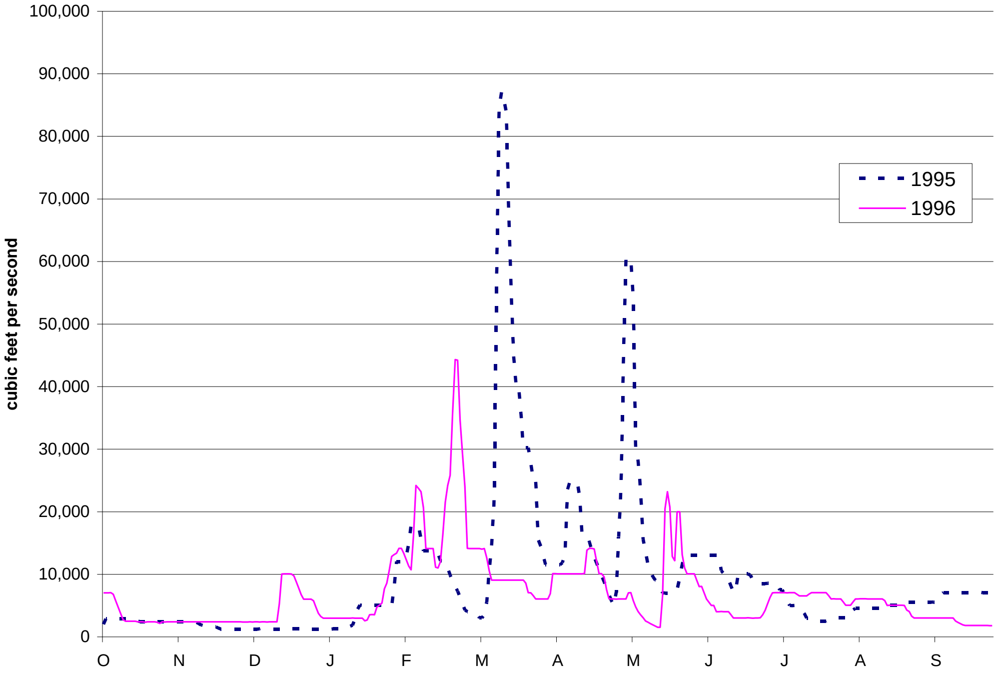


7.3 Gaps in Chinook Salmon Objectives

Spring Pulse

Elimination of high winter and spring flows has substantially reduced the amount of rearing habitat on inundated floodplains and in off-channel habitats. A close examination of flow patterns indicate that later winter and early spring flows are increasingly the lowest flows of the entire year on both the upper Sacramento and Feather River. Under natural conditions, the highest prolonged flows of the year consistently occurred in the late winter and spring. This "spring rise" in flows inundated gravel bars, secondary channels and associated backwaters, and floodplains during the larger events.

Late winter and early spring flows at Bend Bridge on the Sacramento are about fifty to sixty five percent of what they were historically. A recent study of off-channel habitats on the upper Sacramento River (Kondolf and Stillwater, 2007) identified 12,500 cfs as an important threshold for inundating side channel habitats. On the Sacramento River, median spring flows at Bend Bridge seldom fell below 12,000 cfs between February and April prior to Shasta Dam. In the post dam era, median flows are consistently below 10,000 cfs in all but the wettest years. Meanwhile, summer flows which were historically below 5,000 cfs are now consistently above 10,000 cfs. The shift from spring to summer has become even more pronounced in recent years as dam operators have shifted operations to meet water quality and water supply demands for the Sacramento-San Joaquin Delta.

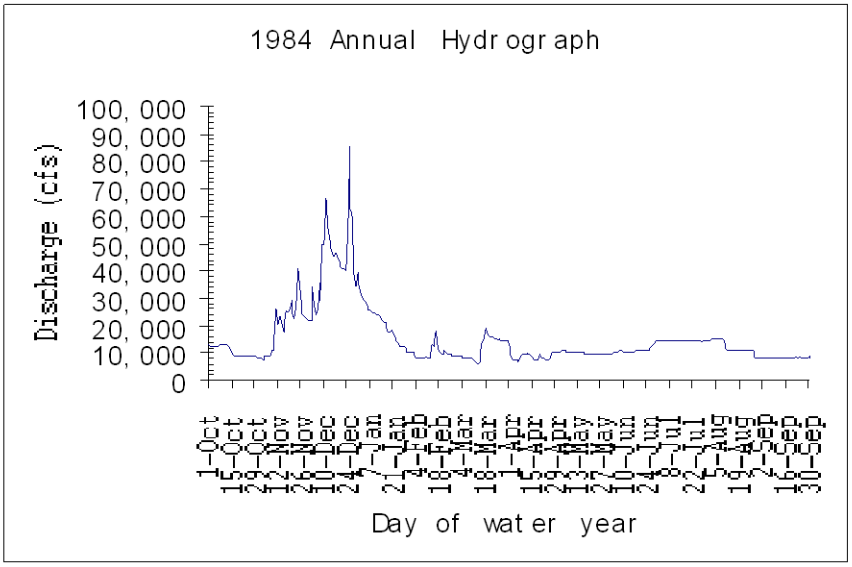
The pattern of reduced spring flows is even more pronounced on the Feather River where median spring flows are fifteen to thirty percent of what they were historically in most year types. The only exception is wet years when they are approximately fifty percent of the historical median. But even in these wetter years, the spring flows are characterized by abruptly fluctuating flood flows as illustrated in figure 6.2, rather then the prolonged spring pulse that characterized historic flows.

Fluctuating Flow Events

The median flow analysis presented in the previous chapter is not well suited for evaluating the frequency of abrupt flow changes, because the composite hydrographs depicted in figure 6 do not reveal individual flow events, which may harm salmon populations. The recent Nature Conservancy study of the Sacramento River (Stillwater, 2007, 2008 appendix F) hypothesized that abrupt increases or decreases in flows in the Sacramento may impact salmon and other species by scouring or dewatering reds, stranding fish, or eroding bank swallow nesting sites. Our cursory analysis of annual hydrographs, illustrated in figures x and xx, indicate that abrupt fluctuations in flow do occur in some years. The timing of these fluctuations may be a significant problem for fish in individual years. Large, rapid fluctuations in the winter or spring could strand juvenile salmon on floodplains or was juveniles downstream to poor habitat. Large reservoir releases in the fall, followed by declines to a significantly lower stage during the remainder of the winter, as illustrated in figure 6.3, could result in dewatering and stranding of redds. Large fall releases are usually limited to periods following very wet years when reservoir levels are high and need to be reduced prior to the rainy season for flood control purposes.

It is clear that large fluctuations in flow occurred under natural conditions on both the Feather and Sacramento Rivers. It is unclear how and whether individuals and populations of these salmon survived these events. Did very high flows that scoured the bed result in reproductive failure? How often did this occur? It is likely that today's regulated flow regime fluctuates in the present day riverine conditions is more likely to harm salmon then fluctuating flows under historical conditions. Under historical flow conditions, high peak flows are often followed by subsequent peaks that might enable stranded fish to reenter the river. More habitat complexity under historical conditions increased the probability that salmon could spawn or take refuge in areas safe from the potential negative effects of high flows. In today's environment, large peaks are often abruptly ended only to be followed by weeks of low flows. Levees and channelization have cut-off important refuge and foraging habitat that fish might have otherwise used during high flows.

Figure 7.3: 1984 annual hydrograph from the Sacramento illustrating high flow falls that could result in salmon redd stranding and reproductive failure.



Base Flows

Base flows in the Sacramento and Feather Rivers have been increased in most months except the spring, as previously discussed. Increased base flows during the summer and fall probably lower water temperatures and improve fish passage conditions. It is unclear whether unnaturally high base flows in the summer and fall have any deleterious impacts on fish such as harboring exotic species.

8 ENVIRONMENTAL FLOW REGIME RECOMENDATION

This chapter identifies flow recommendations for the Sacramento River based on the objectives and flow thresholds identified in chapters three and four, and the analyses of natural and regulated hydrology presented in chapters five and six.

Although this study identifies hypothetical restoration flow regimes for the Sacramento and Feather Rivers, we recognize that the most reliable method for developing a restoration flow regime is through a long-term adaptive management program. The hypothetical flow regime that we have developed and identified is imperfect, but it serves as a reasonable starting point for evaluating the feasibility of reoperating reservoirs without impacts on existing reservoir functions.

The assumptions and uncertainties associated with the hypothetical flow regime are as important as the flow regime itself. To cost effectively achieve restoration, managers will ultimately need to test these assumptions and address the uncertainties through a program of modeling, pilot flow studies, model calibration, and long-term restoration implementation. In the text below, we have explicitly identified some of these uncertainties so that they can be further evaluated.

8.1 Summary Recommendation

The key component of the environmental flow proposal for both the Sacramento and Feather Rivers is to restore higher flows during the late winter and spring. This period was once characterized by sustained, high flows. Under regulated conditions, however, spring flows are nearly half their historic volume and substantially below summer flows. We recommend restoring a stable spring base flow that is sufficient to inundate secondary channels, as well as, a spring pulse flow to inundated floodplains, particularly the Yolo and Sutter Bypasses.

A second key objective of the flow regime is to ensure adequate flows for the geomorphic and riparian processes that are necessary to sustain riverine and riparian habitat. We recommend short duration, high magnitude flows during the late winter to increase the frequency of hydrologic events that will mobilize the river bed or erode river banks. During late winter and early spring, we recommend prolonged duration moderately high flows to create inundated floodplain habitat for salmon. During the spring of wet and normal years, we recommend moderate duration, high flow evernts in wet and normal wet years to facilitate recruitment of Fremont cottonwoods and other riparian vegetation.

Restoring higher flows in the spring will necessarily reduce flows during other times of the year We propose reducing summer base flows to enhance spring flow, but realize that this could reduce suitable habitat for winter-run salmon during the summer months. We are not proposing any changes in the cold water pool management regime, which currently assures cold water releases from Shasta Reservoir. We recommend against diverting additional water away from the winter months, because we believe that existing winter flood events are necessary to create and maintain riverine and riparian habitat.

8.2 Sacramento River

Summary recommendations for Sacramento River base flows, key ecological flows, and a flow schedule are presented in tables 7.1 – 7.3. Illustrative flow recommendation hydrographs for each year type are presented in figure 7.2.

Table 8.1: Sacramento Environmental Flow Targets for Bend Bridge and Verona

8.2.1 Fall Base Flows

We propose stepping flows down from a stable summer base flow (see below) in late September in the upper river (between Keswick and Red Bluff). Under both natural and regulated conditions, flows in early fall are the lowest flows of the year. The primary purpose of lowering fall base flows closer to their historic levels is to economize on water and shift the saved water to the spring months when it is more important. The secondary purpose is to provide stable base flows for spring and fall-run spawning salmon and suitable rearing conditions for winter-run 5,500 cfs release from Keswick is about 1,000 – 1,500 cfs below existing fall base flows, but should be adequate for spawning habitat. The fall base flows must be stable to avoid dewatering or redds that may occur when flows are substantially dropped from the norm. Lower base flows in October could also potentially improve rearing habitat for winter run by creating slightly warmer fall water temperatures and thus an increased food supply.

Below Keswick	5,500
Below Red Bluff Diversion	5,250
Below GCID Diversion	5,000
Below Colusa	4,750

Key Uncertainties

- Are proposed fall base flows sufficient for area of spawning habitat?
- Will lowering fall base flows provide warmer, slower velocity habitat for rearing winter run juveniles, and will this improve their growth and survival?
- Will reduce fall base flows cause adverse impacts in the Delta ecosystem?

8.2.2 Fall Pulse Flow

We considered a pulse flow to improve rearing conditions for juvenile salmon in the fall but did not include it in figure 7.2. The purpose of the fall pulse flow would be to improve food supply and rearing conditions for the winter run salmon and is loosely

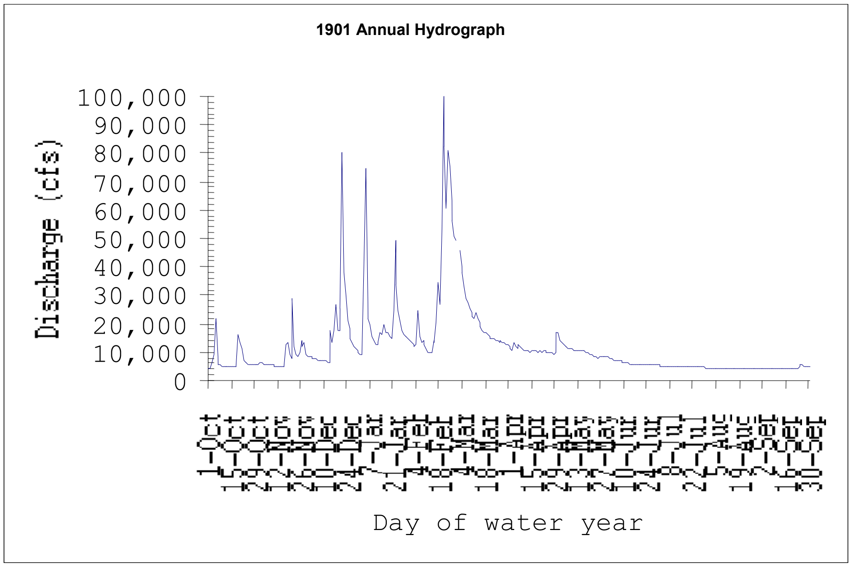
Illustrative Environmental Flow Release from Keswick

based on recommendations of the recently published Sacramento River Environmental Flows Report (Stillwater, 2007; ESSA Technologies, 2008). Rather then releasing a long duration rearing flow as proposed by Stillwater, it may be more economical to release two or three short duration pulses (3-5 days) of 12,000 cfs in late September and early October to inundate secondary channels and channel margins. The initial pulses would inundate the side channels and then be lowered to allow high residence times in the side channels. Each pulse would be followed by a subsequent pulse to flush food resources into the main channel and prevent fish stranding.

The main potential problem with a fall pulse flow would be to enable salmon, particularly spring run, to spawn on areas that would subsequently be dewatered. If the pulses are short enough, this problem may be limited. But the shorter the pulses will provide less potential for rearing habitat and food supply. Early fall pulse flows were rare under natural conditions, but they did occur occasionally as illustrated by the 1901 hydrograph (figure 7.1). Under regulated conditions, the winter run are confined to the mainstem river. The fall pulse, although largely unnatural, is designed to improve rearing conditions for them before cool winter months when food resources will presumably be less abundant.

Figure 8.1: 1901 hydrograph at Bend Bridge illustrating the rare, but natural occurrence of early fall pulse flows.



Key Uncertainties

- Will fall pulse flows for a few days result in dewatered reds once the pulse subsides?
- How long do secondary channel habitats need to be inundated in order to provide prolonged and substantial food supply benefits in the main channel?

8.2.3 Winter Base Flows

The purpose of the winter base flows is to provide stable conditions for incubating salmonids and reduce flashy regulated hydrology that can result when run-off from unregulated tributaries, primarily on the west side, is not modulated by less flashy natural hydrology from the larger, regulated watersheds. We recommend base flows of between 4,500 cfs in critical dry years and 8,000 cfs in wet years (table 7.4), which is similar to both existing regulated conditions and pre-dam historical conditions.

The winter base flows are a minimum base flow and are designed to occur in combination with unregulated run-off and flood control releases. Figure 7.2 shows the winter base flows as a straight line, but it is just a base flow that supports larger, unregulated peak flows. As a result, actual flows at Bend Bridge will be far more variable then depicted in figure 7.2.

Table 8.4: Winter base flow release from Keswick

	Critical	Dry	Normal Dry	Normal Wet	Wet
Winter base flow	4,500	6,000	6,500	7,000	8,000

Fairly substantial winter base flows combined with run-off events from less regulated tributaries will increase the frequency of inundation of channel margins and secondary channels that may serve as important rearing habitat.

8.2.4 Winter and Spring Peak Flows

The geomorphic flow targets discussed below may require additional releases from Shasta but are not explicitly included in figure 7.2 because they are short duration flow events that would be constructed upon unregulated run-off peaks. Smaller magnitude winter and spring peaks for fish rearing discussed below should be sufficient, particularly if reshaped, to achieve geomorphic targets below Red Bluff when combined with unregulated run-off.

Bed Mobilization

We recommend increasing the frequency of channel migration and bed mobilization flows during dry and below normal years for the reasons discussed in Appendix B. On the basis of thresholds discussed in chapter six, we recommend measures to achieve bed mobilization flows in most years (table 7.5). Based on the analysis of flow thresholds presented in chapter five, 35,000 cfs in dry years should be enough to initiate bed mobilization, at least locally, but it is probably not enough to precipitate widespread bed mobilization. The recommended peak flows in wetter years should be sufficient to precipitate significant bed mobilization in below normal, above normal, and wet years.

Table 8.5: Bed mobilization flow targets for Sacramento River between Keswick and Bend Bridge during different year types.

	Critical	Dry	Below Normal	Above Normal	Wet
Bed Mobilization		35,000	65,000	85,000	105,000

Some fish biologists have expressed concerns that high flow, even relative modest high flowss, could scour redds and thereby harm salmonid reproduction (ESSA, 2008; Stillwater, 2007). Based on our flow threshold analysis (chapter 5), we doubt that flows below 25,000 cfs will substantially mobilize the bed or scour redds. Much higher flows will significantly mobilize the bed, but the biological impact is not well documented and dependent on timing.

The ideal timing for bed mobilization is in early March after most salmon fry have emerged from the gravel and before bank swallow initiate nesting on cut banks. We expect that most mobilization events will result largely from unregulated run-off that humans are unable to control. While it seem logical that scouring flows would impair salmon reproduction, the natural hydrograph was characterized by multiple bed mobilization events in most years, raising the question of whether high, scouring flows actually limit salmonid reproduction. Under natural conditions, however, young fish would have had abundant floodplain and backwater habitat that is now scarce due to levees and reduced channel complexity.

Bed Scour

Information regarding the bed scour process and the magnitude of flow necessary to scour the bed is limited. While we recognize the potential importance of bed scour processes, we have not recommended any measures to precipitate bed scour due to the high level of uncertainty and the sheer magnitude of flow that may be necessary. We do, however, expect some bed scour to occur during the larges flow events once every ten years or more.

Channel Migration

Bank erosion and channel migration is a natural process that shapes the river ecosystem and provides habitats for riverine species. Bank swallows nest in recently eroded cut banks. Coarse and fine materials eroded from cut banks create substrates for growth of riparian vegetation and spawning salmon respectively. Turbid water resulting from bank erosion can provide important cover habitat for juvenile fish that would otherwise be very vulnerable to predation.

Some degree of bank erosion and channel migration will occur at the bed mobilization flows identified above and the spring pulse flows described below. Flows sufficient to erode unprotected banks already occurs and will continue to occur in wet and above normal years due to unregulated flows irregardless of a flow prescription. Furthermore, removal of bank revetment may be a more cost water efficient measure to facilitate natural channel migration then intentional flow releases. For all of these reasons, we have not developed a specific flow recommendation for bank erosion and channel migration at this time.

Key Uncertainties:

- How much does the bed need to be mobilized? Is it sufficient to barely move the gravel and cobble substrate on the surface of the bed, or is it necessary to achieve full scale mobilization.
- What duration of peak flow is necessary to adequately mobilize the bed?
- How much does or could natural rates of bank erosion contribute to the overall turbidity and sediment load of the Sacramento River.

8.2.5 Spring Base Flow

The purpose of the spring base flow is to substantially increase rearing habitat along channel margins and within high flow channels for 45 to 120 days. Under natural conditions, spring flows (March and April) were consistently the highest, prolonged flow of the water year and resulted in widespread inundation of flood plain habitats. Under existing conditions, spring flows are substantially reduced, and a system of levees prevents widespread floodplain inundations.

We propose base flows to inundate secondary channels for rearing habitat during the spring months (table x). According to a recent study, a large number of secondary channels become fully connected to the channel at flows above 12,000 cfs (Kondolf, 2007). In critical dry years, flows would average 10,000 for thirty days after March 15, but small pulses greater then 12,000 cfs would increase connectivity with rearing habitat. In wetter years, larger flows would presumably create more rearing habitat and connectivity for longer periods of time.

Figure 8.6: Spring Pulse Flows at Bend Bridge

	3/15 - 3/31	4/1 - 4/14	4/15 - 4/30	4/30 - 5/14	5/1 - 5/14	5/15 - 5/31	6/15 - 6/30
Critical	10,000	10,000	8,500				
Dry	10,000	12,000	12,000	8,500			
Below Normal	12,500	12,500	12,500	8,500			
Above Normal	12,500	14,000	14,000	14,000	8,500		
Wet	14,000	14,000	14,000	14,000	14,000	8,500	

Key Uncertainties:

- Do flows in excess of what is necessary to inundate high flow channels create better rearing habitat and more food then flows barely sufficient to inundate these habitats?
- What is the optimal flow and residence time to create ideal rearing habitat conditions (food supply, temperature, and depth) in the secondary channels.

- Is the secondary channel habitat significant enough to substantially improve rearing conditions relative to the rearing habitat in the channel.

8.2.6 Floodplain Inundation Flows

The purpose of the floodplain inundation flows is to inundate floodplains in the Sutter and Yolo flood bypasses for rearing habitat and food web productivity. The flow objective is to create substantial inundated floodplain habitat for 30-60 days between February 15 and April 15 in most year types. To economize on the amount of water necessary to inundate these bypasses, we propose modifying the Tisdale and Fremont weirs to created inundated flood plain habitat more frequently and for a longer duration. Based on the floodplain process analysis in chapter 5, we developed a schedule of flood flow targets for various year types to create good conditions for floodplain rearing and foodweb productivity in nearly all year types (table 7.7).

The floodplain inundation flows are not explicitly included in figure 7.2. The winter and spring pulse flows described above combined with unregulated run-off at Colusa and environmental flows from the Feather and Yuba should be sufficient to achieve the table 7.7 targets.

Table 8.7: Recommended average monthly flows at Verona and Nicolaus on the Feather to create inundated floodplain habitat in the Yolo and Sutter Bypasses for various year types (30-60 days).

	Year Type				
	C	D	BN	AN	W
Nicolaus (Feather)			12,000	15,000	20,000
Freemont Wier		25,000	30,000	37,500	45,000
Tisdale Weir		25,000	30,000	35,000	40,000
Verona		25,000	35,000	45,000	55,000

Key Uncertainties:

- What magnitude of flow is necessary in the Sacramento and Feather Rivers to move water across the bypasses assuming a modified weir structure?
- What is the optimal timing and flow to create optimal habitat conditions on the bypasses (depth, velocity, temperature, residence time) and food web productivity for the estuary?

8.2.7 Spring Snowmelt Recession Limb

The purpose of the spring, snowmelt recession is to periodically provide conditions for recruitment of Fremont cottonwoods, a keystone species in the riparian ecosystem. As discussed in appendix A and chapter 5, recruitment of cottonwoods requires a high spring flow followed by a gradual decline in order to enable cottonwoods set roots into the groundwater on higher surfaces that are relatively immune from scour during subsequent winter floods. An earlier analyses (TNC, 2003) determined that a range of 23,000 cfs to 37,000 cfs inundates the appropriate seedbed for establishment of cottonwood.

Cottonwood trees need not be recruited in all years to ensure a sustained riparian forest ecosystem.

We recommend recruitment flows of 23,000 in above normal years and 37,000 cfs (or somewhere in that general range) in wet years for 4-7 days between mid April and mid May followed by a gradual recession for 8-10 weeks. This flow regime should enable seeds released in mid spring to germinate on relatively high surfaces and then gradually extend roots to the permanent water table before the subsequent growing season.

8.2.8 Summer Base Flow June 15 to September 15

We have designed summer base flows between Keswick and Red Bluff to economically provide suitable conditions for winter run, spring run, and steelhead that spend a temperature sensitive portion of their life cycle between Keswick Dam and Red Bluff diversion Dam (table 7.8). Under natural conditions, these fish would have migrated upstream of Keswick and Shasta, but there mainstem habitat is now limited to the cold tail water provided by reservoir releases. Current base flows are artificially high to deliver water to Sacramento Valley irrigation districts and the Delta. Ideally, these unnaturally high flows could be shifted to the early spring to restore a prolonged spring pulse flow for rearing habitat and aquatic productivity, but providing a more natural flow regime (3,000 to 5,000 cfs) could result in lethal water temperatures for incubating winter run-eggs. Furthermore, flows of only 3,000-5,000 cfs would not provide sufficient water for both diversion into the north valley canals and base flows all the way downstream to the Delta. Therefore, we have proposed an intermediate level summer base that falls at the mid-range between historic base flows and existing base flows between Keswick and Red Bluff.

Table 8.8: Summer base recommendation at various points on the Sacramento River for all year types.

Below Keswick	8,000
Below Red Bluff Diversion	6,000
Below GCID Diversion	4,500
Below Colusa	4,000

Below Red Bluff and the GCID diversions, we have proposed substantially reduced summer base flows in order to shift more flow to the early spring months without disrupting the cold water pool management regime. The primary purpose is to provide better habitat conditions in the spring, but restoring a more natural summer base flow may have environmental benefits in its own right. Summer base flows substantially below the 8,000 cfs needed to inundate off-channel backwaters will create more natural summer conditions and thus may discourage invasive plant and animal species that may out compete natives under the existing artificial summer base flow regime. Seasonally desiccated off-channel habitats may be more productive then perennially inundated wetlands and less likely to harbor exotics predators such as bull frogs and bass. Lower summer water levels may be less beneficial to late germinating invasive vegetation such as tamarisk that can out compete native cottonwoods.

