ABSTRACT: The match-mismatch hypothesis suggests there is an optimal window for organisms to undergo key life cycle events. Here, we test the importance of match-mismatch dynamics in the timing of salmon arrival to the ocean, relative to ecosystem phenology, for the ocean survival rates of hatchery-origin fall run Chinook salmon originating from California's Central Valley. Specifically, we considered tag recovery data for releases of coded-wire tagged fish released into the San Francisco Estuary during the years 1978 to 2010. We determined a time lag for each release relative to the local spring transition date (initiation of net upwelling). Additionally, we obtained information on fish condition and size at release, the number of fish released corresponding to distinct tag codes, and yearly stock-specific harvest rate estimates. We used generalized linear models, generalized additive models, and cross-validation to identify the best-supported models for the effects of release timing and other covariates on age-3 ocean fishery recovery rates, a proxy of ocean survival rates. Release time is a useful predictor of within-year variation in survival rates, above and beyond the effects of size at release, presence of disease, and the use of net pens, and the lag relative to spring transition was a slightly better predictor than year-day. The optimal release timing appeared to occur around the end of May, and the optimal time lag appeared to be approximately 70 to 115 d after the spring transition date. However, timing is only one of many factors that affected within- and among-year variation in survival.

INTRODUCTION

It has been long recognized that the environment plays a significant role in the variability of fish production. Specifically, when exposed to a poor environment at a critical time, the mortality rate of a population will be great, and ultimately, recruitment will be low (Hjort 1914, Cushing 1990). While these may

be tenets in the fishery literature, most fisheries management is still based on information gleaned only from the population dynamics of the fish (Beverton & Holt 1957) without an explicit consideration of environmental drivers. In the last few decades, however, environmental data series have been widely available to explore the impact of the environment on stock dynamics (Quinn & Deriso 1999, Deriso et al.

*Corresponding author: will.satterthwaite@noaa.gov

2008) and have been at times incorporated into management (Jacobson & MacCall 1995, Logerwell et al. 2003). One recurring challenge in incorporating environmental variables into fisheries management models is that correlations between environmental drivers and fishery dynamics have a tendency to break down over time (Myers 1998). Focusing on explicit mechanistic hypotheses for the relationship between environment and fishery dynamics may increase the ability of environmental covariates to improve our understanding of fish population dynamics and management based upon these dynamics.

Here, we examine the relationship between the phenology of upwelling and the survival of juvenile salmon. The timing of ocean entry is a key life history trait that can profoundly influence the early marine survival of anadromous salmon (Bilton et al. 1982, 1984, Whitman 1987, Quinn 2005, Scheuerell et al. 2009). For example, Scheuerell et al. (2009) reported that Columbia River Chinook salmon and steelhead migrating to the ocean early in the season (early to mid-May) experienced 4- to 50-fold higher survival than individuals migrating late in the season (mid-June). They also noted, however, that the timing of peak survival varied among years and hypothesized that the cause was interannual variation in nearshore conditions—especially variation in physical conditions and trophic dynamics. The natural spread in the timing of ocean entry ensures some degree of match between salmon arrival to the ocean and the timing of favorable ocean conditions but also some degree of mismatch (i.e. match-mismatch hypothesis *sensu* Cushing 1990). Indeed, this natural variation in the timing of ocean entry among and within stocks can be thought of as a bet-hedging strategy that spreads risk of mortality among individuals arriving at different times and thus minimizes the possibility of a complete mismatch between salmon arrival to the ocean and the availability of their prey.

Anthropogenic activities that influence the ocean arrival timing of salmon might then have large consequences for the survival of salmon populations. Such influences might include altered migration timing due to slowed passage around dams (e.g. Raymond 1979, 1988), altered river flows and temperatures from water management (Zabel & Williams 2002, Williams 2008, Petrosky & Schaller 2010), or changes to hatchery release strategies (Rechisky et al. 2012). Another management activity that directly affects salmon ocean arrival timing is barging (e.g. on the Columbia River; Budy et al. 2002) or trucking of the fish from the hatchery for direct release into the estuary (e.g. the California

Central Valley; California Hatchery Scientific Review Group 2012).

Chinook salmon originating from the California Central Valley have shown great variability in abundance in recent years, and mismatch dynamics have been invoked as among the potential explanations for this pattern (Lindley et al. 2009, Woodson et al. 2013). For example, juvenile salmon entering the ocean in 2000 and 2001 produced 2 of the greatest recruitment events on record, while only 5 yr later, early survival was so low that the stock collapsed to record low numbers, leading to an unprecedented emergency closure of commercial and recreational salmon fishing off the coasts of California and southern Oregon (Lindley et al. 2009). The proximate cause identified for this collapse, and likely a major contributor to variation over the longer term, is upwelling dynamics, including strength, duration, and timing (Barth et al. 2007, Lindley et al. 2009, Woodson et al. 2013). Previous work in this system has revealed that upwelling intensity relates to variability in a number of salmon vital rates, including growth (Wells et al. 2007, 2008) and recruitment (Logerwell et al. 2003, Wells et al. 2012, Burke et al. 2013). Here, we focus on the role of variability in the match between the timing of upwelling initiation and the time that emigrating juveniles enter the ocean. Upwelling strength and timing are indirectly and directly related to forage and predator dynamics in central coastal California (Croll et al. 2005, Wells et al. 2008, 2012, Thompson et al. 2012, Woodson et al. 2013). Increased nutrients associated with the initiation of the upwelling season positively correlate to zooplankton prey abundance in the Monterey Bay months later (Croll et al. 2005). Wells et al. (2008) and Thompson et al. (2012) demonstrate that, in addition to the indirect positive effect of providing nutrients for primary production, upwelling has a positive and direct effect on zooplankton and forage fish abundance in central California. The direct relationship is partly a result of physical forcing and advective properties associated with the interaction of wind strength and geographic features, such as Point Reyes, which provide an upwelling shadow in which a forage community can develop and be retained (Graham & Largier 1997, Wing et al. 1998, Santora et al. 2012, in press). Juvenile salmon diet composition, condition, and abundance respond positively to the increased prey associated with upwelling (Thompson et al. 2012, Wells et al. 2012), and when prey is delayed or absent from the region, significant increases in mortality of juvenile salmon have been documented (Lindley et al. 2009, Woodson et al. 2013).

A better understanding of how ocean entry timing affects marine survival is important for informed management of salmon stocks and in particular for managing anthropogenic activities that determine ocean entry timing and its influence on fish survival. Our goal is to examine linkages between hatchery release timing, environmental variability including upwelling linked to food web dynamics, and performance of the Central Valley Chinook salmon stock complex.

To quantify match-mismatch dynamics in this system, we compare the distribution of release dates to the spring transition date. We hypothesize that the phenology of upwelling in this system influences salmon survival by determining the availability of salmon prey in the coastal ocean (Croll et al. 2005). We test this hypothesis by examining success of hatchery-released salmon from the Central Valley with respect to release timing. Furthermore, considering the 30 yr period, we ask if there is an optimal time lag between the timing of release and the spring transition date that maximizes the early marine survival of juvenile salmon. While numerous other factors undoubtedly affect salmon survival, and different factors will moderate the effects of timing on survival differentially across years, our primary question is whether the effect of timing is strong and consistent enough that a clear signal emerges, on average, even in the presence of numerous confounding factors. Given the demonstrated importance of upwelling in this system, we further ask whether the initiation of upwelling, as measured by the spring transition date, captures enough information about important ecosystem drivers and phenology that models measuring time relative to the spring transition date can better explain variability in the data than models based on calendar date alone.

MATERIALS AND METHODS

To examine how marine survival and recruitment to the fishery are affected by release timing and lags relative to ocean phenology as characterized by the timing of initiation of upwelling, we considered ocean recovery rates of individual release groups, identified by unique coded-wire tags (CWT; Johnson 1990, Lapi et al. 1990, Nandor et al. 2010). CWT are small pieces of wire injected into the snouts of juvenile salmon, and each tag is etched with a unique batch-code that identifies all individuals released in a given group (hereafter 'release group'). The Regio-

nal Mark Identification System (RMIS, www.rmpc.org) is an online repository for CWT release and recovery data for the Pacific coast. Associated with each CWT in the RMIS database are descriptors such as the release date(s), total number of marked fish that were released, average weight of fish at release, developmental stage of fish at release, source hatchery, location of release, and a comments field that includes various notes including, for example, whether fish in a release group showed signs of disease or poor condition.

Release groups identified by coded-wire tags

We analyzed CWT groups released directly into San Francisco Bay for which the approximate time of ocean entry is known and results are not influenced by variability in survival during downstream migration. We queried the RMIS for all releases of CWT Central Valley fall run Chinook salmon released into the San Francisco Estuary through 2010. Note that all of these fish were of hatchery origin.

Ocean recovery rates

We also queried RMIS for all recoveries of CWT fish in the ocean recreational or troll fisheries reported by California Department of Fish and Game (CDFG; now the California Department of Fish and Wildlife [CDFW]) or the Oregon Department of Fish and Wildlife (ODFW) and calculated ocean recoveries $O_{i,a}$ as the sum of the 'estimated number' (i.e. expanded for subsampling of the harvest) reported for each recovery of an age a fish from the release group i in the ocean fishery, repeated over all age-year combinations subject to the fishery. To recover the tags, adults are sampled from commercial and sport fisheries. A known fraction, typically ~20%, of the harvest is examined for the presence of CWT. This allows calculation of a sample expansion factor that estimates how many CWT fish from a particular release group were likely in the total sampling stratum for each CWT read. Thus, for every CWT from a particular release group recovered in a particular sampling stratum with sample rate f , it is assumed that $1/f$ fish were caught. We then use the sum of these $1/f$ values across strata to estimate total recoveries. Ages are calculated as the difference between recovery year and brood year, where brood year is the year of spawning and fish are typically released the next calendar year.

Covariates and confounding issues

Our direct interest is in the relationship between release timing and survival as indicated by ocean recovery rates. We characterized years on the basis of spring transition (Schwing et al. 2006, Bograd et al. 2009) at 39°N, 125°W. Spring transition is defined as the day in each calendar year that the cumulative coastal upwelling index (for that year, integrated daily values starting January 1) first starts increasing from its minimum value, and this transition day is highly variable across years (Fig. 1). We hypothesized that 'time lag', the difference between the year-day (i.e. day of year) of release and the spring transition date, would provide a better predictor of relative survival than year-day alone.

We excluded individual release groups whose release dates spanned >30 d since no single release date could be assigned to such groups (amounting to only ~6% of all records). For the remaining groups, we determined the total number of marked fish in each release group N_i released on year-day t of year y . When a release group was released over multiple days, we characterized the group based on the midpoint of the release dates.

Our analyses also allowed for expected effects of numerous covariates, such as the use of acclimation (net) pens prior to release, and notes of disease or poor condition associated with individual release groups. Many studies (Ward et al. 1989, McGurk 1996) have found an effect of size at emigration on survival (but see Tomaro et al. 2012), so we included weight as a covariate as well. We removed data for release groups with no weight information (~2% of records).

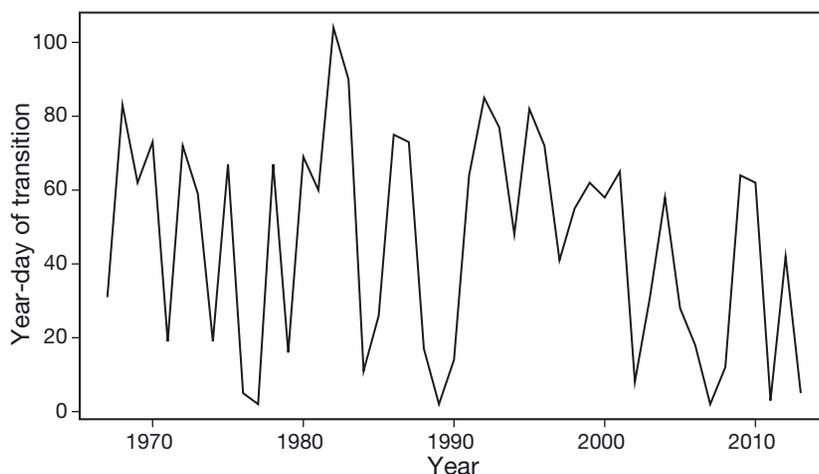

Fig. 1. Annual variation in spring transition date measured at 39°N, 125°W (see 'Materials and methods: Covariates and confounding issues' for methodological details); 'year-day' = day of year

Because release times varied among hatcheries, and some hatcheries had a very restricted range of release dates, we restricted our analysis to Feather River Hatchery releases, which released fish over a protracted period (see Supplement 1 at www.int-res.com/articles/suppl/m511p237_supp.pdf for further details). To reduce the collinearity between weight and release timing, we restricted our analysis to fish released as 'fingerlings' or 'advanced fingerlings' which make up the majority of releases (~90%), rather than the much larger smolts or much smaller fry. We considered only age 3 ocean recoveries because prior to being caught at age 3, the predominant source of mortality is from natural causes, and recoveries of age 2 and age 4 fish are comparatively rare (Supplement 1; age 3 recoveries typically an order of magnitude higher than age 2 and age 4, with negligible recoveries of other ages). We excluded releases from years 2006 and 2007 due to closures of the fishery in 2008 and 2009, precluding recovery of age 3 fish. Data filtering is described more fully in Supplement 1.

We also integrated into our analysis an approximation of Sacramento River fall run Chinook (SRFC) adult harvest rate based on the Sacramento Index (see 'Modeling recoveries' below) (O'Farrell et al. 2013). SRFC harvest rates were applied to recovery years of age 3 fish. Yearly estimates of SRFC harvest rates do not exist prior to 1983, limiting data to fish released after 1980.

Finally, one observation was excluded in which the year-day of release was far greater than other release groups. In total, we used information from 164 Feather River Hatchery release groups that were released in years 1981 to 2010 (Table 1).

Modeling recoveries

The expected number of age a ocean recoveries of release group i ($O_{i,a}$) is a product of the probability of surviving until being caught in ocean fisheries ($s_{i,a}$), the conditional probability of a live fish being caught at age a after being released in year y ($c_{y,a}$, accounting for fishery effects in year $(y-1) + a$), and the number released (N_i). We assume the conditional probability of being caught at age 3 is proportional to the SRFC harvest rate ($c_{y,3} = \phi h_y$), where ϕ is a constant of

Table 1. Annual number of release-groups released directly into San Francisco Bay by each California Central Valley fall Chinook hatchery (CM: Coleman; MC: Merced; MK: Mokelumne; NB: Nimbus; TC: Tehema-Colusa; FE: Feather). Releases spanning >30 d were excluded, as were releases without information on release weight or those that reached age 3 in years before the Sacramento River fall run Chinook (SRFC) harvest rates were estimated. Only fingerling (finger.) and advanced fingerling (adv. finger.) releases from Feather River Hatchery were included in the models presented in this study (see Supplement 1 at www.int-res.com/articles/suppl/m511p237_supp.pdf)

proportionality, and the yearly SRFC harvest rate (h_y) is the estimated number of age 3 to age 5 SRFC caught as a proportion of an index of yearly abundance (O'Farrell et al. 2013). If we further assume the fates of fish are independent, ocean recoveries of age 3 fish from N_i number of tagged releases are binomially distributed:

$$O_{i,3} \sim \text{Bin}(N_i, s_{i,3}\phi h_y) \quad (1)$$

Since the unconditional probability of being caught ($s\phi h$) is small, the number of recoveries can be well approximated by a Poisson distribution (Raff 1956). However, due to the non-independent fates of individual fish, the presence of measurement error, and

the complex forces and interactions acting on ocean survival, there is likely to be much unexplained variation. For these reasons, we allow the variance (σ^2) of the Poisson to be greater than the mean (μ) (Ver Hoef & Boveng 2007). The variance of the related overdispersed Poisson distribution is calculated as follows:

$$\sigma^2 = \theta\mu \quad (2)$$

such that θ is an estimated overdispersion parameter ($\theta > 1$).

Age 3 ocean recoveries (count data) are then modeled as an overdispersed (quasi) Poisson regression with mean μ . We chose to use a quasi-Poisson distribution to allow for overdispersion rather than a negative binomial distribution due to its better computational performance and the lack of specific motivation for using a negative binomial. Our data do not allow separate estimation of ϕ and s ; thus, we assume constant ϕ and interpret their product (which is itself modeled as a function of various covariates) as a measure of relative survival. Thus, the expected number of fish recovered (μ) from an initial release of N fish is $s\phi hN$, yielding the following relation:

$$\log(\mu) = \log(Nh) + \log(\phi s) \quad (3)$$

In the null model, no covariates other than year affect survival, resulting in the following relation:

$$\log(\mu) = \log(Nh) + \gamma_y \quad (4)$$

where γ_y is the combined effect of release year y to recovery year $y + 2$, and $\log(Nh)$ is treated as a model offset. Year effects (γ_y) are modeled as random effects and include unaccounted effects of natural mortality prior to being caught, exploitation and maturation of age 2 fish, ignored interacting effects between release timing and year, and temporal deviations in the proportional difference (otherwise assumed constant at ϕ) between conditional recovery probabilities and the SRFC harvest rate.

Additional models are based on the null model and include a linear effect of release weight ($\beta_1 W$), an additive effect of net pens (β_n), and/or an effect of disease/poor condition (β_d). Also, 2 other suites of

models include either an effect of year-day of release or an effect of time lag relative to spring transition date. Without the effects of weight, disease, or net pens, the mean of a model that includes the effect of time lag (i.e. year-day of release $[t]$ – year-day of spring transition $[\tau]$) is generalized as follows:

$$\log(\mu) = \log(Nh) + f(t - \tau, \nu) + \gamma_y$$

$f()$ is a smooth function of a generalized additive model (GAM; Wood 2011) allowing for nonlinear effects of release timing on survival with a maximum of ν degrees of freedom, where ν ranges from 1 to 5 or is unspecified (i.e. unconstrained), and the maximum possible number of knots is $\nu + 1$. This results in a total of 104 models, 8 with no release timing effects, 48 with potentially nonlinear effects of year-day of release, and 48 with similar effects of time lag.

One assumption of these models is that different release groups from the same year are equally vulnerable to fisheries (and thus that release timing does not have major effects on ocean distribution or size-at-age, affecting the proportion of fish reaching legal size). Similar ocean distributions might be expected for similar run types originating from the same or adjacent watersheds, based on the results of Weitkamp & Neely (2002) and Satterthwaite et al. (2014). Previous work (Hankin 1990) has suggested that later releases may be smaller than earlier releases in subsequent years (since later releases have spent less time growing in the more favorable ocean environment) but also found that later releases more often exhibit delayed maturation. Another assumption is an equal effect of release timing across years. For interpretability, we did not consider an interaction between release time and year (aside from that implied by changing the measure of release time to the lag from the spring transition date, which varies by year), but in Fig. 2, we present the relationship between release time and recovery rates standardized by SRFC harvest rates for individual years without a formal analysis.

Models were fit using the *mgcv* package (Wood 2011) in R 2.15.1 (R Development Core Team 2012).

We used Monte Carlo cross-validation rather than Akaike's information criterion due to concerns about non-independence of different release groups and a tendency for Akaike's criterion to favor overparameterized models (Shao 1993). The Monte Carlo cross-validation method involves randomly splitting the data into k subsets and calculating the prediction error for each subset. This is repeated over a number of iterations. We performed 1500 Monte Carlo cross validation iterations, each time randomly selecting

41 subsets (k) with 4 data points per subset. Then, for each subset, we quantified the error when predicting a single subset (4 data points) from a model fitted to the remaining 40 subsets. The median number of releases per brood year is 6; thus, $k = 41$ mostly ensures that if data from a particular release year are included in the validation subset, they are also included in the training data. Model errors for a validation subset were not calculated if release years in the validation subset were not included in the training data. Our model selection criterion is the minimum root weighted mean squared prediction error (RWMSE). Since release groups varied in size and thus in the certainty with which recovery proportions could be estimated, we weighted each datum on the basis of the number of total fish present in the corresponding initial release. We also consider a cross validation metric similar to R^2 , denoted R_{CV}^2 (equivalent to OCV^* in Rupp et al. 2012). Diagnostic plots for the best-supported model are presented in Supplement 2 at www.int-res.com/articles/suppl/m511p237_supp.pdf.