Key Uncertainties:

1. Assuming no changes to the cold water pool management, what flow is necessary to maintain sufficient water temperatures for over summering life stages of winter-run, spring-run, late fall-run and steelhead?
2. Will low flows and corresponding higher temperatures increase populations of non-native warm water fish that prey upon or compete with native species?
3. Will summer base flows be sufficient between Red Bluff and GCID to maintain water temperature conditions suitable for juvenile salmonids or adult migrating salmonids?
4. Will more "natural" conditions provide better habitat and feeding conditions for native species?

8.3 Feather River

Summary recommendations for Sacramento River base flows, key ecological flows, and a flow schedule are presented in tables 7.1 – 7.3. Illustrative flow recommendation hydrographs for each year type are presented in figure 7.2.

8.3.1 Fall Base Flows

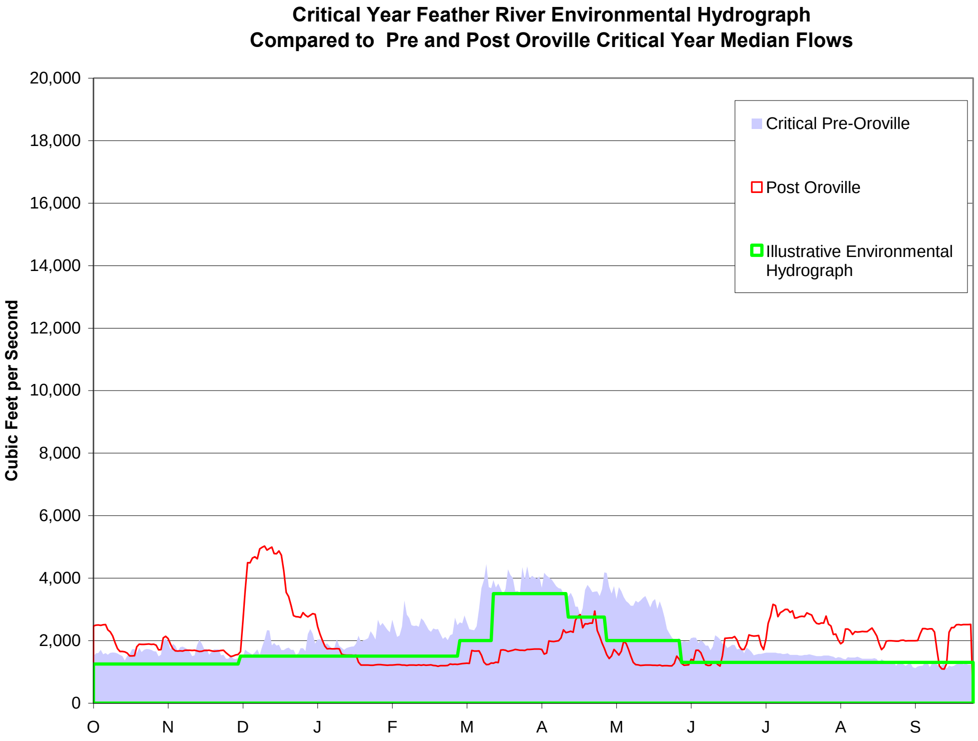
We propose stepping flows down from a stable summer base flow (see below) in late September (table 7.10) to fall spawning flows specified by the recent Oroville relicensing proceeding. The new minimum instream flows below Thermalito Afterbay range from 1,000 cfs in the late spring and summer to 1,200 -1,700 cfs during the fall winter months. Under both natural and regulated conditions, flows in early fall are the lowest flows of the year. The primary purpose of lowering base flows in the fall closer to their historic and regulatory minimum levels is to economize on water and shift the saved water to the spring months when it is more important. The secondary purpose is to provide stable base flows for spring and fall-run spawning and potentially to trigger spring-run spawning. The fall base flows must be stable to avoid dewatering or redds that may occur when flows are substantially dropped from the norm.

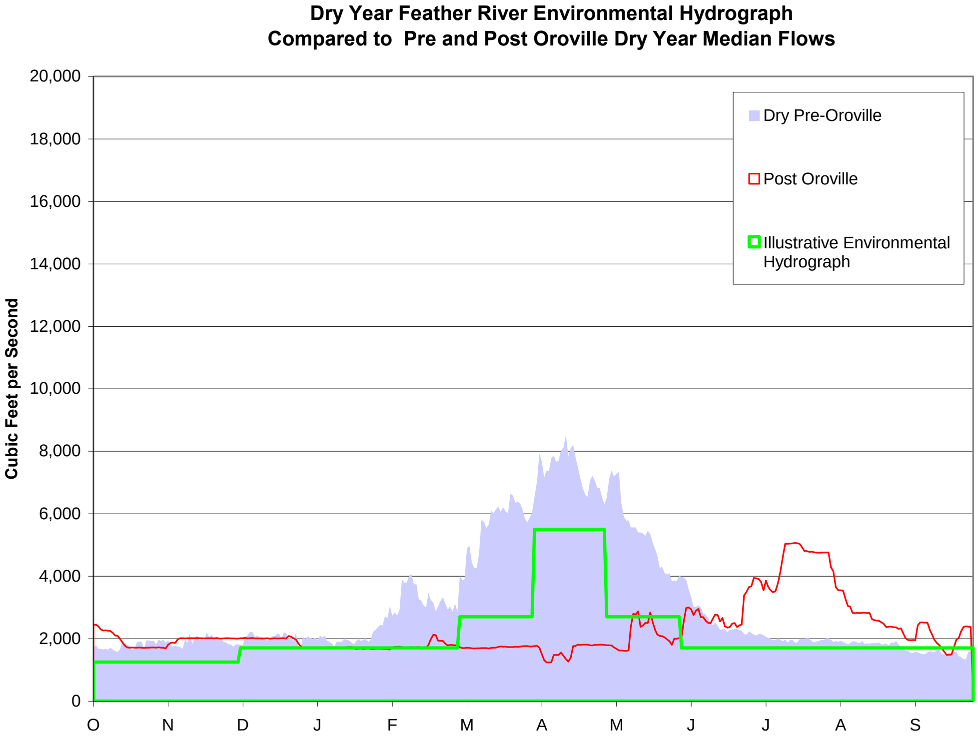
Key Uncertainties

- Are proposed fall base flows sufficient for area of spawning habitat?

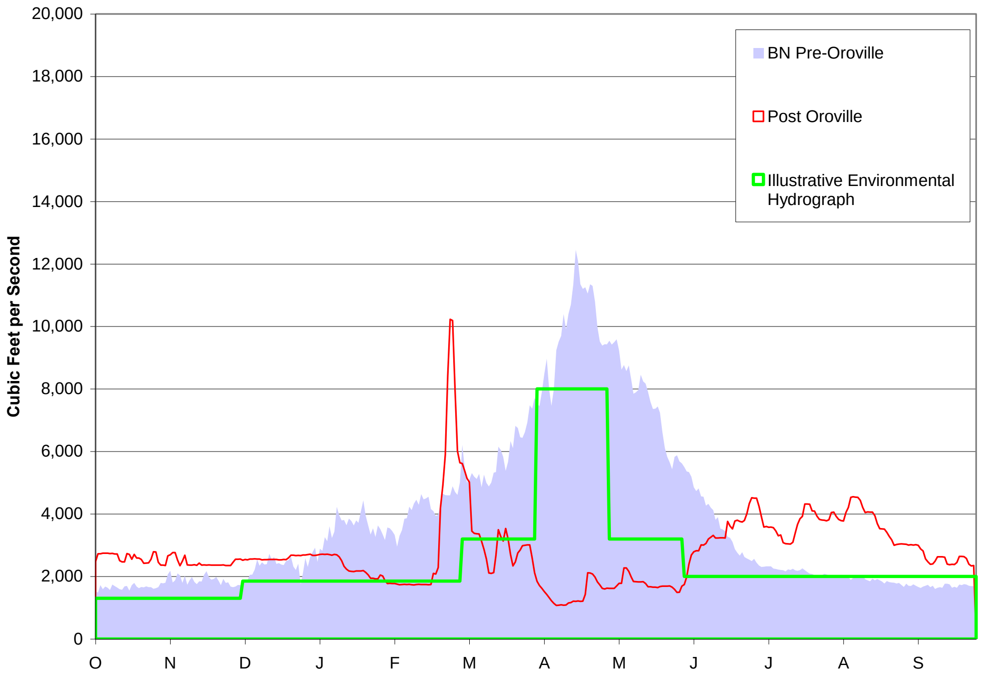
Will reduce fall base flows cause adverse impacts in the Delta ecosystem?

Figure 8.3: Illustrative environmental hydrographs for five year types on the Feather River relative to pre and post Oroville hydrographs.

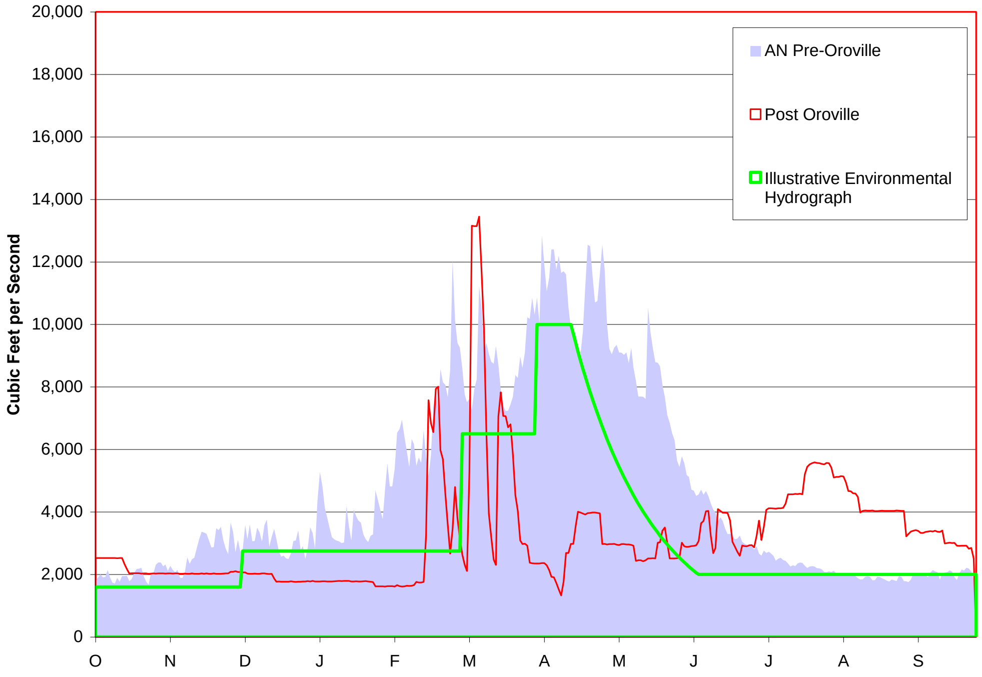


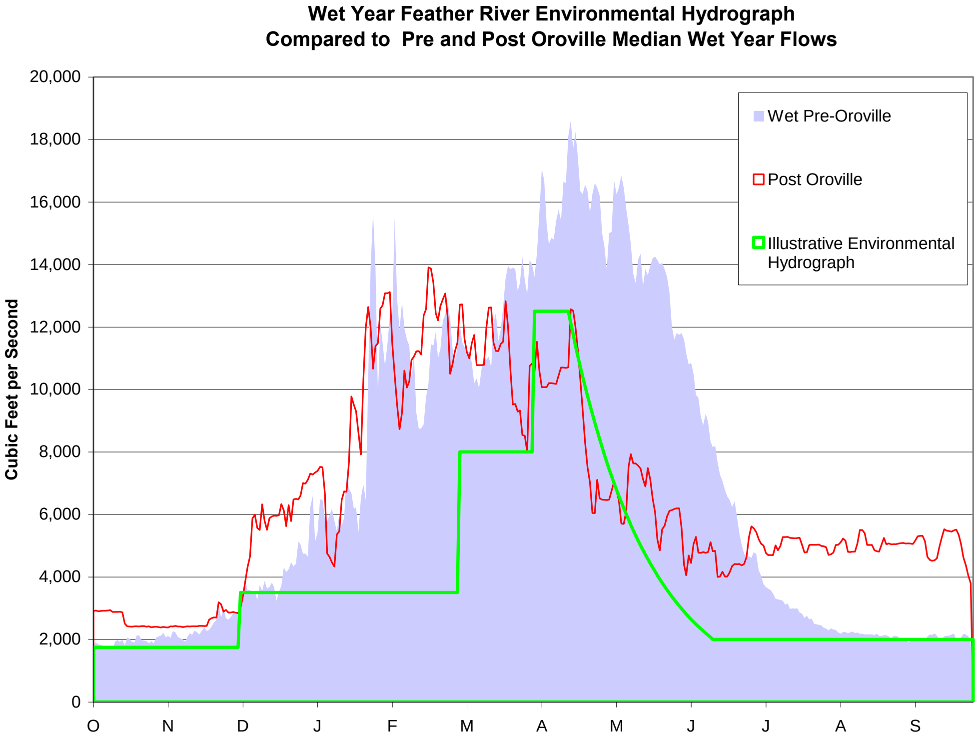


Below Normal Year Feather River Environmental Hydrograph Compared to Pre and Post Below Normal Oroville Median Flows



Above Normal Year Feather River Environmental Hydrograph Compared to Pre and Post Oroville Above Normal Median Flows





8.3.2 Winter Base Flows

The purpose of the winter base flows is to provide stable conditions for incubating salmonids and reduce flashy regulated hydrology that can result when run-off from unregulated tributaries, particularly the South Fork Yuba, is not modulated by less flashy natural hydrology from the larger, regulated watersheds. We recommend base flows of between 1,500 cfs in critical dry years and 3,500 cfs in wet years (table 7.10), which is similar to both existing regulated conditions and pre-dam historical conditions.

The winter base flows are a minimum base flow and are designed to occur in combination with unregulated run-off and flood control releases. Figure 7.3 shows the winter base flows as a straight line, but it is just a base flow that supports larger, unregulated peak flows. As a result, actual flows below the confluence with the Yuba will be far more variable then depicted in figure 7.3.
Fairly substantial winter base flows combined with run-off events from less regulated tributaries will increase the frequency of inundation of channel margins and secondary channels that may serve as important rearing habitat.

8.3.4 Winter and Spring Peak Flows

The geomorphic flow targets discussed below may require additional releases from Shasta but are not explicitly included in figure 7.3 because they are short duration flow events that would be constructed upon the spring rise or ordinary flood control releases. Smaller magnitude spring pulse flows for fish rearing discussed below should be sufficient, particularly if reshaped, to achieve geomorphic targets.

Bed Mobilization
We recommend increasing the frequency of channel migration and bed mobilization flows during dry and below normal years for the reasons discussed in Appendix B. On the basis of thresholds discussed in chapter six, we recommend measures to achieve bed mobilization flows in most years (table 7.5). Based on the analysis of flow thresholds presented in chapter five, 35,000 cfs in dry years should be enough to initiate bed mobilization, at least locally, but it is probably not enough to precipitate widespread bed mobilization. The recommended peak flows in wetter years should be sufficient to precipitate significant bed mobilization in below normal, above normal, and wet years.

Table 8.12: Bed mobilization flow targets for Feather River below Oroville

	Critical	Dry	Below Normal	Above Normal	Wet
Bed Mobilization		10,000	25,000	35,000	50,000

Some fish biologists have expressed concerns that high flow, even relative modest high flowss, could scour redds and thereby harm salmonid reproduction on the Sacramento River (ESSA, 2008; Stillwater, 2007). Because are bed mobilization flows for the Feather River are based on statistical estimates rather then empirical evidence of bed mobility, the potential for red scour is a big uncertainty, but we doubt it will occur at 25,000 cfs or less and the greater magnitude flows prescribed for above normal and wet are likely to happen from flood control releases regardless of our flow recommendations.

The ideal timing for bed mobilization after late February when most salmon fry have emerged from the gravel. We expect that most mobilization events will result largely from unregulated run-off that humans are unable to control. While it seem logical that scouring flows would impair salmon reproduction, the natural hydrograph was characterized by multiple bed mobilization events in most years, raising the question of whether high, scouring flows actually limit salmonid reproduction. Under natural conditions, however, young fish would have had abundant floodplain and backwater habitat that is now scarce due to levees and reduced channel complexity.

Bed Scour
Information regarding the bed scour process and the magnitude of flow necessary to scour the bed is limited. While we recognize the potential importance of bed scour processes, we have not recommended any measures to precipitate bed scour due to the high level of uncertainty and the sheer magnitude of flow that may be necessary. We do, however, expect some bed scour to occur during the larges flow events once every ten years or more.

Channel Migration

Bank erosion and channel migration is a natural process that shapes the river ecosystem and provides habitats for riverine species. Bank swallows nest in recently eroded cut banks. Coarse and fine materials eroded from cut banks create substrates for growth of riparian vegetation and spawning salmon respectively. Turbid water resulting from bank erosion can provide important cover habitat for juvenile fish that would otherwise be very vulnerable to predation.

Some degree of bank erosion and channel migration will occur at the bed mobilization flows identified above and the spring pulse flows described below. Flows sufficient to erode unprotected banks already occurs and will continue to occur in wet and above normal years due to unregulated flows irregardless of a flow prescription. Furthermore, removal of bank revetment may be a more cost water efficient measure to facilitate natural channel migration then intentional flow releases. For all of these reasons, we have not developed a specific flow recommendation for bank erosion and channel migration at this time.

Key Uncertainties:

- How much does the bed need to be mobilized? Is it sufficient to barely move the gravel and cobble substrate on the surface of the bed, or is it necessary to achieve full scale mobilization.
- What duration of peak flow is necessary to adequately mobilize the bed?
- How much does or could natural rates of bank erosion contribute to the overall turbidity and sediment load of the Sacramento River.

8.3.5 Spring Base Flow

The purpose of the spring base flow is to substantially increase rearing habitat along channel margins and within high flow channels for 45 to 120 days. Under natural conditions, spring flows (March and April) were consistently the highest, prolonged flow of the water year and resulted in widespread inundation of flood plain habitats. Under existing conditions, spring flows are substantially reduced, and a system of levees prevents widespread floodplain inundations.

On the Feather River, we do not have good information regarding the flows necessary to inundate back-water channels. As a result we developed spring flow targets based on historical hydrology and an assessment of the flows necessary to inundate the Sutter Bypass (table 7.13). Wetter year spring flow pulses begin later in the spring and last longer, while dryer year targets economize on water early to get salmon out of the river before temperatures could become a problem in the lower Sacramento.

Figure 8.13: Spring Pulse Flows below Oroville

	3/1- 3/14	**3/14- 3/30**	**4/1- 4/14**	**4//14 - 4/30**	**5/1 - 5/14**	**5/15 – 5/31**
Critical	2,000	3,500	3,500	2,000		
Dry	2,700	2,700	5,500	5,500	2,700	
Below Normal	3,200	3,200	8,000	8,000	3,200	
Above Normal	6,500	6,500	10,000	10,000	5,000	3,000
Wet	8,000	12,500	12,500	11,000	6,000	4,000

Key Uncertainties:

- Do flows in excess of what is necessary to inundate high flow channels create better rearing habitat and more food then flows barely sufficient to inundate these habitats?
- What is the optimal flow and residence time to create ideal rearing habitat conditions (food supply, temperature, and depth) in the secondary channels.
- Is the secondary channel habitat significant enough to substantially improve rearing conditions relative to the rearing habitat in the channel.

8.3.6 Floodplain Inundation Flows

The purpose of the floodplain inundation flows is to inundate floodplains in the Sutter and Yolo flood bypasses for rearing habitat and food web productivity. The flow objective is to create substantial inundated floodplain habitat for 30-60 days between February 15 and April 15 in most year types. To economize on the amount of water necessary to inundate these bypasses, we propose modifying the Tisdale and Fremont weirs to created inundated flood plain habitat more frequently and for a longer duration. Based on the floodplain process analysis in chapter 5, we developed a schedule of flood flow targets for various year types to create good conditions for floodplain rearing and foodweb productivity in nearly all year types (table 7.7).

The floodplain inundation flows are not explicitly included in figure 7.3. The spring pulse flows described above combined with unregulated run-off from the Sacramento and Yuba Rivers will be sufficient to achieve the table 7.7 targets.

Table 8.14: Recommended average monthly flows at Verona and Nicolaus on the Feather to create inundated floodplain habitat in the Yolo and Sutter Bypasses for various year types (30-60 days).

	Year Type				
	C	D	BN	AN	W
Nicolaus (Feather)			12,000	15,000	20,000
Freemont Wier		25,000	30,000	37,500	45,000
Tisdale Weir		25,000	30,000	35,000	40,000
Verona		25,000	35,000	45,000	55,000

Key Uncertainties:

- What magnitude of flow is necessary in the Sacramento and Feather Rivers to move water across the bypasses assuming a modified weir structure?
- What is the optimal timing and flow to create optimal habitat conditions on the bypasses (depth, velocity, temperature, residence time) and food web productivity for the estuary?

8.3.7 Spring Snowmelt Recession Limb

The purpose of the spring, snowmelt recession is to periodically provide conditions for recruitment of Fremont cottonwoods, a keystone species in the riparian ecosystem. As discussed in appendix A and chapter 5, recruitment of cottonwoods requires a high spring flow followed by a gradual decline in order to enable cottonwoods set roots into the groundwater on higher surfaces that are relatively immune from scour during subsequent winter floods. Since we did not have estimates of flows suitable for riparian recruitment on the Feather River, we estimated a seedling establishment flow target based on the Sacramento riparian recruitment target. We simply scaled down the Sacramento target based on the ratio of the seedling establishment flow to the Q1.5. The seedling establishment flow on the Sacramento (23,000 – 30,000 cfs) is twenty seven to thirty seven percent of the bankfull discharge (Q1.5 to Q2) on the Sacramento. Assuming a similar proportional relationship on the Feather River, flows in the range of 9,500 to 18,000 would be suitable for seedling establishment.

We recommend seedling establishment flows of 10,000 in above normal years and 12,500 cfsin wet years for 4-7 days between mid April and mid May followed by a gradual recession for 8-10 weeks. This flow regime should enable seeds released in mid spring to germinate on relatively high surfaces and then gradually extend roots to the permanent water table before the subsequent growing season.

8.3.8 Summer Base Flow June 15 to September 15

The purpose of the summer base flow is to provide suitable temperature and rearing conditions for over summering salmonids, both juvenile and adult spring-run and steelhead. We propose base flow targets ranging from 1,300 in critical dry years to 2,000 cfs in above normal and wet years. These flows are very similar to natural summer base flows and are higher then the minimum existing minimum flows established during the recent relicensing proceedings. Existing minimum regulatory flows are 1,000 cfs in the summer. Existing actual flows are far higher then are recommendation.

APPENDIX A

LITERATURE REVIEW OF ENVIRONMENTAL FLOW METHODS

APPENDIX A

LITERATURE REVIEW OF ENVIRONMENTAL FLOW METHODOLOGIES

Over the past five decades, the development and application of environmental flow methodologies (EFMs) has rapidly progressed, as a means to help sustain or restore natural aquatic functions and ecosystems in the face of increasing demands for limited water resources. EFMs are science-based processes for assessing and/or recommending instream flows for regulated rivers. Their purpose may be as general as maintaining a healthy riverine ecosystem or as specific as enhancing the survival of targeted aquatic species. The growing prominence of EFMs in river management planning reflects a trend towards more sustainable use of the world's freshwater resources and a shift in focus from water quality to water *quantity* as a major factor in the degradation of rivers (O'Keeffe 2000).

In a comprehensive study of environmental flow methodologies, Tharme (2000) documented the existence of more than 200 EFMs, recorded worldwide. These included various modifications and hybrids of some commonly applied methods, site-specific approaches with limited applications, and procedures that are no longer in use. In actuality there are only a few dozen EFMs that are still widely applied. They can be divided into four major categories: 1) hydrological, 2) hydraulic rating, 3) habitat simulation, and 4) holistic methodologies (Tharme 2000). An overview of each of these categories is provided below, along with general strengths, weaknesses, and associated trends.

1.1. Hydrological Methods

Hydrological methodologies make up the largest proportion (30%) of environmental flow methodologies developed (Tharme, 2000). Hydrological methods are usually simple office procedures that recommend a proportion of a river's historical unregulated or naturalized flow regime as the minimum flow to maintain a fishery or other aquatic features. Recommended flows may be given on a monthly, seasonal, or annual basis. For example, the Tennant (Montana) method suggests 20% of mean annual flow (MAF) during the wet season and 40% MAF during the dry season to maintain "good" river conditions. Because of their simplicity and low resolution, Tennant and other hydrological methods are most appropriate for early reconnaissance-level project planning, to provide relatively quick and inexpensive estimates of flows to allocate for environmental purposes. Although biological factors are not explicitly considered in these methods, most were developed with some general biological basis (Caissie and El-Jabi 1995). In addition, hydrological methods assume that a minimum flow within the historic flow range for a river will sustain some proportion of native aquatic biota because the species survived such conditions in the past (Jowett 1997).