RESULTS

Combining data from a wide range of release years (1981 to 2010) for Feather River Hatchery releases, the relationship between release timing and age 3 ocean recovery rates standardized by SRFC harvest rates appeared to vary across years (Fig. 2). This illustrates that, given current practices and covariation among factors, there is no consistent optimal release time that applies for all years, with 'optimal' defined as yielding the greatest availability to the fishery.

The best-supported model when applied to releases from Feather River Hatchery included the effects of net pen, disease, and release time as measured by time lag rather than year-day. This model had a mean RWMSE of 0.0037 and a mean R_{CV}^2 of 0.60 (Table 2). A similar model with release year-day in place of time lag was less supported ($\overline{RWMSE} = 0.0047$ and $\overline{R_{CV}^2} = 0.45$), but including either measure of release timing was better than including none at all ($\overline{RWMSE} = 0.0051$ and $\overline{R_{CV}^2} = 0.41$).

The earliest releases appeared to survive poorly (Fig. 3a,b), and releases approximately 90 d after the spring transition appeared to do better than even later releases (Fig. 3a). Very late releases may have also fared well (Fig. 3a,b), but there were few data points driving this part of the curve and most points were from early release years. Releases of heavier

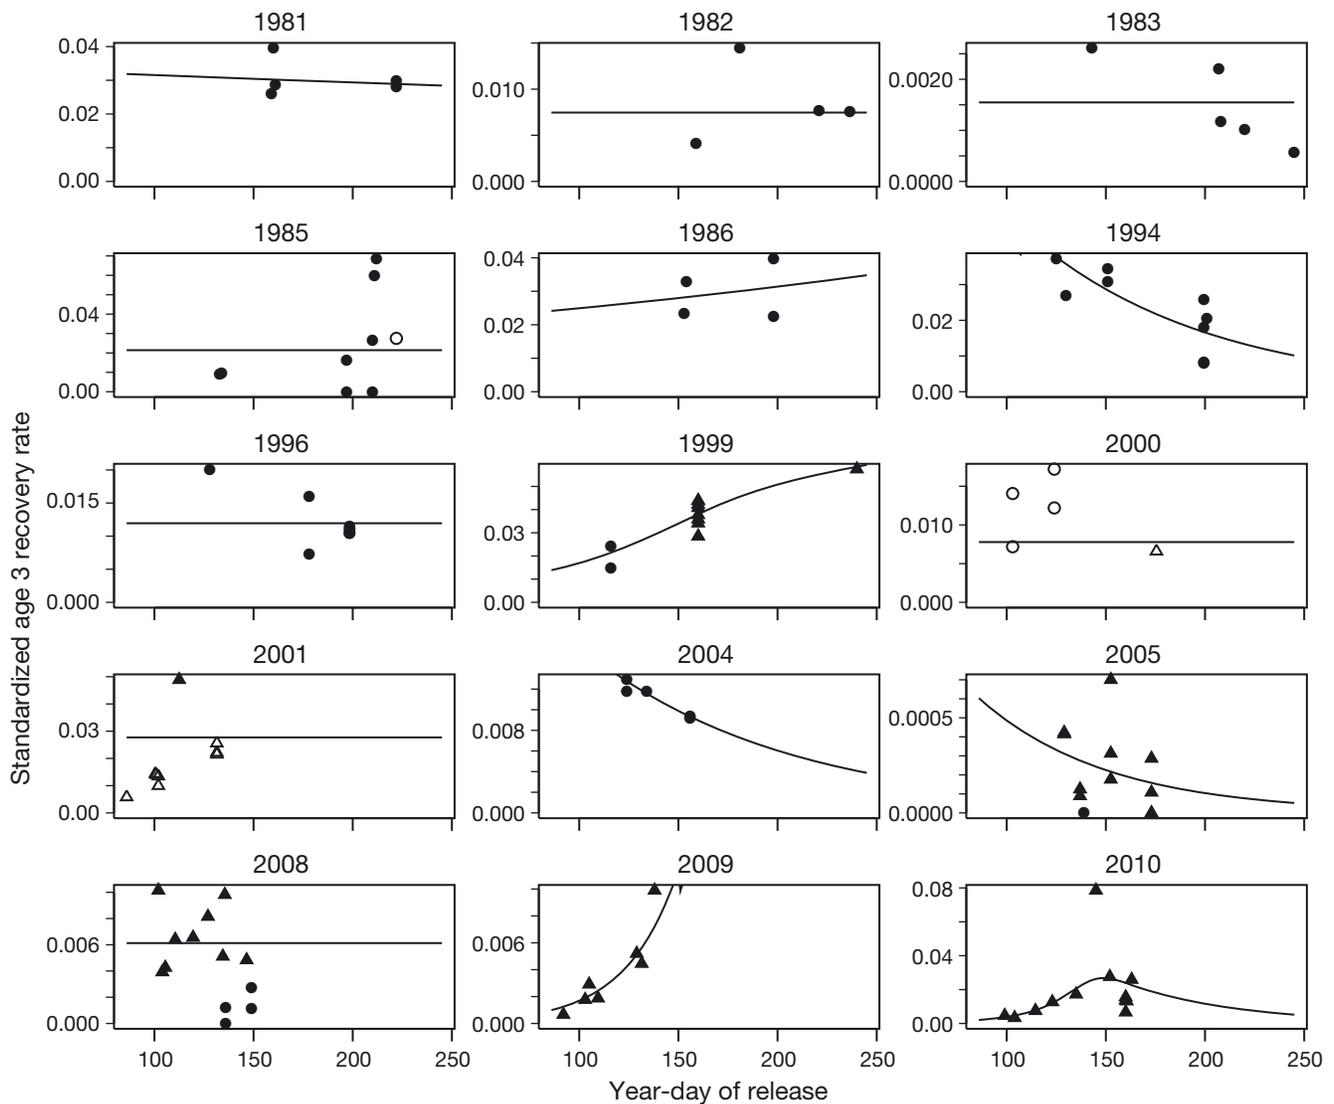

Fig. 2. Age 3 ocean recovery rates standardized by SRFC harvest rates as a function of release date (year-day) for Feather River Hatchery releases. Releases spanning >30 d were excluded, as were release groups with missing weight information and those released as smolts or fry. Open symbols denote mention of disease or poor condition, and triangles denote releases that were acclimated in net-pens. Filled circles are fish that were not diseased and not acclimated in pens. Fitted lines are intercept-only or GAM models chosen based on leave-one-out cross validation and minimum root weighted mean squared error (RWMSE). Note that y-axis scales vary among panels

fish had higher survival rates (Fig. 3c), and fish with disease were less likely to survive (Fig. 3d). Fish acclimated in net pens may have had poorer survival but not significantly so (Fig. 3e). Even after accounting for these effects, there was substantial variation in estimated year effects on recovery (Fig. 4).

DISCUSSION

The overall goal of this study was to investigate the importance of ocean arrival timing on salmon sur-

vival to test the hypothesis that timing relative to ecosystem phenology would influence salmon ocean survival. We found support for the importance of arrival timing relative to spring transition to driving intra-annual variation in salmon survival (i.e. our 'Time lag' model received the strongest support; Table 2), but we also found an effect of calendar date irrespective of ocean phenology (i.e. our 'Year-Day' model received more support than a model without any time effect; Table 2).

The use of model comparison techniques and GAMs allowing for nonlinear relationships provided

strong support for a relationship between ocean entry timing and survival, inferred by recovery rates in ocean fisheries standardized by SRFC harvest rates. At the same time, we note very strong year effects (i.e. controlling for modeled effects of release time and other covariates such as fish size) on survival rates irrespective of timing. For example, the central 90% of year effects corresponded to predicted age 3 survival rates that varied 19-fold according to the best-supported model applied to the full dataset (Fig. 4a). Note that this period excluded 2 years of very low recovery rates corresponding to the recent salmon collapse and fishery closure

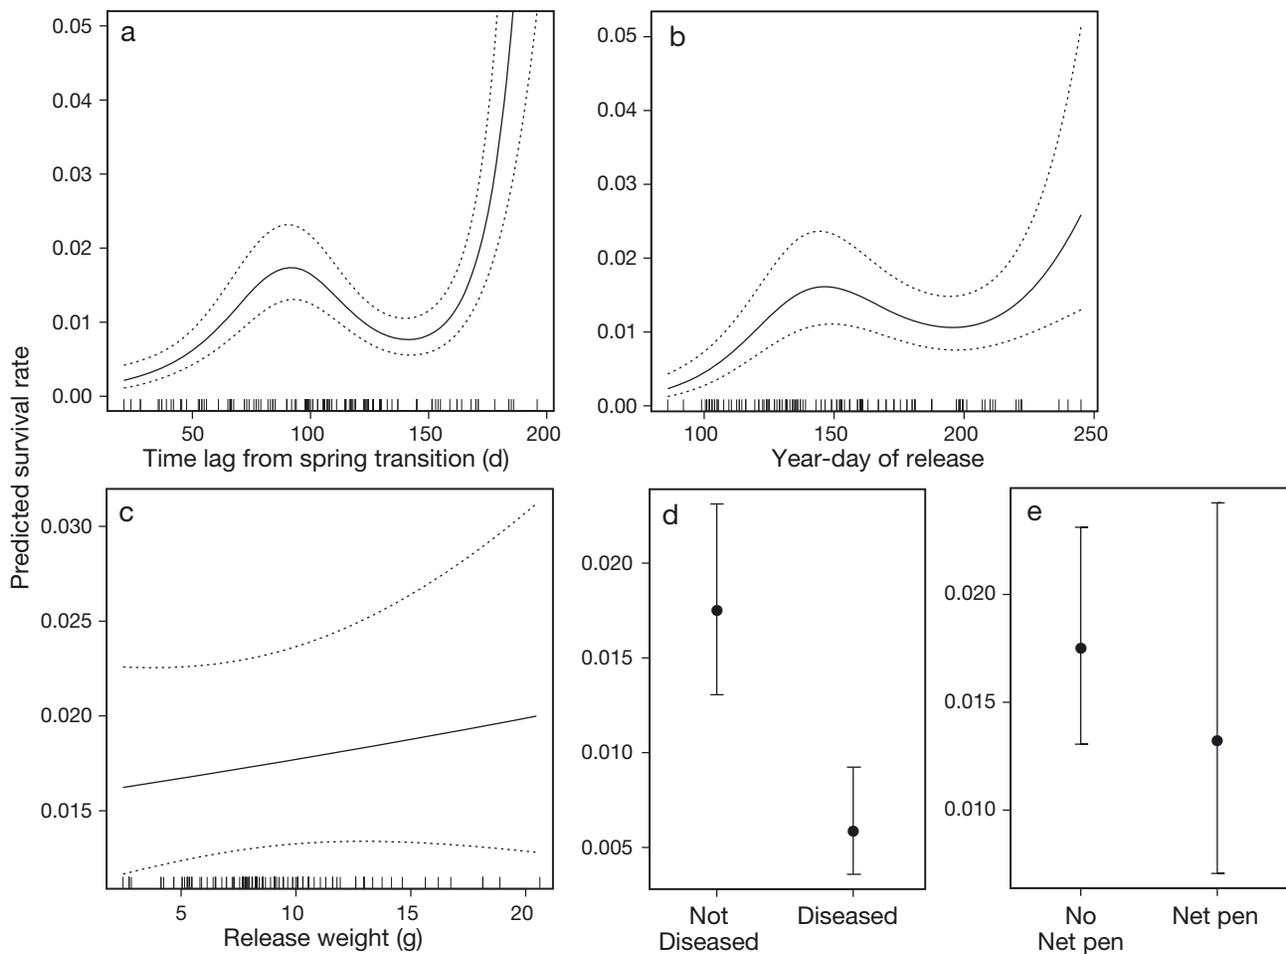

Fig. 3. Model predicted survival rate (harvest-adjusted recovery rates with approximate 95% predictive intervals) illustrating the fitted effects of timing measured as (a) time lag from spring transition, (b) timing measured as year-day, (c) release weight, (d) the presence of disease, and (e) the use of net pens. Predictions are for the year with median fitted year effect (1996), and at the optimal time lag of 92 days (all but a and b), median release weight (all but c), without disease (all but d), or without net pen (all but e). The rug-plots represent values of the independent variable with associated data

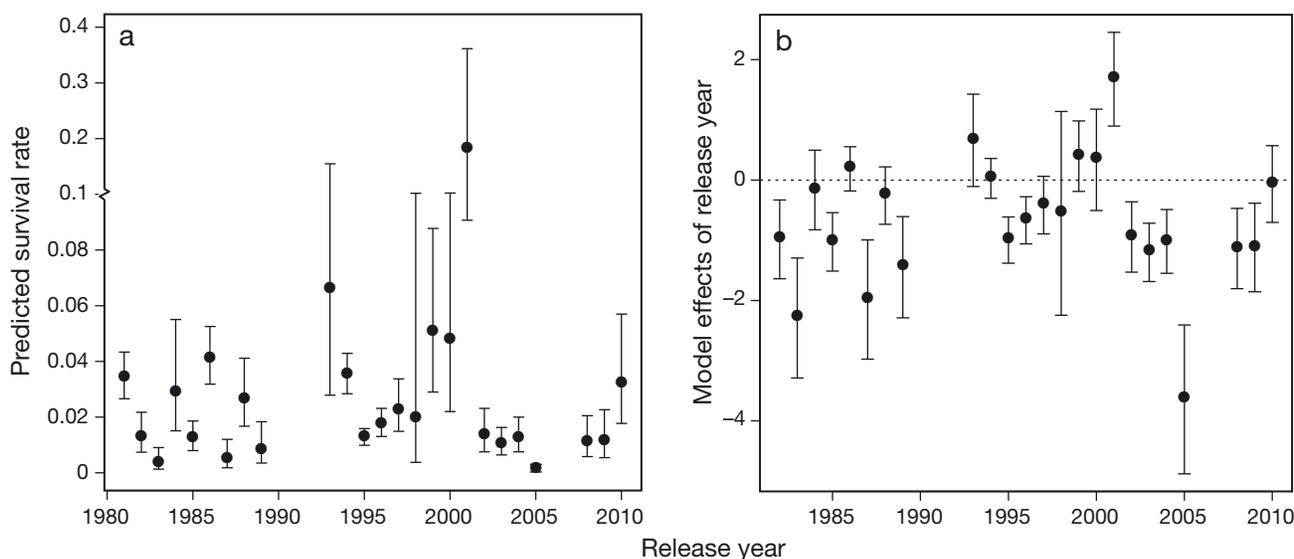

Fig. 4. Fitted year effects in the best-supported model, presented as (a) predicted harvest-adjusted recovery rates (with approximate 95 % prediction intervals) given release of non-diseased, non-net pen, median-weight fish at the optimal time lag from the spring transition date (92 d). Also presented are (b) model year effects (with approximate 95 % prediction intervals) on the log scale

(Lindley et al. 2009), so overall variation in year effects may be even greater.

The degree of variation in year effects is not surprising given the numerous ecological factors acting at longer time scales that may affect early ocean survival—for example, important effects of upwelling intensity, mixing, mesoscale activity, and advection are apparent in this system (Santora et al. 2011, 2012, in press, Ralston et al. 2013), as are preconditioning effects carried over from the previous year (Schroeder et al. 2009, 2013). For instance, the most extreme year effect is associated with release year 2005 and is highly negative (Fig. 4b); while the timing of spring transition was earlier than average in 2005, upwelling that followed was particularly weak (Lindley et al. 2009). This year was also characterized by anomalous poleward transport during the winter 2005 and low krill survival in spring (Dorman et al. 2011). Apparent year effects on age 3 recovery may also reflect temporal variation in age 2 maturation, natural mortality, and/or exploitation, but we do not attempt to model age 2 dynamics due to limited data, as described in Supplement 1.

While our results provide strong support for the existence of a nonlinear relationship between release timing and survival rates within years, there is some ambiguity regarding the explanatory power of timing per se (i.e. year-day) versus timing relative to characteristics of ecosystem phenology (here, using the spring transition date as a metric of phenology).

In addition, effects of release time on survival rates are not fully consistent across years (see Fig. 2; variation among years was also reported by Scheuerell et al. 2009). Indeed, previous studies have reported effects of smolt size or early growth rates on marine survival in some years but not others (in particular, size or growth rate may only be strong predictors in stressful years: Holtby et al. 1990, Tomaro et al. 2012, Woodson et al. 2013), so it is not surprising that relationships between release timing and survival may vary across years as well. Thus, variable timing of ocean entry may amount to little more than making the most of a bad situation in some years.

Further, the apparent effects of timing and release weight are complicated by the collinearity between release time and fish size, although with $r = 0.50$, the observed correlation in the analyzed dataset is below the threshold often invoked as problematic (Dormann et al. 2013). In this case, our results suggested poor survival of either very early releases or releases of small fish, which tend to occur together. Teasing apart the relative influence of timing versus size is challenging because these traits are often correlated. However, in a series of experimental releases designed to test the relative importance of timing versus size, Bilton et al. (1984) and Morley (1988) reported stronger effects of timing than size on survival of coho salmon and Whitman (1987) found similar results for Chinook salmon.

Even using cross validation methods, the very large apparent sample sizes made possible by multiple CWT release groups can easily lead to overfitting if the assumption of statistical independence is violated, making it difficult to unambiguously identify the most important predictors of survival or rigorously quantify their effects. An additional concern is the leverage of extreme values when our dataset contains only a few late releases from early years. Finally, the unbalanced design is a concern, both in terms of potentially conflating year effects with covariates unequally distributed among years and differential influence on overall model results of years with different sample sizes and temporal spread of releases. Unfortunately, uncertainty and sensitivity to model specification and choice of dataset is an unavoidable consequence of using ocean recovery rates to infer survival, a problem affecting this and other studies with important management implications. We are attempting to address a complicated problem with data collected by a fishery, not a planned sampling scheme executed in the context of a designed experiment. Thus, we did not attempt to fit even more complicated models including year-by-timing interactions or additional environmental covariates.

Nevertheless, despite the presence of numerous confounding factors we did not attempt to model directly, we found evidence for a relationship between ocean entry or hatchery release timing and survival rates that was strong enough for a clear signal to emerge for the average effect. In addition, there appeared to be an optimal time after accounting for other effects such as body size, with some suggestion that this optimal timing within a given year could be predicted relative to the spring transition date. A similar analysis by Ryding & Skalski (1999) also supported optimal conditions for early marine survival of coho salmon related to the date of spring transition. Even though the predicted effects of small changes in release timing are generally small, given very large total releases (average 32 million yr^{-1} from 2000 to 2010 across all 5 hatcheries; E. Huber & S. Carlson unpubl.), a small change in survival may still translate into a large number of returning adult fish. Of course, regardless of release timing, we expect reduced survival overall in years of generally poor ocean conditions (e.g. Barth et al. 2007, Lindley et al. 2009).

Translating these results into advice on hatchery practices may prove difficult for several reasons. For example, the effects of timing described here were generally small aside from poor survival of the earli-

est releases and the apparent but uncertain increase in survival of the very late releases (Fig. 3a,b). Specifically, survival rates increase 2.3-fold when time lag decreases from the local minimum of 149 d to the local maximum of 92 d, compared to a 19-fold difference in survival due to year effects. Beyond a weak effect of timing, the 'peaks' corresponding to optima were generally broad. Moreover, spring transition date is variable from year to year (Fig. 1) and may not be known far enough in advance to alter hatchery conditions such that fish will be prepared for release at a target time. Further, we found significant effects of fish size, which is difficult if not impossible to manipulate independently of release time (i.e. releasing fish at a later date often involves releasing them at a larger size).