Hydrological methods have the primary advantages of being simple, straightforward, and relatively inexpensive to apply. Most require only historical flow records for a site, with little or no additional fieldwork. The simplicity of these methods, however, is also their greatest weakness. Because they do not incorporate site-specific habitat data, their ecological validity is often questionable (King et al. 2000). For example, these methods are frequently applied without regard to artificial changes in channel conditions (due to flow regulation or man-made structures) that may influence the ecological impact of recommended flows. EFMs in this category also should not be applied to river systems that do not approximate in size and type the reference river systems on which they were developed. Many hydrological methods do not address ecologically important intra- and interannual variations in flows. And unlike other methods, hydrologically based EFMs usually cannot be used to compare alternative flow regimes. Finally, for some river systems it may be difficult to obtain the unregulated or naturalized flow data necessary to calculate recommended flows.

Despite their many limitations, Tharme (2000) suggested that hydrological methods will continue to be the EFMs of choice for the foreseeable future. However, we can expect to see progress in their development towards more ecologically defensible and sophisticated methodologies. The Range of Variability Approach (RVA) is one such recently developed EFM that is considered to represent a significant advance over earlier hydrological methods. Unlike other EFMs in its category, the RVA captures the complex intra- and interannual variability of natural flow regimes over multiple temporal scales, incorporates a large number of ecologically based hydrologic indices in its analysis, and utilizes an adaptive management program for monitoring and refinement (Richter et al. 1996, 1997). Since its inception, the RVA has attracted considerable interest among river scientists and managers as a new class of ecologically grounded hydrologically based environmental flow methodologies (King et al. 2000).

1.2. Hydraulic Rating Methods

Hydraulic rating methodologies comprise 11% of the global total of EFMs. They differ from purely hydrology-based methods in that they incorporate site-specific information on hydraulic parameters, such as wetted perimeter or maximum depth, as measured across riffles or other limiting river cross sections. These parameters are used as surrogates for the habitat available for target biota such as fish or macroinvertebrate communities. Hydraulic rating methods assess changes in the habitat surrogates in response to changes in discharge. Recommended flows are commonly set at a breakpoint in the parameter-discharge curve, interpreted as the flow below which habitat decreases rapidly with a decrease in flow and above which habitat increases slowly with an increase in flow (Loar et al. 1986).

Although they require some fieldwork and data analysis, hydraulic rating methods enable a relatively quick and simple assessment of flows for maintaining habitat of target biota. They are considered more advanced and biologically relevant than hydrological methods. Their inclusion of site-specific field measurements better adapts them to different river systems. Hydraulic rating methods, however, are based on a number of simplistic assumptions that often cannot be verified. Key among these is that the chosen hydraulic variable(s) can be used to determine the flow requirements of the target species. In addition, the validity of results is highly dependent on appropriate sampling of critical river cross sections and proper identification of a breakpoint in the parameter-discharge curve. The latter is frequently complicated by the existence of multiple breakpoints or the lack of any defined breakpoint in the curve. And like most hydrological methods, EFMs in this category generally do not address ecologically important intra- and interannual variations in flows.

In the past decade there have been few advances in the development or application of hydraulic rating methodologies. Instead, this category of EFMs seems to have been superceded by the more advanced habitat simulation methodologies for which they are precursors. The Wetted Perimeter Approach, the best-known EFM in this category, is still widely applied in North America and globally (Reiser 1989, King et al. 2000). However, it is likely that many other hydraulic rating methods will gradually fall into obsolescence as the science of EFMs advances in alternate directions (Tharme 2000).

1.3. Habitat Simulation Methods

Habitat simulation methodologies (28%) rank second only to hydrological methods in proportion of total EFMs. This group of flow methodologies includes the U.S. Fish and Wildlife Service's Instream Flow Incremental Methodology (IFIM), which is the most widely used EFM in North America and the world (Reiser 1989, Tharme 2000). IFIM and many other habitat simulation methods comprise systems of highly sophisticated computer modeling techniques that integrate site-specific hydraulic and hydrologic data with species specific habitat preference data (in the form of habitat suitability curves). Computer outputs are usually in the form of habitat usability-flow discharge curves for the various factors of interest, e.g., different life stages of one or two fish species. Practitioners evaluate these curves and determine flow regimes based on the levels of protection (habitat usability) desired for each factor of interest. Because there is considerable potential for conflicting habitat requirements in this final step, it is necessary to have clear management objectives and a good understanding of the stream ecosystem when using IFIM and other habitat simulation methods to develop flow regimes.

Habitat simulation methods are flexible and adaptable. They incorporate site-specific and species specific information, so can be tailored for particular conditions and management goals. They can be used to analyze flow-related trade offs among multiple species and life stages. They may be modified to recommend flows for riparian vegetation, sediment flushing, recreation, and any number of other instream purposes. They are capable of addressing ecologically important intra- and interannual variations in flows for target species. Habitat simulation methods are also often perceived as scientifically objective and legally defensible; thus, they may be suitable for allocating instream flows in highly controversial situations (Estes 1996).

The focus of habitat simulation methods on specific target species and/or instream uses raises the risk that other essential components of the stream ecosystem may be overlooked (Prewitt & Carlson 1980). On the other hand, when these methods are used to address multiple management objectives for a river system, there are no set procedures for resolving conflicting flow requirements. The flexibility that habitat simulation methods provide make them among the most difficult EFMs to apply and interpret. Another important consideration, especially for developing countries, is that habitat simulation methods are often time-consuming, costly, and require considerable technical and scientific expertise for proper application. Modeling applications can be run without sufficient understanding of input and output processes; therefore, there is high potential for misuse by improperly trained persons. Other important sources of error or bias for modeling outputs include selection of representative cross sections for collecting hydraulic data, and construction of species-specific habitat suitability curves. Finally, a commonly cited criticism of PHABSIM, the modeling system used with IFIM, is the seeming lack of relation between fish and habitat usability estimates produced by the models (Orth and Maughan 1982).

Habitat simulation models, though the subject of much criticism, are still highly regarded by many river scientists. Current trends in their development are more advanced modeling techniques, multi-dimensional graphics, and integration of GIS display platforms.

1.4. Holistic Methods

These methods are relatively new to the science of environmental flow management. They were first documented by Tharme (1996) and currently make up 7.7% of total EFMs (Tharme 2002). Holistic approaches rely largely on multidisciplinary expert panels to recommend instream flows (Tharme 2000). They represent a significant departure from earlier environmental flow methods, in that their recommendations are almost wholly subjective. However, more advanced holistic methods, such as the Building Block Methodology (BBM), may utilize several of the analytical tools described for other EFMs to assist in the decision-making process (Tharme 2000). An early step in the BBM and some other holistic methods is identification of the magnitude, timing, duration, and frequency of important flow events for various ecosystem components and functions. The decision-making process for integrating these flow events may include a number of activities, including workshops, site visits, and limited data collection and analysis. The final output of the consensus process is a recommended flow regime to meet various specific management objectives.

Most holistic methods are relatively quick and inexpensive to apply. They have limited requirements for technical expertise and hydrologic data. And with appropriate interdisciplinary representation, these methods can comprehensively address all major components of the riverine ecosystem, including geomorphological, riparian, biological, water quality, social and other elements. Holistic methods can recommend flows at a variety of temporal scales. They are site-specific and allow for assessment of whole stretches of river rather than extrapolation from sample cross sections. The major weakness of holistic methods is the subjectivity of their approach, which may open their findings to controversy and criticism.

Holistic methods are still very much in the infancy of their development. Most of these methods have their roots in South Africa and Australia. Few have been applied outside of these countries of origin. Application of holistic methods for environmental flow management is expected to grow rapidly over the next decade, as EFMs become better established as river management tools in developing countries. Holistic methods are well suited for use in these countries, where data, finances, and technical expertise are frequently limited.

2. METHOD FOR DEVELOPING ENVIRONMENTAL FLOW RECOMMENDATIONS FOR THE SACRAMENTO AND FEATHER RIVERS

We have employed a version of the holistic approach practiced in South Africa and Australia (King et. al. 2000) to identify an environmental flow regime for the Sacramento River. This approach relies heavily on hydrological evaluations, previous studies, and expert opinion to estimate environmental flow requirements and develop a long-term adaptive management plan for implementing and refining an environmental flow regime over time. The results of the holistic approach provide a framework for increasing knowledge regarding the relationship between flow and environmental objectives and refining water management practices over time. The output of the holistic method envisioned here provides not only an estimate of environmental flow requirements, but more importantly, an explicit identification of key assumptions and uncertainties that need to be tested overtime to more accurately describe the flow requirements necessary to achieve environmental objectives.

We made two important assumptions in generally applying this method to the Sacramento River.

- Similarities in both the restoration objectives and the hydrologic, geomorphic, and ecological conditions on the Sacramento River will result in relatively similar prescriptions for environmental management flows. We believe this assumption is well supported by the environmental conditions and historical alteration of this river.

- The flow necessary to achieve restoration objectives may vary greatly depending on non-flow restoration actions such as improving spawning habitat, reconstructing degraded channel, removing levees to restore floodplain habitat, modifying and screening water diversions, reducing polluted run-off, managing ocean harvest, and other factors. In general, non-flow restoration actions will reduce the amount of water necessary to achieve restoration objectives.

The holistic approach applied in this study consists of the following 6-step process to identify an environmental flow regime:

1. Identify specific environmental objectives (i.e,. target species, aquatic and riparian communities, and desired ecological conditions that are flow dependent).
2. Approximate the timing, magnitude, frequency, and duration (TMDF) of flows necessary to support target species, communities and desired ecological processes.
3. Compare existing vs. historical hydrology to understand natural hydrologic patterns and how they have been altered.
4. Identify obvious gaps between objective flow requirements and existing flows.

5. Develop an environmental flow hydrograph to achieve ecological objectives based upon a clear understanding of historical and existing hydrologic patterns, and identify key hypotheses and uncertainties regarding the relationship between flow patterns and environmental objectives.
6. Design an adaptive management program to further test and refine environmental flows.

1) Identify specific environmental objectives (i.e,. target species, aquatic and riparian communities, and desired ecological conditions that are flow dependent).

Well-articulated target ecological conditions and desired species and communities are necessary for establishing environmental flows. Despite the correctly vogue concept of restoring ecosystem processes and avoiding species specific approaches, there is no getting around the fact that key species need specific hydrologic conditions at specific times. This analysis will include both aquatic and riparian communities and the flow parameters necessary to sustain these communities such as floodplain inundation, appropriate water temperature, or creation of structural habitat through geomorphic processes. These specific environmental objectives may vary by region, sub-basin, and reach of the river.

2) Approximate the timing, magnitude, frequency, and duration (TMDF) of flows necessary to support target species, communities and desired ecological processes.

An environmental flow regime encompasses the adequate timing, magnitude, duration, and frequency of flows necessary to support target species and facilitate specific ecological processes encompassed in the stated environmental objectives. Where we understand the life cycle timing of various target species, it is relatively easy to identify the approximate timing and duration of flows necessary to support different life stages of target species. Estimating the required flow magnitude is far more difficult but can be informed by field data, results of numerical models, and general relationships described in the literature. Most short lived target species require adequate flows each year to reproduce, while longer lived species can sustain their populations with a lower frequency of flow conditions conducive to reproduction. For example, riparian forest species may only require recruitment flows every five to ten years to establish new seedlings.

Estimating the magnitude of flows necessary to support or optimize conditions for target species and processes is by far the most difficult element of the environmental hydrograph to approximate. Environmental engineers and biologists have developed relatively elaborate methods for determining ideal flow regimes such as physical habitat simulation (PHABSIM) and Instream Incremental Flow Methodology (IFIM) to identify optimum flow magnitudes based on known habitat preferences of target species, measured habitat conditions (velocity and depth) at various flows, and numerical models that predict habitat conditions at a range of flows. Numerical models that describe the width, depth, and velocity of the rivers at various discharges are useful for predicting river stage and temperature at various locations, factors that are important considerations for habitat or facilitating geomorphic and hydrologic processes. As discussed above, these models tend to focus on the needs of specific species and can sometimes produce results that are inconsistent with both holistic ecological process restoration and common sense. Furthermore, these models are often not calibrated, particularly at higher flows relevant to riparian recruitment, geomorphic processes, and spring outmigration temperatures. Nevertheless, we utilized the results of these models as a guide combined with other information to develop our environmental flow management hypothesis.

Where possible, we relied on actual data and measurements to estimate the flows necessary to achieve suitable conditions to support biological, riparian, and geomorphic objectives for temperature, floodplain inundation, and bed mobilization. In particular, we relied on USGS temperature gauges to characterize the relationship between temperature and flow. Similarly, we relied on previous studies of the rivers to characterize flows necessary to mobilize bed material and inundate the floodplain.

3) Compare existing vs. historical hydrology to understand natural hydrologic patterns and how they have been altered.

Analyses of historical hydrologic data is useful for describing natural patterns and identifying potential links between hydrology and the requirements necessary to maintain species and precipitate key processes. An analysis of historical patterns can provide clues about the timing, magnitude, duration, and frequency of flows under which target species have evolved. Identification of major changes between historical and hydrologic patterns combined with the life history requirements of various species can help generate hypotheses about how flow regulation may be limiting target species. We will use the an analysis similar to the Index of Hydrologic Alteration approach (Richter et al. 1996) and the Hydrograph Component Analysis (HCA) (Trush et al. 2000) to evaluate changes in flow patterns. The analysis similar to the IHA provides a quick statistical overview of how several important hydrologic attributes have changed. The analysis similar to the Hydrograph Component Analysis (HCA) method developed by McBain and Trush provides a detailed graphical analysis of historical and existing hydrologic conditions. While valid and useful, the statistical analysis in the IHA method is not substitute for visually comparing and evaluating key components of the pre- and post-dam hydrographs. Similarly, visual comparisons of pre- and post-alteration hydrographs don't always reveal important changes identified by the IHA method.

4) Identify obvious gaps between objective flow requirements and existing flows.

An analysis of historical flow patterns combined with an approximation of the TMDF of flows necessary to achieve objectives compared with the regulated flow regime can help illustrate obvious gaps between regulated flows and flows that may be necessary to achieve environmental objectives. We will plot TMDF flow requirements developed in Step 2 as an annual hydrograph and compare it with average regulated and historical conditions.

5) Develop an environmental flow hydrograph to achieve ecological objectives based upon a clear understanding of historical and existing hydrologic patterns, and identify key hypotheses and uncertainties regarding the relationship between flow patterns and environmental objectives.

This project identifies hypothetical restoration flow regimes but recognizes that the most reliable method for developing a restoration flow regime is through a long-term adaptive management program including a series of trials that test the effectiveness of various flow prescriptions. The purpose of developing the hypothetical flow regime is to develop a comprehensive hypothesis regarding the range of flows that may be necessary to restore ecological processes to the Sacramento River. However, the assumptions and uncertainties associated with the hypothetical flow regime are as important as the flow regime itself.

6) Design an adaptive management program to further test and refine environmental flows.

To cost effectively achieve restoration, managers will ultimately need to test these assumptions and limit the uncertainties through an adaptive management program consisting of a combination of numerical modeling, pilot flow studies, model calibration, and long-term restoration implementation.

CONCEPTUAL MODELS
FOR
GEOMORPHIC PROCESSES, FREMONT COTTONWOODS,
AND CHINOOK SALMON

APPENDIX B: CONCEPTUAL MODELS

Geomorphic Conceptual Model

1.0 Geomorphic Conceptual Model

Geomorphic processes are generally initiated at threshold flow levels. Bed mobilization and floodplain inundation do not occur until flows reach a threshold level sufficient to flow over bank or create sheer stresses necessary to mobilize gravel. Theoretically, no benefit occurs unless the threshold flow is achieved. No amount of flows less than the threshold will initiate bed mobilization or floodplain inundation, but in reality the actual threshold flow varies spatially from reach to reach. Research from several gravel bedded river systems indicates that a flow with a natural (unregulated) recurrence interval of every 1.5 years is generally needed to mobilize the bed and initiate over bank flows (Leopold et al. 1964). In reality, however, the threshold flows necessary to initiate geomorphic processes naturally vary from reach to reach depending on channel dimensions, slope, and the size of bed material. In general, sand bedded reaches mobilize at lower flows than gravel bedded reaches with larger particle sizes. Similarly, low gradient reaches flood at lower discharges than steeper reaches, particularly where large woody debris is allowed to accumulate.

Human modifications of the channels from their natural state have changed the relationship between flows and geomorphic processes and have therefore complicated the already difficult task of determining the flows necessary for precipitating various geomorphic processes. Gravel and channel restoration projects have changed and could continue to change the particle size of gravels and the channel dimensions and will thus further change the relationship between flow and geomorphic processes. More importantly, there is no single bed mobility threshold for any reach of the Sacramento River or any other river channel due to spatial vaiabilty in particle size and channel form (Kondolf et al, 2000; Wilcock, 1996).

There are varying degrees of bed mobilization, further complicating the definition of mobility and its distinction with bed scour. For this study, we attempted to estimate the flows necessary to mobilize and scour the bed. Bed mobility and bed scour are two different processes that occur at different flow thresholds. We use the term bed mobility to refer to mobilization of the surface of the channel bed. Bed scour is the process of scouring the bed deeper than its coarse surface layer. Incipient bed mobility is the threshold at which bed material begins to mobilize and occurs when the ratio of the critical sheer stress to the D_{50} equals 1. Incipient mobility can cause small movement of gravel across the top of the riffle without general mobilization of the riffle surface. Relatively frequent (every 1–2 years) incipient motion of gravels on a riffle may be adequate for certain objectives such as flushing fines from the gravels, but is probably not sufficient for certain geomorphic objectives such as restoring sediment transport or maintaining a dynamic, alternating bar sequence (Trush et al. 2000). General bed mobility mobilizes the entire riffle surface and occurs when the ratio of critical sheer stress to particle size D_{50} exceeds 1.3. General bed mobility may be necessary for restoring basic alluvial functions such as transporting coarse sediment from one riffle to the next.

Lastly, there is relatively little information regarding the flows necessary to perform various geomorphic objectives. Geomorphic processes associated with these objectives occur at very high flows, when field measurement is difficult. Hydraulic models and equations have been applied on the Sacramento to provide insight into the flows necessary to mobilize the bed and banks and inundate the floodplain, but in many cases these models have not been adequately calibrated at high flows or do not accurately describe the actual hydraulics at specific cross sections (Kondolf, 2000). Empirical observations are generally more reliable, but are often limited to specific study sites. In this study, we have relied on previously reported field measurements, modeling analysis, and general principles from the literature to roughly estimate the magnitude of flows necessary to initiate geomorphic processes.

For all of the reasons discussed above, it is not possible to estimate future flow levels necessary to initiate geomorphic processes across an entire river, but for the purposes of this study, a rough estimate will be sufficient to evaluate the feasibility of reoperating reservoir releases for the purpose of achieving geomorphic objectives. In this study, we have focused on the flows necessary to mobilize the gravel bedded reaches, because they are more relevant to salmon restoration and because they will also result in mobilization of the sand bedded reaches. For floodplain inundation, we have focused on the lowland floodplains because they can be inundated at lower flows with demonstrated fisheries benefits.

The geomorphic conceptual model in its most succinct form is that high flows exert sheer stress on and transport sediment over the many structural components of a river channel and floodplain (bed, banks, other exposed surfaces) causing them to change, erode, migrate, and otherwise respond in a qualitatively predictable manner.

The geomorphic conceptual model described below is based on inputs and outputs. Inputs into the model are in three categories: flow, topography, and sediment. The outputs of the model are physical functions that in turn support habitat and biotic responses in the river system.

The Sacramento River requires a variety of high flows ($Q_{1.5} – Q_{10}$) to clean sediment, rejuvenate alternate bar sequences, prepare the floodplain for vegetation recruitment, and drive channel migration. Each one of these functions supports a biotic or habitat response described previously in this chapter.

Figure 1 illustrates the relationships between flow, sediment, and topographic inputs, and ensuing geomorphic processes. The model has been simplified to focus primarily on restoration objectives of this project and the inputs we propose to modify to achieve these restoration objectives (outlined in bold).

Inputs

The driving inputs in the conceptual model fall into three categories: flow, topography, and sediment. In reality, the conceptual model is at least partly cyclic, where the outputs are also inputs into successive cycles.

Flow Inputs

Flow inputs can be divided into three broad categories: regulated runoff, unregulated runoff, and groundwater inputs. Regulated runoff refers to flow releases from reservoirs over which humans exert some control. This is of particular importance to this conceptual model because it is the input we propose to modify. Unregulated runoff refers to flow inputs on streams and rivers over which humans do not exert much control. As the distance between any point on a river and an upstream dam or diversion increases, so too does the influence of unregulated runoff. More tributaries enter the river and the unregulated drainage area increases downstream from the dam or diversion.

Groundwater refers to any inputs from subsurface flows. These are not, in fact, entirely independent of regulated or unregulated runoff. Interaction of high flows with floodplain surfaces, flow durations, and flow frequencies impact the quantity and timing of groundwater inputs. Similarly, groundwater inputs impact base flow levels in both regulated and unregulated systems. For the sake of simplicity and focus, groundwater is considered an independent input.

Topographic Inputs

The shape of the river channel and floodplain, the location of the levees, the amount and type of vegetation in the channel and on the floodplain, and other structural characteristics comprise the topographical inputs of the conceptual model. They determine the distribution and velocity of any given flow quantity. For example, if one hundred acre-feet of water enter into a river, the water will pass much more quickly and smoothly if the river channel resembles a pipe - smooth and straight. If the channel is small, the water may spill onto the floodplain. If the channel is flat and wide, the water may travel very slowly. If the channel is full of vegetation, it may impede the flow of water or concentrate it between walls of vegetation.

Upstream Sediment Inputs

Upstream sediment inputs refer to silts, sands, cobbles, gravels or boulders transported in the river system. The quantity and quality of upstream sediment input create the building blocks for depositional processes. Because dams capture most upstream sediment, in regulated rivers sediment inputs are mostly from unregulated tributaries and storage in banks and bars below the reservoir.

Flow Outputs

Regulated flow, unregulated flow, and groundwater establish the amount of water in a river system. The topographic features determine the surface over which the water flows, and how it flows over that surface. Together, they determine the discharge, stage, and velocity of the flows (producing sheer stress). Combined with the frequency of these flows, and the upstream sediment inputs, they drive various geomorphic processes in river systems (described below).

Process Responses

Gravel Bed Mobilization

Gravel bed mobilization refers to the entrainment of D50[1] gravels. This generally occurs in alluvial rivers during the historic annual or biannual floods or roughly the $Q_{1.5}$ flow or Q_2. The mobilization of the gravels "cleans" them by removing accumulated silt, algae and other fine particulates (Stillwater Sciences, 2001).

Floodplain Inundation

Floodplain inundation is a hydrogeomorphic process that serves important ecological functions. Floodplain inundation provides temporary access to floodplain habitat for aquatic species, recruits nutrients from the floodplain into the river, and helps to recharge groundwater levels in riparian zones. Inundated floodplains provide important spawning and rearing habitat for numerous species. Sacramento splittail are largely dependent on inundated floodplains for successful spawning and rearing. Juvenile salmon grow two to three times as fast on floodplains compared to channels. Due to large surface area, the volume of area in the photo zone, and relatively warm temperatures during cool winter and early spring months, floodplains generate larges amounts of phytoplankton and zooplankton during the critical spring months.

Determining the flow necessary to inundate floodplains is complicated by the fact that different types of rivers and river reaches overflow their banks at different flows. Floodplain inundation in gravel bedded streams generally occurs during flows at or above the historic biannual flood (Q_2) (Stillwater Sciences, 2001). However, floodplain inundation on lowland Rivers such as the lower Sacramento and Feather Rivers occurr far more often, creating extensive flood basins that were inundated for weeks or months in all but the driest years (Bay Institute, 1998). Even under post dam hydrology, many of these basins, such as the Yolo Bypass, would flood for weeks or days at flows far below the bankfull discharge.

It is not realistic to restore floodplain inundation to the historic flood basins of the Sacramento Valley. It would simply be too disruptive to the water supply and economic functions of the Sacramento River and its historical floodplains. It is, however, more realistic to intentionally inundate the system of flood bypasses designed to safely accommodate flood flows in the Sacramento River. The magnitude of flows necessary to inundate bypasses, as well as the frequency of bypass inundation is controlled by weirs at the upstream end of each bypass. Water does not enter the bypass and create inundated habitat until the river stage is high enough to overtop the weir. A study sponsored by the US Army Corps of Engineers, however, demonstrated that it is possible to inundate the bypasses at greater frequency and lower flows by intentionally notching the weirs (NHI, 2002). For the purposes of this study, we have assumed that you could inundate

---

[1] D refers to the length of the intermediate axis of gravels in a gravel bed. The D50 refers to the gravels in the 50th percentile size class, relative to the other gravels in the bed.

floodplains in flood bypass areas using this method at multiple weirs in the Sacramento Valley.

Bed Scour and Deposition

Bed scour and deposition refer to the removal of sediment and the corresponding replacement of sediment that occurs during storm events. The bed scour and deposition process discourages the river channel from being "fossilized" by riparian encroachment, maintaining it in a dynamic alluvial state. It is a greater level of mobilization than simply gravel bed mobilization, in that the bed degrades during the ascending limb of the hydrograph and aggrades on the receding limb of the hydrograph. Q_5 to Q_{10} floods generally provide the necessary shear stress to scour beds and redeposit with little net change in channel elevation (Trush et al. 2000)

Floodplain Sediment Scour and Deposition

Floodplain sediment scour requires greater sheer stress than simply inundation and generally occurs during flows equivalent to the historic Q_{10}. By exerting sheer stress, scour prepares floodplain surfaces for recruitment of riparian vegetation by removing existing vegetation, depositing clean sand and transporting new seed across the floodplain. Depositional processes also require higher flows to transport sediment away from the channel onto the floodplain. As flows increase, they spill across the floodplain, velocities slow, and the river deposits its sediments. Most floodplain sediments are the result of this process (Leopold et al., 1964). Deposition on the floodplain further reshapes and prepares the surfaces for recruitment.