In addition, our results suggest that the relationship between relative survival and release timing does not always show a consistent within-year pattern (Fig. 2), and this variability combined with a lack of prior knowledge of spring transition timing might argue for staggered release times. Such staggering might be accomplished through direct staggering of release timings by hatchery managers or by increased on-site releases, as has been advocated recently for other reasons (California Hatchery Scientific Review Group 2012). Indeed, different release strategies among hatcheries could contribute relevant variation to the portfolio effect in this system, akin to stock or run-specific variation typical of less-impacted systems (Hilborn et al. 2003). On-site releases would also tend to staggered ocean entry timing as fish made their individual paths down the river, although on-site releases do face added mortality risks in rivers. Williams (2006, his Fig. 5-28) notes that Chinook believed to be fall or spring run are recovered in San Francisco Bay all year, but recoveries peak in April or May and are very low before February or after July (consistent with the full distribution of Feather River Hatchery release dates analyzed but wider than a typical single year; Fig. S1 in the Supplement). In addition, fish migrating downstream may be able to adjust their transit time in response to environmental cues, possibly allowing fish to arrive during more favorable conditions.

Acknowledgements. This work was supported by funding from California Sea Grant (R/FISH-217) and the California Sea Grant Ocean Protection Council. We thank A. Grover, D. Hankin, M. Mohr, M. O'Farrell, and I. Schroeder for helpful discussions and assistance with accessing data and O. Shelton and A. Winhip for helpful comments on earlier drafts of the manuscript.

Supplement 1. Data Filtering

In addition to the 5 extant Central Valley hatcheries producing fall run Chinook (Coleman National Fish Hatchery, Feather River Hatchery, Nimbus Hatchery, Mokelumne River Fish Installation, and the Merced River Fish Facility) and the discontinued Tehama-Colusa Spawning Channel, the RMIS identifies 2 additional ‘hatcheries’: the Tiburon Minor Port and Tiburon Net pens, which release only Feather River Hatchery-sourced fish. We recategorized these fish as Feather River Hatchery.

We compared the distribution of release times across hatcheries to identify the potential confounding of source hatchery and release timing. There were clear differences among hatcheries in their release times (Fig. S1; ANOVA $F_{3,284}=13.4$, $p < 0.01$). Among the 2 hatcheries with substantial variability in release times, nearly all of the variation for the Mokelumne River Hatchery was across years rather than within years (Fig. S2), while the Feather River Hatchery had substantial within-year variability, although releases tended to occur earlier and with less temporal spread in later years (Fig. S2). We therefore focused our analysis on Feather River Hatchery releases, since such releases provide the majority of the available data (Table 1 in the main article) and cover the widest range of release times (Fig. S1).

In general, later releases tend to be of larger fish. To reduce the collinearity between weight and release timing, we restricted our analysis to fish released as ‘fingerlings’ or ‘advanced fingerlings’, which make up the majority of releases (~90%), rather than the much larger smolts or much smaller fry. Excluding fish released as smolts or fry substantially reduces the extent of collinearity between release weight and release timing of release groups (from $r = 0.73$ for year-day and release weight, $r = 0.63$ for time lag and release weight to $r = 0.52$ for year-day and release weight, $r = 0.40$ for time lag and release weight).

Historically, estimates of age 2 recoveries are, on average, ~0.1% (SD = 0.14) of tagged releases, whereas recoveries of age 3 fish are ~0.9% (SD = 0.93). Age 4 recovery rates are similar to those for age 2 (mean \pm SD = $0.1 \pm 0.13\%$). Estimating such low recovery rates of age 2 and age 4 fish could result in relatively high sampling errors. Thus, we restricted our analysis to age 3 recoveries. However, age 3 availability is affected by (generally low) harvest or early maturation of age 2 fish, potentially confounding the effects on survival. Another concern is the amount of time that different release groups spend in the ocean (i.e. greater cumulative daily mortality can accrue for earlier releases), but for recoveries at age 3 or later, the differences in cumulative time spent in the ocean are relatively small. An additional reason for restricting our analysis to age 3 ocean recoveries is that age 2 harvest data are more uncertain due to generally low recoveries and uncertainty in how much age 2 harvest actually occurred in a sampling stratum from which no age 2 tags were recovered, but only a fraction of the harvest was examined for tags. In addition, age 3 fish are nearly always of legal size to retain in the fishery but age 2 fish often are not, so attempting to model age 2 harvest would introduce major confounding due to annual variability in fish

size, variation from year to year in minimum size limit regulations, and variability in the relative magnitude of recreational versus commercial fisheries which have substantially different minimum size limits and thus very different relative impacts on age 2 versus older fish.

It should be noted that O'Farrell et al. (2013) define fish as reaching age 3 in September 2 yr after the brood year; thus, the harvest metric h was calculated including a small number of fish harvested toward the end of the calendar year in which we would still refer to them as age 2 using the aging convention in this paper. Similarly, we would consider a fish harvested in October 3 yr after the brood year to be age 3, but in the O'Farrell et al. (2013) calculation, such fish would be considered age 4. However, since the majority of the fishery occurs in spring and summer, the vast majority of harvest would be considered age 3 under either designation, and the calculations and assumptions underlying the calculation of h in O'Farrell et al. (2013) do not distinguish age 3 from age 4 and older fish.

Fig. S1. Box-and-whisker plot of release dates of different release groups (not of individual fish) by hatchery. Thick lines denote median release date, boxes the central 50%, whiskers the furthest data points within 1.5 times the interquartile range, and open circles any outliers beyond this

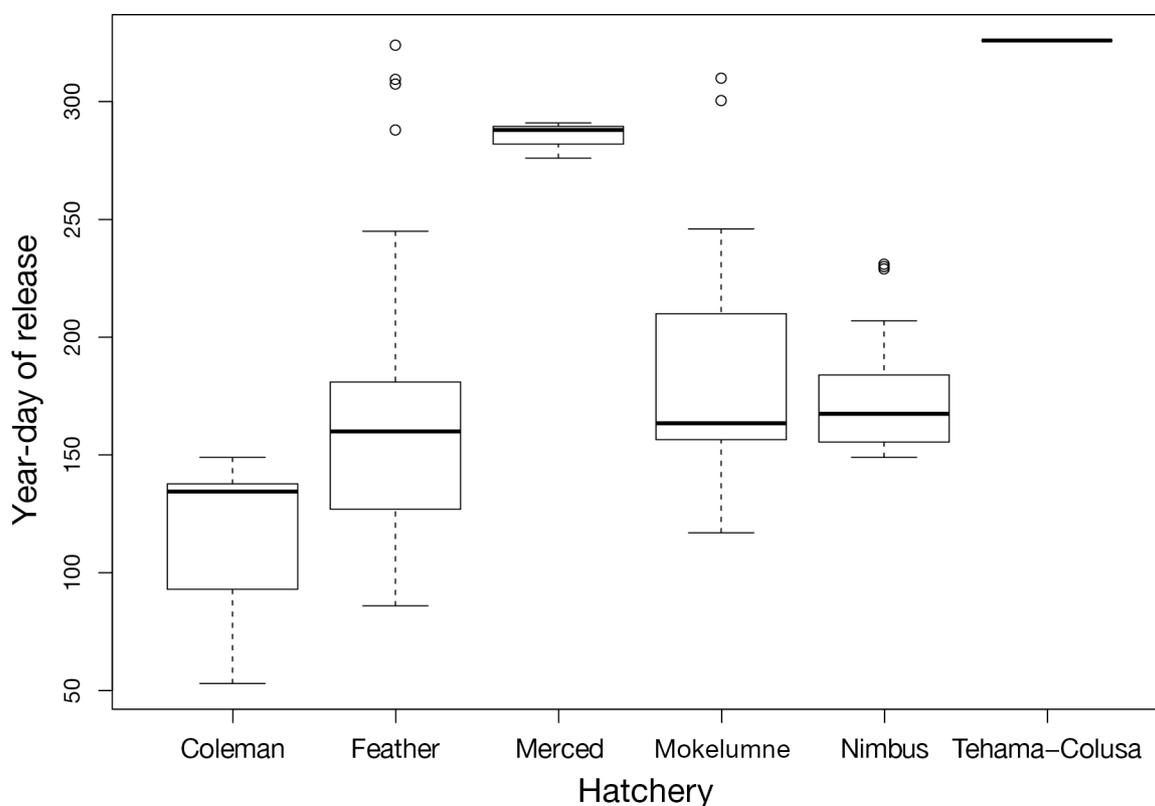

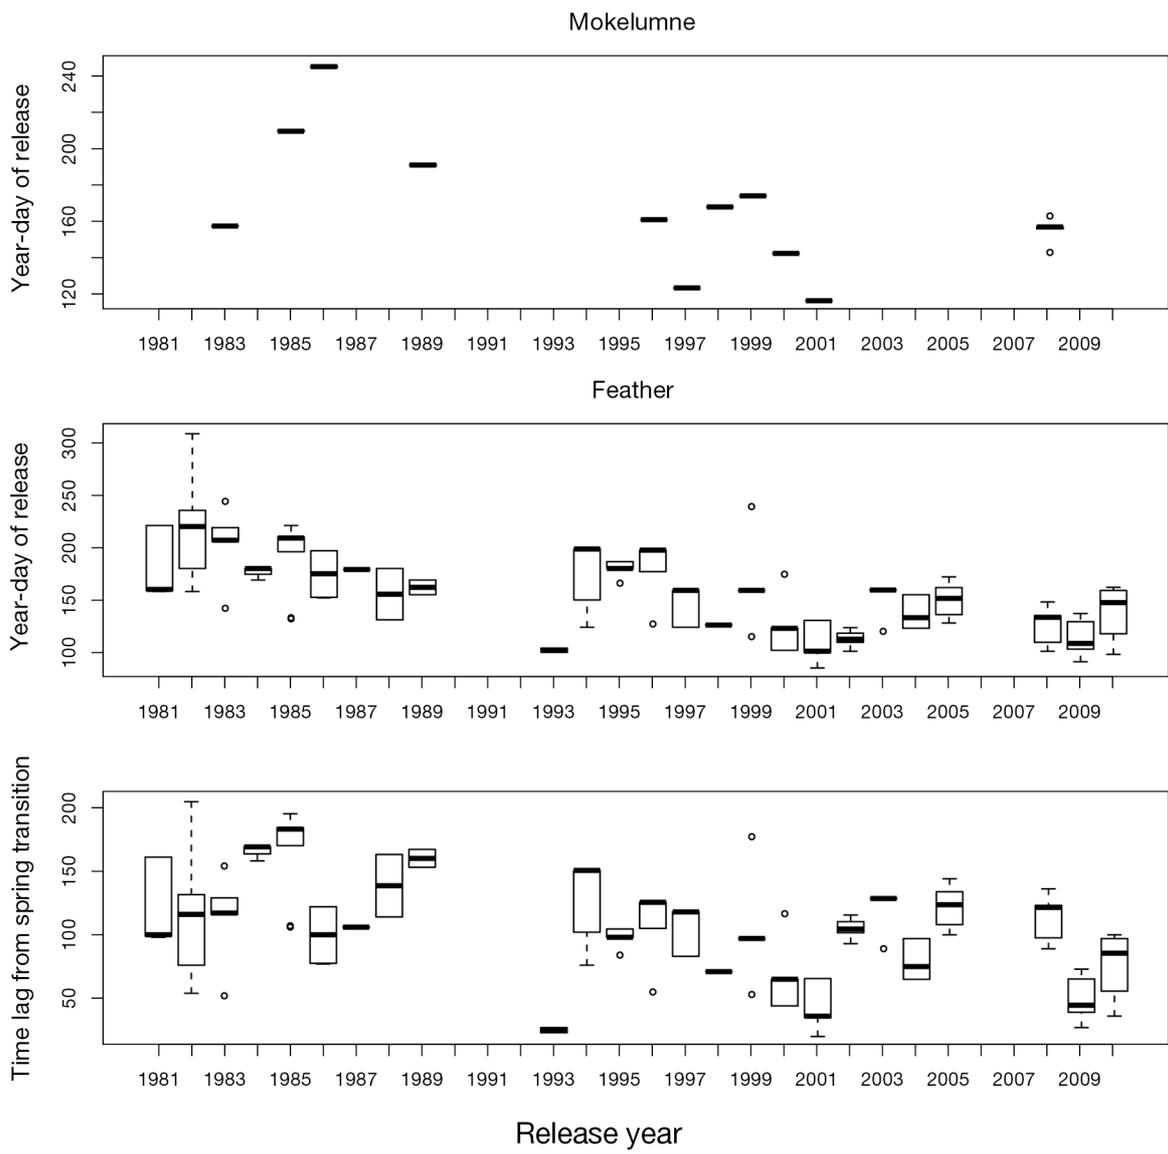

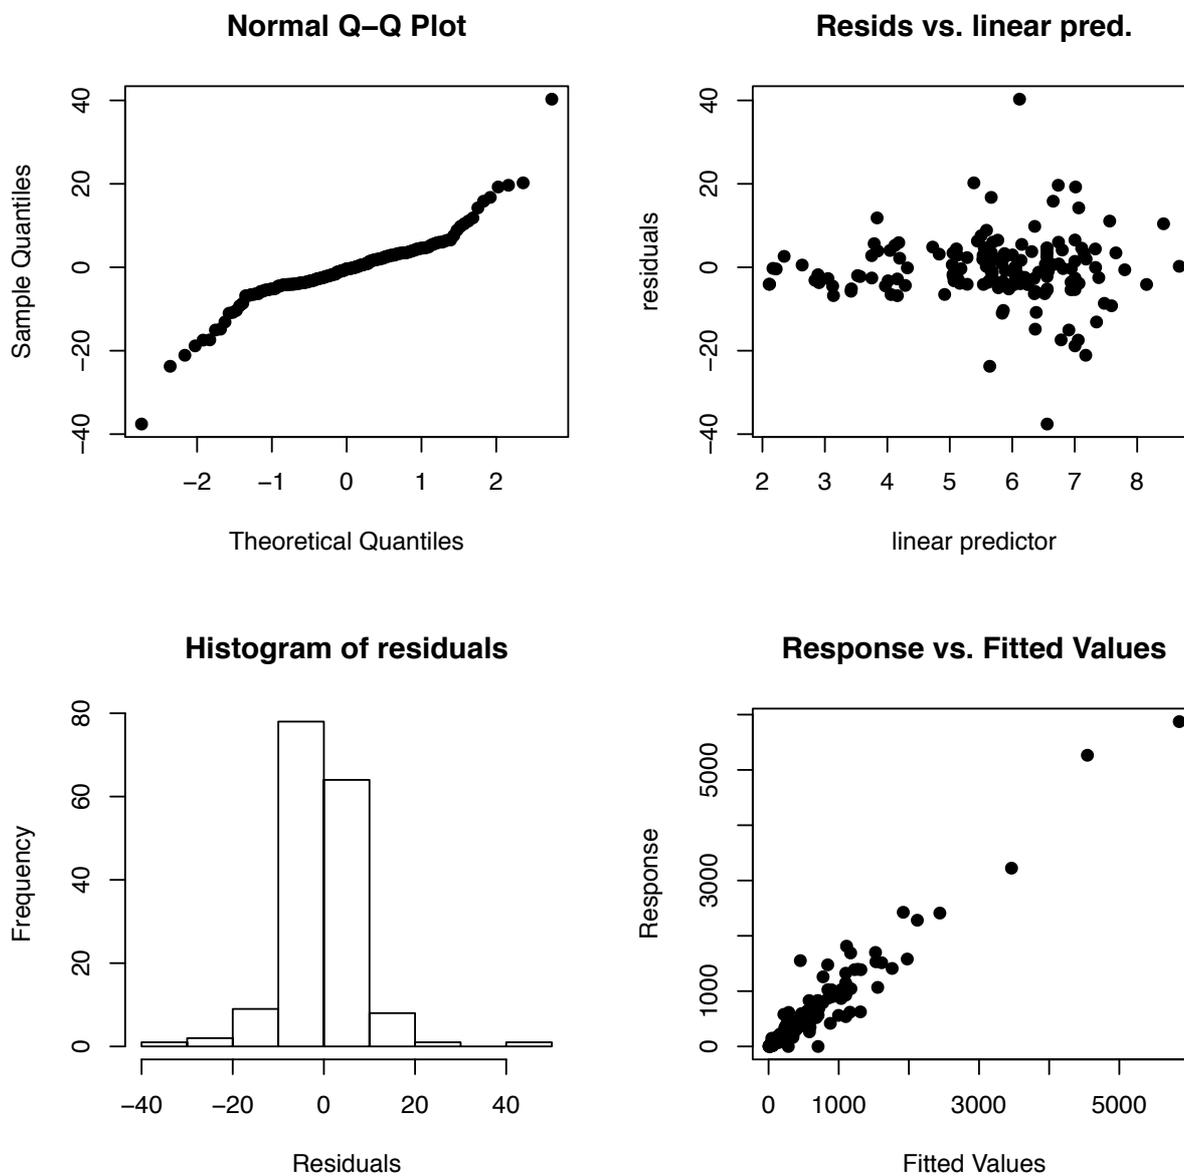

Fig. S2. Box-and-whisker plot of release dates of different release groups (not of individual fish) by year for Mokelumne and Feather hatcheries (the hatcheries with the largest range in reported release dates) and time lag from spring transition for Feather River Hatchery only. Releases spanning >30 d were excluded, as were release groups with missing weight information and those released as smolts or fry (see 'Materials and Methods'). Thick lines denote median release date, boxes the central 50%, lines the furthest data points within 1.5 times the interquartile range, and open circles any outliers beyond this. In most years, the Mokelumne River hatchery released all its fish in a single day

Supplement 2. Diagnostic Plots

Fig. S3. Diagnostic plots for the best-supported model for releases from Feather River Hatchery that included a nonlinear effect of time lag from spring transition day, a linear effect of weight, and fixed effects of net pen and disease. Releases spanning >30 d were excluded, as were release groups with missing weight information and those released as smolts or fry

Abstract North American green sturgeon, *Acipenser medirostris*, was petitioned for listing under the Endangered Species Act (ESA). The two questions that need to be answered when considering an ESA listing are; (1) Is the entity a species under the ESA and if so (2) is the “species” in danger of extinction or likely to become an endangered species in the foreseeable future throughout all or a significant portion of its range? Green sturgeon genetic analyses showed strong differentiation between northern and southern populations, and therefore, the species was divided into Northern and Southern Distinct Population Segments (DPSs). The Northern DPS includes populations in the Rogue, Klamath-Trinity, and Eel rivers, while the Southern DPS only includes a

single population in the Sacramento River. The principal risk factors for green sturgeon include loss of spawning habitat, harvest, and entrainment. The Northern DPS is not considered to be in danger of extinction or likely to become an endangered species in the foreseeable future. The loss of spawning habitat is not large enough to threaten this DPS, although the Eel River has been severely impacted by sedimentation due to poor land use practices and floods. The two main spawning populations in the Rogue and Klamath-Trinity rivers occupy separate basins reducing the potential for loss of the DPS through catastrophic events. Harvest has been substantially reduced and green sturgeon in this DPS do not face substantial entrainment loss. However there are significant concerns due to lack of information, flow and temperature issues, and habitat degradation. The Southern DPS is considered likely to become an endangered species in the foreseeable future. Green sturgeon in this DPS are concentrated into one spawning area outside of their natural habitat in the Sacramento River, making them vulnerable to catastrophic extinction. Green sturgeon spawning areas have been lost from the area above Shasta Dam on the Sacramento River and Oroville Dam on the Feather River. Entrainment of individuals into water diversion projects is an additional source of risk, and the large decline in numbers of green sturgeon entrained since 1986 causes additional concern.

Introduction

The North American green sturgeon, *Acipenser medirostris*, have been petitioned for listing under the Endangered Species Act (ESA) and this is a review of the scientific considerations that the National Marine Fisheries Service uses to consider listing. Sturgeons in general have a life history that is susceptible to overharvesting and degradation of freshwater habitat and a number of species have some kind of protection or conservation status (Secor et al. 2002). In the United States, there are five ESA listed sturgeon: short-nose sturgeon, *A. brevirostrum*, Endangered (USFWS 1967); Pallid sturgeon, *Scaphirhynchus albus*, Endangered (USFWS 1990); Gulf sturgeon, *A. oxyrinchus desotoi*, Threatened (USFWS and NOAA 1991); white sturgeon, Kootenai River Population, *A. transmontanus*, Endangered (USFWS 1994); and Alabama sturgeon, *S. suttkusi*, Endangered (USFWS 2000). Green sturgeon has a status designation of Special Concern in Canada (Houston 1988) because of its population characteristics that make it particularly sensitive to human activities or natural catastrophic events. Sakhalin sturgeon, *A. mikadoi*, a species that was at one time synonymized with green sturgeon, is extirpated throughout Japan, Korea, and China. In Russia, Sakhalin sturgeon now only occurs in the Tumnin River where there is a hatchery supporting it.

There are two key questions that must be addressed in determining whether a listing under the ESA is warranted: (1) Is the entity in question a “species” as defined by the ESA, and (2) if so, is the “species” in danger of extinction or likely to become an endangered species in the foreseeable future throughout all or a significant portion of its range? For the purpose of the ESA, a species is defined as “any subspecies of fish or wildlife or plants, or any distinct population segment (DPS) of any species of vertebrate fish or wildlife which interbreeds when mature.” The ESA allows listing of “distinct population segments” of

vertebrates as well as named species and subspecies. Two elements are necessary for a decision to identify separate DPSs (USFWS and NOAA 1996): discreteness and significance of the population segment to the species. A DPS may be considered discrete if it is markedly separate from other populations of the same taxon as a consequence of physical, physiological, ecological, or behavioral factors or if it is delimited by international governmental boundaries. If a population segment is considered discrete, its biological and ecological significance will be considered on the basis of considerations including, but not limited to its persistence, evidence that loss of the DPS would result in a significant gap in spatial structure, evidence of the DPS representing the only surviving natural occurrence of a taxon, or evidence that the DPS differs markedly in its genetic characteristics.

The ESA defines the term “endangered species” as “any species which is in danger of extinction throughout all or a significant portion of its range.” The term “threatened species” is defined as “any species which is likely to become an endangered species within the foreseeable future throughout all or a significant portion of its range.” In evaluating the level of risk faced by a species or DPS, important considerations include (1) absolute numbers and their spatial and temporal distribution; (2) current abundance in relation to historical abundance and carrying capacity of the habitat; (3) any spatial and temporal trends in abundance; (4) natural and human-influenced factors that cause variability in survival and abundance; (5) possible threats to genetic integrity (e.g., artificial rearing); and (6) recent events (e.g., a drought or a change in management) that have predictable short-term consequences for abundance of the species. Additional risk factors, such as disease prevalence or changes in life history traits, may also be considered in evaluating risk to populations. The determination of whether a species as “in danger of extinction” or “likely to become an endangered species within the foreseeable future” should be made on the basis of “the best scientific and commercial information” available regarding its current status. The use of “best scientific and commercial information” is a standard makes the risk assessment process

fundamentally different than typical scientific investigation. This standard requires the gathering of all information possible, including some that would not meet traditional scientific guidelines, and requires making recommendations based on imperfect and incomplete information.

Green sturgeon life history

Green sturgeon is the most widely distributed member of the sturgeon family Acipenseridae. Like all sturgeons, they are anadromous, but are also the most marine oriented of the sturgeons. The only known green sturgeon spawning locations are in Oregon and California rivers where they experience anthropogenic impacts similar to other anadromous fishes (Moyle 2002). Adults migrate into their spawning rivers, peaking in May–June, and then hold in deep pools or “holes” in the mainstem of large turbulent rivers to stage for spawning (Erickson et al. 2002). Eggs are likely broadcast spawned over large cobble substrate where they settle into the spaces between the cobbles. Fecundity is lower than other sturgeons, but the egg size is larger (Deng 2000). The large egg size provides more yolk stores for the nourishment of embryos, presumably resulting in more viable larvae. The adhesiveness of green sturgeon eggs is lower than that of white sturgeon and the eggs may not attach to the substrate after fertilization like white sturgeon, but become trapped in crevices and gravel during embryo development. The juveniles spend from 1–4 years in freshwater, before migrating to the ocean. Once in the ocean, green sturgeon range in coastal waters from Mexico to the Bering Sea (Moyle 2002). Tagging has shown that they make long migrations in the ocean, generally to the north¹ and analyses of Oregon trawl catch found them almost exclusively inside the 110-m contour (Erickson and Hightower in press). Recent hydro-acoustic tagging information has shown that green sturgeon congregate near the Brooks

Peninsula, and immediately north of Vancouver Island.² Green sturgeon congregate in coastal bays and estuaries in late summer and early fall, with particularly large concentrations in the Columbia River Estuary, Willapa Bay, and Grays Harbor.³ The reasons for these concentrations are unclear. Green sturgeon have delayed sexual maturity, somewhere between 13 and 20 years, and they apparently only spawn every 2–5 years (Moyle 2002).

What is the “species” unit for ESA listing?

Review of “species” data

Green sturgeon that occur within United States and Canadian waters are now known to be a geographically isolated and genetically distinct species. The species was first described as *Acipenser medirostris* by Ayres (1854) from San Francisco Bay. The North American form was considered conspecific with a previously described Asian species Sakhalin sturgeon, *A. mikadoi*, and the two forms were synonymized (Berg 1948). More recent molecular data on three mitochondrial genes show large differences between the North American and Asian forms (Birstein and DeSalle 1998), and these two forms are now considered separate species. Morphometric data shows differences between the two forms with the snout of the Asian form being longer (North et al. 2002). Other morphometric and meristic data between the two forms are similar. Both Green and Sakhalin sturgeon occur in coastal waters and in estuaries. The only currently documented Sakhalin sturgeon spawning population occurs in the Tumnin River, Russia, which also has a hatchery for this species.

Sturgeons are known to have strong homing capabilities and this leads to high spawning site fidelity (Bemis and Kynard 1997). It is common to

¹ Adams, P.B., C.B. Grimes, J.E. Hightower, S.T. Lindley, and M.L. Moser. 2002. Status Review for the North American green sturgeon. Final Report to Southwest Region, NOAA Fisheries. Long Beach, CA. 50 p.

have a large numbers of genetically separated races or morphs within a species (Wirgin et al. 1997). The trend of sturgeon homing to individual rivers is so strong that river by river analysis is common in sturgeon ESA recovery plans. This general pattern in sturgeon population genetics led to consideration that green sturgeon might have multiple DPSs.

The actual historical and current geographical extent of green sturgeon spawning is difficult to assess because green sturgeon make non-spawning movements into coastal lagoons and bays in the late summer to fall, and because their original spawning distribution may have been reduced due to harvest and other anthropogenic effects. Green sturgeon commonly occur in coastal waters from San Francisco Bay to Canada,¹ but actual spawning has only been documented (by the presence of juveniles) in the Rogue (Erickson et al. 2002), Klamath (Scheiff et al. 2001), Trinity (Scheiff et al. 2001), Sacramento,⁴ and Eel⁵ rivers. The historical status of the Umpqua, Feather, and San Joaquin rivers as green sturgeon spawning areas remains unknown.

In late summer and early fall, green sturgeon commonly occur in estuaries where there has been no known spawning. The exact reason for this behavior is not known, but it greatly complicates identification of natal rivers and designation of DPSs. Green sturgeon have occurred in many estuaries where there are no records of their occurrence further up the river system. Therefore, we used the presence of juveniles to confirm green sturgeon spawning in a given river system.

Historic green sturgeon spawning distribution may never be known due to sturgeon's vulnerability to overharvest and other anthropogenic impacts (Boreman 1997, also see extinction risk section). Smaller less productive populations may

have extirpated by harvest and habitat degradation long before there was any scientific recognition of their existence.

Green sturgeon population genetic analyses have recently become available (Israel et al. 2004, also⁶), but these analyses are limited by small sample size and mixed samples of different spawning populations in different years. Genetic samples were analyzed from the Klamath River, from San Pablo Bay, juveniles from the Sacramento River, from the Rogue River, from the Columbia River estuary, and from the Umpqua River estuary. Nine microsatellite loci were amplified for analysis of allele frequencies; six of these loci were tetrasomic and therefore do not permit standard genetic analysis. The genetic analyses of existing samples are problematic in those samples from estuaries since these fish may be a mixture of different spawning stocks. Ideally, coast-wide genetic studies should be conducted on juveniles collected in their natal rivers.

The results of the genetic analyses showed strong separation between a northern and southern group of spawning fish (Israel et al. 2004, this volume). The northern group contains spawning populations in the Klamath and Rogue rivers that have similar genetic composition. Non-spawning green sturgeon sampled in Umpqua Bay are also grouped with the northern group because of similar genetic composition. The southern group, which contains the Sacramento River juveniles samples and fish from San Pablo Bay, has a distinctly different genetic composition from the northern group.

The genetic data showed a complex relationship between Columbia River green sturgeon samples and samples from San Pablo Bay and the Sacramento River. There was no significant genotypic differentiation detected between San Pablo Bay and Columbia River collections. However, the San Pablo Bay samples were not identical to the Sacramento River samples from juveniles. There are a number of possible explanations for these results. One is that Columbia River fish generally come from the Sacramento River. Another is that both Columbia River and

San Pablo Bay are a mixture of other spawning populations. Finally, it is possible that by chance, the small number of Columbia River samples come largely from fish that were spawned in the Sacramento River.

Conclusions and discussion on the “species” question

North American green sturgeon are clearly a species under the ESA. The North American species, *A. medirostris*, is a separate species from the western Pacific Tumnin River population, *A. mikadoi*, due to the lower chromosome number (Birstein et al. 1993) and morphological differences (North et al. 2002).

Current evidence justifies the separation of green sturgeon into Northern and Southern DPSs. Sturgeons generally show fidelity to their spawning sites so they have a general pattern of multiple DPSs (Bemis and Kynard 1997). The Northern DPS includes populations from the Rogue, Klamath-Trinity, and Eel rivers, and the Southern DPS currently includes only the Sacramento River population (Fig. 1). The Eel River, for which there is no genetic information, is assigned to the Northern DPS on an “isolation by distance” argument since the mouth of the Eel River is much closer to the Northern DPS. The ESA “discreteness” test that populations are markedly separated from each other is clearly met by the genetic data discussed earlier. The ESA “significance” test is also clearly met by genetic evidence, distribution, and adaptation to different habitats. The Northern and Southern DPSs represent the northern and southern extent of the green sturgeon’s range. The loss of either of these DPSs would result in a significant shrinkage of the species distribution and would be considered the loss of a portion of the species’ range. The two DPSs are also significantly separate because spawning occurs in very different habitats. The Northern DPS spawning occurs in the more coastal Klamath Mountain Province, a cooler, wetter area that supports a number of uniquely adapted salmonids (Busby et al. 1996). The Southern DPS spawning occurs in the dry, hot California Central Valley that has experienced large anthropogenic change (Lindley et al. 2006).

The loss of ability to spawn in either of these different habitats would be a major loss of adaptation. There may be green sturgeon spawning locations and population structure that are not apparent now and which may cause this assessment of DPS structure to change in the future.

What is the level of “extinction risk”?

Review of “extinction risk” data

Loss of spawning habitat

The amount of lost green sturgeon spawning habitat is unclear. Although there have been claims that as many as twice the number of green sturgeon spawning populations have been extirpated as currently remain,⁷ these claims are impossible to evaluate because it is unknown how many spawning populations there were and if spawning populations are actually extirpated. In the Northern DPS, there is no evidence of green sturgeon spawning north of the Umpqua River, Oregon. Spawning does appear to occur in the Umpqua River, but probably is rare. There are two confirmed records of green sturgeon captured above tidal influence in the Umpqua River,⁸ approximately 150 km up river. However, Oregon Department of Fish and Wildlife sampled the Umpqua River in 2002, 2003, and 2004 using gill nets, beach seines, snorkeling, and underwater video and did not collect any green sturgeon above tidal influence. Green sturgeon in the South Fork of the Trinity River were reportedly extirpated by the 1964 flood (Moyle 2002), but juvenile green sturgeon are captured at Willow Creek on the Trinity River (Scheiff et al. 2001). These fish could be coming from either the South Fork or the Trinity River. Green sturgeon still appear to occasionally occupy the Eel River.

In the Southern DPS, recent habitat evaluations conducted in the upper Sacramento River for salmonid recovery planning suggests that significant potential green sturgeon spawning habitat was made inaccessible or altered by dams (historical habitat characteristics, temperature, and geology summarized in Lindley et al. (2004, 2006). This spawning habitat may have extended up into the three major branches of the Sacramento River; the Little Sacramento River, the Pitt River system, and the McCloud River. Green and white sturgeon adults have been observed periodically in small numbers in the Feather River¹¹ There are no records of larval or juvenile sturgeon of either species, even prior to the 1960's when Oroville Dam was built.¹² There are reports that green sturgeon may reproduce in the Feather River during high flow years, but these are not specific and are unconfirmed.⁴ California Department of Fish and Game regards the Feather River to be “the most likely loss of spawning habitat [of green sturgeon in the Central Valley]”.⁴ They suggests that Oroville Dam blocks access to potential spawning habitat and that Thermalito Afterbay warm water releases may increase temperatures to levels that are undesirable for green sturgeon spawning and incubation. No green sturgeon has ever been documented in the San Joaquin River or its tributaries.^{4, 11} Small numbers of adult sturgeon occur in the San Joaquin River, but all those identified to date have been white sturgeon. Two juvenile white sturgeon caught at Woodbridge on the Mokelumne River (rkm 63) in 2003 are the first confirmation of sturgeon reproduction in the San Joaquin River system.¹¹ The San Joaquin River and its tributaries have been heavily modified in ways that reduce suitability for sturgeon since the 1940's, so the lack of contemporary information cannot be

considered evidence of historical green sturgeon absence.

Harvest

Green sturgeon harvest is now almost entirely bycatch in three fisheries: white sturgeon commercial and sport fisheries, Klamath Tribal salmon gill-net fisheries, and coastal groundfish trawl fisheries (Table 1). Historically, the larger take was bycatch from white sturgeon commercial and sport fisheries. Large commercial fisheries developed in the late 1800's for previously unexploited white sturgeon, and these fisheries collapsed because fishing mortality far exceeded sustainability (Galbreath 1985). The excessive white sturgeon fishing mortality likely caused an accompanying decline in green sturgeon, but the degree of green sturgeon decline is unknown. Green sturgeon do have longer ocean residence than white sturgeon and therefore may be less available to fisheries. A smaller part of the harvest occurs directly on spawning fish as bycatch to the Klamath River Yurok and Hoopa tribal gill-net salmon fishery. The tribal salmonid fishery is used for subsistence.

The total average annual harvest of green sturgeon declined substantially from 6494 fish in 1985–1989 to 1072 fish in 2000–2003 (Table 1) and has continued to decline to 512 in 2003. Historically, harvest came predominately from the Columbia River (51%), coastal trawl fisheries (28%), the Oregon fishery (8%), and the California Tribal fishery (8%). Much of the harvest reduction in recent years is due to increasingly restrictive Columbia River fishing regulations. Coastal trawl fisheries have declined to low levels since 1999 (Rein 2002). In 2003, Klamath and Columbia River Tribal fisheries accounted for 65% of the total catch.

The California Klamath Tribal fishery has historically accounted for approximately 8% of green sturgeon harvest (Table 1). This fishery is especially important because the Klamath fishery operates directly on what is thought to be the largest green sturgeon spawning population. Harvest averaged 279 fish annually with no apparent trend from 1985 to 2003. There was one extremely high catch in 1981 of 810 fish. Green

See footnotes for data sources

sturgeon catch is incidental to the chinook gill-net fishery by the Yurok and Hoopa Tribes on the lower portions of the Klamath and Trinity rivers. The green sturgeon catch is monitored but there is no direct regulation of the fishery for green sturgeon. In 2004, the tribal fisheries adopted additional conservation measures that will change the character of the catch time series.

California sport catch of green sturgeon, primarily in San Pablo Bay, is not monitored, but is thought to be only a few fish each year.⁴ Until very recently, there has been no differentiation between green and white sturgeon in the regulations and the current slot limits are 117 cm to 183 cm (46 to 72 in.). In 2006, California announced an emergency closure of recreational fishing for green sturgeon.

Harvest data provide limited information about population status. Average length of Columbia River commercially caught green sturgeon has been increasing since 1990 (Rien et al. 2001), and the largest average sizes have been in recent years. In the California Klamath Tribal fishery, the percentage of green sturgeon over 175 cm TL remained unchanged from 1984 to 2001. Larger fish are increasing in proportion to the total catch in recent years.

Population abundance

Musick et al. (2000) state that green sturgeon suffered “an 88% decline in most of their range.” The statement¹⁶ comes from the fact that “the abundance of all west coast sturgeons, including green, suffered approximately an 88% decline in California, inferred from commercial catch rates (Cech 1992).” However, the only statistics in the Cech (1992) article are the reduction of all commercial sturgeon landed (white and green, but primarily white) from 1.63 million pounds in 1887 to 0.2 million pounds in 1901 an 88% reduction. If these statistics are the basis of the 88% population decline reported in Musick et al. (2000), then these claims are hard to relate to current green sturgeon status.

The only estimates of green sturgeon population size are made incidentally to white sturgeon monitoring in San Pablo Bay.⁴ These estimates are calculated from a multiple-census or Peterson mark-recapture estimate of legal-size white sturgeon taken by trammel nets. The tagging experiments have been conducted irregularly since 1954, but since 1990, tagging has been conducted for 2 years consecutively and then the next 2 years are skipped. Over this period, a total of 536 green sturgeon were captured and

233 were tagged. The green sturgeon estimate was obtained by multiplying the ratio of legal-size green sturgeon to legal-size white sturgeon caught in the tagging program by the legal-size white sturgeon population estimate. There is no long-term trend in legal-size green sturgeon abundance, ($r^2 = 0.146$, slope = 0.029, $P = 0.177$, Fig. 2) even though the highest value occurred in 2001, based on linear regression¹⁹ These estimates have a number of potential biases; the most important being the assumption of equal vulnerability of both species to the gear. Green sturgeon concentrate in estuaries only during summer and fall whereas white sturgeon may remain in estuaries year around and therefore, the temporal and spatial vulnerabilities of the two species can be very different.

Two additional green sturgeon harvest population time series were analyzed because of their length, their relative lack of bias, and their geographical importance. These were the Klamath Yurok Tribal fishery catch and catch-per-unit-effort (CPUE) series and Columbia River commercial landings. Both of these population time series came from fisheries targeting other species. The raw catch time series suffers from changing regulations and effort levels. Also, green sturgeon are not an abundant species, and therefore the numbers captured are small and variable with a large number of zero observations. Simple linear regressions were calculated for each time series providing a slope with a standard error and confidence intervals.