Channel Migration

Channel migration is a function of stream energy and substrate strength. By eroding, channel migration recruits gravels and large woody debris into the system and directly and indirectly creates habitat complexity in the channel and floodplain. By depositing, channel migration prepares surfaces for pioneer species allowing for a diversity of riparian habitats. The process of channel migration is responsible backwater areas, sloughs, oxbow lakes, and secondary or abandoned channels (Bay Institute, 1998).

Channel migration requires the greatest amount of stream energy and generally requires large flows for a prolonged period, which can require very large volumes of water. Flows larger than the bank full discharge may be necessary to cause major channel migration or channel avulsion, but gradual channel migration may occur each year at some bends with flows well below the bank full discharge.

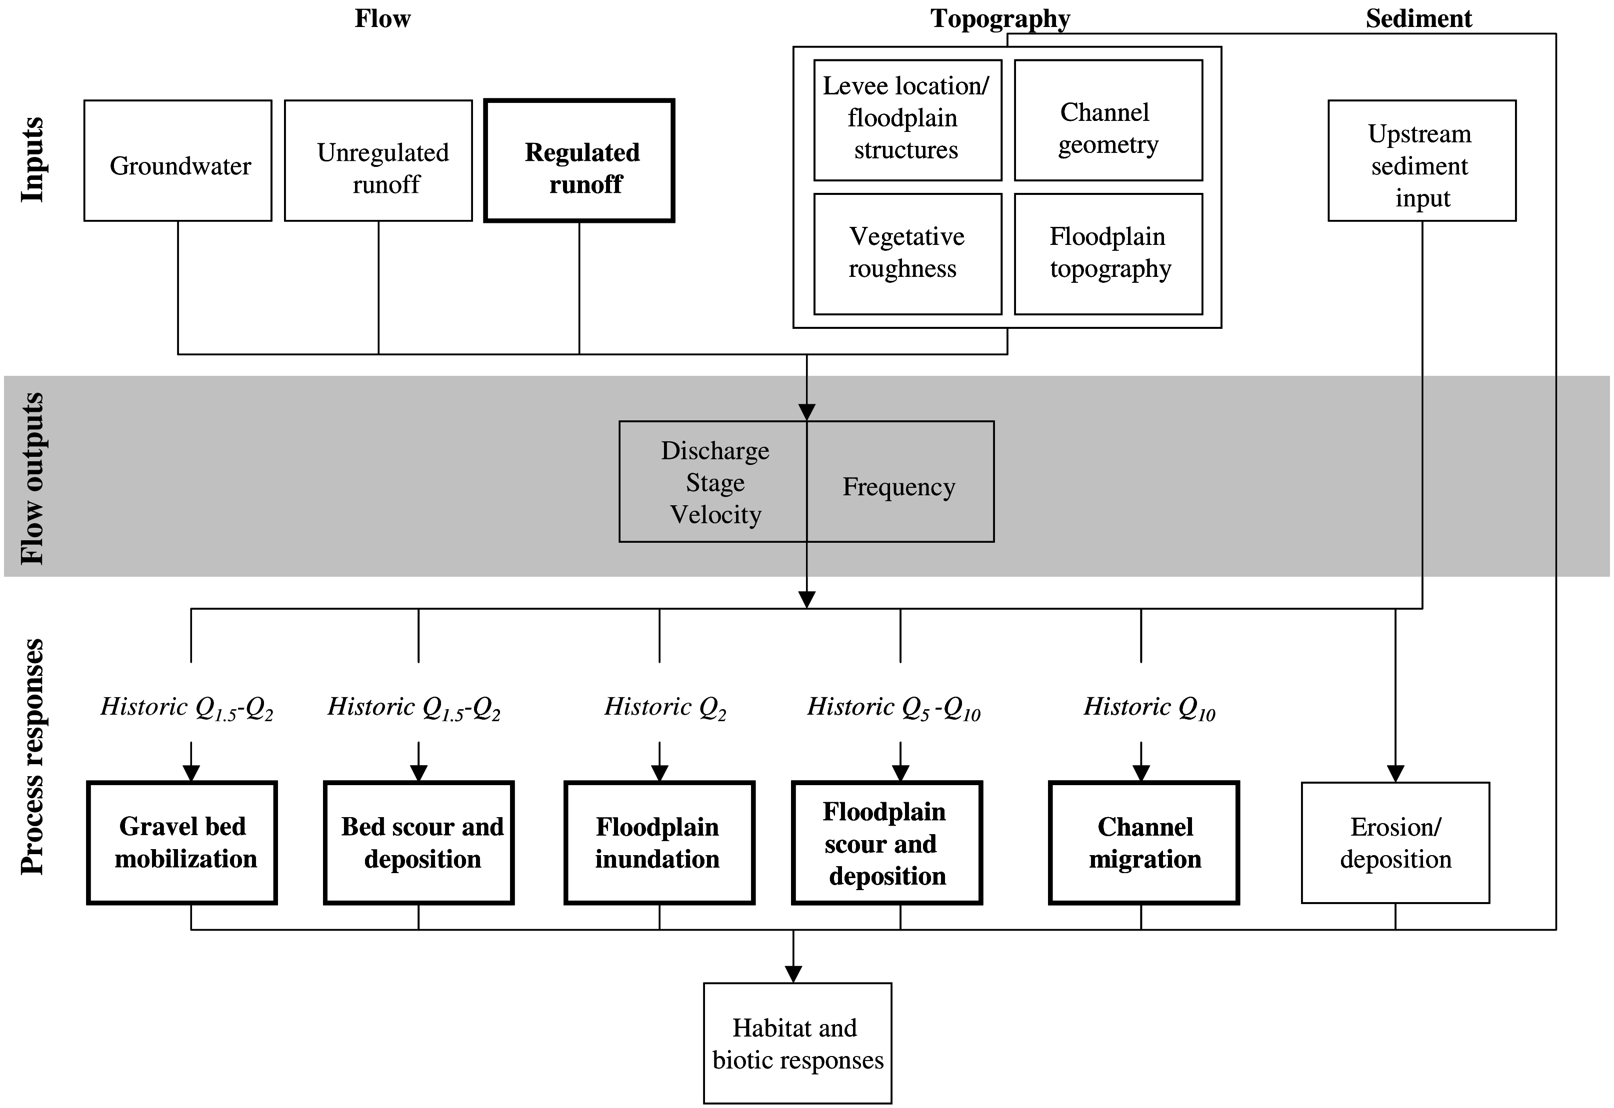

Figure 1. Geomorphic Conceptual Model. The figure above illustrates the relationships between flow, sediment, and topographic inputs, and ensuing geomorphic processes. The model has been simplified to focus primarily on restoration objectives of this project and the inputs we propose to modify to achieve these restoration objectives (outlined in bold).

Appendix C: Cottonwood Conceptual Model

4.2 Cottonwood Conceptual Model

Critical life history stages of cottonwoods and other pioneer riparian species in the Sacramento River basin are tightly linked with the hydrologic and geomorphic processes described in the previous conceptual model. Floodplain scour/deposition, channel migration, channel avulsion, and erosion/deposition processes generate new sites for cottonwood seedling establishment. Floodplain inundation provides moist substrates to sustain seedlings through their first growing season. Gravel and sand bed mobilization and bed scour/deposition help define a minimum elevation for cottonwood recruitment. Over time, these processes play a key role in determining the distribution, extent, and age structure of cottonwood communities in the Sacramento River basin. In turn, as cottonwoods mature, they have the potential to impact sediment deposition processes, channel stability, and channel dynamics. Both geomorphic processes and riparian habitat structure are important determinants of abundance and distribution of aquatic species such as chinook salmon, as described in the next section.

Land use activities and managed flow operations have greatly reduced the extent and integrity of riparian forests, particularly cottonwood forests, in the Sacramento Basin. Most existing cottonwood stands in the basin are mature, exhibiting older age structure than typical under natural conditions (McBain and Trush 2000, Stillwater Sciences 2002a, Jones & Stokes 1998). The absence of sapling cohorts in many reaches of the basin suggests that natural recruitment processes are not occurring under current conditions (McBain and Trush 2000, Jones & Stokes 1998, Stillwater Sciences 2002a). Without younger age classes, senescent trees cannot be replaced as they die, potentially leading to further substantial loss of this once dominant riparian vegetation community.

This conceptual model describes the ecological flows and geomorphic processes that drive establishment and recruitment of cottonwoods under natural conditions (Figure 2). The model identifies factors that currently limit cottonwood recruitment in the Sacramento Basin and opportunities for restoring this process through modification of flows and/or channel-floodplain geomorphology. Because channel attributes may differ widely among rivers and reaches of the Sacramento Basin, flow characteristics for restoration are described qualitatively in this model, with respect to channel and floodplain elevations.

Various species of cottonwoods share the characteristics discussed below. Any discussion specific to the Fremont cottonwood *(Populus fremontii),* the predominant species of the Central Valley (Stillwater Sciences 2002a, 2002b, 2006: McBain and Trush 2000), is noted as such.

4.2.1 Site Preparation

The creation of barren nursery sites through erosional and depositional processes is the first step in cottonwood seedling recruitment. Because cottonwood seeds contain very little endosperm, seedlings require full sunlight to produce photosynthates for growth and development; thus, cottonwood seedlings compete poorly on vegetated sites (Fenner et al. 1984). Under natural flow regimes, moderate 5- to 10-year flood events precipitate channel migration and the creation of point bars suitable for cottonwood seedling establishment (McBain and Trush 2000, Trush et al. 2000). Large flows scour away herbaceous plants and/or deposit fine sediments on floodplains, preparing new seed beds for pioneer riparian species (Mahoney and Rood 1998). In addition to point bars and floodplains, cottonwood forests may occur in high flow scour channels, oxbows, and other off-channel backwaters that receive scouring and sediment deposition (Stillwater Sciences 2002a).

Over the past century, continued agricultural and urban encroachment into riparian zones have greatly decreased the landscape area upon which cottonwood recruitment can occur (Stillwater, 2006; McBain and Trush 2000, Jones & Stokes 1998). In addition, flow regulation has reduced the intensity and frequency of winter and spring flood flows. The lower flows have led to a moderate reduction in the high-energy processes that, in less regulated river systems, create new seedbeds for recruitment—channel migration, point bar accretion, bed scour, and floodplain inundation. Levees and bank stabilization practices have reduced floodplain width and channel migration, in addition to isolating riparian backwaters (Stillwater, 2006). In addition, the loss of upstream sediment supply may have resulted in channel incision, requiring greater discharges for flows to inundate adjacent floodplains (TNC, 2003). The cumulative result of these processes has been a significant reduction in favorable germination sites for cottonwood seedlings.

There are several options for human intervention to increase availability of suitable recruitment sites for cottonwoods. Flood operations can be modified in wet years to allow shorter duration, but higher winter or spring peak flows sufficient to inundate floodplains and mobilize channel sediments (Jones & Stokes 1998). Reservoirs can be operated to release flows that mimic the 5- to 10-year flood events historically associated with cottonwood recruitment. Mechanical approaches include lowering floodplain surfaces for greater inundation frequency at current low flows, setting back or breaching levees to increase floodplain area, restoring the river's connection with abandoned side channels and backwaters, and artificially clearing floodplain sites to reduce plant competition.

Reductions in peak flows can lead to vegetation encroachment of more aggressive native riparian species into the formerly active river channel, further limiting cottonwood recruitment (Jones & Stokes 1998). Under natural hydrologic conditions, surfaces at the edge of low-flow channels were high-scour zones that generally prohibited the establishment of riparian vegetation. Under regulated conditions where the frequency of scouring flows has decreased significantly, vegetation —primarily alders and willows and forbes— can encroach along channel margins that were previously characterized by shifting and exposed gravel or sand bars (Stillwater Sciences 2002a, McBain and Trush 2000, FWUA and NRDC 2002). Vegetation encroachment can ultimately result in simplified and confined river channels resistant to fluvial geomorphic processes (e.g., channel migration) that create barren seedbeds for cottonwood recruitment. This does not appear to be a problem on the Sacramento River due to relatively frequent high flow events, but vegetation studies do indicate that recruitment is currently dominated by willows (TNC, 2003) to the potential detriment of cottonwoods. Therefore, maintaining the proper frequency and magnitude of high flows is necessary for maintaining habitats where cottonwoods are likely to become established and dominant.

4.2.2 Seedling Establishment

Establishment describes the process of seed release, germination, and growth through the end of the first year. This stage in the life cycle of cottonwoods is marked by high mortality rates, in both natural and regulated river systems (Mahoney and Rood 1998).

Most studies on Fremont cottonwood recruitment have focused on establishment of new stands through seed release, rather than vegetative sprouts. In the Sacramento Basin, mature female Fremont cottonwoods release hundreds of thousands to millions of seeds between April and June. Timing and duration of seed release are influenced by photoperiod and temperature, with maximal seed release generally occurring over a three-week period (FWUA and NRDC 2002, Stillwater Sciences 2002a). Seeds are dispersed by wind and water. They may travel up to a couple miles away, but more often they are deposited within a several hundred feet of the parent tree (Braatne et al. 1996). Dry Fremont cottonwood seeds are viable for one to three weeks (Horton et al. 1960). Once they are wet, their viability decreases to a few days (Braatne et al. 1996). Thus, for riparian restoration purposes it is important to understand the mechanisms that influence cottonwood seed release and dispersal, to ensure that timing of spring (snow-melt) pulse flows coincides with cottonwood seed dispersal. The spring pulse flows provide the moist nursery sites necessary for immediate germination of seeds (Mahoney and Rood 1998).

Cottonwoods germinate within 24–48 hours of landing on bare, moist substrates such as silt, sand, or gravel (John Stella, Stillwater Sciences, pers. com., 8 April 2003). For one to three weeks after germination, the upper layer of substrate must maintain moisture as the seedlings' root systems grow. Post-germination decline of river stage, which is presumed to control adjacent groundwater levels (JSA and MEI 2002), should not exceed approximately one inch per day (Mahoney and Rood 1998, Busch et al. 1992). This is the rate at which seedling root growth (0.16–0.47 inches/day; Reichenbacher 1984, Horton et al. 1960) can maintain contact with the capillary fringe of a receding water table in a sandy substrate. Cottonwood root growth and seedling establishment rates are higher in these soils than in coarser textured soils, which are more porous (Kocsis et al. 1991). In reaches with gravelly substrates, slower draw-down rates are necessary to support seedling establishment.

Mahoney and Rood (1998) describe the temporal and spatial window of opportunity for cottonwood seedling establishment as a "recruitment box", defined by timing of spring pulse ("establishment") flows/seed release and by seedling elevation relative to river stage. Optimal timing of seed release for successful establishment is during the gradually declining limb of a spring pulse flow. Optimal elevation relative to river stage is set at the upper end by the seedling's ability to maintain contact with the declining water table, and at the lower end by scouring and inundation flow levels in the first year, especially during the first winter.

The vast majority of cottonwood seedlings in this life stage die of drought stress because root growth is unable to keep pace with the decline in the water table (Mahoney and Rood 1998). Regulated ramp-down rates after spring pulse flows are often steep, in order to conserve water for human uses (Stillwater Sciences 2002b). Alternatively, decreased spring flows in regulated systems may cause seedlings to initiate at elevations too low to protect seedlings from flooding and scouring flows later in the growing season or during the winter (Mahoney and Rood 1998). In some rivers overwinter mortality of cottonwood seedlings is particularly high because flow regulation has reduced spring peak flows relative to winter peak flows (Stillwater Sciences 2002a).

High seedling mortality rates suggest that opportunities for improving cottonwood recruitment may be greatest in this life stage. In the first year of life, drought stress can be minimized by managing flood release flows for slow ramp-down rates after 5- to 10-year flood releases. Since reservoir spills often occur in wet years, reduced ramp-down rates may be accomplished by reshaping existing flood release flows without reducing water supply deliveries.

Artificial floodplain irrigation, either through flooding or a drip system, can also relieve summer drought stress for newly initiated seedlings. Agricultural irrigation close to the channel during the dry season would achieve similar gains in groundwater level. Grazing and trampling of seedlings by livestock can be minimized through grazing management practices or by building exclosures to protect cottonwood nurseries. To reduce winter mortality due to scouring and inundation, establishment flows can be discharged in spring rather than winter.

4.2.3 Vegetative Reproduction

In addition to seed dispersal and seedling establishment, vegetative reproduction is a potentially significant but commonly overlooked method for cottonwood recruitment along newly formed or previously established floodplains and point bars. Fremont cottonwoods can reproduce clonally through sprouting of buried broken or detached branches, or through development of suckers from shallow roots. This little-studied phenomenon has been alluded to in the riparian literature, and reported anecdotally and in unpublished studies (Tu 2000; Mike Roberts, TNC, pers. com., 27 February 2003). Additional insight into the process can be gained from studies of vegetative reproduction in other cottonwood species (Rood et al. 1994, Reed 1995).

Vegetative reproduction may be particularly important for sustaining Fremont cottonwood populations in altered hydrologic systems such as the Sacramento Basin. Tu (2000) reported that three years after the floods of 1996 established a new sandbar along the lower Cosumnes River, successful Fremont cottonwood recruits from vegetative branches outnumbered those from seeds by almost six to one. This is especially notable in light of the fact that the original 1996 cohort studied included 7,898 Fremont cottonwood seedlings compared to only 36 vegetative branches. Thus, the greater number of surviving 3-year-old recruits from vegetative branches compared to seedlings was due to their considerably higher survival rates rather than initial predominance. Most of the seedlings in this study died in their first year post-germination as a result of desiccation. Tu (2000) surmised that vegetative branches were better able to survive the critical first year by virtue of their greater nutrient storage, higher competitive ability for light, and greater proximity to declining water tables (most were partially buried in the soil).

In many parts of the Sacramento Basin, it is possible that the loss of natural recruitment processes under current conditions has increased the importance of vegetative propagation relative to seed propagation for sustaining cottonwood populations. An intervention opportunity based on natural vegetative reproduction is to plant cuttings collected from local cottonwood populations. Although this option would be time and labor intensive, cottonwoods have been successfully re-established by this method in Clear Creek and on the Sacramento and Merced Rivers (Mike Harris, USFWS, pers. com., 26 February 2003; John Stella, Stillwater Sciences, pers. com., 8 April 2003). Once a small number of individuals are successfully recruited to a new site, expansion of the population may subsequently occur via sprouting, suckering, or seed dispersal. Due to the uncertainties of seed dispersal timing, availability of flows, and high cost of flows (unless part of flood release flows), a dual strategy of vegetative reproduction and improved flow management may be the most cost effective option for improving rates of cottonwood recruitment in the Sacramento Basin.

4.2.4 Recruitment

The recruitment phase occurs from the end of the first year to sexual maturity, at five to ten years of age for Fremont cottonwoods (Reichenbacher 1984). Flow-related mortality is relatively low during this period because a plant has generally developed a sufficient root and shoot system to survive seasonal conditions of drought and flooding. Growth rates are very high in the second year, by the end of which roots may be almost ten feet deep (Ware and Penfound 1949). After the second year, growth rates level. Despite extensive root development during this stage, cottonwoods are still somewhat susceptible to drought stress. Thus, yearly flows must be sufficient to maintain groundwater levels within 10 to 20 feet of ground surface elevations (JSA and MEI 2002).

Groundwater extraction and reduced flows can reduce groundwater levels and induce drought stress in cottonwood saplings (Jones & Stokes 1998). In regulated river systems, low frequency of scouring flows may also allow exotics such as eucalyptus, tamarisk, and giant reed to establish and outcompete early successional native species such as cottonwood (Jones & Stokes 1998, McBain and Trush 2000). Relatively low flow-related mortality during this stage diminishes the importance of flow management opportunities. However, mortality due to herbivory (e.g., beavers, voles, mice) may be significant during this phase (John Stella, Stillwater Sciences, pers. com., 8 April 2003). Density-dependent mortality (self-thinning) may also occur if initial seedling density is high.

4.2.5 Maturity & Senescence

Maturity begins with the first flowering of a sexually mature adult. Senescence begins when reproductive capacity declines. Field studies indicate that a large proportion of existing cottonwood stands in the Sacramento Basin comprise mature and senescing individuals (McBain and Trush 2000, Stillwater Sciences 2002a, Jones & Stokes 1998). As these cottonwoods die (lifespan >130 years; Shanfield 1983), they are unlikely to be replaced by new generations of cottonwoods. Although cottonwood seedlings are readily germinating on the Sacramento River, most cohorts are not surviving to reproductive maturity, for the reasons outlined above. In addition, urban and agricultural conversion of mature cottonwood forests in the Sacramento Basin further reduces seed sources and threatens future prospects for this once-abundant riparian habitat (McBain and Trush 2000, Jones & Stokes 1998, Stillwater Sciences 2002a).

Cottonwood Conceptual Model

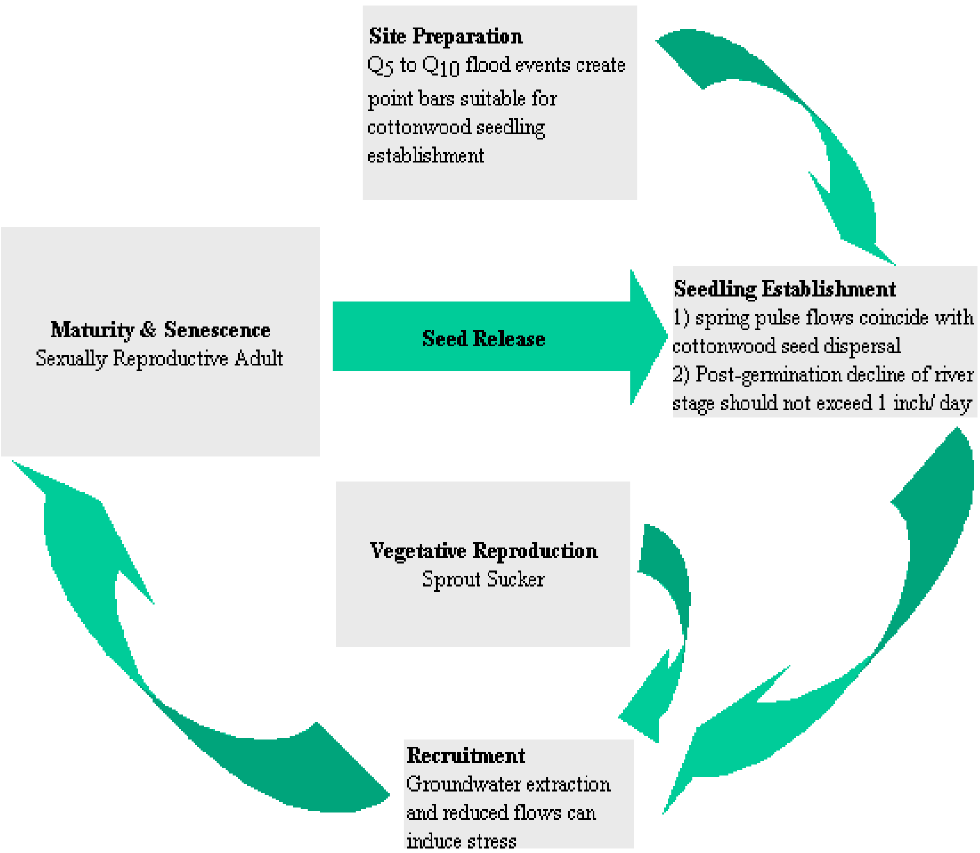

Figure 2. Cottonwood Conceptual Model for Sacramento Basin highlights characteristics of the flow regime that effect different life stages.

Chinook Salmon Conceptual Model

This conceptual model focuses on the flow related factors that affect populations of Chinook in the Sacramento and Feather Rivers. There are many non-flow factors that affect salmon populations, but we have only focused on the flow related factors for the purpose of developing an environmental flow regime. The model addresses flow-related factors for four runs of Chinook salmon and steelhead by life stage.

There are four distinct runs of Chinook salmon in the Sacramento River, the fall-run, the late fall-run, winter-run and spring-run. The different runs of Chinook differ in the timing of their life history. In general each run is named for the time that it begins migrating back to its natal stream. Table 1 shows that each run has the same life stages, but different runs move through the life-cycle at different times of the year and often employ different life stage strategies. For example, fall-run salmon are sometimes referred to as ocean type because they generally migrate to the ocean before their first year, while spring run generally spend a full year in the stream before migrating. Differences in timing and life history strategies mean that different runs can be vulnerable to different stressors. For example, winter run eggs incubate over the summer months and are therefore limited by summer water temperatures, while fall run eggs are much less likely to endure temperature stress since they incubate during the relatively cool winter months. The Chinook Conceptual Model lists the limiting factors that may impact the success of each life stage, the degree to which the limiting factor is relevant may depend on the particular run of Chinook which is being considered.

Table 2: Chinook Salmon (CHS) Thermal Tolerances. All lethal temperature data is presented as incipient upper lethal temperatures (IULT), which is a better indicator of natural conditions because experimental designs use a slower rate of change (1oC/d). (Modified from Moyle 2005, information largely from McCullough 1999.)

	Sub-Optimal	Optimal	Sub-Optimal	Lethal	Notes
Adult Migration	<10°C	10-20°C	20-21°C	21-24°C	Migration usually stops when temps climb above 21°C. Under most conditions fish observed moving at high temps are probably moving to refugia.
Adult Holding	<10°C	10-16°C	16-21°C	10-20°C	Fish in Butte Creek experience heavy mortality above 21°C but will survive temperatures as high as 23.5°C for short periods of time. In some holding areas fish have been observed in temperatures of 20°C for over 50 days during the summer.
Adult Spawning	<13°C	13-16°C	16-19°C	10-20°C	Egg viability may be reduced at higher temperatures
Egg Incubation	<19°C	9-13°C	13-17°C	10-20$_{o}$C	This is the most temperature sensitive phase of life cycle American River CHS experience 100% mortality in temperatures greater than 16.7°C; Sacramento River fall-run CHS mortality exceeded 82% in temperatures greater than 13.9°C
Juvenile Rearing	<13°C	13-20°C	20-24°C	10-20$_{o}$C	Past exposure (acclimation temperatures) has a large effect on tolerance. Fish with high acclimation temps may survive at 28-29°C for short periods of time. When food is abundant, fish that live under conditions between 16 and 24°C may grow very rapidly.
Smoltification	<10°C	10-19°C	19-24°C	10-20$_{o}$C	Smolts may survive and grow at suboptimal temps but are primarily avoiding predators

Temperature is one of the key factors that can limit salmon population numbers, but different life-stages display widely different temperature tolerances (Table 2). In general, salmon are most vulnerable to temperature stress in the egg life stage and least vulnerable in the juvenile life stage. Winter run are acutely sensitive to temperature, because their eggs are present during the summer months. Thus, different runs are effected differently by temperature stress due to the differences in run timing.

4.2.6 Life in the Ocean

All four runs of Chinook salmon spend approximately 1 to 5 years in the ocean before returning to spawn in their natal stream (Moyle, 2002), though historically, most Chinook salmon returning to the Sacramento River are approximately 4 years old (Clark 1929, in USFWS 1995).

Mortality of salmon in the ocean is based on natural and non-natural factors. Natural stressors include predation by other species, and ocean conditions, such as nutrient flow patterns (CMARP and CALFED Appendix C). The non-natural mortality factor affecting salmon is harvest. From 1967 to 1991, 60-80% of total salmon production was harvested (CMARP).

Changes in river management will do little to decrease natural mortality of salmon in the ocean. This study is not considering restoration of Chinook populations by limiting ocean harvest of salmon at this time. However, it is important to emphasize that large-scale harvesting of salmon in the ocean may be severely limiting salmon populations. If we could manage ocean stocks to increase the number of older fish, it may be possible to increase the ecosystem resilience against drought.

4.2.7 Adult Upstream Migration

Adult salmon migration can be limited by high temperatures and low dissolved oxygen. In the Sacramento River where flows are severely limited, adult salmon migration are delayed or disrupted by low flows and poor water quality. In particular, low levels of dissolved oxygen (DO) during summer and early fall at the Stockton Deep Water Ship Channel and high levels of ammonia from the Stockton wastewater plant in October cause poor water quality to delay adult Chinook migration up the lower San Joaquin, which causes an increase in poaching, lower egg and sperm viability and greater threats to outmigrating juveniles (Hallock et al, 1970 in CMARP). Fish migration does not appear to be limited by existing flow conditions, but reduced flows combined with polluted or warm water agricultural discharges could create problems for migrating fish.

Fall-Run

Adult fall-run Chinook salmon migrate into the Sacramento River and its tributaries from June through December (Yoshiyama, et al. 1998) Migration Peaks in September and October and spawning by mature adults begins shortly thereafter. Cool water releases in the Sacramento and Feather rivers are unnaturally high in late-summer and fall due to hypolimnetic discharge from

Shasta Reservoir (Stillwater, 2006). Increased summer and fall discharge, therefore may improve water quality and temperature conditions for migrating fall-run salmon. High ambient temperatures during late summer and early fall combined with warm or polluted agricultural drain water could become a problem for migrating salmon at lower stream flows (Domagalski, et al.). By mid October, however, water and ambient temperatures are cool enough for migrating salmon (Figure 4).

High water temperatures can prevent upstream migration, and can cause physiological damage and exhaustion (CALFED C-9). Temperatures above 70°F (21.1°C) prevented the upstream migration of adult Chinook salmon from the Delta to the Sacramento River, but the Chinook began migrating into the lower Sacramento as water temperatures fell from 72°F-66°F (22°C-18.9°C) (Hallock 1970 in USFWS, 1995). Temperatures ranging between 50°F and 67°F were found to be suitable for upstream migration of fall-run Chinook (Bell, 1986; Bell, 1973 in USFWS, 1995; and Bell, 1991 in Oroville). Although water temperatures below 38°F are reported to decreases adult survival (Hinze 1959 in USFWS, 1995), temperatures this low are not likely to occur in the Sacramento Basin tributaries.

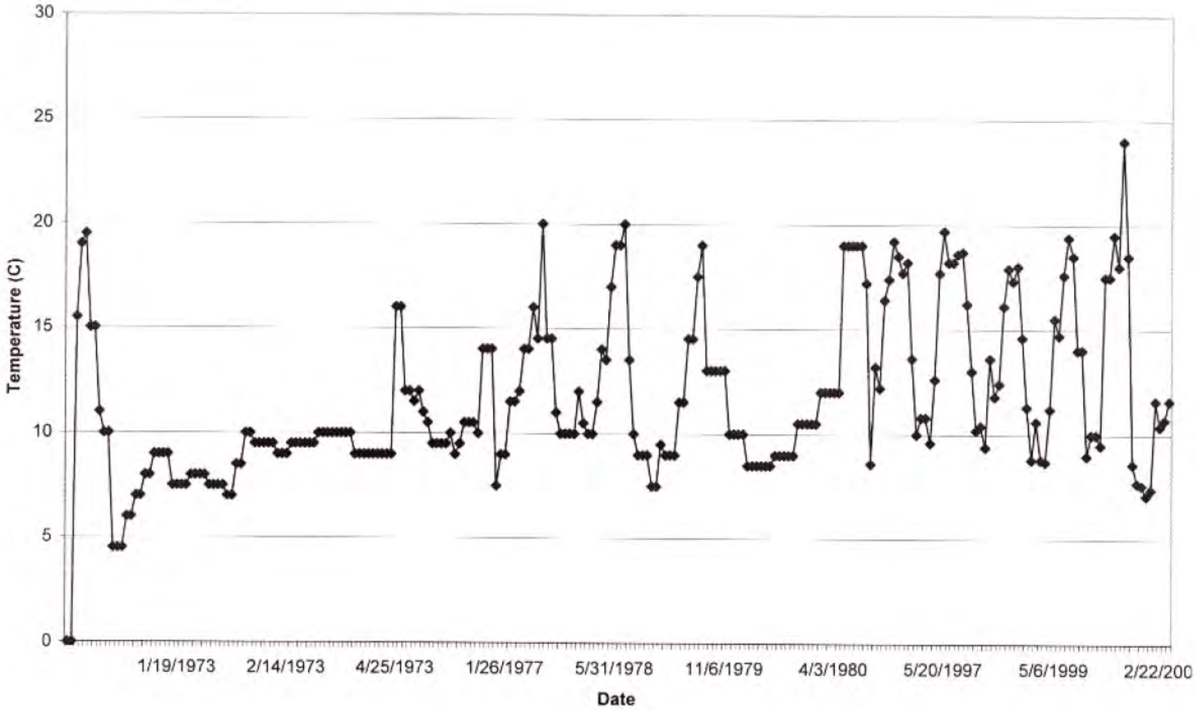

Figure 3: Temperature data collected on the Sacramento River downstream of Wilkins Slough (RM 118) between 1973 and 2000 at the Wilkins Slough gaging station (#11390500). Modified from Figure 4.2-7 in the Sacramento River Ecological Flows Study State of the System Public Review Draft.

A more natural flow regime in the late summer and fall could delay or impede the migration of fall-run salmon. Observations from the San Joaquin Basin where fall flows are lower and warmer suggest that the peak of the fall-run migration would shift to October and November. This may not reduce the overall population of fall-run salmon spawners, but it could create problems for recruitment by delaying emergence until the later spring months. Based on experience from the San Joaquin River (Stillwater, 2003) fall-run that emerge latter may have difficulty migrating out of the Sacramento and Feather Rivers before temperatures begin to rise in the late spring.

Increasing instream flows in the early fall in the Sacramento basin could improve conditions for migrating adult fall-run Chinook by reducing straying, improving water quality, improving passage barriers, decreasing water temperatures and decreasing the delay in migration. If salmon migration is motivated by major storms, early freshets or pulses after the first rain, and most of the large flows from storm events are trapped behind dams, reservoir operators can simulate pulse events by releasing water from the reservoir. However, “There is [a] concern that pulse flow releases in mid October to attract salmon may cause the fish to enter the rivers earlier than normal, which may expose them to high water temperatures when the pulse flows cease.” (CMARP). Therefore, if flows are increased during this mid-fall period, it is important to continue to maintain adequate flows for migrating adults and subsequent spawning.

Late-Fall Run

Adult late fall-run Chinook salmon migrate up the Sacramento River between mid-October and mid April, with peak migration occurring in December (Vogel and Marine, 1991). Water temperature and flow conditions within the natural range of variability will be suitable for late fall-run since water temperatures are within optimal levels.

Winter-Run

Adult winter-run Chinook salmon enter San Francisco Bay from November through June (Van Woert 1958, Hallowck et al. 1957 in NMFS 1997). Migration past Red Bluff Diversion Dam begins in mid-December and can continue into early August but the majority of winter run adults migrate past Red Bluff Diversion Dam between January and May with a peak in mid-March (Hallock and Fisher, 1985). Current RBDD operations facilitate upstream passage of winter-run adults by raising gates between September 15 and May 15.

Lower fall and winter flows are unlikely to create temperature adverse to winter-run migration, but lower spring flows could conceivably become a problem in drier years if spring flows are further reduced. Similarly, increased spring flows could be beneficial particularly for the latter part of the migration, but there is no evidence that the current adult migration is stressed by low flows or high temperatures.

Spring-Run

Although spring-run were probably the most abundant run historically in the Sacramento River (Mills and Fischer, 1994), most spring-run fish currently spawn in three tributaries: Deer, Mill, and Butte Creeks. Mainstem habitat was mostly blocked by Shasta Dam, but some spring-run still spawn below the dam, although they have apparently hybridized to some extent with the fall-run (Stillwater, 2006).

Adult spring-run enter the Sacramento-San Joaquin Delta beginning in January, entering their natal spawning streams from March to July (Myers et al. 1998). Adult spring-run migrate upstream to spawn in different tributaries at somewhat different times, suggesting some degree of life-stage flexibility. Butte Creek fish migrate up beginning in February and peaking March and April when flows peak in that stream. Adults from Deer and Mill Creek begin migration in March and peak in May, concluding in June.

Increased spring flows in the Sacramento during the late spring may provide some small benefits for migrating salmon in drier years, but there is no evidence that the adults are currently under stress during their migration. Increased flows in the Sacramento in drier years will not benefit conditions in the tributaries where most spring-run salmon migrate.

4.2.8 Spawning, Egg Incubation, and Emergence

Different runs spawn throughout the year and construct their redds in gravels that are typically 6 inches (15 cm) or less in diameter (Flosi et al., 1998). High water temperatures (greater than 56°F) due to low reservoir storage, high air temperatures and low flow releases could decrease available spawning habitat and affect sperm and egg viability. High temperatures cause spawners to concentrate in the upper reaches where water temperatures are lower, which increases the rate of superimpostion of redds (CMARP). “Mature females subjected to prolonged exposure to water temperatures above 60°F have poor survival rates and produce less viable eggs” (USFWS, 1995) and water temperatures below 38°F also can result in lower egg viability (Hinze 1959 in USFWS, 1995).

In order to provide quality areas of spawning habitat, adequate flows need to be released from dams into the tributaries during the spawning period. Over the long run, periodic high flows are necessary to mobilize gravels and flush-out fine sediments. However, large peak flow events that occur in channels that have been excessively incised and leveed cause excessive gravel mobilization, which can disrupt spawning and cause egg mortality (CMARP). Therefore, these flows should be released during periods when most fry have already emerged from the gravels so they reduce mortality to incubating salmon eggs (McBain and Trush, 2000).

Eggs usually incubate in the gravel for approximately 6 1-64 days before hatching (Healey 1991) and it takes about 70 days for fry to emerge from the gravel (USFWS 1998 in SP Cramer, 2000). This is consistent with EA Engineering’s findings, (1991 in CMARP) which found that eggs incubate for 40-60 days and remain in the gravel for 45-90 days. When fry first emerge from the gravel they are known as alevins and have an attached yolk sac that they depend on for food and nourishment.

The development of eggs into fry appears to be a difficult time for Chinook (Healey, 1991). High water temperatures, fine sediment capping, dewatered redds, poor quality gravel, and low substrate flow may contribute to the high mortality rate during egg and alevin development. High water temperatures (greater than 56°F), due to low reservoir storage, high air temperatures and low flow releases (CMARP, Loudermilk 1996) may cause egg mortality and decrease the incubation period when eggs are in the gravel (EA Engineering 1993 in CMARP). The late-fall and winter period of incubation combined with hypolimnetic discharge from the reservoirs generally maintains adequate water temperatures.

Low substrate flow through spawning gravels is known as an important cause of mortality in egg and alevin development. “Adequate water percolation through the spawning gravel is essential for egg and alevin survival. There is no doubt that percolation is affected by siltation and that siltation in spawning beds can cause high mortality” (Shaw and Maga 1943, Wickett 1954, and Shelton and Pollock 1966 in Healey 1991). Fine sediment capping occurs when redds become covered with fine silt (fines) due to small storm events that transport and deposit fines downstream. Shaw and Maga (1943) observed that siltation resulted in greatest mortality when it affected eggs in their early incubation stage (in Healey, 1991). Although common in steep coastal watersheds, fine sediment capping is relatively rare in the Sacramento basin due to sediment trapping in upstream reservoirs and the general lack of unregulated tributaries upstream of spawning areas.

Dewatering of redds is a known mortality factor effecting development of alevins. (Becker et al., 1982, 1983 in Healey, 1991). Dewatering of redds can be minimized below dams by careful flow regulation. Contaminated groundwater caused by seepage from agricultural or urban areas causes an increase in water temperature and reduces dissolved oxygen within spawning gravel, which may be harmful to incubating salmon eggs (CMARP).

Adequate base flows during the incubation and emergence period combined with periodic flushing flows outside the period should reduce the mortality factor of eggs and alevins. Instream flows, at or above spawning flows, should be maintained throughout the incubation and emergence period to avoid dewatering redds. Siltation and capping from fine sediments could be minimized with small reservoir releases timed to coincide with rainfall induced local run-off. These releases would help convey fine sediments out of the spawning reach.

Fall-Run, Late-Fall, and Spring Run

The mature adults spawn shortly after arriving at their spawning grounds between September and December. In the Sacramento and its tributaries, incubation and alevin development occurs from October through March (CMARP). Flow or temperature conditions are unlikely to be a problem except when Shasta Reservoir levels are drawn down. High water temperatures is probably not an important factor affecting fall, late fall and spring- run Chinook in the Sacramento Basin because incubation occurs between September and April when water temperatures do not rise above 14°C (57.2°F).

Winter-Run

Temperature stress induced by lower flows or lower reservoir levels in the summer, could be a significant problem for winter-run Chinook that incubate during the summer months. Temperatures in the winter-run spawning reach below Keswick Dam are largely controlled by the cold water pool in Shasta Reservoir and the Shasta temperature control device constructed in the 1990’s to manage cold water pool releases for the benefit of salmon. Currently, however, summer time flows are unnaturally high. Substantially reducing summer time flows, may result in elevated temperatures to the extent that it substantially increases travel time for cool water releases to reach the downstream end of the spawning reach, resulting in more time for the water to warm. However, stream temperatures will be controlled by a combination of cold water pool management in the reservoir j(reservoir level) and releases from that cold water pool (instream flows).

It is unclear how much, and at what point reduced flows in summer will increase temperature and how much that will negatively impact winter run. If substantially reducing flows creates negative impacts the endangered winter run irregardless of cold water pool management, then managers will be forced to maintain artificially high summer flows during winter run at incubation at the expense of increasing flows during other parts of the year for other species and other life-stages.

4.2.9 Juvenile Development and Rearing

Growth and rearing of juveniles is crucial to ensure that they grow fast enough to smolt before the onset of high temperature stresses common in the late spring. Smolts are typically >70-80mm and are able to survive in saltwater. Larger juveniles have a better chance of succeeding and surviving to the smoltification phase. “The rate of downstream migration of Chinook fingerlings appears to be both time and size dependent and may also be related to river discharge and the location of the Chinook in the river…Larger Chinook traveled downstream faster, and the rate of migration increased with the season” (Healey 1991). Growth is also important for avoiding other sources of stress and mortality such as lack of food, entrainment, predation, and disease. Larger fish are better able to compete for larger prey and avoid entrainment and predation. Larger juveniles have a competitive advantage over smaller fish in selecting prime positions in rearing areas (Fausch 1984 in Myrick and Cech), which can increase feeding rates (Alanara and Brannas 1997 in Myrick and Cech 2001). Larger fish also have more energy stores to withstand stresses imposed by disease.

There is great uncertainty about the suitability of the Delta for juvenile rearing and growth relative to rearing conditions farther upstream in the spawning reaches. The CALFED Strategic Plan for Ecosystem Restoration identified this question as one of the major uncertainties constraining the restoration planning process in the Bay-Delta watershed. Although Chinook salmon use other estuaries for rearing, most research and previous management actions on salmon in the Delta assume that juveniles suffer very high mortality in the Delta and has thus focused on moving smolt through the Delta as quickly as possible. Moyle (2002) found that “juveniles from other runs apparently do not spend as much time in the estuary, but pass through fairly rapidly on their way to sea. Whether or not this rapid passage is a recent phenomenon as the result of drastic changes in estuarine habitat or is the historical pattern is not clear”.

Fry appear to develop and grow in the tributaries, on inundated floodplains and in the Delta at different times until they become smolts and are large enough to migrate to the Ocean. There is strong evidence that juveniles rearing on inundated floodplains in the Yolo Bypass, a lowland transition zone between the spawning reaches and the Delta, had significantly higher growth rates than juveniles reared in the mainstem of the Sacramento River (Sommer et al. 2001). Sommer et al. (in preparation) attributed the higher growth rates to the increased area of suitable habitat, increased temperatures and increased food resources. Sommer et al. (2001) found that drift insects (primarily chironomids) were an order of magnitude more abundant in the Yolo

Bypass than the adjacent Sacramento River channel during 1998 and 1999 flood events. Seasonally inundated floodplains are also relatively free of exotic predators. "In the Central Valley during high flow periods, these fish historically moved into the floodplain, where they could rear for several months." (Moyle, 2002). Today, however, most of the rivers in the Sacramento Basin have been cut off from their floodplains, decreasing the available habitat for juveniles to develop and grow.

Less is known about the value of inundated floodplains relative to the gravel bedded reaches of the tributaries, which produce abundant food resources from macro-invertebrate production. Numerous studies indicate that gravel bedded reaches are more productive than sand and clay bottomed reaches that characterize the lower Sacramento. The increased food resources in the gravel bedded spawning reaches may be somewhat offset by the constant cold water, hypolimnetic releases from the dams, which may dampen growth. Channel incision, degraded riparian vegetation and degraded streambed complexity have been found to reduce the supply of organic detritus that invertebrates depend on for food, which may limit growth and survival of juvenile salmon that depend on invertebrates (Allan 1995 in CMARP). Incised channels in the Sacramento basin have cut off the rivers from their floodplains, which further limit access to food supplies (CMARP). These incised channels combined with high flows can result in fry and juveniles being washed down stream into less productive lowland reaches with high predator populations. Despite lower macroinvertebrate production, warmer water temperatures in the low-lying rivers and in the Delta may result in higher growth rates similar to observations from the Yolo bypass. Healey (1991) found that fry grow more rapidly in the Sacramento-San Joaquin estuary than in the rivers. However, others report that "fry that rear in the upper rivers experience a higher survival to smolting than fry that rear in the delta" (Kjelson et al. 1982, Brown 1986 in Healey, 1991).

Temperature has a major impact on growth. High water temperatures were found to stimulate smoltification and growth (Kreeger and McNeil 1992 in CMARP and SP Cramer, 2000 and Castleberry et al., 1991 in Myrick and Cech, 2001). Myrick and Cech (2001) conducted an extensive review of temperature effects on growth of juvenile Chinook in the Central Valley (Table 3.6). Although they found conflicting results, generally temperatures in the 60-66°F (15-19°C) range lead to high juvenile growth rates. When juveniles are rearing in February and March, temperatures in the tributaries are relatively low, cooler than temperatures needed for optimal growth. SP Cramer (2000) found that "higher water years result in cooler river temperatures [in the spring], which in turn can slow growth rates…However, Cramer et al. (1985) concluded from a variety of growth measurements that warmer temperatures, rather than lower flows, were driving growth of juvenile Chinook" (SP Cramer 2000). Higher growth rates may be a factor of slightly higher temperatures on the floodplains and in the Delta during this early spring period.

Table 3. Effects of temperature on growth of Juvenile Chinook in the Central Valley (Myrick and Cech, 2001 and Moyle, 2002)

Source	**Location**	**Maximum Growth**
Moyle (2002 referencing Marine)		55-64°F (13-18°C)
Rich (1987)	Nimbus State Fish Hatchery on American River	56-60°F (13-15°C)
Marine (1997)	Coleman National Fish Hatchery on Sacramento River	63-68°F (17-20°C)
Cech and Myrick (1999)	Nimbus State Fish Hatchery on American River	66°F (19°C)

Water temperatures greater than 77°F (25°C) were found to be lethal to juveniles in the Central Valley when exposed to these high temperatures for a long period of time, but they could withstand brief periods of high temperatures up to 84.2°F (29°C) (Myrick and Cech, 2001).

Although the mid water trawl surveys at Chipps Island measure smolt outmigration from the Delta (Baker et al. 1995), there are no measurements that identify where these outmigrating fish reared. Without this information it is impossible to estimate the relative importance to the population of fry reared in the Delta and on lower river floodplains compared with fry that rear in the tributaries before outmigrating. It is fairly clear, however, that the majority of juveniles migrate to the lower river and Delta soon after emergence. Therefore, we hypothesize that improving rearing conditions in the lower river and the Delta should increase overall escapement. Present management seems to focus on the quality of rearing habitat in the tributaries, but if the majority of young are moving out of the tributaries, it seems prudent to improve conditions for them as well. In order to understand where to focus limited resources where they will have the most impact on successful rearing, we need better information on the relative success of fish rearing in the lower river and Delta relative to fish rearing in the gravel bedded reaches of the tributaries.

Entrainment in water diversion facilities and predation, particularly from non-native bass, are also a major problem for salmon during the juvenile life stage. “Predators are commonly implicated as the principal agent of mortality among fry and fingerlings of chinook…[and] other fish are generally considered to be the most important predators of juvenile salmon” (Healey, 1991). Entrainment and predation are less related to flow then morality associated with high temperatures during the outmigration period. Juvenile growth rates probably affects mortality from predation and entrainment because smaller juveniles are more susceptible to mortality. Juvenile growth rates may also affect ultimate survival because faster growing juveniles and smolts migrate out of the system earlier in the spring before temperature becomes a major source of mortality and because larger juveniles travel downstream faster (Healey 1991, CMARP).

Contaminated agricultural and urban runoff may also increase outmigrating juvenile salmon’s susceptibility to disease, such as *Ceratomyxa*, which causes a high mortality rate in Chinook and flourishes in organic sediments and possibly in mine pits (CMARP p 19 and 20).

We hypothesize that improving juvenile growth rates will improve the rates of successful smolt outmgration and may also reduce mortality from diversions and predation. Based on robust results from research in the Yolo Bypass, it appears providing seasonally inundated floodplain habitat is perhaps the best way to ensure adequate growth before outmigration to the Delta and Ocean. If nothing else, providing seasonally inundated floodplain habitat will provide better habitat for the young that migrate or are washed out of the gravel bedded reaches early.

Increased flows during the rearing period combined with floodplain restoration should help increase overall growth rates and potentially decrease predation. Increased flows during this period should also dilute poor water quality. Increased flow may also decrease negative effects on salmon from contaminants and disease. Agricultural return flow from the west side of the San Joaquin did not cause any detrimental effects on growth and survival of hatchery-born Chinook salmon when the return flows were diluted by 50% or more with water from the San Joaquin (Saiki et al., 1992, from CMARP p 19).

Fall-Run

Fall-run Chinook usually emerge from the gravel as fry between January and March. Large portions of fry are immediately dispersed downstream to the lower rivers and the Delta, while some fry remain in the tributaries to rear (Kjelson et al. 1982 in Healey 1991, Moyle, 2002, and SP Cramer, 2000). SP Cramer (2000) found that peak migration of fry on the Stanislaus was associated with an increase in daily average flows. Different studies have found that fry and smolts are more abundant in the Sacramento-San Joaquin Delta at different times, depending on how long they remain in the upstream tributaries, before migrating to the ocean. “Most rearing occurs in freshwater habitats in the upper delta area, and the fry do not move into brackish water until they smoltify” (Kjelson et al., 1981, 1982 in Healey, 1991).