The Klamath Yurok Tribal fishery catch and CPUE are the most consistent green sturgeon data sets. Catch and CPUE data are available from 1984 to 2003 and it is the time series least impacted by changes in regulations.²⁰ Analyses were performed on \log_e -transformed catch and CPUE from April and May. This time period was considered to be the most representative of the green sturgeon presence in the river. The regression analyses¹⁹ for the \log_e -transformed catch

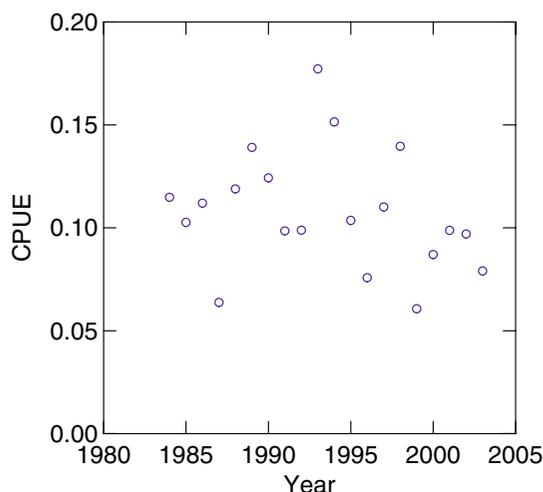

Fig. 3 Yurok Tribal green sturgeon April and May CPUE (numbers/gill net set) for 1984 to 2003 regressed against year

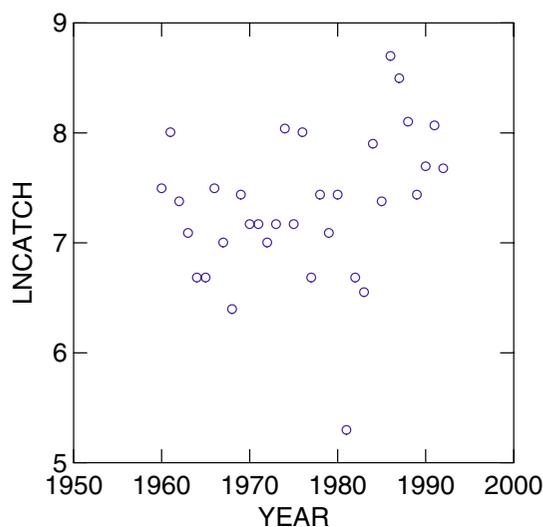

Fig. 4 Columbia River green sturgeon catch (\log_e transformed) in numbers (see text) regressed against year. The time period ends in 1992 due to regulatory changes in the fishery

($r^2 = 0.494$, slope = 0.053, $P = 0.012$) and CPUE ($r^2 = 0.055$, slope = -0.0008 , $P = 0.320$, Fig. 3) both had slopes that were not significantly different from 0. \log_e transformed catch and CPUE were not well correlated with each other ($r^2 = 0.166$). Length–frequency data over this time period showed no trends.¹

The Columbia River commercial landings are the longest green sturgeon time-series available

and represent the largest source of removals from the population (Fig. 4). Landings were recorded in pounds in early years, but catch in numbers were estimated by Oregon Department of Fish and Wildlife (Rien et al. 2001). Fishery regulations drastically changed in 1993, so the regression was only conducted until 1992. Catch in numbers is not only affected by effort and size regulations, but also by the amount and timing of green sturgeon occurrence in the estuary during the summer. The regression analysis¹⁹ of \log_e -transformed catch in numbers on years was not significant ($r^2 = 0.082$, slope = 0.020, $P = 0.108$, Fig. 4). There was a significant positive trend ($r^2 = 0.083$, slope = 0.022, $P < 0.0001$) when the commercial landings were adjusted for total sturgeon effort based on trip tickets¹⁸ Length–frequency distribution of catch from 1985 to 2001 showed no trend (Rien et al. 2001).

Entrainment

Substantial numbers of green sturgeon were killed in pumping operations at state and federal water export facilities in the Sacramento-San Joaquin River Delta (Table 2). Green sturgeons taken in both water export facilities are juvenile fish in the 28 cm to 38 cm FL size range.¹ These numbers are higher in the period prior to 1986 than from 1986 to the present (CDFG 2002). For the state facility (1968–2001), the average number of green sturgeon taken per year prior to 1986 was 732; while the average number was 47 from 1986 on. For the federal facility (1980–2001), the average number prior to 1986 was 889; while the average number was 32 from 1986 on. Trends at each facility were similar with or without adjustment for volume of water pumped (per 1 000 acre-feet). Further examination of the salvage estimates founded that the actual number of actual green sturgeon observed were three-and-one-half times higher in the pre-1986 period.²¹ However, a General Linear Model (GLM) analysis of the green sturgeon estimates compared to observed fish in the pre-1986 period showed that one observed fish was

converted to 48 estimated fish (coefficient = 47.9, $F = 303$ with 16 df, $P = 0.001$). The same analysis for the period from 1986 on showed that one observed fish was converted into 9.7 estimated fish (coefficient = 9.7, $F = 12.4$ with df = 14, $P = 0.003$). So while the numbers of green sturgeon still were higher in the pre 1986 period, it appears that the expansion procedure exaggerated that difference. These entrainment estimates suffer from problems of species identification (green sturgeon were not identified until 1981 at the federal facility), and the estimates are expanded catches from brief sampling periods.⁴ Additional entrainment must also occur from a large number of smaller, unmonitored water diversions on the Sacramento River.

Conclusions and discussion on the “extinction risk” question

Species wide threats

Ocean and estuarine green sturgeon harvest is considered a species wide threat since its impact could not be apportioned to one particular DPS (except for the Klamath tribal in-river catches). Even catches in San Pablo Bay could be fish that originated in the Northern DPS. Harvest impact could be very different if there were disproportionately high harvest of only one DPS. Current total harvest has been reduced to 6% of its 1986 value of 9065 fish. The recent reductions are due in large part to newly imposed fishing regulations

in Oregon and Washington. Commercial fisheries targeting sturgeon have not been allowed in the Columbia River or Willapa Bay since 2001. Klamath tribal catch has remained relatively constant during the entire time series, but recently instituted conservation measures will decrease that catch in the future. The very recent closure of the California recreational fishery will reduce catch even further. The decrease in catch due to changes in regulations and conservation measures represents a reduction in risk to green sturgeon.

No estimates of fishing mortality or exploitation rates exist for green sturgeon, although an annual survival rate of about 85% has been suggested by examining preliminary age data for the Klamath River.²² Secor et al. (2002) note that sturgeon populations can be harvested on a sustainable basis, but only if sufficient spawner escapement is maintained. They noted that sturgeon populations typically can not tolerate more than 5% fishing mortality during spawning runs. Similar rates of annual survival (S) have been assumed in population models for adult Gulf sturgeon in the Suwannee River, Florida ($S = 0.84$, maximum age 25; Pine et al. 2001) and age-1 + shortnose sturgeon ($S = 0.865$, max age 37; Gross et al. 2002). Higher survival rates were assumed in models for Hudson River Atlantic sturgeon ($S = 0.93$, max age 60; Gross et al. 2002) and lower Columbia River white sturgeon ($S = 0.91$, max age 100; Gross et al. 2002). Fishing mortality rates for green sturgeon are affected by slot limit regulations that restrict harvest of adults. In terms of population impacts, however, it is worth noting that sturgeon populations can be substantially affected by harvest of subadults, because of the long interval prior to maturity (Gross et al. 2002; Secor et al. 2002).

One way to judge the impact of fishing is to examine age structure and consider how many opportunities an adult sturgeon would have to spawn. This is particularly critical for sturgeon species, given that strong year classes occur infrequently and adults may only spawn every 3–

5 years. Based on preliminary age data,²⁰ female green sturgeon in 1999–2000 Klamath River catches ranged in age from 17 to 33 although most were 25–31. Using a female maturity of age 20 and their 5 year spawning periodicity, most female green sturgeon would only spawn twice. In comparison, a restoration goal for Atlantic sturgeon (NMFS 1998) is to have at least 20 adult age classes in the spawning stock prior to any consideration of lifting the current harvest moratorium.

The northern green sturgeon DPS

The Northern DPS has two known well-established spawning populations, one in the Rogue River and one in the Klamath-Trinity River system. This spreads the risk over more than one spawning area. In addition, the two systems are not geographically close and thus do not share the same risks of catastrophic events. Spawning appears to occur infrequently in the Umpqua and Eel rivers. The principal threats to green sturgeon in this DPS are flow and temperature factors, habitat degradation, and harvest (Table 3).

The extent of green sturgeon spawning in the Rogue River has only been recently documented (Erickson et al. 2002). The river is less manipulated and habitat seems to be of better quality than in other green sturgeon spawning rivers. Blockages to migration do not seem to be limiting and habitat seems to be roughly what it was historically. Other anadromous fishes are generally doing well in the Rogue River (Weitkamp et al. 1995; Busby et al. 1996; Myers et al. 1998).

The Klamath River is considered to have the largest green sturgeon spawning population. The Yurok catch data were judged to be the most representative available population measure, since the data were based on spawning fish rather than on fish involved in their summer concentration behavior. Neither catch nor CPUE had a negative slope, but trends for both were also not statistically significant. The length data did not indicate that large fish were decreasing within the population, but sample sizes were very small. Spawning still occurs upstream to the historical limit of its habitat range (Ishi Pishi Falls). Out-

³⁹ Loss of habitat due to sedimentation from land use practices and large scale floods (NMFS 2002).

Table 4 Historical and current spawning status of green sturgeon within the Southern DPS, including specific threats to river systems (but excluding ocean and estuarine harvest, which is considered as a coastwide threat)

River system	Historical spawning status	Present spawning status	Threats/changes
Sacramento River	Known spawning	Known spawning ¹	Impassible barriers (Keswick and Shasta dams) ²¹ Adult migration barriers ⁴⁰ Insufficient flow ²¹ Increased temperatures ⁴¹ Juvenile entrainment ¹ Exotic species (e.g., striped bass) ⁴ Poaching ¹ Pesticides and heavy metals ²¹ Local Harvest
Feather River	Suspected spawning ⁴	No evidence ¹¹	Impassible barriers (Oroville Dam) ⁴² See Sacramento River Threats
San Joaquin River	No evidence ^{1,43}	No evidence ¹¹	Impassible Barriers (Friant Dam) ⁴⁴ Extreme low flow ⁴⁵ See Sacramento River Threats

fishery that takes less than 30 adult green sturgeon each year (Table 1). Juvenile out-migrant green sturgeon are captured in most years in small numbers at Willow Creek (Scheiff et al. 2001). There are similar concerns about the temperature and flow regime here as there are in the Klamath (NRC 2004).

The Eel River is the southern most known spawning area in the Northern DPS. Moyle

(2002) suggested that green sturgeon were lost from the Eel River following the 1964 flood. This event along with the 1955 flood and poor land use practices brought large amounts of sediment into the Eel River, and this high sediment level is present today. Some portion of the deep holes that green sturgeon use for holding must have been filled in by these events, but the extent is unknown. Green sturgeon do not appear to be extirpated from the Eel River since there were sightings of adults in both 1995 and 1996 and juveniles in the estuary in 1994. The adult surveys were only conducted in those years and the estuary surveys were only conducted in one other year. Nevertheless, green sturgeon are almost certainly severely reduced in the Eel River from historical levels.

Green sturgeon in the Northern DPS are not considered in danger of extinction now nor are they likely to become endangered in the foreseeable future throughout all of their range, although the lack of data introduces a great deal of uncertainty into this decision. The risk of catastrophic events is spread over a larger geographically area in this DPS, because there are two known spawning populations in the Rogue and Klamath-Trinity rivers. Population trends are not

⁴⁰ Other barrier that are not impassible, RBBB and ACID. Also, sturgeon attracted to stranding areas such as Yolo Bypass. J. McLain. 2004. NOAA Fisheries, Sacramento, CA.

⁴¹ High water temperatures previous to winter-run chinook flow management (J. McLain. 2004. NOAA Fisheries, Sacramento, CA.

⁴² No evidence of spawning but continued presence of green sturgeon in the Feather and Yuba rivers suggest that they are trying to migrate into presumed spawning areas now blocked by Oroville Dam.

⁴³ Adult presence documented in Delta.¹ Evidence of white sturgeon spawning in San Joaquin.¹¹ Accounts of unspecified sturgeon sport catch in San Joaquin River as far as the Merced River (Kohlhorst 1976).

negative and harvest has been reduced. Green sturgeon populations in this DPS face serious potential threats (Table 3) that are particularly worrisome given the lack of data to adequately monitor population status. We recommend that appropriate monitoring of these populations be implemented so that a serious decline in population status could be detected in a timely manner.

The southern green sturgeon DPS

Green sturgeon face a larger number and severity of threats in the Southern DPS (Table 4). The principal threat to this DPS comes from the reduction of green sturgeon spawning to a single area in the Sacramento River. The Sacramento River has impassible barriers blocking green sturgeon access to what were almost certainly historical spawning grounds upstream from Shasta and Keswick dams constructed in the 1940's and 50's.⁴⁶ The same is also true for Feather River and Oroville Dam,⁴⁷ completed in 1968.⁴⁸ In addition, there are also other migration barriers such as Red Bluff Diversion Dam (RBDD) and Anderson-Cottonwood Irrigation District Dam that do not complete block migrations or only block fish seasonally. The Sacramento River now has both reduced and controlled flow.²¹ A strong correlation has been found between mean daily temperature and white sturgeon year-class strength.²¹ Similar relationships may exist for green sturgeon. High temperatures may be less of a problem that it once was due to the installation of the Shasta Dam temperature control device in 1997, although Shasta Dam has a limited storage capacity and cold-water reserves could be depleted in long droughts. Temperatures at RBDD have not been

higher than 16 °C since 1995. This is near green sturgeon egg and larvae optimal temperatures of 15–19 °C (Mayfield and Cech 2004). However, green sturgeon reproduction before 1995 probably was adversely affected by temperature. This may have caused population reductions that could still affect the overall population size and age-structure even now. The average number of juvenile green sturgeon entrained at both the state and federal facility prior to 1986 were higher than they were from 1986 on. There are no apparent reasons for the large reduction in numbers entrained. Exotic species are an ongoing problem in the Sacramento-San Joaquin River and Delta systems (Cohen and Carlton 1998). Probably, the largest problems with exotic species regard the replacement of native food items. The exotic bivalve *Potamocorbula amurensis*, introduced in 1988, has become the most common food of white sturgeon and was found in the only green sturgeon examined.⁴ Moreover, the overbite clam is known to bioaccumulate selenium, a toxic metal (Linville et al. 2002). Green sturgeon may also experience predation by introduced species including striped bass. Sturgeon have high vulnerability to fisheries and the trophy status of large white sturgeon makes them the target of poachers.⁴ Green sturgeon are caught incidentally in these white sturgeon fisheries and may also be taken in illegal fisheries. Pollution within the Sacramento River increased substantially in the mid-1970s when application of rice pesticides increased.²¹ Estimated toxic concentrations for the Sacramento River during 1970–1988 may have deleteriously affected striped bass larvae (Bailey 1994). White sturgeon may also accumulate PCB and selenium,⁴⁹ substances know to be impair embryonic development.

The Sacramento River supports the only known green sturgeon spawning population in this DPS. There has almost certainly been a substantial loss of spawning habitat behind Keswick and Shasta dams.²¹ The historical habitat data has been

summarized in Lindley et al. (2004). Green sturgeon occur up to the impassible barrier at Keswick Dam. It is unlikely that green sturgeon historically reproduced in their current spawning area based on the historical temperature regime that occurred before the construction of Shasta and Keswick dams. At the present, water temperatures in the current spawning area are lower due to cool-water releases from Shasta Dam. Green sturgeon almost certainly spawned further up the mainstem that they do now. It possible that the additional habitat behind Shasta Dam in the Little Sacramento, Pitt, and McCloud systems would have supported separate populations or at least, a single larger population that was less vulnerable to catastrophes than the current one.

Green sturgeon almost certainly no longer spawn in the Feather River. Access to a substantial amount of habitat in the Feather River was lost with the construction of Oroville Dam. California Department of Fish and Game concluded that the Feather River spawning habitat was most likely lost due to habitat blockage by Oroville Dam and from thermal barriers created by the Thermaltio Afterbay facility.⁴ U.S. Fish and Wildlife Service stated¹⁷ that “Evidence also suggests that sturgeon reproduction occurs in both the Feather and Bear rivers.” in reference to white sturgeon prior to dam construction. Again, it must be assumed that a similar conclusion could be made for green sturgeon in the face of the paucity of data. Sturgeon (including some documented green sturgeon) still regularly occur in the Bear and Yuba rivers^{4,11} and therefore must migrate through the Feather River. Threats to green sturgeon are similar to those faced in the Sacramento River.

There is not sufficient information to establish whether the San Joaquin River system ever had supported a viable green sturgeon population. There is no evidence of green sturgeon occurrence or spawning in the San Joaquin River.^{1,4,11} White sturgeon do occur in the San Joaquin River system, particularly in wet years⁴ and the first record of white sturgeon spawning in the San Joaquin system was made in 2003.¹¹ Moyle (2002) suggests that green sturgeon reproduction may have taken place in the San Joaquin River because adult green sturgeon were captured at Santa Clara Shoal and Brannan Island

Recreational Area in the Delta. If green sturgeon occurred in the San Joaquin system, the potential threats would be similar in nature to those faced in the Sacramento River, but would probably be more extreme.

The green sturgeon Southern DPS population trend information was less definitive than in the Northern DPS, and less convincing. The San Pablo Bay population estimates had a slightly positive trend, which was not statistically significant, even though the 2001 estimate was the highest on record. The usefulness of these estimates was reduced because they are based on the green sturgeon’s summer concentrations, a situation which is not understood. In addition, unequal vulnerabilities to sampling gear of these two species make these estimates less reliable.

Green sturgeon in the Southern DPS are likely to become an endangered species in the foreseeable future. The Southern DPS is at substantial risk, primarily because green sturgeon are confined to a single spawning area in the Sacramento River. Potential threats faced by green sturgeon are substantially greater in the Southern DPS than in the Northern one. Threats in this DPS include vulnerability due to concentration of spawning, smaller population size, lack of population data, potentially growth-limiting and lethal temperatures, harvest concerns, loss of spawning habitat, entrainment by water projects and influence of toxic material and exotic species. Catastrophic events have occurred in this DPS, such as the large-scale Cantara herbicide spill which killed all fish in a 10-mile stretch of river upstream from Shasta Dam, and the 1977–1978 drought that caused year-class failure of winter-run chinook salmon. Population sizes are unknown in this DPS, but are clearly much smaller than in the northern one and therefore this DPS is much more susceptible to catastrophic events. As is the case for the Northern DPS, the Southern DPS is in need of adequate population monitoring.

Recommended Streamflow Schedules To Meet the AFRP Doubling Goal in the San Joaquin River Basin

27 September 2005

Introduction

The goal of the Anadromous Fish Restoration Program (AFRP) is to make all reasonable efforts to at least double natural production of anadromous fish in California's Central Valley streams on a long-term, sustainable basis. However, production of fall-run Chinook salmon (Chinook Prod) between 1992 and 2004 has declined by 28% in the Stanislaus River, 46% in the Tuolumne River, and increased by only 4% in the Merced River, which is a hatchery supported stream, compared to the 1967-1991 baseline period. Evidence is provided here that the declines in salmon production primarily resulted from a reduction in the frequency and magnitude of spring flooding in the San Joaquin River Basin during the 1992-2004 period compared to the baseline period. Additional evidence is provided that the most likely means of increasing adult production would be to increase flows during February and March to substantially increase the survival of juveniles in the lower half of the tributaries and the San Joaquin River and thereby increase the production of smolts, and then to increase flows between April and mid-June to increase smolt survival. It is also likely that production can be further increased by (1) providing fall pulse flows that help minimize the number of adult salmon that stray to the Sacramento Basin when Delta export rates are high and minimize delays of adults in the Delta that may impair gamete viability; (2) gradually ramping down spring flows during June to facilitate riparian vegetation recruitment and thereby increase the input of allochthonous organic matter and food into the aquatic habitat; and (3) increasing summer flows to increase the survival of juvenile Central Valley steelhead and Chinook yearlings.