Higher flows during January through March d are more likely to result in inundated flood-plain or channel margin habitat ideal for rearing.

Late Fall-Run

Due to their late emergence in April and May, late-fall run are not able to migrate downstream before summer temperatures in the lower river become lethal. Rather most escapement probably results from juveniles that rear and over summer in the upper river. Increasing late spring and early summer may improve conditions for those fish that attempt to migrate out in the late spring and early summer as juveniles. Very large flows, however, would be necessary to create suitable temperature conditions in the lower river.

Winter-Run

Winter-run fry emerge from the spawning gravels from mid-June through mid-October (NMFS 1997). Because winter-run salmon spawning is concentrated upstream in the reaches below Keswick Dam, the entire Sacramento River serves as a nursery area for juvenile winter-run Chinook as they migrate downstream. Downstream movement of juveniles typically begins in August soon after fry emerge from redds. Rotary screw traps at RBDD usually record peaks in the abundance of winter-run salmon fry in September and October. However, following these initial pulses of fry, winter-run juveniles steadily stream past RBDD through March (Kimmerer and Brown, in prep.). Most juvenile winter-run Chinook reach the Delta between January and April, when they pose a conflict with Delta pumping operations designed to increase South of Delta storage during winter months when conflicts with protections for Delta smelt are reduced.

Higher flows during the out migration period for winter run are likely to result in inundated flood-plain or channel margin habitat ideal for rearing. More food will reduce mortality to the extent food is limiting and faster growing fish will have higher survival against gape limited predators or through the smoltification process.

Spring-Run

The rearing and outmigration patterns exhibited by spring-run Chinook salmon are highly variable, with fish rearing anywhere from 3 to 15 months before outmigrating to the ocean (Fisher 1994). Variation in length of juvenile residence may be observed both within and among streams (e.g., Butte versus Mill creeks, USFWS 1995, as cited in Yoshiyama et al. 1998). Some may disperse downstream soon after emergence as fry in March and April, with others smolting after several months of rearing, and still others remaining to oversummer and emigrate as yearlings (USFWS 1995, as cited in Yoshiyama et al. 1998). Scale analysis indicates that most returning adults have emigrated as subyearlings (Myers et al. 1998). Calkins et al. (1940, as cited in Myers et al. 1998) conducted an analysis of scales of returning adults and estimated that greater than 90% had emigrated as subyearlings, at about 3.5 in (88 mm).

Spring-run that migrate early in their first year could benefit substantially from inundated floodplain habitat and channel margins that higher flows could provide. The excerpt below drafted by Stillwater (2003) clearly explains the phenomena:

> "As stream-type salmon, a fraction of spring-run juveniles may spend a summer rearing in natal streams before emigrating to the ocean. After emergence, spring-run juveniles display agonistic behavior, establishing and defending territories. This behavior means that summer rearing habitat can be quickly saturated, even if escapements are low, because of the area required to support each juvenile. Spring-run that migrate downstream as fry often represent those individuals displaced as a result of rearing habitat saturation in upstream reaches. Because these fry are forced to migrate downstream at a small size < 1.6 m (40 mm), they are vulnerable to predation, such that the fry component may not contribute significantly to future escapements. However, recent research conducted on the Butte Creek population of spring-run salmon suggest that successful rearing by spring-run fry in the Sutter Bypass may be stimulating the recent increase in escapements. Generally, the Deer and Mill creek populations spring-run do not seem to have the same success in fry rearing. To improve fry rearing potential for the Deer and Mill Creek populations, we recommend the creation of a dedicated floodplain/bypass area along the mainstem Sacramento River downstream of Deer and Mill creeks. A bypass in the vicinity of Deer and Mill creeks would provide rearing habitat to fry and juveniles outmigrating to the main stem from these important spawning tributaries for remaining wild-type spring-run Chinook. Such a bypass should be constructed to provide high-quality rearing habitat at relatively low flows, so that the habitat is available for a large portion of every winter, even during drier years.

4.2.10 Smolt Outmigration

As mentioned in the previous section, after fry emerge from the gravel the majority disperse downstream, especially during increases in flows or after storm events. Whether young fish migrate out of the tributaries soon after emergence or whether they rear in the tributaries, they eventually undergo smoltification and make their physiological transition to salt water. Several factors trigger smoltification, including changing hormone concentrations, increasing photoperiod, increasing temperature, and increasing body size (Myrick and Cech, 2001). While most of these factors cannot be influenced by changing management actions in the tributaries or the Delta and are not discussed in this report, temperature and body size are affected by flow and can be influenced by reservoir reoperation.

Smolts require lower temperatures than rearing juveniles. While higher temperatures in the 60-66°F (15-19°C) range can optimize growth of juveniles and better prepare them for smoltification earlier, lower temperatures are more optimal during the smoltification process. A comprehensive study by Myrick and Cech (2001) found that Chinook have a better chance of surviving in the Ocean if they undergo smoltification at lower temperatures, ranging from 50-63.5°F (10-17.5 °C). Warmer temperatures in the February –March period (which occur on floodplains) stimulate growth of juveniles so they are larger before they undergo smolification and therefore larger when they enter the Ocean (Myrick and Cech, 2001). Larger juveniles are also able to smolify before harmful high late spring temperatures set in. Cooler temperatures are necessary in the smolt outmigration period of April – June. The need for warmer temperatures in the early spring and cooler temperatures in late spring reflects the historical hydrograph, where large, cold snowmelt flows dominated the Sacramento Basin later in the spring.

Body size is an important function of the success of outmigrating smolts and the development to smoltification (Dlarke and Shelbourn 1985; Johnssson and Clarke 1988 in Myrick and Cech, 2001). It is important that Chinook reach an appropriate size for smolting before they arrive in saltwater. Relatively warm temperatures can be beneficial for growth provided adequate food supply. Increases inundated floodplain habitat provides the type of habitat that allow juveniles to grow larger before smoltification (Sommer et al, 1991).

High water temperatures, low flows and entrainment may cause increased mortality rates in outmigrating smolts and affect growth of juvenile Chinook. High water temperatures, particularly in May and June may pose the largest threat to juveniles that remain in the tributaries and in the Delta later in the spring. Baker et al (1995) found that 50% of Chinook smolt that migrate through the Delta die when temperatures reach 72-75°F (22-24°C) McCullough (1999 in Moyle) found that few fish can survive temperatures greater than 75.2°F (24°C) even for short periods of time.

Prolonged periods of high flows from January through June, especially from late February through mid-April, will reduce temperatures and help flush out outmigrating juveniles and smolt (CMARP). There are several programs underway and several measures that could be taken to improve juvenile outmigration and survival. Increased flows during outmigration improve juvenile/smolt survival in the Sacramento basin tributaries and Delta. Studies have shown that survival of fry and smolts passing through the Sacramento-San Joaquin River delta were highly correlated with discharge of the Sacramento River (Healey, 1991 and USFWS, 1998 in SP Cramer). Studies from the Stanislaus River shows that Smolt survival was high (about 78%) when releases from were increased in late April in 1986 and 1988, but were low (28%) when releases were lower in April 1989. A substantial increase in migrating juvenile was measured when flows were increased in the Stanislaus River for seven days in April 1995 (SP Cramer 1995 in CMARP).

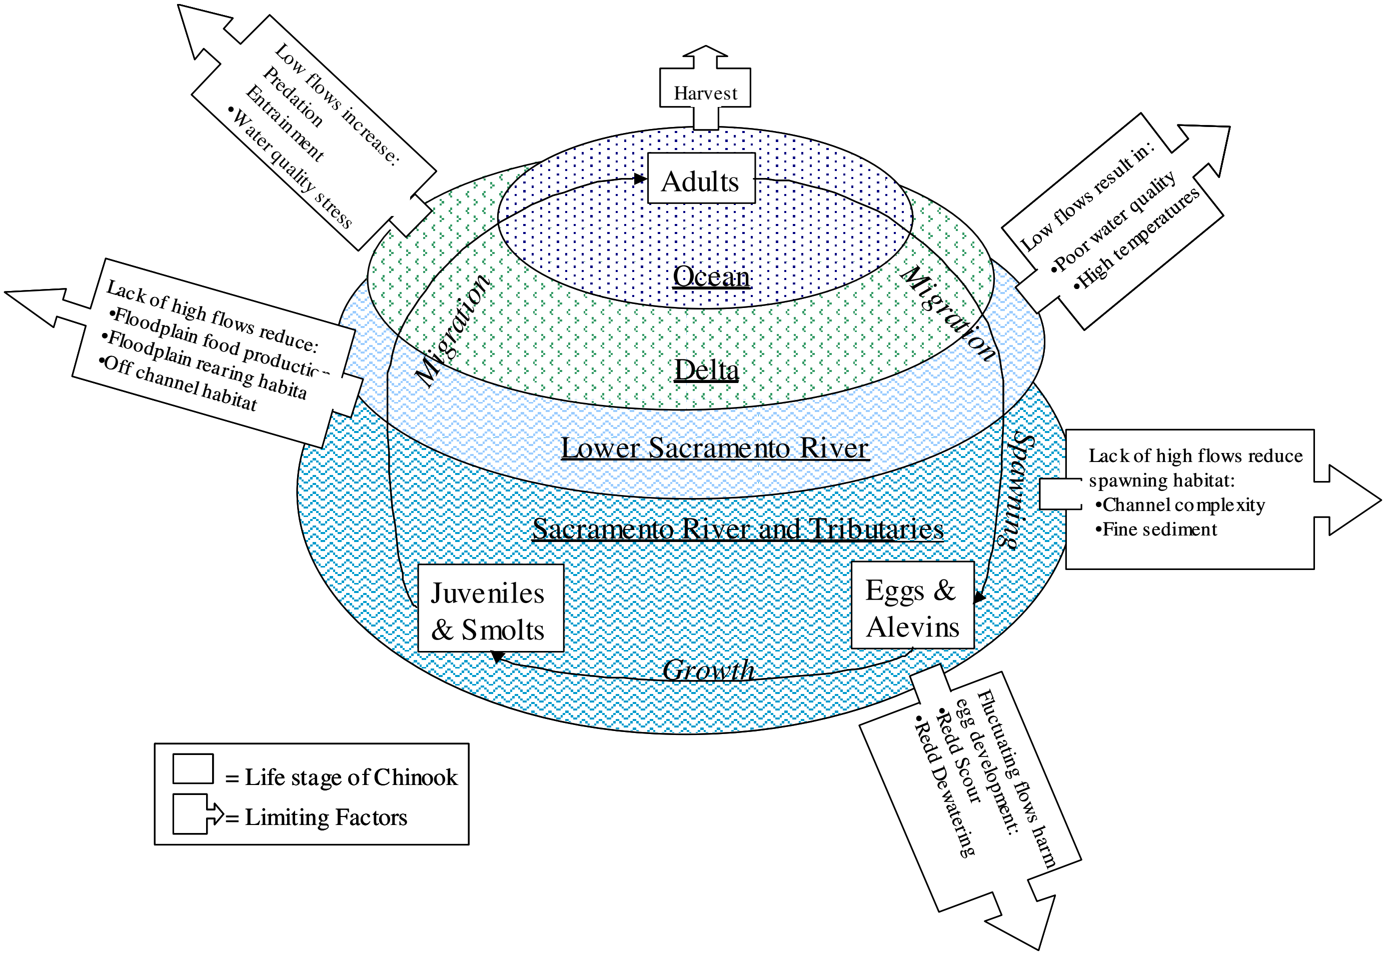

Figure 4: This conceptual model for Chinook salmon illustrates the life cycle of the Chinook in the Sacramento River, factors that increase Chinook mortality during their life cycle, and how restoration can improve the conditions of these fish.

DATE: October 4, 2011

SUBJECT: Estimation of Sacramento Valley Conjunctive Water Management Program Costs

Background and Objectives

The objective of this effort was to estimate implementation costs for Sacramento Valley Conjunctive Water Management Program. The cost estimates were developed based on an evaluation of capital, operations, maintenance, and mitigation costs associated with program. All costs were estimated in 2010 dollars.

The following pumping scenarios were evaluated:

- 300 TAF Summer Pumping, New Well Field
- 300 TAF Summer Pumping, Existing Well Field
- 150 TAF Summer Pumping, New Well Field
- 150 TAF Summer Pumping, Existing Well Field
- 150 TAF Fall Pumping, New Well Field
- 150 TAF Fall Pumping, Existing Well Field
- 150 TAF Summer and Fall Pumping, New Well Field
- 150 TAF Summer and Fall Pumping, Existing Well Field

This brief technical memorandum describes the estimation of implementation costs.

Summary of Program Implementation Cost Items

Capital, operations and maintenance, and mitigation cost items associated with the Program are summarized in Table 1. For each cost item, the nature of the cost is described, along with the basis upon which the associated cost was estimated.

Global Cost Parameters

The following cost parameters were assumed for the cost estimates:

- Contingency applied to all cost items: 20%
- Engineering and project management as a percentage of up-front capital costs: 12%
- Percent of normal maintenance required for Program wells in non-pumping years: 20%
    - Assumes that maintenance requirements are less in years the Program wells are not operated.
- PG&E energy rate paid for project pumping: $0.22/kWh

Table 1. Capital, O&M, and Mitigation Cost Items Associated with Sacramento Valley Conjunctive Water Management Program.

Cost Category	Cost Item	Item Description	Basis/Comment
Capital	Construct and equip shallow irrigation well	Construct new, typical ~450 foot deep irrigation production well in regional aquifer. Purchase land, electrical line extension, install well pad, pump, electrical motor and controls, discharge piping and connection to open canal, security enclosure.	Well driller interview/discussion to estimate unit costs. Estimate quantities based on available well surveys and project pumping requirements.
Capital	Construct and equip deep irrigation well	Construct new, typical ~1,400 foot deep irrigation production well in deep aquifer. Purchase land, electrical line extension, install well pad, pump, electrical motor and controls, discharge piping and connection to open canal, security enclosure.	Recent SCF bids to estimate unit costs. Estimate quantities based on available well surveys and project pumping requirements.
Capital	Rehabilitate existing shallow irrigation well (inspect and reinstall)	Remove existing pump and motor; perform downhole video and qualification assessment; reinstall existing pump and motor; discharge piping and connection to open canal, security enclosure. In some cases, well may require rehabilitation (acid wash) and/or upgrade of electrical. Also, conversion from Diesel to electric and electrical line extension may be required.	Well driller interview/discussion to estimate unit costs. Estimate quantities based on available well surveys and project pumping requirements.
Capital	Rehabilitate existing shallow irrigation well (inspect and rebuild)	Remove existing pump and motor; perform downhole video and qualification assessment; rebuild existing pump and motor, upgrade electric controls; discharge piping and connection to open canal, security enclosure. In some cases, well may require rehabilitation (acid wash) and/or upgrade of electrical. Also, conversion from Diesel to electric and electrical line extension may be required.	Well driller interview/discussion to estimate unit costs. Estimate quantities based on available well surveys and project pumping requirements.
Capital	Rehabilitate existing shallow irrigation well (inspect and replace)	Remove existing pump and motor; perform downhole video and qualification assessment; replace existing pump and motor; discharge piping and connection to open canal, security enclosure. In some cases, well may require rehabilitation (acid wash) and/or upgrade of electrical. Also, conversion from Diesel to electric and electrical line extension may be required.	Well driller interview/discussion to estimate unit costs. Estimate quantities based on available well surveys and project pumping requirements.
Capital	Purchase and install SCADA equipment at production or monitoring well site	Furnish and install RTU, sensors, enclosure, radio, antenna, complete, installed.	Estimate unit costs based on data from ITRC. Estimate quantities based on number of project and monitoring wells required.
Capital	Construct dedicated monitoring well	Contruct new, typical 1,200-foot triple completion, dedicated monitoring well	Estimate unit costs based on input from DWR and well driller. Estimate quantites based on required number of project wells.
O&M	Electrical energy costs for project pumping	PG&E energy costs associated with project pumping.	Estimate unit costs based on PG&E rates, estimated lift from GW model and typical flow rates, OPPE from CIT APEP. Estimate quantities from SW model.

Table 1 (Continued). Capital, O&M, and Mitigation Cost Items Associated with Sacramento Valley Conjunctive Water Management Program.

Cost Category	Cost Item	Item Description	Basis/Comment
O&M	Water level monitoring, feedback and realtime management	During and following years of project pumping, conduct water level monitoring, operate and maintain GW model, manage pumping in real time to minimize or avoid impacts, confer with appropriate authorities, prepare periodic reports of project operations.	Estimate staffing requirements and costs for individual tasks during pumping and non-pumping years based on professional judgement.
O&M	Project operations	Operations forecasting and scheduling according to program objectives and operating rules.	Estimate staffing requirements and costs for individual tasks during pumping and non-pumping years based on professional judgement.
Mitigation	Construct domestic well	Replacement of domestic wells with yield impacted by project pumping.	Estimate unit costs based on well driller information. Estimate quantities based on analysis of yield impacted wells using GW model results from 1987 to 2003.
Mitigation	Payments for incremental agricultural pumping costs	Reimbursement for energy costs associated with increased lift caused by interference drawdown from the project.	Estimate unit costs based on PG&E rates, estimated lift from GW model and typical flow rates, OPPE from CIT APEP. Estimate quantities from GW/SW model.
Mitigation	Payments for incremental domestic pumping costs	Reimbursement for energy costs associated with increased lift caused by interference drawdown from the project.	Estimate unit costs based on PG&E rates, estimated lift from GW model and typical flow rates, OPPE from CIT APEP. Estimate quantities from spatially distributed Census data and USGS per capita water use rates.
Mitigation	Administration, outreach, complaint response and dispute resolution, mitigation operations, and legal counsel.	Provide administration of monitoring and mitigation, conduct public outreach regarding observed impacts, handle impacts complaints/disputes. Provide legal support.	Estimate staffing requirements and costs for individual tasks during pumping and non-pumping years based on professional judgement.

Domestic Well Replacement Quantities and Costs

Domestic Well Replacement Quantities

The number of domestic wells requiring replacement was estimated for each pumping scenario based on the analysis of peak drawdown relative to screened interval length for domestic wells in the project area with available screen length data, described elsewhere. The number of wells impacted was scaled up based on the total number of domestic, industrial, public, stock, and other potentially wells in the study area, as reported by DWR. The estimated number of wells requiring replacement is summarized in the table below.

Pumping Scenario	Well Field	Impacted Wells[1] Min	Max	Average
300K Summer	New	63	172	118
	Existing	167	310	238
150K Summer	New	7	29	18
	Existing	99	189	144
150K Fall	New	7	32	19
	Existing	92	196	144
150K Summer and Fall	New	9	27	18
	Existing	69	142	105

1. Estimates of probable range of impacts based on analysis of peak interference drawdown relative to screened interval length for domestic wells in the project area with available screen length data. The number of wells impacted was scaled up based on the total number of domestic, industrial, public, stock, and other potentially impacted wells within the study area.

Unit Cost for Domestic Well Replacement

The unit cost of replacement for domestic wells was estimated to be $18,200, as summarized below. Based on an amortization rate of 3%, the annualized cost per well replaced was estimated to be $1,580.

Cost Item	Capital	Life (yr)	Amort. Rate	Annual Capital
Construction of New Domestic Well	$10,000	30	3%	$ 510
Installation of pump/motor/tank	$2,500	10	3%	$ 293
Abandon Old Domestic Well	$1,500	30	3%	$ 77
SUBTOTAL	$14,000			$880
Engineering and Project Management	$1,400		(10%)	$140
Contingencies	$2,800		(20%)	$560
TOTALS	$18,200			$1,580

NOTE: It is assumed that domestic wells replaced by the program will be maintained at the expense of the well owner.

Total Cost of Domestic Well Replacement

Combining the estimated quantity of domestic wells requiring replacement with the estimated unit cost of well replacement, the total cost of domestic well replacement was calculated and is summarized below.

		Total Capital			Annual Capital		
Pumping Scenario	Well Field	Min	Max	Average	Min	Max	Average
300K Summer	New	$1,151,660	$3,137,280	$2,144,470	$99,966	$272,322	$186,144
	Existing	$3,037,999	$5,639,161	$4,338,580	$263,705	$489,491	$376,598
150K Summer	New	$119,137	$536,117	$327,627	$10,341	$46,536	$28,439
	Existing	$1,806,914	$3,435,123	$2,621,018	$156,844	$298,176	$227,510
150K Fall	New	$119,137	$575,830	$347,484	$10,341	$49,983	$30,162
	Existing	$1,667,921	$3,574,116	$2,621,018	$144,779	$310,241	$227,510
150K Summer and Fall	New	$158,850	$496,405	$327,627	$13,788	$43,089	$28,439
	Existing	$1,250,941	$2,581,306	$1,916,123	$108,584	$224,063	$166,323

Project Well Construction and Rehabilitation Costs

Quantity of Project Wells Required

The number of project wells required was estimated based on estimates of the number and distribution of existing production wells in the study area, typical production well capacities in the study area, peak monthly pumping volumes for each pumping scenario, and assumptions regarding downtime for project wells. Estimated well capacities are summarized below.

Average Flow Rate per Well (gpm)[1]

	GCID	WCWD	Richvale
Existing Wells	2800	2400	2400
New Shallow Wells[2]	2800	2400	2400
New Deep Wells[2]	2800	2400	2400

1. GCID and WCWD average flow rates estimated based on average values from well surveys in each district. Richvale ID flow rate assumed to be similar to WCWD.
2. New wells assumed to have flow rates similar to existing wells.

Maximum monthly pumping volumes by scenario, estimated based on the reservoir operations model, are summarized below.

Maximum Monthly Pumping Volume (ac-ft)

Pumping Scenario	GCID	WCWD[3]	Richvale[3]
300K Summer	50,000	12,500	12,500
150K Summer	25,000	6,250	6,250
150K Fall	40,000	10,000	10,000
150K Summer and Fall	15,000	3,750	3,750

3. Equal pumping volumes assumed for WCWD and Richvale ID

The quantities of simultaneously operated project wells required to meet peak pumping requirements for each pumping scenario are summarized below.

Number of Simultaneously Operated Wells Required to Satisfy Project Pumping Requirements[4]

Pumping Scenario	Well Field	GCID	WCWD	Richvale
300K Summer	New	133	39	39
	Existing	133	39	39
150K Summer	New	66	19	19
	Existing	66	19	19
150K Fall	New	106	31	31
	Existing	106	31	31
150K Summer and Fall	New	40	12	12
	Existing	40	12	12

4. Assume pumps will operate every day, 24 hours per day at peak.

Due to periodic maintenance and other unknowns, it is likely that some project wells will be inoperable at times. As a result, the number of additional project wells required to ensure sufficient pumping capacity during peak production was estimated as described below.

Additional Wells Required to Allow for Downtime

Contingency for maintenance/repair of existing wells during peak pumping: 5%
Contingency for strategic shutdown of project wells to avoid yield impacts to domestic wells: 10%
TOTAL CONTINGENCY: 15%

Total Number of Project Wells Required to Satisfy Project Pumping Requirements

Pumping Scenario	Well Field	GCID	WCWD	Richvale
300K Summer	New	153	45	45
	Existing	153	45	45
150K Summer	New	76	22	22
	Existing	76	22	22
150K Fall	New	122	36	36
	Existing	122	36	36
150K Summer and Fall	New	46	13	13
	Existing	46	13	13

Quantity of Additional Production Wells Needed for Existing Well Field Scenarios

Even under the existing well field scenarios, additional production wells are needed to meet peak pumping demands in some areas.

Only a portion of existing wells are likely to enter the program due to lack of grower willingness, well condition, or other issues. As a result, the number of existing wells entering the program will be less than the total number of existing wells.

The estimated number of existing production wells in each area, the number of existing wells expected to enter the program, and the corresponding number of additional production wells required for the existing well field scenarios are summarized on the following page.

Existing Wells Potentially Available to Support Project Pumping

	GCID[5]	WCWD[6]	Richvale[7]
Existing Irrigation Wells	155	131	77

5. Estimated as number of wells listed in GCID well survey.
6. Estimated as number of wells listed in WCWD well survey, multiplied by 50%. It appears some wells listed may be domestic or abandoned.
7. Estimated based on number of wells in WCWD assuming equal number of wells per section.

Existing Wells Ultimately Included in Program

Existing wells not suitable for project due to nonideal location, owner unwillingness, or well unsuitable:	67%

	Existing Wells Entering Program		
Pumping Scenario	GCID	WCWD	Richvale
300K Summer	51	43	25
150K Summer	51	22	22
150K Fall	51	36	25
150K Summer and Fall	46	13	13

Additional New Shallow Irrigation Wells Needed for Existing Well Field Pumping Scenarios

Pumping Scenario	GCID	WCWD	Richvale
300K Summer	102	2	20
150K Summer	25	-	-
150K Fall	71	-	11
150K Summer and Fall	-	-	-

Existing Well Rehabilitation Quantities

Existing wells entering the Program will need inspection and in many cases rehabilitation. Estimates of the quantity of wells entering the program requiring rehabilitation are summarized below for each of the existing well field pumping scenarios.