The population models described below suggest that the physical habitat in the Stanislaus, Tuolumne, and Merced rivers can support the progeny of no more than 2,000 spawners. If true, restoring the spawning, rearing, and/or floodplain habitats should substantially increase salmonid production in all three tributaries. However, it is likely that habitat restoration by itself will not increase juvenile production, unless flows are increased to increase the amount of rearing habitat, the frequency of floodplain inundation, and thereby increase juvenile survival.

There is also a slight possibility that increasing flows during spawning in early November to increase the amount of habitat with suitable water temperatures would reduce redd superimposition and thereby increase juvenile production; however, screw trap data from the Stanislaus River, which are presented below, do not support this hypothesis.

Ten analyses that were used to justify and determine the flow schedules needed to help achieve the AFRP doubling goal are summarized below:

1. Relationships between salmon recruitment and flow in the Stanislaus and Tuolumne rivers;
2. Relationships between juvenile survival and flow in the Stanislaus River;
3. Salmon production models for the San Joaquin River Basin;
4. Spring flows required to double fall-run Chinook salmon populations;
5. Fall pulse flows required for adult passage through the Delta;
6. Fall flows required for spawning and incubation habitat;
7. Ramping down spring flows to promote riparian vegetation;
8. Summer flows required to increase habitat for yearling steelhead and salmon;
9. The effect of Delta Exports rate reductions on Chinook salmon production; and
10. Comparison of Flow Schedules for a 53% increase in production and doubling.

1. Relationships Between Salmon Recruitment And Flow In The Stanislaus And Tuolumne Rivers

Fall-run Chinook salmon production in the San Joaquin River Basin is well correlated with flow, particularly in the San Joaquin River at Vernalis, during the spring when the juveniles are migrating from the tributaries (Mesick 2005). Mesick's analysis converts production, which consists of several different cohorts of fish that all return to spawn in the tributaries during the same year, into recruitment, which consists of same-aged adults that all migrated through the Basin as juveniles during the same year. This conversion requires age data to segregate escapement into cohorts, which was not collected on the Merced River until 1988; therefore, these analyses that compare the baseline and post-baseline periods could only be done for the Tuolumne and Stanislaus rivers.

Comparing the regressions of average flow in the San Joaquin River at Vernalis for the March through May period and salmon recruitment suggests that the slope of the regressions has declined by about 10% for the Stanislaus River (Figure 1) and 20% for the Tuolumne River (Figure 2); however, statistical tests cannot be conducted to determine the significance of the declines because the tests can only be conducted if the variances of the two regressions are not significantly different (Snedecor and Cochran 1989) and *F*-tests indicate that the variances of the baseline and 1992-2002 regressions were significantly different ($p \leq 0.01$). Therefore, most if not all of the declines in production observed in the Stanislaus and Tuolumne rivers since 1992 are a result of a lower frequency of wet years during the 1992-2004 period compared to the baseline period. For example, the average March through May flows at Vernalis during the slightly wet years (San Joaquin River Index of 4.0 to 5.0 million acre feet) ranged between 5,000 and 10,000 cfs during the 1992-2004 period and between 15,000 and 20,000 cfs during the baseline period (Figure 3). The lower flood magnitudes observed after 1992 are primarily due to differences in climate because the large San Joaquin reservoirs that capture all or most of flood flows were all completed prior to 1992: New Melones was completed in 1980, New Don Pedro was completed in 1971, and New Exchequer was completed in 1966.

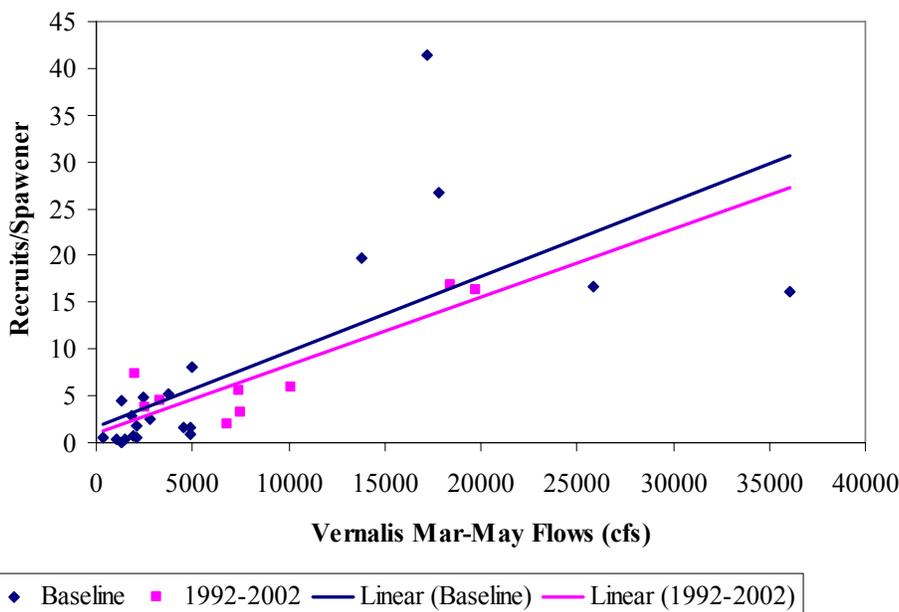

Figure 1. The relationship between the number of fall-run Chinook salmon recruits/spawner to the lower Stanislaus River and the average flow in the San Joaquin River at Vernalis between 1 March and 31 May during the 1967-1991 baseline period and the 1992-2002 AFRP period. The lines labeled as “linear” show the linear regression models for each period. The adjusted R-Squared for the linear regression model is 0.50 for the 1967 to 2002 dataset.

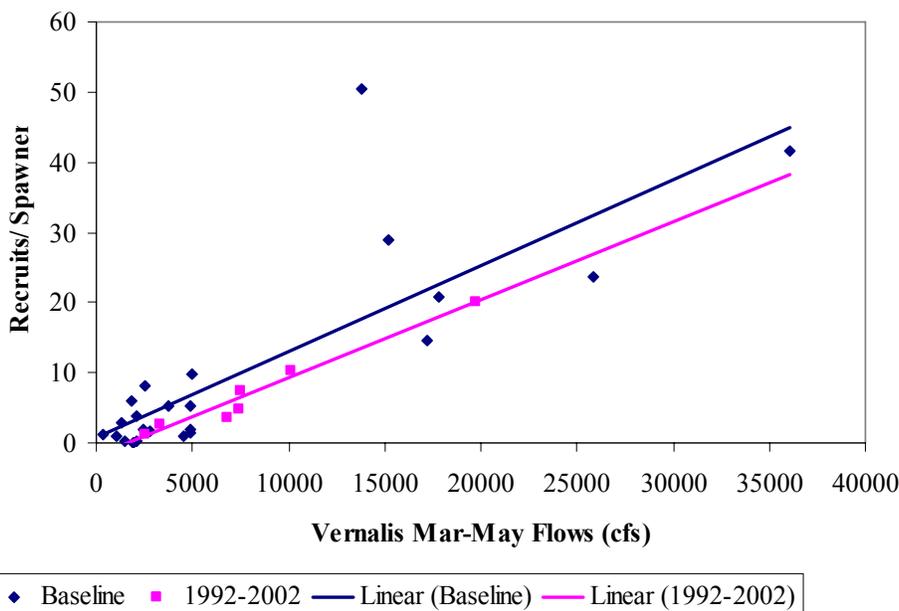

Figure 2. The relationship between the number of fall-run Chinook salmon recruits/spawner to the lower Tuolumne River and the average flow in the San Joaquin River at Vernalis between 1 March and 31 May during the 1967-1991 baseline period and the 1992-2002 AFRP period. The lines labeled as “linear” show the linear regression models for each period. The adjusted R-Squared for the linear regression model is 0.59 for the 1967 to 2002 dataset.

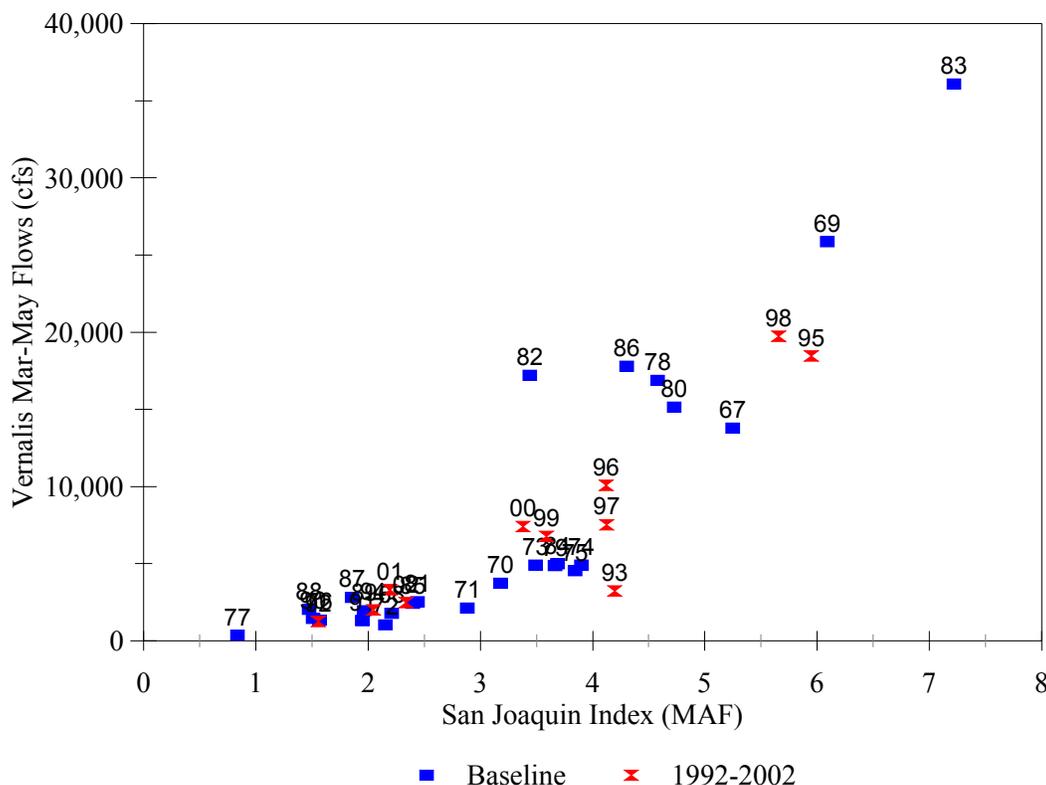

Figure 3. The relationship between the mean March through May flow in the San Joaquin River at Vernalis and the San Joaquin Index in millions of acre-feet (MAF) for the baseline and 1992-2002 periods.

2. Relationships between juvenile survival and flow in the Stanislaus River

The survival of fry and parr migrating and rearing in the Stanislaus River between Oakdale and Caswell State Park is highly dependent on flow between March and early June and presumably the same is true for the Tuolumne and Merced rivers. Many more fry, parr, and smolts were captured in the Stanislaus River at the Caswell traps when the flow at Ripon in February and March ranged between 1,000 and 5,000 cfs during above normal and wet years (1998-2000) than when it was typically less than 600 cfs during dry and normal years (2001-2004; Appendix 1). The fact that more juveniles passed the downstream Caswell trap (RM 5) than the upstream Oakdale trap (RM 40) in April and May during the above normal and wet years strongly suggests that high February and March flows may be needed for fry and parr to rear in the lower river. It is also likely that the extended periods of high flows in April, May and early June during the above normal and wet years were responsible for the high survival rates of migrating smolts. Supporting evidence is provided by the strong correlations between adult recruitment and Vernalis flows in March, April, May, and June (Mesick 2005). The relatively weak correlations between recruitment and Vernalis flows in February suggest that February

flows may be as important as those between March and mid June. It is assumed that high flows in February through mid June would also be important for juvenile salmonids in the Tuolumne and Merced rivers as well.

3. Salmon production models for the San Joaquin River Basin

Regression equations were computed for the number of Chinook salmon recruits per spawner in each of the San Joaquin River tributaries (Mesick 2005) and the average flow at Vernalis during April and May for the purpose of estimating the amount of flow required to double populations. It was assumed that the magnitude of flow during April and May was more directly related to juvenile salmon survival because this is the period when most of the smolt-sized fish are migrating¹ and water temperatures are in the range that may affect smolt survival². Vernalis flows were used in the model instead of tributary reservoir releases for two reasons. First, juvenile survival in the Stanislaus River is much more highly correlated with flow at Vernalis (adjusted-R² = 0.53) than with flow at Goodwin Dam in the Stanislaus River (adjusted-R² = 0.16), which suggests that Delta flows are more important than tributary flows (Mesick 2005). Second, there were insufficient flow data at Snelling to estimate reservoir releases in the Merced River during the entire AFRP baseline period, which precludes model development based on tributary flows.

Stanislaus River model: $\text{Recruits/Spawner} = 0.0008611 * \text{April-May Vernalis Flows} + 1.17688$. The adjusted-R² was 0.53 with a probability level of 0.0000 for the model developed with the estimates for 1983 to 2002. Recruitment was computed by multiplying the model's predicted number of recruits/spawner by the number of spawners. It was assumed that recruitment increased linearly until 2,000 spawners, after which and there was no further change in recruitment as the number of spawners exceeded 2,000 fish. This assumption reflects the relationship between stock and the total estimated number of juveniles passing the Oakdale Screw trap between 1996 and 2004 (Mesick 2005). Figure 4 compares the recruitment estimates based on escapement surveys (Mesick 2005) with the model results.

Tuolumne River model: $\text{Recruits/Spawner} = 0.00140 * \text{April-May Vernalis Flows} + 0.18957$. The adjusted-R² was 0.65 with a probability level of 0.0000 for the model developed with the estimates for 1980 to 2002. Recruitment was computed by multiplying the estimated number of recruits/spawner by the estimated number of spawners. It was assumed that recruitment increased linearly until 2,000 spawners, after which there was no further change in recruitment as the number of spawners exceeded 2,000 fish. This assumption was made because the model's adjusted-R² declined to 0.44 and then to 0.32 as the spawner-recruit inflection point was increased to 3,000 and 4,000 spawners respectively. Figure 5 compares the recruitment estimates based on escapement surveys (Mesick 2005) with the model results.

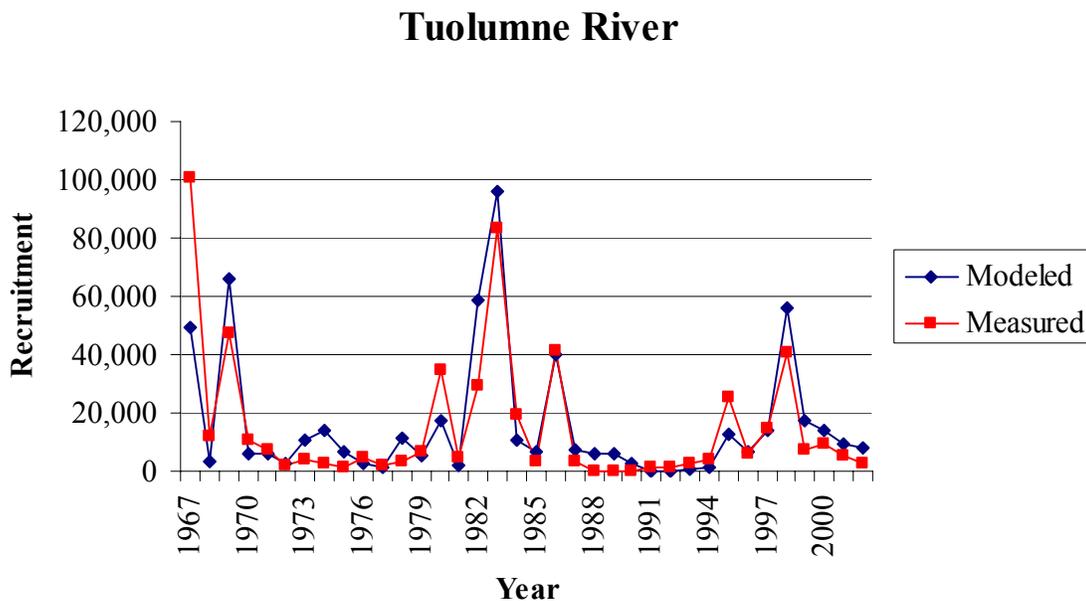

Figure 5. Adult Chinook salmon recruitment to the Tuolumne River from 1967 to 2002 based on escapement surveys (Measured) and regression model predictions (Modeled).

Merced River model: $\text{Recruits/Spawner} = 0.000554 * \text{April-May Vernalis Flows} + 0.07938$. The adjusted- R^2 was 0.61 with a probability level of 0.0000 for the model developed with the estimates for 1980 to 2002. The recruitment estimates between 1980

and 1986 were based on Age 2 estimates from the Tuolumne River whereas the later estimates were based on length-frequency derived Age 2 estimates from the Merced River (Mesick 2005). Recruitment was computed by multiplying the estimated number of recruits/spawner by the estimated number of spawners. It was assumed that each fish collected in the Merced River Fish Hatchery, up to the approximate hatchery's capacity of 1,000 spawners, contributed twice the in-river production compared to naturally spawning adults. It was also assumed that recruitment increased linearly until 2,000 in-river spawners, after which there was no further change in recruitment after the number of spawners exceeded 2,000 fish. This assumption was made because the physical condition of the spawning and rearing habitat in the Merced River is more degraded than those habitats in the Stanislaus and Tuolumne rivers³. In addition, the number of recruits produced per spawner in the Merced River is substantially lower than in the Tuolumne and Stanislaus rivers, and so it is highly unlikely that the habitat in the Merced River can support the progeny of more than 2,000 spawners. Figure 6 compares the recruitment estimates based on escapement surveys (Mesick 2005) with the model results.

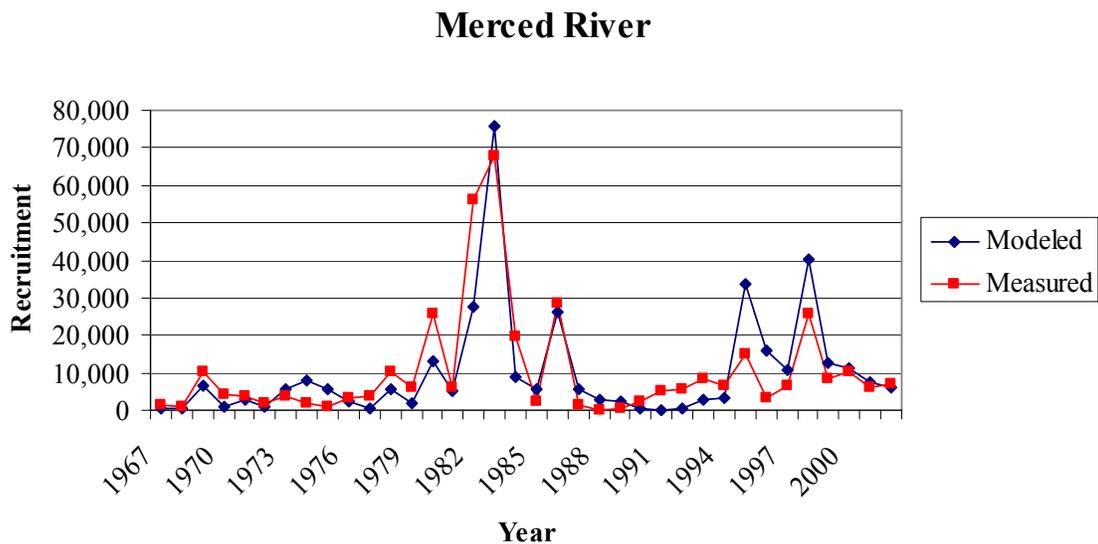

Figure 6. Adult Chinook salmon recruitment to the Merced River from 1967 to 2002 based on escapement surveys (Measured) and regression model predictions (Modeled).