Number of Existing Wells Requiring Upgrades or Repairs

Proportion of existing wells requiring down hole inspection:	100%	
Proportion of existing wells requiring rehabilitation:	30%	
Proportion of existing wells requiring well seal:	20%	(based on GCID well survey number of wells with no seal)
Proportion of existing wells requiring reinstallation of existing pump and motor:	50%	
Proportion of existing wells requiring rebuild of existing pump and motor:	30%	
Proportion of existing wells requiring replacement of pump and motor:	20%	
Proportion of existing wells requiring Diesel --> Electric conversion:	80%	

	Downhole Inspection			Well Rehabilitation			Construct Well Seal

Unit Costs for Well Construction, Rehabilitation, Operation, and Maintenance

Unit costs for well construction and rehabilitation were estimated based on discussion with well drillers and based on recent well costs for test wells.

The estimated unit cost for construction, operation, and maintenance of a new deep project well is summarized on Page 9.

The estimated unit cost for construction, operation, and maintenance of a new shallow project well is summarized on Page 10.

The estimated cost for purchase, operation, and maintenance of an existing production well is summarized on Page 11.

It is anticipated that existing Diesel wells would be converted to electrical power upon entering the program. The estimated cost for conversion of existing Diesel wells to electrical drive is summarized on Page 12.

Estimated unit costs for well rehabilitation are summarized on Page 13.

It is anticipated that project wells will be equipped with SCADA to support monitoring of well operation, water level, and pumped volume. Estimated unit costs for SCADA are summarized on Page 14.

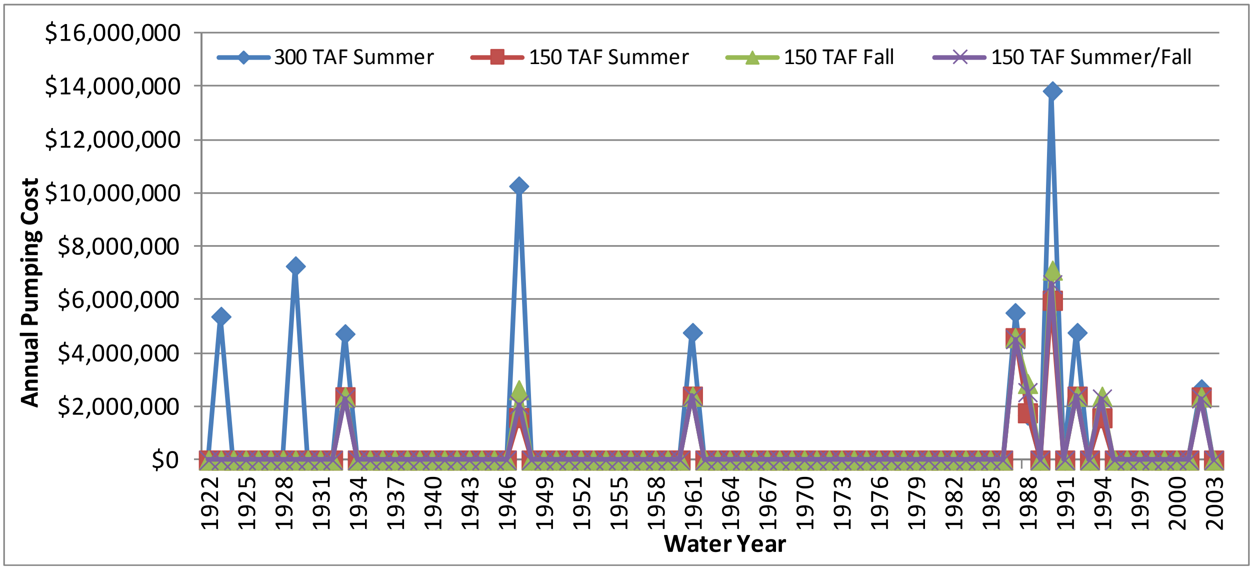
3. Maintenance costs represent annual amounts estimated as a percent of initial capital cost.

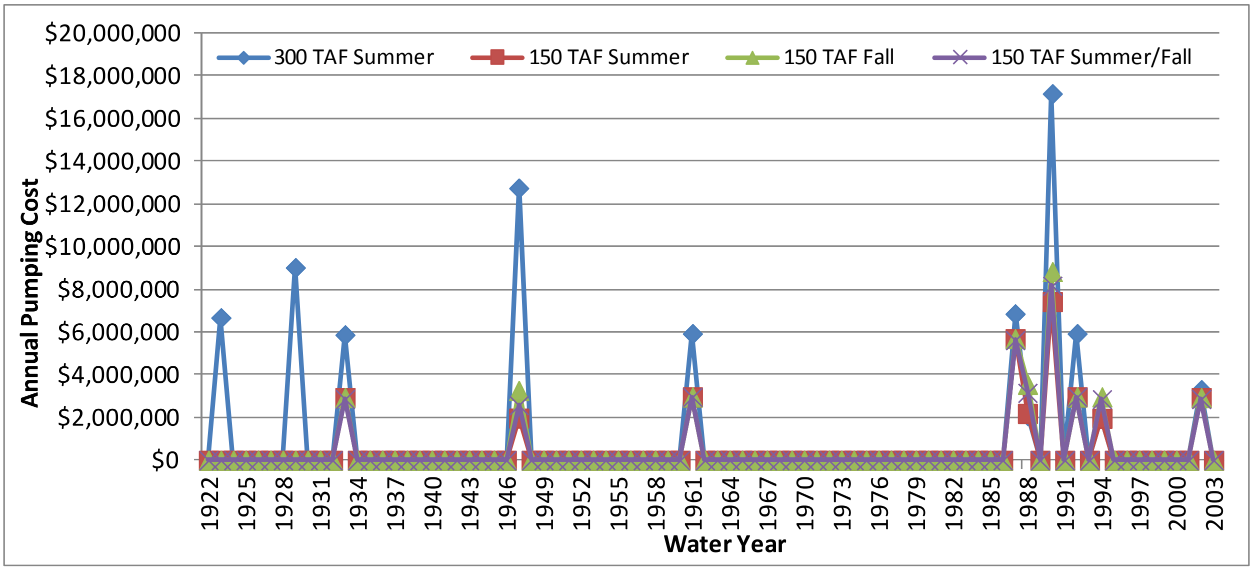
Annual Pumping Costs

Annual pumping costs were calculated based on pumped volumes and estimated cost per acre-foot pumped for shallow and deep production wells. Total pumping costs for the full study period are summarized in the table below. The time series of annual pumping costs for new well field pumping scenarios is shown in the following figure.

Pumping Scenario	Well Field	Pumping Costs	
		Total (full study period)	Average (years with pumping)
300 TAF Summer	New	$ 30,060,829	$ 5,010,138
	Existing	$ 37,321,899	$ 6,220,316
150 TAF Summer	New	$ 18,672,745	$ 3,112,124
	Existing	$ 23,183,070	$ 3,863,845
150 TAF Fall	New	$ 21,708,314	$ 3,618,052
	Existing	$ 26,951,868	$ 4,491,978
150 TAF Summer/Fall	New	$ 20,657,963	$ 3,442,994
	Existing	$ 25,647,809	$ 4,274,635



The time series of annual pumping costs for existing well field pumping scenarios is shown in the following figure.



As indicated, pumping costs tend to be greater for the existing well field scenarios as compared to the new well field scenarios. This is due to the lower aquifer having a greater specific capacity, which results in less pumping drawdown and required lift as compared to pumping from the shallow regional aquifer.

Project Operations Costs

The cost of operating the project was estimated based on the estimated level of effort required to operate the project and estimated salaries and overhead for project operators. Estimated operation costs for years with and without pumping are provided on the following page.

Estimated cost for project operations. Responsibilities include forecasting and scheduling project pumping according to program objectives and operating rules; coordination with USBR, DWR, and other agencies; and overall project management.

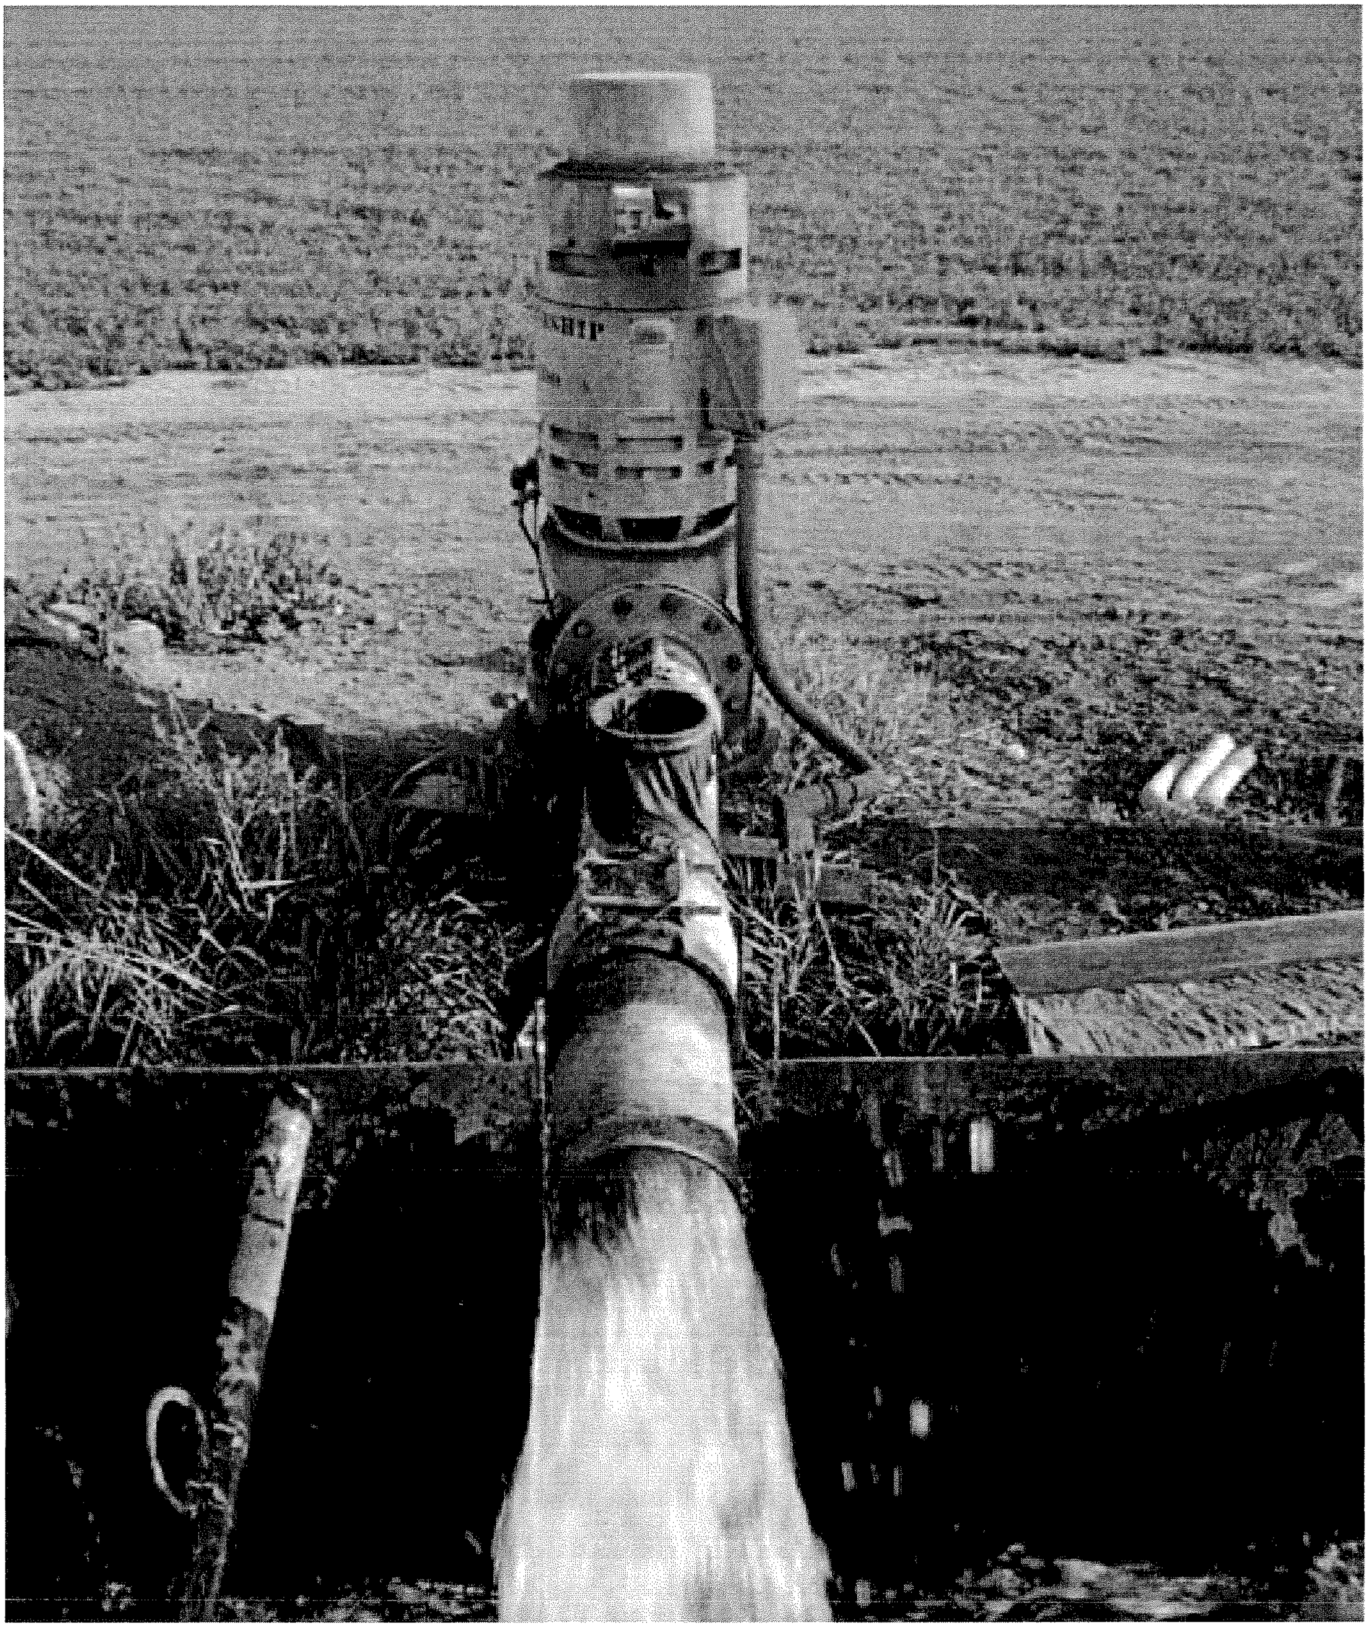
Chapter 4 Conjunctive Management and Groundwater Storage



Conjunctive management allows surface water and groundwater to be managed in an efficient manner by taking advantage of the ability of surface storage to capture and temporarily store storm water and the ability of aquifers to serve as long-term storage. (DWR photo)

Chapter 4 Conjunctive Management and Groundwater Storage

Conjunctive management is the coordinated operation of surface water storage and use, groundwater storage and use, and conveyance facilities to meet water management objectives. Although surface water and groundwater are sometimes considered to be separate resources, they are connected by the hydrologic cycle. Conjunctive management allows surface water and groundwater to be managed in an efficient manner by taking advantage of the ability of surface storage to capture and temporarily store storm water and the ability of aquifers to serve as long-term storage.

There are three primary components to a conjunctive management project when the primary objective is to increase average water deliveries. The first is to recharge groundwater when surface water is available to increase groundwater storage (see Box 4-1). In some areas this is accomplished by reducing groundwater use and substituting it with surface water, allowing natural recharge to increase groundwater storage (also called in-lieu recharge). The second component is to switch to groundwater use in dry years when surface water is scarce. The third component is to have an ongoing monitoring program to evaluate and allow water managers to respond to changes in groundwater, surface water, or environmental conditions that could violate management objectives or impact other water users. Together these components make up a conjunctive management project. Conjunctive management projects may have other objectives in place of or in addition to improving average water deliveries. These other objectives may include improving water quality, reducing salt water intrusion, and reducing groundwater overdraft.

Other topics in the Water Plan that are related to conjunctive management include the strategies on Groundwater Remediation / Aquifer Remediation, Recharge Areas Protection, Water Transfers, and System Reoperation.

Conjunctive Management in California

Conjunctive management has been practiced in California to varying degrees since the Spanish mission era. The first known artificial recharge of groundwater in California occurred in Southern California during the late 1800s and is now used as a management tool in many areas. Two examples illustrate the types of conjunctive management under way on a regional and local scale. In Southern California, including Kern County, conjunctive management has increased average-year water deliveries by more than 2 million acre-feet (AGWA, 2000). Over a period of years, artificial recharge in these areas has increased the water now in groundwater storage by about 7 million acre-feet.

Box 4-1 Groundwater Recharge

Groundwater recharge is the movement of surface water from the land surface, through the topsoil and subsurface, and into de-watered aquifer space. Recharge occurs naturally from precipitation falling on the land surface, from water stored in lakes, and from creeks and rivers carrying storm runoff. Recharge also occurs when water is placed into constructed recharge ponds (also called spreading basins), when water is injected into the subsurface by wells, and when water is released into creeks and rivers beyond what occurs from the natural hydrology (for example, by releases of imported water). These later examples of recharge are often called artificial, intentional, managed or induced recharge. Significant amounts of recharge can also occur either intentionally or incidentally from applied irrigation water and from water placed into unlined conveyance facilities.

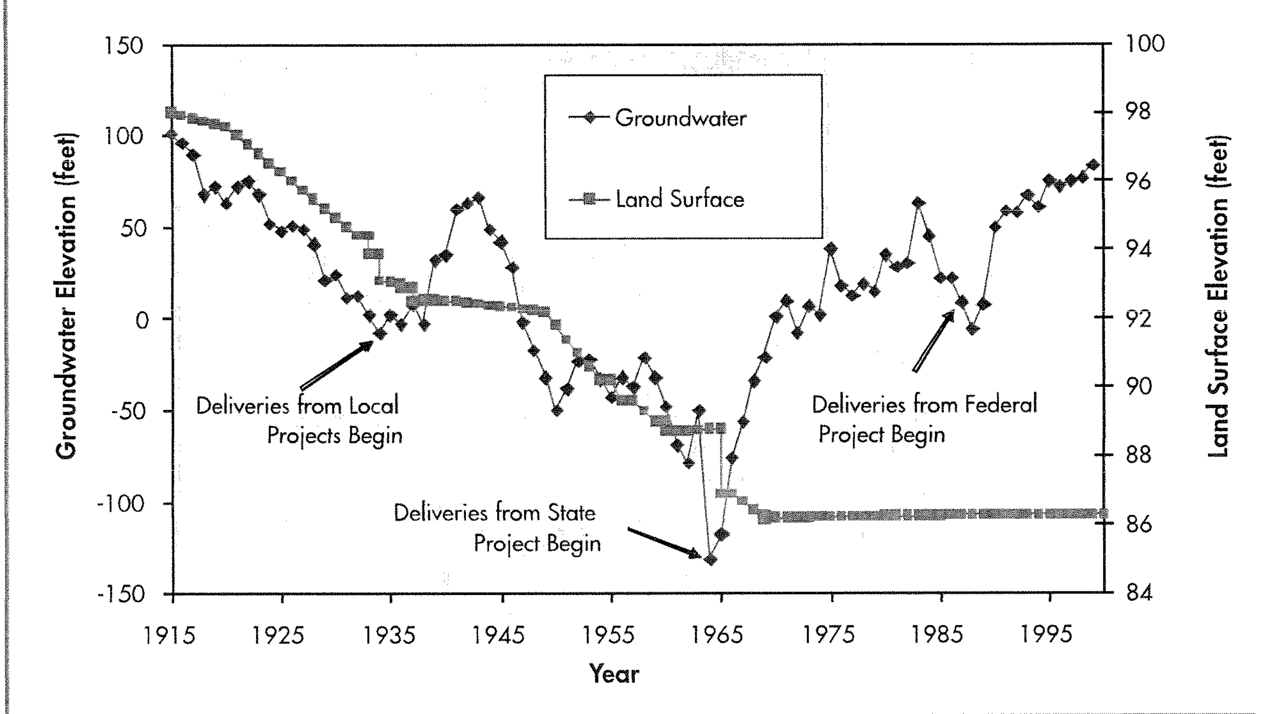
Santa Clara Valley Water District releases local supplies and imported water into more than 20 local creeks for artificial instream recharge and into more than 70 recharge ponds with an average annual recharge capacity of 138,000 acre-feet. Conjunctive management has virtually stopped land subsidence caused by heavy groundwater use and has allowed groundwater levels to recover to those of the early 1900s (see Figure 4-1).

There is no comprehensive statewide data on the planning and implementation of conjunctive management at the local agency level, but DWR's Conjunctive Water Management Program provides an indication of the types and magnitude of projects that water agencies are pursuing. In fiscal years 2001 and 2002 the program awarded more than $130 million in grants and loans to leverage local and regional investment in projects throughout California with total costs of about $550 million (see Figure 4-2).

Potential Benefits from Conjunctive Management

Conjunctive management is used to improve water supply reliability, to reduce groundwater overdraft and land subsidence, to protect water quality, and to improve environmental conditions. Conservative estimates of additional implementation of conjunctive management indicate the potential to increase average annual water deliveries throughout the state by 500,000 acre-feet with 9 million acre-feet of "new" groundwater storage[1]. New storage includes both reoperation of existing groundwater storage and recharging water into de-watered aquifer space. More aggressive estimates from screening level studies indicate the potential to increase average annual water deliveries by 2 million acre-feet with about 20 million acre-feet of new storage. The more aggressive estimates are based on assumptions that require major reoperation of existing surface water reservoirs and

Figure 4-1 Relationship between groundwater elevations and land subsidence in Santa Clara County

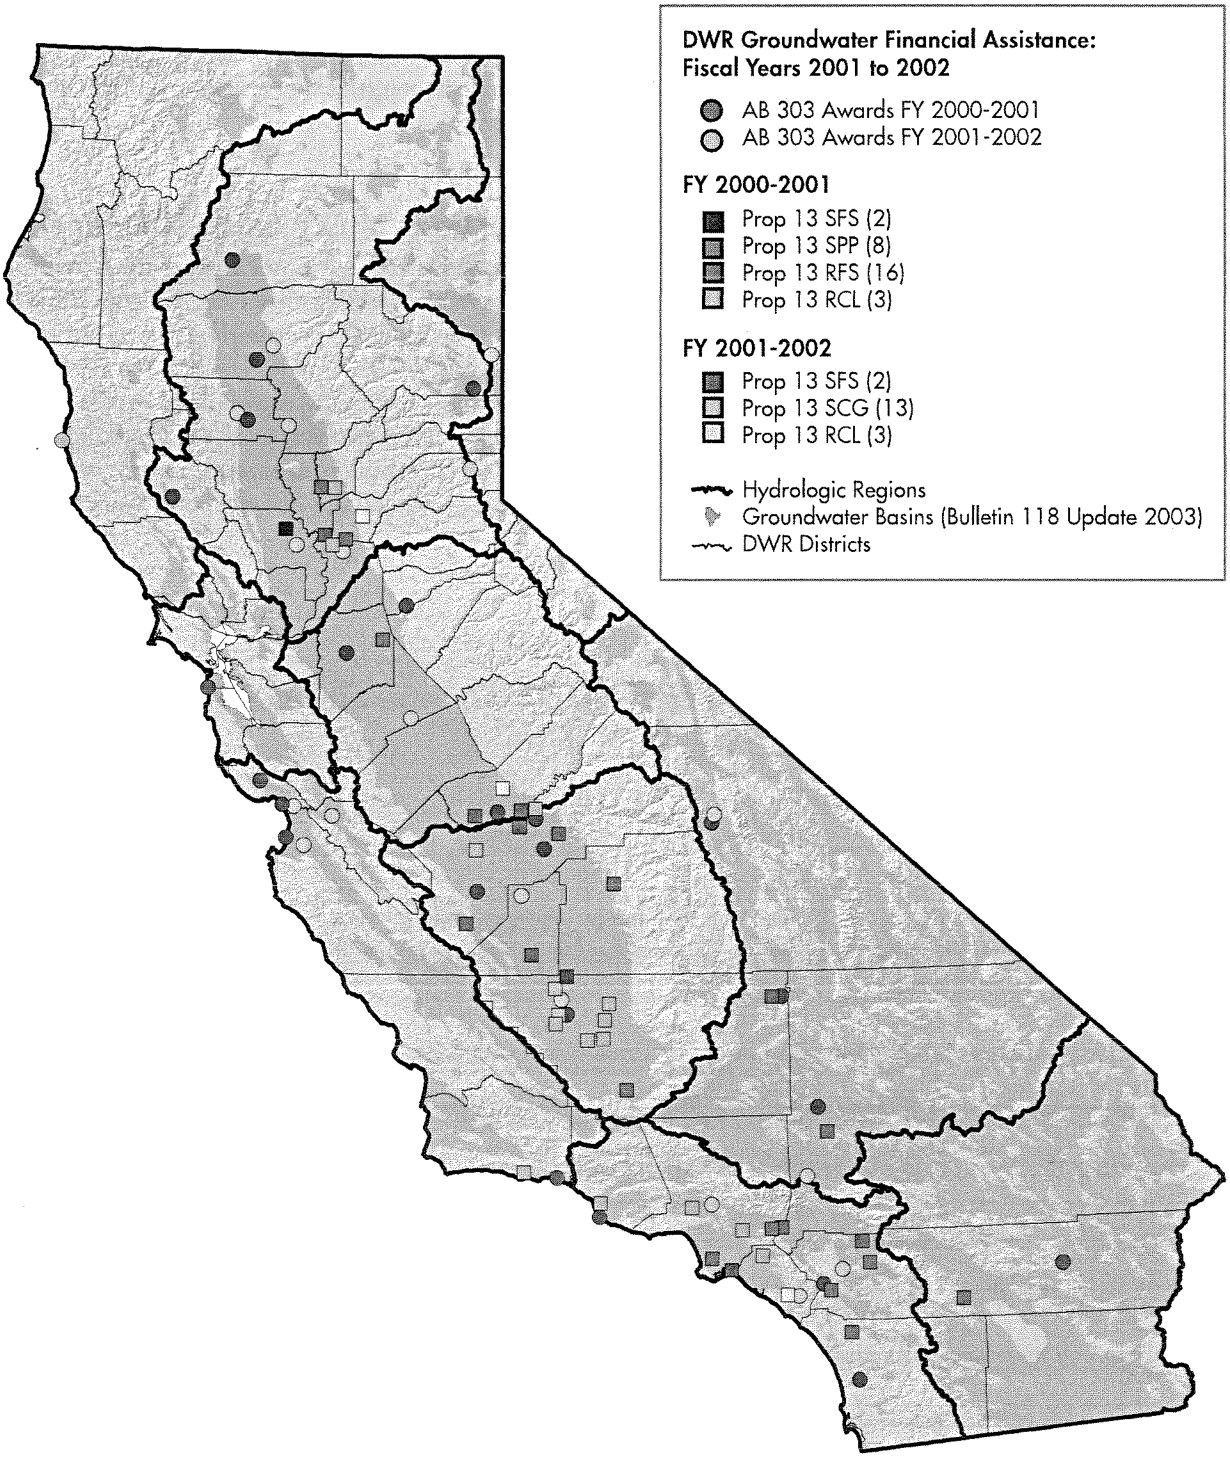


Conjunctive management in Santa Clara County has virtually stopped land subsidence caused by heavy groundwater use, allowing groundwater to recover to early 1900s levels. Santa Clara Valley Water District releases local supplies and imported water into creeks for artificial instream recharge and into recharge ponds.

---

[1] Information in this section was derived from five sources: 1) Proposition 13 Groundwater Storage Applications to DWR for fiscal year 2001-2002, 2) A 2000 report by the Association of Groundwater Agencies entitled, "Groundwater and Surface Water in Southern California", 3) A 1998 report by the Natural Heritage Institute entitled, "Feasibility Study of a Maximal Program of Groundwater Banking", 4) A 2002 report by the Natural Heritage Institute entitled, "Estimating the Potential for In-Lieu Conjunctive Management in the Central Valley", 5) A 2002 report by the U.S. Army Corps of Engineers report entitled, "Conjunctive Use for Flood Protection".

Figure 4-2 Department of Water Resources, Division of Planning and Local Assistance groundwater grant and loan programs: AB303 and Proposition 13, FY's 2001-2002



In fiscal years 2001 and 2002, DWR's Conjunctive Water Management Program awarded more than $130 million in grants and loans to leverage local and regional investment in projects throughout California with total costs of about $550 million.

groundwater storage to achieve the benefits and do not fully consider the conveyance capacity constraints for exports from the Delta and other conveyance facilities.

The potential benefits from additional conjunctive management are highly dependent on adequate water quality and the ability to capture, convey, and recharge surface water. The above estimates are based on increases in local water deliveries from individual projects with project specific sources of recharge supply and do not necessarily reflect a statewide increase in supply reliability. An increase in statewide supply reliability only occurs when the individual projects use water that would otherwise not be used by other water users or that is not needed for regulatory requirements such as water quality, fish and wildlife, and navigation. Expanding existing or developing new storage or conveyance infrastructure can increase the flexibility and ability to conduct conjunctive management projects. It is also possible to reoperate the existing system and to improve the underlying operational conditions to overcome these constraints.

In addition to water supply benefits, conjunctive management can provide environmental benefits when recharge basins are designed to be compatible with wildlife habitat, such as using natural floodplains and wetlands as recharge areas. Re-operation of surface water storage and using the water conjunctively with groundwater can avoid impacts to aquatic species by allowing better management of instream flow and water quality conditions.

Potential Costs of Conjunctive Management

Grant applications from DWR's fiscal year 2001-2002 Conjunctive Water Management Program show project costs ranging from $10 to $600 per acre-foot of increase in average annual delivery. The wide range of costs is due to many factors including project complexity, regional differences in construction and land costs, availability and quality of recharge supply, availability of infrastructure to capture, convey, recharge, and extract water, intended use of water, and treatment require-

Box 4-2 Conjunctive Management Case Example: Orange County Groundwater Replenishment System

The Groundwater Replenishment (GWR) System is a groundwater management and water supply project jointly sponsored by the Orange County Water District (OCWD) and Orange County Sanitation District (OCSD). The project will take highly treated urban wastewater and treat it to beyond drinking water standards using advanced membrane purification technology. The water will be used to expand an existing underground seawater intrusion barrier by injecting the water into the groundwater basin along the coast. Extraction wells throughout the basin will draw potable water for municipal and industrial uses.

The GWR System will provide many benefits to Orange County and California, including:

- Supplements existing water supplies by providing a new, reliable, high-quality source of water to recharge the Orange County Groundwater Basin and protect the basin from further degradation because of seawater intrusion.
- Reduces the amount of treated wastewater released into the ocean and delays the need for another ocean outfall.
- Decreases Orange County's reliance on imported water from Northern California and the Colorado River.
- Helps drought-proof Orange County using a locally-controlled project.
- Reduces mineral build up in Orange County's groundwater by providing a new source of ultra-pure water to blend with other sources, including imported water.
- Uses about half the energy of imported water supplies.

Implementation of the GWR System will be phased. The schedule calls for Phase 1 of the proposed project to produce up to 72,000 acre-feet per year of recycled water for groundwater recharge to begin operation in 2007. The total cost of the project is estimated to be $453 million. The unit cost of the supply is $516 per acre-foot.

ments. In general, urban uses can support higher project costs than agricultural uses. The average project cost of all applications received by DWR is $110 per acre-foot of increase in average annual delivery. This average unit cost translates to statewide implementation costs of approximately $1.5 billion for the conservative level of implementation and $5 billion for the aggressive implementation[2].

Major Issues Facing Additional Conjunctive Management

Lack of Data

There is rarely a complete regional network to monitor groundwater levels, water quality, land subsidence, or the interaction of groundwater with surface water and the environment. Data is needed to evaluate conditions and trends laterally over an area, vertically at different depths, and over time. Also, there is often a reluctance of individuals who own groundwater monitoring or supply wells to provide information or allow access to collect additional information. The result is that decisions are often made with only approximate knowledge of the system. This uncertainty can make any change in groundwater use controversial. Additional investment in a monitoring network and data collection can help reduce this uncertainty, but must be done in accordance with a groundwater management plan that is acceptable to stakeholders in the basin.

Infrastructure and Operational Constraints

Physical capacities of existing storage and conveyance facilities are often not large enough to capture surface water when it is available in wet years. Operational constraints may also limit the ability to use the full physical capacity of facilities. For example, permitted export capacity and efforts to protect fisheries and water quality in the Delta often limit the ability to move water to groundwater banks south of the Delta. Facilities that are operated for both temporary storage of flood water and groundwater recharge require more frequent maintenance to clean out excessive sediment often present in flood water.

Surface Water and Groundwater Management

In California, water management practices and the water rights system treat surface water and groundwater as two unconnected resources. In reality, there is often a high degree of hydrologic connection between the two. Under predevelopment conditions many streams received dry weather base flow from groundwater storage, and streams provided wet weather recharge to groundwater storage. Water quality and the environment can also be influenced by the interaction between surface water and groundwater. Failure to understand these connections can lead to unintended impacts. For example, studies by the University of California, Davis, indicate that long term groundwater pumping in Sacramento County has reduced or eliminated dry season base flow in sections of the Cosumnes River with potential impacts to riparian habitat and anadromous fish.

In California, authority is separated among local, State and federal agencies for managing different aspects of groundwater and surface water resources. Several examples highlight this issue: 1) SWRCB regulates surface water rights dating from 1914, but not rights dating before 1914; 2) SWRCB also regulates groundwater quality, but not the rights to use groundwater; 3) County groundwater ordinances and local agency groundwater management plans often only apply to a portion of the groundwater basin, and those with overlapping boundaries of responsibility do not necessarily have consistent management objectives; and 4) Except in adjudicated basins, individuals have few restrictions on how much groundwater they can use, provided the water is put to beneficial use on the overlying property. Failure to integrate water management across jurisdictions makes it difficult to manage water for multiple benefits and provide for sustainable use including the ability to identify and protect or mitigate potential impacts to third parties, ensure protection of legal rights of water users, establish rights to use vacant aquifer space and banked water, protect the environment, recognize and protect groundwater recharge and discharge areas, and protect public trust resources. The Protecting Recharge Areas and Urban Runoff Management strategies describe how land use planning can affect groundwater recharge and groundwater quality.

Water Quality

Groundwater quality can be degraded by naturally occurring or human introduced chemical constituents, low quality recharge water, or chemical reactions caused by mixing water of differing qualities. Protection of human health, the environment, and groundwater quality are all concerns for programs that recharge urban runoff or reclaimed/recycled water. The intended end use of the water can also influence the implementation of conjunctive management projects. For example, agriculture can generally use water of lower quality than needed for urban use, but certain crops can be sensitive to some constituents like boron.

---

[2] Cost estimates are extrapolated from Proposition 13 Groundwater Storage Applications to DWR for fiscal year 2001-2002. Cost estimates assume that the supply benefit is not restricted by Delta export constraints or conveyance capacity.

New and changing water quality standards and emerging contaminants add uncertainty to implementing conjunctive management projects. A water source may, at the time it is used for recharge, meet all drinking water quality standards. Over time, however, detection capabilities improve and new or changed water quality standards become applicable. As a result, contaminants that were not previously identified or detected may become future water quality problems creating potential liability uncertainties. In some cases, conjunctive management activities may need to be coordinated with groundwater clean up activities to achieve multiple benefits to both water supply and groundwater quality.

Environmental Concerns

Environmental concerns related to conjunctive management projects include potential impacts on habitat, water quality, and wildlife caused by shifting or increasing patterns of groundwater and surface water use. For example, floodwaters are typically considered "available" for recharge. However, flood flows serve an important function in the ecosystem. Removing or reducing these peak flows can negatively impact the ecosystem. A key challenge is to balance the instream flow and other environmental needs with the water supply aspects of conjunctive management projects. There may also be impacts from construction and operation of groundwater recharge basins and new conveyance facilities.

Funding

There is generally limited funding to develop the infrastructure and monitoring capability for conjunctive management projects. This includes funding to develop and implement groundwater management plans, to study and construct conjunctive management projects, and to track, both statewide and regionally, changes in groundwater levels, groundwater flows, groundwater quality (including the location/spreading of contaminant plumes), land subsidence, changes in surface water flow, surface water quality, and the interaction and interrelated nature of surface water and groundwater.

Recommendations to Help Promote Additional Conjunctive Management

1. Local water management agencies should coordinate with other agencies that are involved in activities that might affect long term sustainability of water supply and water quality within the basin or adjacent to the basin. Such regional coordination will take different forms in each area because of dissimilar political, legal, institutional, technical, and economic constraints and opportunities, but will likely include agencies with authority over managing groundwater and surface water quantity and quality, land use planning, human health, and environmental protection. Regional groundwater management plans should be developed with assistance from an advisory committee of stakeholders to help guide the development, educational outreach, and implementation of the plans.
2. Continue funding for local groundwater monitoring and management activities and feasibility studies that enhance the coordinated use of groundwater and surface water. Additional monitoring and analysis is needed to track, both statewide and regionally, changes in groundwater levels, groundwater flows, groundwater quality (including the location/spreading of contaminant plumes), land subsidence, changes in surface water flow, surface water quality, and the interaction and interrelated nature of surface water and groundwater. There is a need to develop comprehensive data and data management systems to track existing, proposed, and potential conjunctive management projects throughout the state and identify and evaluate regional and statewide implementation constraints including availability of water to recharge, ability to convey water from source to destination, water quality issues, environmental issues, and costs and benefits.
3. Give priority for funding and technical assistance to conjunctive management projects that are conducted in accordance with a groundwater management plan, increase water supplies, and have other benefits including the sustainable use of groundwater, maintaining or improving water quality, and enhancing the environment. Additional preference should be given for projects conducted in accordance with a regional groundwater management plan. In addition, allow funding for projects that make use of wet season/dry season supply variability, not just wet-year/dry-year variability.
4. Assess groundwater management throughout the state to provide an understanding of how local agencies are implementing actions to use and protect groundwater, an understanding of which actions are working at the local level and which are not working, and how State programs can be improved to help agencies prepare effective groundwater management plans.
5. Improve coordination and cooperation among local, State, and federal agencies with differing responsibilities for groundwater and surface water management and monitoring to facilitate conjunctive management, to ensure efficient

use of resources, to provide timely regulatory approvals, to prevent conflicting rules or guidelines, and to promote easy access to information by the public.

6. Encourage local groundwater management authorities to manage the use of vacant aquifer space for artificial recharge and to develop multi-benefit projects that generate source water for groundwater storage by capturing water that would otherwise not be used by other water users or the environment. For example, through reservoir reoperation, water recycling and reuse, and water conservation.
7. Work with wildlife agencies to streamline the environmental permitting process for the development of conjunctive management facilities, like recharge basins, when they are designed with pre-defined benefits or mitigation to wildlife and wildlife habitat.

Re: Independent Panel Review of the Bay Delta Conservation Plan

Dear Interested Stakeholder:

The attached report was prepared by an independent panel of experts convened by Dr. Jeff Mount for American Rivers and The Nature Conservancy to assist in our deliberations regarding the Bay Delta Conservation Plan. Dr. Mount assembled a balanced, interdisciplinary, and objective group of experts with long experience in the San Francisco Bay-Delta estuary to conduct this review of the March 2013 BDCP Administrative Draft and associated documents released during the Spring of 2013. This report will now join a growing library of independent reviews of efforts to resolve the Delta crisis.

The opinions, analyses, and recommendations provided in the report are solely those of the authors. Our organizations will use the information in the report along with our own analysis of BDCP to develop a proposal for increasing the probability that BDCP will substantially improve environmental conditions in the Delta. This report does not represent the position of American Rivers or the Nature Conservancy.

American Rivers and The Nature Conservancy have been active participants in the BDCP planning process for the last seven years. Our organizations have not taken a formal position in support of the proposed project described in the administrative draft of the BDCP, but we are fully committed to continue our work in good faith to develop a conservation plan for the Delta ecosystem that advances the co-equal goals of ecosystem restoration and water supply reliability. The status quo condition in the Delta is unacceptable, and without action, will result in the inexorable decline of the Delta ecosystem and the species it supports.

Please direct questions regarding the report to Leo Winternitz or John Cain at lwinternitz@TNC.ORG and jcain@americanrivers.org. Thank you for your consideration.

Sincerely:

Leo Winternitz

Preface

The Bay-Delta Conservation Plan is more than 15,000 pages long and covers a wide range of issues ranging from water supply, new facility construction, aquatic and terrestrial ecosystem management, governance and costs. Few outside of the handful of people deeply involved in BDCP actually know what is in the document due to its imposing size. This is particularly true for the various stakeholder groups who lack either the staff or the technical capacity to review the document and to evaluate the complex analyses that underpin it.

Saracino & Mount, LLC, was asked to assemble a panel of independent experts to review portions of the Plan to help guide decision-making by two non-governmental organizations: The Nature Conservancy and American Rivers. Guided by a narrow set of questions about how the Plan would impact water supply and endangered fishes, the panel reviewed the Plan documents and conducted analyses of data provided by the project consultants. The following document is a summary of our results.

It is important that this analysis not be over-interpreted. We do not endorse or reject the Plan. We only assess effectiveness of various conservation measures, guided by narrowly targeted questions. In addition, we make a handful of modest proposals to improve the performance of the Plan, particularly for issues of concern to the two non-governmental organizations. Thus, the scope of this review is quite limited.

The authors wish to thank the S.D. Bechtel, Jr. Foundation for its generous support. The staff of The Nature Conservancy and American Rivers provided abundant time and energy as we scoped this review. Jennifer Pierre, Armin Munevar, Chandra Chillmakuri, and Laura King-Moon provided voluminous data, answered our many questions and addressed our concerns. Spreck Rosecrans and Drs. Peter Moyle and Jay Lund provided comment on portions of the manuscript, although their comments do not constitute formal peer review. All errors of omission or commission are our own.

Jeff Mount, Panel Chair

Executive Summary

Two non-governmental organizations, The Nature Conservancy (TNC) and American Rivers (AR), are evaluating their options for engagement with the Bay Delta Conservation Plan (BDCP). If approved, the Plan would become a Habitat Conservation Plan (HCP) under the federal Endangered Species Act and a Natural Communities Conservation Plan (NCCP) under California law. The purpose of the Plan is to allow for construction of new water diversion facilities in the Sacramento-San Joaquin Delta while also protecting aquatic and terrestrial species that may be adversely affected by the project and accompanying changes in the State Water Project (SWP) and Central Valley Project (CVP) operations. The Plan also includes habitat restoration and a commitment to assist in the conservation and recovery of species that are listed for protection under the federal and state Endangered Species Acts.

With financial support from the S.D. Bechtel, Jr. Foundation, Saracino and Mount, LLC, convened an independent panel of experts, with technical support from NewFields, Inc., to evaluate portions of the Plan. The panel, working jointly with TNC and AR, developed a series of technical and legal questions about the Plan. This report provides answers to these questions, along with limited recommendations on how to improve BDCP.

To simplify analysis, this review focuses on conditions for federally listed fishes during the Early Long Term (ELT), a decade after a permit would be issued (approximately year 2025). These are described in detail in the BDCP Effects Analysis and accompanying Environmental Impact Statement/Environmental Impact Report. We compared the performance of three different scenarios: a No Action Alternative (NAA) where no new North Delta diversion facility is constructed, a High Outflow Scenario (HOS) where the facilities are operated in a way that allows for occasional high spring and fall outflows, and a Low Outflow Scenario (LOS) with lower spring and fall outflows. The review also emphasizes in-Delta and Sacramento River watershed conditions during the ELT, with less attention to San Joaquin River conditions and fishes.

Although multiple data sources were used in this analysis, most hydrologic data came from CALSIM simulations conducted by BDCP consultants. The Panel strongly cautions about the conclusions drawn from these simulations. Flow simulations have three compounding uncertainties that can lead to significant error: (1) uncertainty in system understanding and future conditions, (2) model uncertainties (particularly the relationships between 1-, 2-, and 3-dimensional models), and (3) behavioral/regulatory uncertainty where the models cannot capture the scope of human behavior in operating the projects under various conditions. These uncertainties, which are not described in BDCP documents well, makes all of our conclusions contingent on the projects *actually being operated as simulated.*

Do Operations Shift Delta Exports from Dry to Wet Years?

The BDCP calls for increasing exports in wet years and reducing them in dry years, taking advantage of the increased operational flexibility provided by two points of diversion. This would reduce stress on Delta ecosystems during drier periods. Our analysis of simulation data suggests that while there is some increase in flexibility, export operations are highly constrained by upstream consumptive uses, regulations that cover reservoir operations, and flow and water quality standards. This greatly limits the anticipated benefit associated with operation of the dual facilities. Despite these limitations, as modeled, there is an increase in exports in wet years. In most dry years there are no substantial changes over NAA conditions. However, significant improvements in outflow and Old and Middle River (OMR) conditions occur in some dry years. We were unable to identify the regulatory or operational requirements that would lead to this.

Are Impacts of the North Delta Facility Fully Assessed and Mitigated?

The Plan identifies multiple near- and far-field effects of the new North Delta facility. Based on our review of the Effects Analysis, the Plan appears to have properly identified the most significant effects and uses standard models to assess them. Outmigrating juvenile winter-run and spring-run Chinook salmon will be most heavily affected, leading, in the absence of mitigation, to significant losses. The Plan identifies multiple mitigation strategies, including pulse flow management, predator control, entrainment reduction, non-physical barriers, real-time operations and development of alternative migration pathways (Yolo Bypass). With the exception of benefits from diverting juveniles onto the Yolo Bypass, all of these mitigation approaches have high uncertainties. Done well and successfully, however, they appear to offset the losses associated with operation of the North Delta facility. The HOS appears most protective of conditions upstream of the Delta and adjacent to the new facility. However, mitigation actions are unlikely to contribute significantly to recovery of these species. Additionally, successful mitigation is likely to occur only if there is a robust adaptive management and real-time operations program. The Plan provides neither.

Are In-Delta Conditions Significantly Improved for Smelt?

We evaluated the modeling results in the Plan and conducted our own modeling to evaluate how changes in conditions would affect delta and longfin smelt. As noted, we are concerned that anomalously positive (or less negative) OMR flows and high Delta outflows that are modeled during some drier years would not actually occur in real operations. However, if these changes were to occur we find modest to significant improvement in in-Delta conditions for smelt, particularly delta smelt. Improvements in OMR flows under HOS and LOS result in substantial decreases in entrainment, leading to significant increases in long-term survival percentages for delta smelt. However, increases in spring and fall outflow under HOS lead to small increases in longfin smelt abundance and modest improvements in delta smelt recruitment.

Will Pelagic Fishes Benefit from Floodplain and Tidal Marsh Restoration?

The Plan properly identifies food limitation as a significant stressor on smelt populations in the Delta. The Plan proposes to address this issue by restoring physical habitat to help subsidize pelagic food webs. Based on simple modeling and comparison with other systems, we find that restored floodplains and tidal marshes are unlikely to make a significant contribution to smelt rearing habitat conditions. Tidal marshes can be sinks or sources of food, with most appearing to be sinks for zooplankton. The Plan appears to be too optimistic about the benefits of tidal marsh and floodplain restoration. However, there is likely to be benefit where fishes have direct access to productivity, such as in Cache Slough. In addition, although benefits for listed pelagic fishes are low, there are broad benefits of restoration for many aquatic and terrestrial species covered by the Plan.

Does the Plan Provide an Effective Governance Structure?

We reviewed the proposed BDCP governance structure to evaluate its likely effectiveness in meeting the Plan's goals and objectives. Implementation of BDCP would be overseen by an Authorized Entity Group (AEG) comprising the California Department of Water Resources (DWR), the U.S. Bureau of Reclamation (USBR), and the state and federal water contractors if they are issued incidental take permits pursuant to the BDCP. A Permit Oversight Group (POG), consisting of the U.S. Fish and Wildlife Service (USFS), the National Marine Fisheries Service (NMFS), and the California Department of Fish and Wildlife (CDFW), would monitor implementation of the Plan and compliance with the biological objectives and conservation requirements. The draft BDCP includes a 50-year "no surprises" guarantee, as well as other regulatory assurances. We found that, when examined in detail, the draft BDCP blurs the lines between implementation and regulation and grants the permittees unusual decision authority. Additionally, the regulatory assurances in the Plan, especially the "no-surprises" policy, place undue financial responsibilities on the state and federal governments if certain modifications to the Plan become necessary during its 50-year term. Given the complexity of the Delta ecosystem, predicted changes in hydrology, anticipated changes in the Delta not included in the Plan, and significant scientific uncertainties, Plan modifications are likely to be needed in the future.

Is There a Robust Science and Adaptive Management Plan for BDCP?

The Plan is committed to adaptive management in order to address the high uncertainties. Most of the unresolved issues in the Plan are to be resolved at a future date through adaptive management. A "decision tree" approach is proposed to resolve conflicts over starting operations. We found that the governance structure, whereby the AEG may exercise veto authority over changes to the biological objectives and conservation measures, is likely to create disincentives for adaptive management. In addition, a proposed consensus-based Adaptive Management Team made up of POG, AEG, and scientific community members creates conflicting relationships between decision-makers and providers of key information. The limited information available about the science program suggests that BDCP proposes to develop a wholly new science program that is not integrated, but should be, with existing programs. Finally, our review of the "decision tree" process indicates that it is unlikely to achieve the goal of significantly reducing uncertainties before the North Delta facility is constructed and ready for operation.

Recommendations

Based on answers to these six questions, the Panel formulated a list of nine recommendations for improving BDCP.

- All parties need to recognize the model uncertainties in BDCP and factor that into decision-making. It is unlikely that actual operations will follow simulated operations.
- Given the high uncertainty over mitigation for the North Delta facility, all mitigation efforts should be in-place and tested *before* the facility is completed. This includes completion of the Fremont Weir modifications on the Yolo Bypass as well as large scale, significant experiments in real-time flow management, predator control and non-physical barriers.
- The improvements in long-term survival percentages for delta smelt in response to changes in OMR need to be more rigorously evaluated, particularly in light of uncertainties over operations. If further examination supports these findings, operational rules should be developed that insure that the anomalous, significantly improved drier-period OMR and outflow conditions occur.
- The limited benefit derived from changes in outflow under HOS requires a second look at options for significant increases in outflow, including finding sources of water outside the direct control of BDCP.
- Although we find that marsh and floodplain restoration is unlikely to create the benefits for pelagic fishes described in the Plan, this can only be resolved through experimental restoration projects. These projects need to be designed and implemented rapidly to resolve this issue.