4. Spring flows required to double fall-run Chinook salmon populations

To use the above recruitment models to estimate the amount of flow at Vernalis that would be needed to double salmon production in the San Joaquin Basin, it is necessary to maintain the historical conditions that formed the basis of the model. This means that each of the three San Joaquin River tributaries must maintain the similar contributions to Vernalis flows as well as maintain a similar hydrograph. Based on the estimated annual unimpaired flows, the Stanislaus River contributes 28%, the Tuolumne River contributes

³ The physical condition of the Merced, Tuolumne, and Stanislaus rivers was visually assessed by Carl Mesick, USFWS, during boat surveys in 2005, 2004, and 2002 respectively.

49%, and the Merced River contributes 23% of Vernalis flows historically. To convert the modeled flows into monthly averages for March, April, and May in a functional flow schedule, a constant percentage of the average unimpaired historical flow (1901 to 2004) was used for each month. For example, the Merced River Model indicates that an average flow of 3,480 cfs would be needed for the months of April and May during wet years to double production. The flow schedule was determined by multiplying the average unimpaired flow during wet years by 76.86%, which computes to a March flow of 2,279 cfs, an April flow of 2,559 cfs, and a May flow of 4,402 cfs. Suitable February flows were assumed to be either half of March flows or a minimum of 350-500 cfs, which was slightly lower than the recommended March flow.

Two sets of recommended flows were developed. The first set of flows simply extended the Vernalis flow standards in the State Water Resources Control Board's 1995 Water Quality Control Plan from April 15 to May 15 to April 1 to May 30, and then proportioned the flow during each month between March and May to match the natural hydrograph. Based on all three recruitment models, the total modeled population for the San Joaquin River Basin would increase by 53% from 36,494 fish during the AFRP baseline period to 55,945 fish, if the flows in Table 1 were implemented. The increase in recruitment varies between the three tributaries: 59% for the Stanislaus River, 42% for the Tuolumne River, and 57% for the Merced River, because the populations respond differently in terms of the effects of flow on juvenile survival and increases in spawner abundance. Historically, spawner abundance limited recruitment more frequently on the Stanislaus and Merced rivers than in the Tuolumne River and so an increase in flow would improve both spawner abundance as well as smolt survival in the Stanislaus and Merced rivers to a greater degree than for the Tuolumne River, and thereby, produce the largest increases in recruitment in the Stanislaus and Merced rivers. The rate that recruitment increases with flow would be expected to decline after spawner abundance consistently reaches the habitat's capacity of 2,000 fish.

The second set of flows would be expected to double the total predicted San Joaquin Basin recruitment from 36,494 fish during the AFRP baseline period to 72,916 fish. The increase in recruitment varies considerably between the three tributaries: 114% for the Stanislaus River, 86% for the Tuolumne River, and 112% for the Merced River. The following table indicates the average flow for February, March, April, and May in the Stanislaus, Tuolumne, and Merced rivers that would be expected to double salmon production for the basin.

Table 1. The average flow (cfs) for February, March, April, and May for the Stanislaus, Tuolumne, and Merced rivers that would be expected to achieve a 53% increase in total predicted Chinook salmon production for the basin.

5. Fall pulse flows required for adult passage through the Delta

Poor water quality in the deep-water ship channel near Stockton and excessive exports at the State Water Project and Central Valley Project at Tracy in October can either delay the upstream migration of adults or cause them to stray to the Sacramento River basin.

Delayed Adult Migration

Hallock and others (1970) showed that radio-tagged adult Chinook salmon delayed their migration at Stockton whenever dissolved oxygen (DO) concentrations were less than 5 mg/l and/or water temperatures exceeded about 65 °F in October. DO concentrations near Stockton in October were greater than 5 mg/l from 1983, when DWR began

monitoring, to 1990, but were lower than 5 mg/l for most of October in 1991 and 1992. The Head of the Old River Barrier was installed in fall 1992 to maximize flows in the deep water ship channel, but it did not correct the problem until late October (Figure 7). In 1993, DO levels were low until about 10 October and it is likely that pulse flows that raised Vernalis flows to about 4,000 cfs on 7 October were responsible for increasing DO levels at Stockton (Figure 7). Similarly in 1994, DO levels were low until 15 October when pulse flows raised Vernalis flows to about 2,000 cfs (Figure 7). In 1995, DO levels were at least 6 mg/l in October when Vernalis flows ranged about 3,000 cfs to 6,000 cfs through mid October. DO levels were low or greatly fluctuated in 1996 until 13 October when pulse flow releases increased Vernalis flows from 2,000 to about 3,000 cfs (Figure 7).

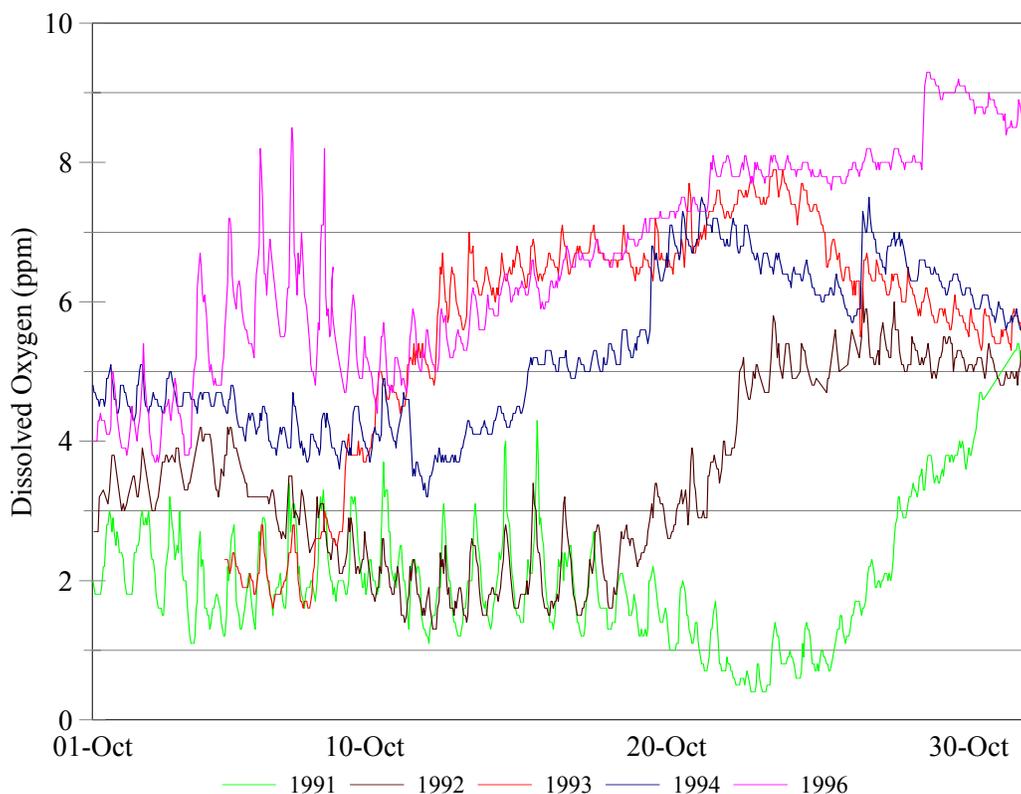

Figure 7. Hourly dissolved oxygen measurements at the Department of Water Resources' Burns Cut Off Road monitoring station during October in 1991 through 1994 and in 1996.

There are concerns that delaying the migration of adult salmon in the deep-water ship channel near Stockton may reduce gamete viability if the fish are exposed to high temperatures for prolonged periods. Egg survival at the Merced River Hatchery increased from a mean of 46% from 1990 to 1992 during the peak of the drought to a mean of 77% from 1993 to 1999 after fall pulse flows were made⁴. A more in-depth

⁴ Merced River Hatchery Production Reports by CDFG

analysis should be conducted to determine whether the mid-October pulse flows help maintain gamete viability in Chinook salmon migrating in the Delta.

Adult Straying

Delta export rates at the State Water Project and Central Valley Project were increased to near maximum (about 9,600 cfs) in fall 1996 and in subsequent years to “make-up” for reduced pumping rates during the spring outmigration period to improve salmon smolt survival (Mesick 2001). The adult fall-run salmon are migrating upstream through the Delta primarily in October typically when San Joaquin River flows at Vernalis are low (Mesick 2001). It is likely that when exports are high relative to San Joaquin River flows, little if any San Joaquin River water reaches the San Francisco Bay where it may be needed to help guide the salmon back to their natal stream. An analysis by Mesick (2001) of the recovered adult salmon with coded-wire-tags (CWT) that had been reared at the Merced River Fish Facility and released in one of the San Joaquin tributaries suggests straying occurred when more than 400% of Vernalis flows were exported at the CVP and SWP Delta pumping facilities. The analysis indicates that during mid October from 1987 through 1989 when export rates exceeded 400% of Vernalis flows, straying rates ranged between 11% and 17% (Figure 8). In contrast, straying rates were estimated to be less than 3% when Delta export rates were less than about 300% of San Joaquin River flow at Vernalis during mid-October. Between 1993 and 2002, pulse flow releases from the San Joaquin tributaries and/or reductions in Delta exports for 10 days in mid-October have kept Delta export rates to less than 300% of the San Joaquin River flow at Vernalis (Figure 8).

To maintain high levels of gamete viability in migrating salmon and minimize straying during periods of high exports (i.e., export no more than 300% of Vernalis flows), it is recommended that a 1,000-cfs pulse flow should be released for 10 days in mid-October from each of the three San Joaquin River tributaries.

6. Fall flows required for spawning and incubation habitat

Adult Chinook salmon typically crowd into the uppermost six miles of habitat in the Tuolumne and Merced rivers, and to a lesser extent the Stanislaus River, in early November. Crowding of spawning is thought to be detrimental because the rate of redd superimposition, where females either destroy or bury the eggs in pre-existing redds, would be abnormally high and thereby reduce the production of juvenile fish. Crowding may be a result of inadequate fall spawning flows that result in excessively warm temperatures in the downstream areas. Although the percentage of spawners that use the downstream areas increases as water temperatures decline with declining air temperatures, there is no evidence that increased fall flows reduces spawner crowding or improves juvenile production (Figure 9).

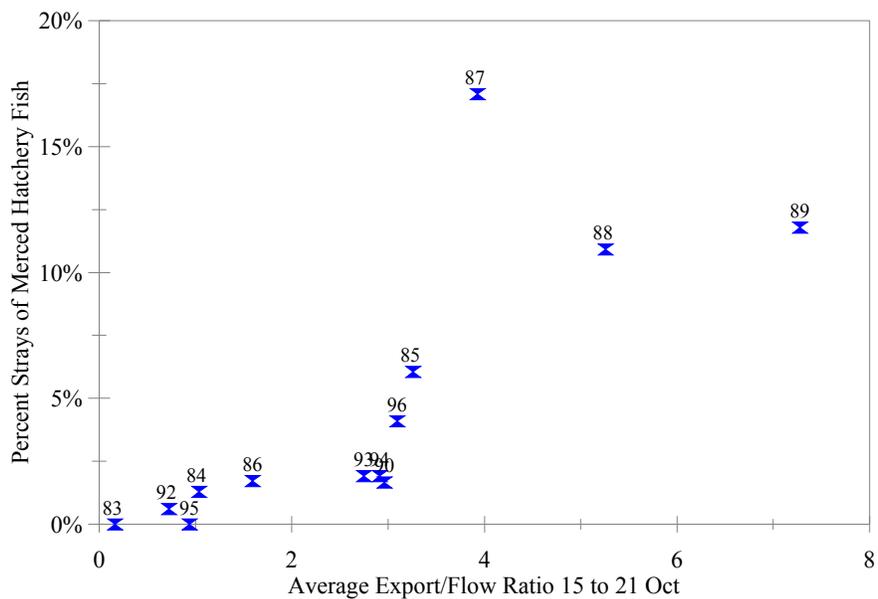

Figure 8. Estimated percent of adult CWT Chinook salmon that were reared at the Merced River Hatchery, released in the San Joaquin basin as juvenile salmon, and subsequently strayed to the Sacramento River and eastside tributary basins to spawn relative to the average ratio of the export rate at the CVP and SWP pumping facilities in the Delta to the flow rate in the San Joaquin River at Vernalis between 15 and 21 October from 1983 to 1996.

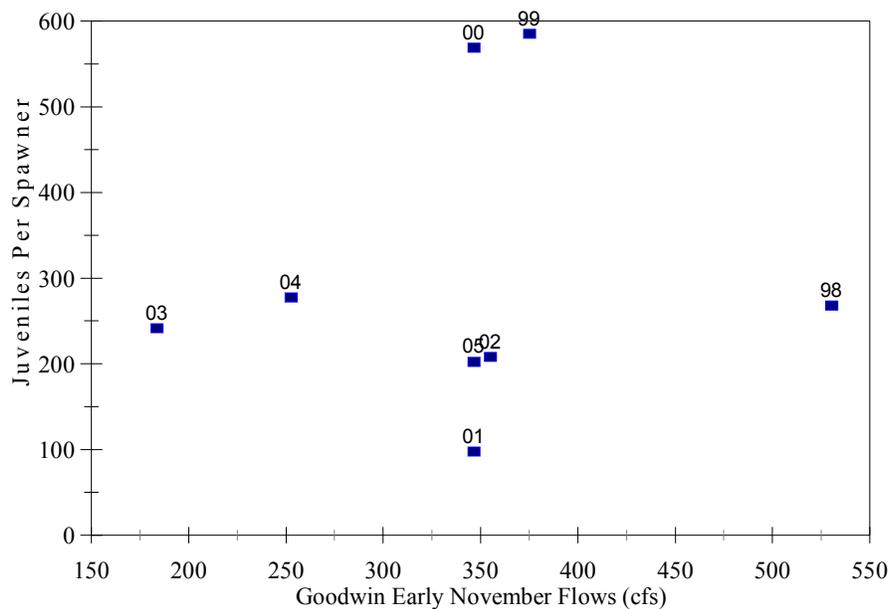

Figure 9. Relationship between the estimated number of juvenile salmon passing Oakdale per spawner and the Goodwin Dam flow release in early November in the Stanislaus River from 1998 to 2004.

It is recommended that studies should be conducted to determine the relationship between the magnitude of fall spawning flows and juvenile production in the Tuolumne and Merced rivers where spawner crowding is high. In the meantime, it is recommended that fall flows should be based on the optimum amount of physical habitat as determined by the PHABSIM model: 300 cfs for the Stanislaus River, 175-300 cfs for the Tuolumne River, and 200-250 cfs for the Merced River. These flows should be implemented from late October following the pulse flows until the end of January when flows begin to increase for juvenile rearing.

7. Ramping down spring flows to promote riparian vegetation

A likely benefit of spring flooding is the flushing of food and organic matter that produces food from the floodplains into the rivers where it can benefit juvenile salmonids. A healthy riparian forest is an integral component of the food chain.

A key factor for successful riparian recruitment is ensuring that the general rate of stage decline during the recession limb of flood control releases is gradual enough to support riparian seedling establishment. Another important issue is the timing of the recession limb. Recruitment flows should be targeted from mid-April to late-May to improve cottonwood recruitment and mid-May to late June to benefit black willow.

Research on a variety of cottonwood and willow species suggests that 1 to 1.5 inches/day is the maximum rate of water table decline for seedling survival (McBride et al. 1989; Segelquist et al. 1993; Mahoney and Rood 1992, 1998; Amlin and Rood 2002). However, a recent manipulation experiment of Fremont cottonwood, black willow, and narrow leaf willow seedlings found that water table declines of one inch or more resulted in 80% mortality within 60 days, even when the water table was maintained near the soil surface for several weeks before drawdown (Stillwater Sciences, unpublished data). Therefore more conservative rates may be appropriate. Flow recession rates of 100 to 300 cfs/day in the San Joaquin Basin are thought to prevent seedling desiccation under the assumed 1 inch/day maximum root growth rate.

A secondary benefit of a gradual ramp down of flows during June would be to increase juvenile salmon survival. Juvenile salmon migrate from the tributaries through early June and it is likely that they require 10 to 14 days to complete their migration through the Delta.

To promote the riparian vegetation recruitment and enhance the survival of juvenile salmon through the Delta, it is recommended that flows should be gradually ramped down at a constant rate between May 31 and June 30.

8. Summer flows required to increase habitat for yearling steelhead and salmon

Naturally produced juvenile steelhead typically rear in fresh water for two years before smolting and it is likely that successful rearing must occur in the tributaries because of

the unsuitable conditions that occur in the Delta during the summer. The physical habitat is most suitable for rearing steelhead in the 12-mile reach below the lowermost dams in the Stanislaus, Tuolumne, and Merced rivers. Although it would be preferable to provide water that is cooler than 65°F throughout the entire 12-mile reach during all water year types, doing so would require an unreasonable volume of water and could possibly exhaust the cold water pool in the primary reservoirs. A more reasonable alternative would be to maintain suitable water temperatures in at least a 5-mile reach, which presumably would be sufficient to sustain a population.

It is recommended that a block of water should be allocated in each of the tributaries to manage flows on a daily basis so that water temperatures do not exceed 65°F in the uppermost 5-mile reach between July 1 and mid October when the pulse flows begin. Flow management should be based on the new water temperature model for the Stanislaus River and on empirical flow-water temperature data for the Tuolumne (Figure 10) and Merced rivers until new models can be developed. It is anticipated that summer flows will range between 150 and 325 cfs depending on air temperatures and the desired length of river with suitable water temperatures.

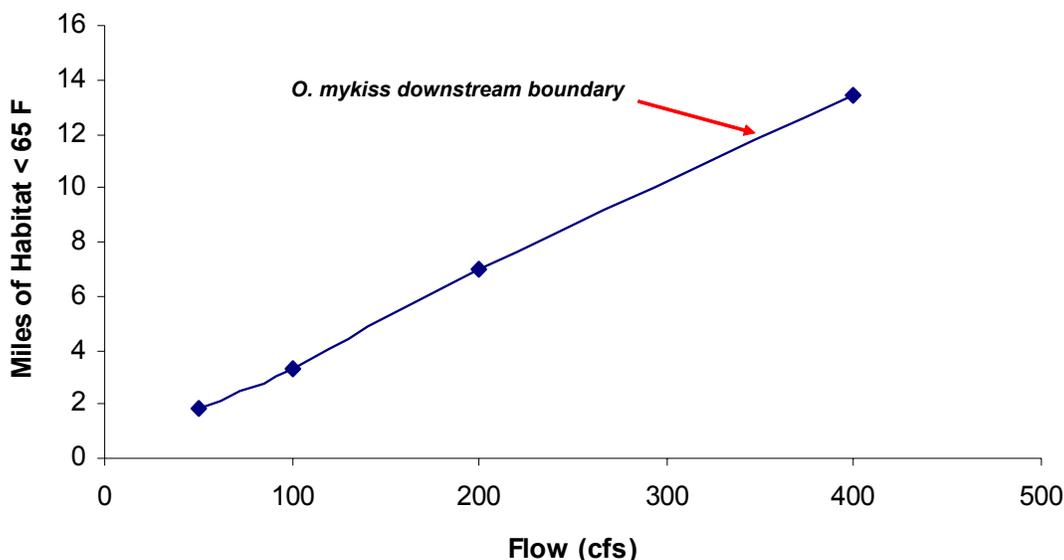

Figure 10. Relationship between the flow from La Grange Dam and the amount of habitat with water temperatures less than 65°F in the Tuolumne River based on a simple water temperature model (EA Engineering, Science, and Technology 1991).

9. The effect of Delta Exports rate reductions on Chinook salmon production

Export rates at the State's Harvey O. Banks pumping facilities (SWP) and the Federal pumping facilities at Tracy (CVP) have been substantially reduced during the VAMP period (typically April 15 to May 15) since 1996 to improve the survival of outmigrating smolts. However, the numbers of recruits-per-spawners in the Stanislaus and Tuolumne rivers are similar since the export reductions began in 1996 compared to the years when

exports were high prior to 1996 (Figures 11 and 12). This suggests that reducing exports below 400% of Vernalis flows for 31 days has had no detectable affect on adult recruitment. If true, experimental water transfers that increase flows in the San Joaquin Basin tributaries as prescribed above could be captured at the SWP and CVP pumping facilities without affecting the expected increase in salmonid recruitment.

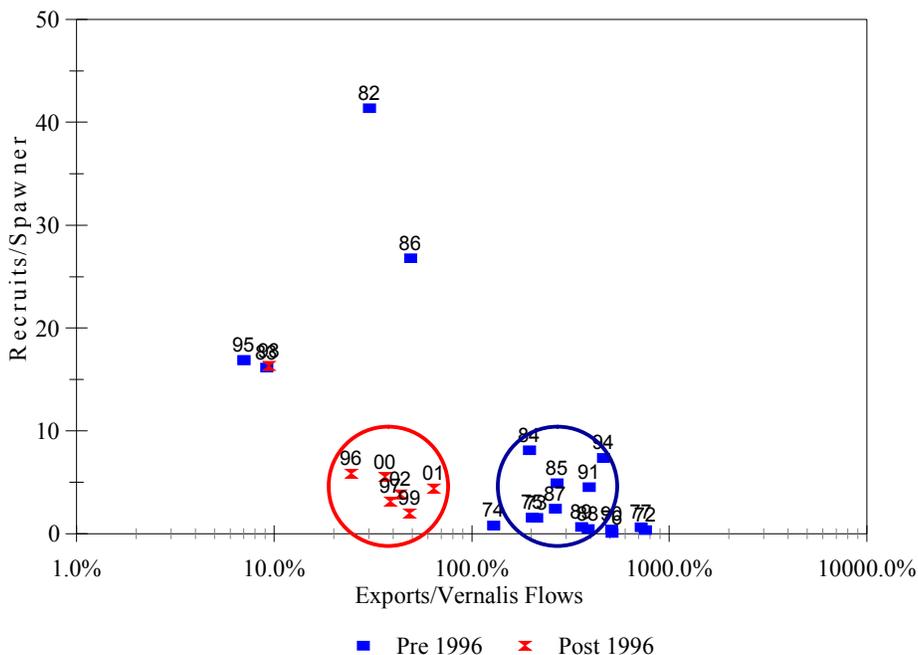

Figure 11. The relationship between the number of fall-run Chinook salmon recruits/spawner to the lower Stanislaus River and the average ratio of combined CVP and SWP exports to the flow in the San Joaquin River at Vernalis between 15 April and 15 May from 1972 to 2002. Exports were reduced during this period since 1996 (Blue Symbols) to improve the survival of outmigrating smolts.

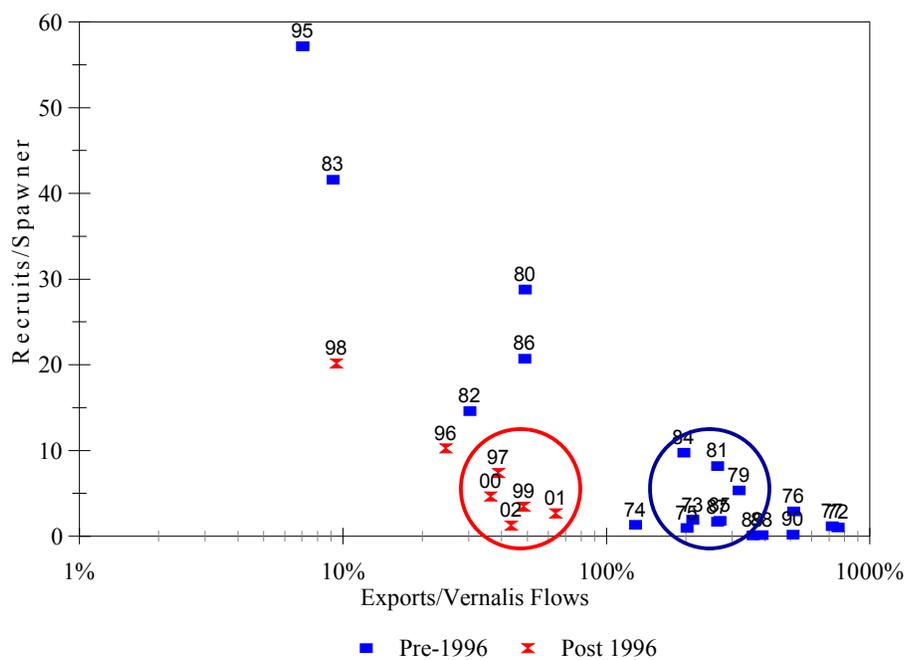

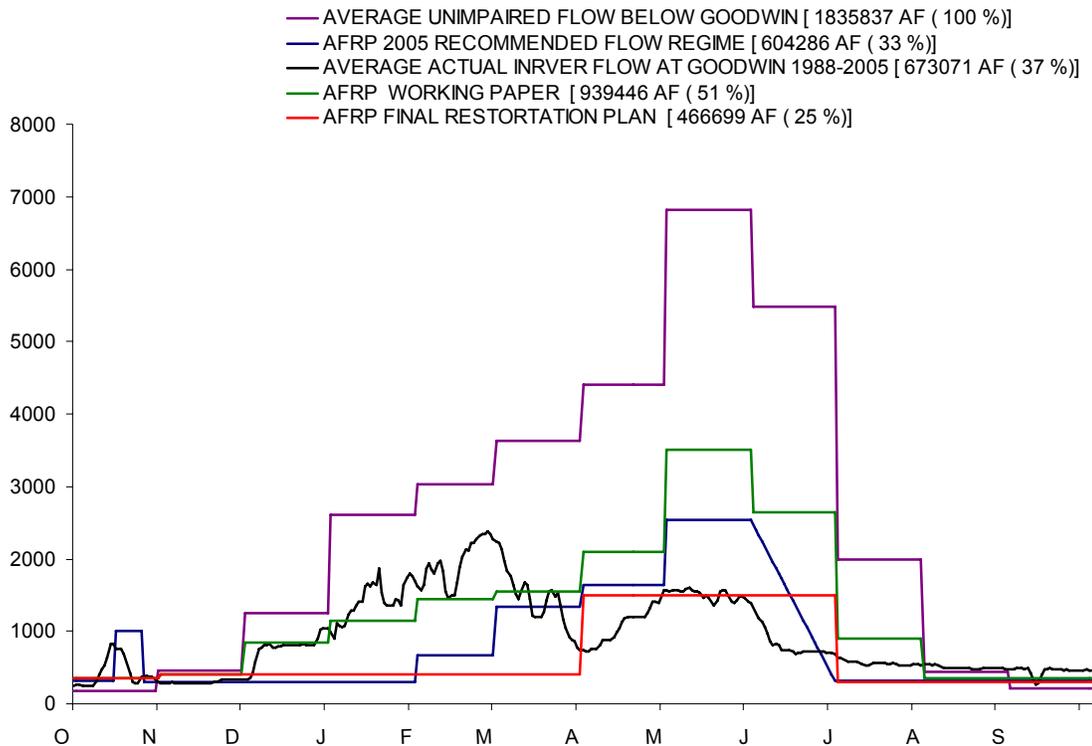

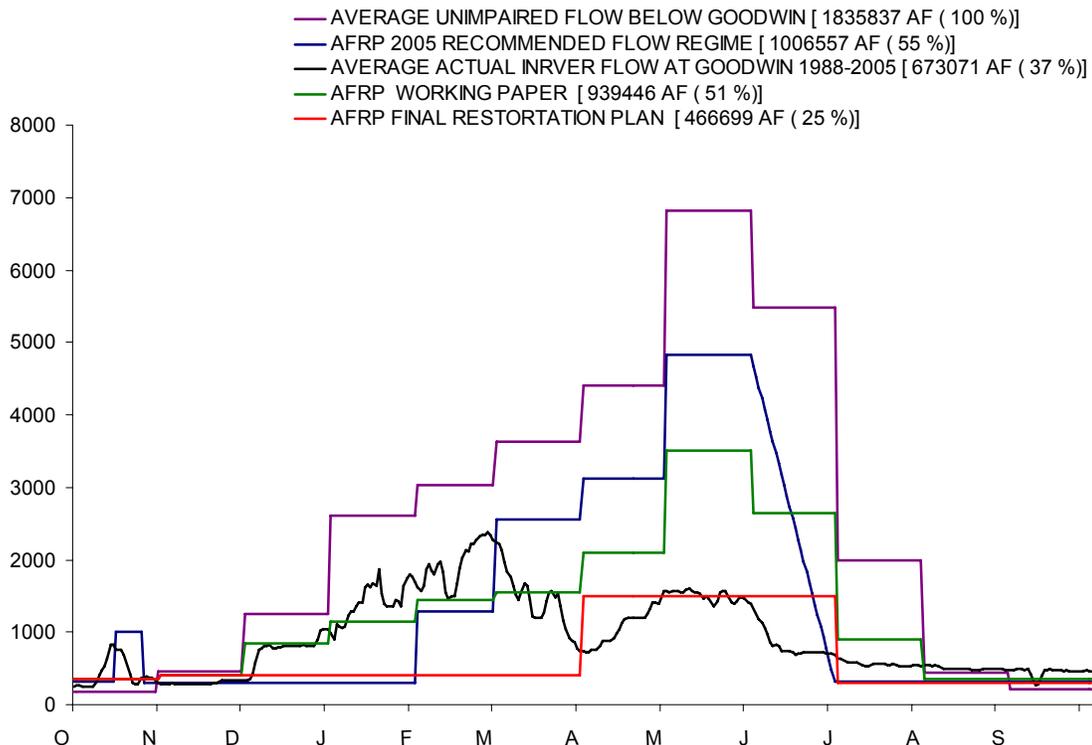

Figure 12. The relationship between the number of fall-run Chinook salmon recruits/spawner to the lower Tuolumne River and the average ratio of combined CVP and SWP exports to the flow in the San Joaquin River at Vernalis between 15 April and 15 May from 1972 to 2002. Exports were reduced during this period since 1996 (Blue Symbols) to improve the survival of outmigrating smolts.

Phytoplankton growth rates in a light-limited environment, San Francisco Bay

Andrea E. Alpine, James E. Cloern

US Geological Survey MS496, 345 Middlefield Road, Menlo Park, California 94025, USA

ABSTRACT: San Francisco Bay has a high degree of spatial variability in physical properties (e.g. suspended sediment concentrations, water depths, vertical mixing rates) that affect biological processes. We used this setting to test the hypothesis that light availability is the primary control of phytoplankton growth in this turbid nutrient-rich estuary. In situ incubations (24 h), designed to simulate vertical mixing over the water column at 2 rates, were done at 4 sites. The photic depth to mixed depth ratio ($Z_p:Z_m$) at the 4 sites ranged from 0.12 to 1.1. Phytoplankton growth rates were estimated by ^{14}C assimilation and by changes in cell number. Growth rates were highest (approximately 2 divisions d^{-1}) where the photic depth was large relative to the mixed depth, and small or negative where $Z_p:Z_m$ was small. Growth rate increased with total daily light exposure and fit a hyperbolic function that predicts maximum specific growth rate of about 2 divisions d^{-1} and a compensation irradiance of about $1.4 \text{ Einst. m}^{-2} \text{ d}^{-1}$.

INTRODUCTION

Phytoplankton cells reside in a turbulent medium partitioned into an upper photic zone that sustains photosynthesis, and a lower aphotic zone that does not. In estuaries, vertical mixing rates between these 2 zones can be rapid (< 1 generation time) because of tidal stirring and because the mixing depth is generally shallow. Moreover, the photic depth is characteristically shallow in estuaries because of the high seston concentrations that typify these systems (e.g. Cloern 1987). Hence the mean light exposure of phytoplankton cells, and their rates of photosynthesis and growth in estuaries, should be related to the ratio of photic depth Z_p to mixing Z_m (defined as either the water column depth, or the surface layer depth in a stratified estuary).

Grobbelar (1985) has measured phytoplankton production in turbid waters and used the ratio $Z_p:Z_m$ as a simple index to quantify the degree of light limitation. Harris and his colleagues have examined in detail the importance of the $Z_p:Z_m$ ratio in lakes for influencing variability of phytoplankton production and photosynthetic parameters (Harris et al. 1980), and variability of species composition both temporally (Harris & Piccinin 1980) and spatially (Haffner et al. 1980). Phytoplankton growth rates have only rarely been measured

in estuaries (Malone 1977, Furnas 1982, Harding et al. 1986) where cycling rates between the photic and aphotic zones can be much faster than in lakes or the open ocean.

This study was motivated by the need for quantitative measures of phytoplankton population growth rate in an estuarine environment, and was designed around the presumption that growth rates can be related empirically to light exposure. We conducted the study in San Francisco Bay (California, USA), which has large horizontal gradients in light availability ($Z_p:Z_m$) typical of many coastal plain estuaries, and nutrient concentrations that often exceed those presumed to limit phytoplankton growth (Cloern et al. 1985). We tested the hypothesis that light availability is the primary control of phytoplankton growth, and that previous estimates of growth rate based on the ratio of productivity to biomass (Cloern et al. 1985) are realistic. Specifically, we wanted to verify that growth rate varies spatially along horizontal gradients of light availability indexed as $Z_p:Z_m$, such that phytoplankton turnover rate is rapid in shallow clear areas (high $Z_p:Z_m$) and slow in deep turbid areas (low $Z_p:Z_m$). We used an in situ incubation technique which simulated vertical mixing, and measured both changes in cell number and carbon production as independent estimates of growth rate across a range of $Z_p:Z_m$ ratios.

METHODS

Experimental design. San Francisco Bay has a central deep (10 to 30 m) channel flanked by a broad expanse of subtidal shoals (< 3 m depth). It also has a wide range of SPM (suspended particulate matter) concentrations reflected in contours of the light extinction coefficient k (e.g. Fig. 1). To examine growth rates over a range of light environments (i.e. $Z_p:Z_m$ ratios), 4 experimental sites (Fig. 1) were chosen: 2 channel sites (depth 10 m), one each in the extremely turbid North Bay and the less turbid South Bay; and 2 shoal sites (depth 2 m), one from each bay. Four $Z_p:Z_m$ ratios were used in these experiments (Fig. 2), based upon measured mean k at each site during 1980 (Cloern et al. 1985). Although the deep channel of San Francisco Bay can be density stratified, particularly during the winter-spring period of high river discharge, the upper estuary and South Bay are well mixed or only weakly stratified during the dry summer-autumn (Walters et al. 1985). Our experiments were designed to simulate conditions

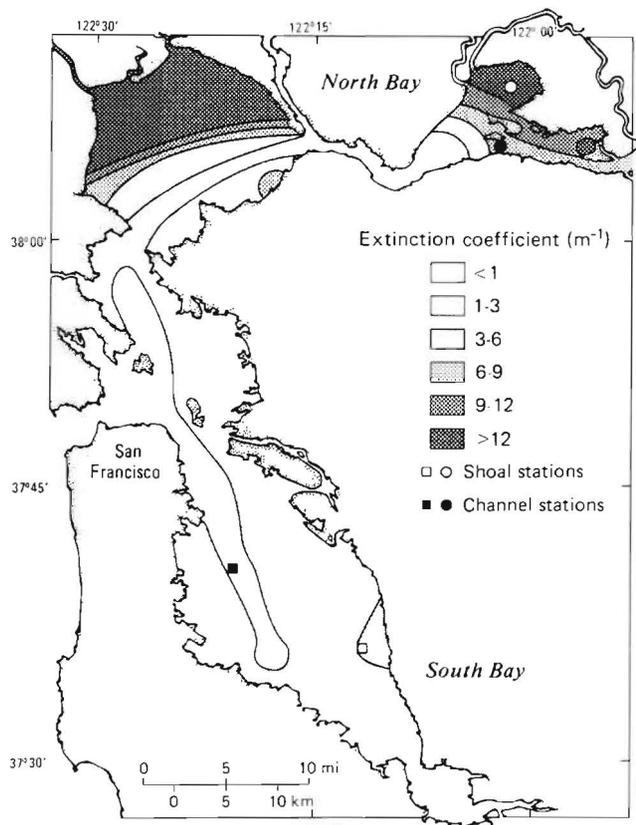

Fig. 1. Contours of the light extinction coefficient measured in San Francisco Bay during August 1980, representative of the summer-fall season. Turbidity measurements were made at 94 sites throughout the estuary with a nephelometer. These measurements were calibrated against extinction coefficients obtained with a LiCor 192S quantum sensor. Also shown are the 4 sampling sites for the experiments described here.

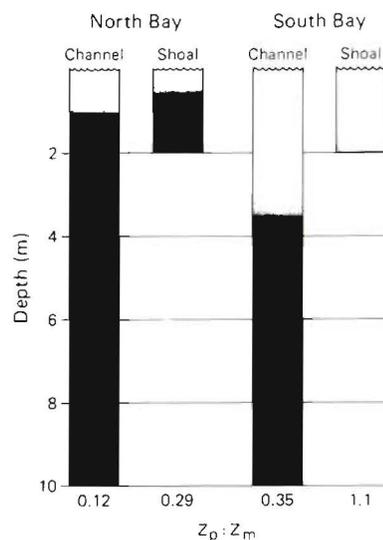

Fig. 2. Photic depth to mixed depth ratio ($Z_p:Z_m$) at the 4 experimental sites.

of a well-mixed estuary (i.e. $Z_m =$ water depth). These experiments were done in September to represent the summer-autumn period when growth rates are presumably maximal in San Francisco Bay (Cloern et al. 1985), and when freshwater inflow and stratification are minimal.

Growth rates were measured by incubating samples in situ and simulating high frequency variations in light exposure that phytoplankton cells mixed throughout a turbulent water column might experience. Our incubation technique was not designed to measure changes in photoadaptive parameters as a function of mixing speed (e.g. Lewis et al. 1984), but rather was a technique to simulate transport of phytoplankton between the photic and aphotic zones so that dark processes (respiration) would be included in the growth estimates. This approach differed from previous studies (e.g. Jewson & Wood 1975, Marra 1978, Gallegos & Platt 1982) which simulated mixing within the photic zone only. Preliminary numerical experiments from computer models indicated that results of such measurements can be sensitive to vertical mixing rates (i.e. nature of light exposure during incubations), so we chose 2 mixing rates that correspond to the range in vertical eddy diffusivities over the neap-spring tidal cycle. These vertical speeds were calculated as depth Z_m divided by the estimated time scale for vertical mixing in a homogenous water column (Walters et al. 1985). Because the eddy diffusivity scales with tidal current speed, and hence water depth (Walters et al. 1985), a different range of mixing speeds was specified for the channel (1.0 and 5.0 $m h^{-1}$) and shoal sites (0.5 and 1.5 $m h^{-1}$). Although these estimates of vertical mixing rate are crude approximations, they are within

the range calculated by Denman & Gargett (1983) for turbulent mixing in the upper ocean. It should be noted, however, that these mixing speeds are considerably slower than other researchers have used to simulate organized motions such as those of Langmuir circulation cells (e.g. Marra 1978, Yoder & Bishop 1985).

The incubation experiments were designed to simulate high frequency variations in light exposure due to vertical motions as well as diurnal changes in surface irradiance, for mean summer-autumn conditions in San Francisco Bay. To do this, we incubated water samples in situ and moved the incubation bottles vertically during the course of the experiment according to a prescribed schedule using the following equation (Parsons et al. 1977):

$$I_t = I_{\max}[\sin^3\{(\pi/D)t\}]e^{-kz} \quad (1)$$

where I_t = prescribed irradiance at time t (h); I_{\max} = surface irradiance at solar noon (= 2000 $\mu\text{Einst. m}^{-2} \text{ s}^{-1}$); D = photoperiod (= 13 h); and k = mean extinction coefficient specific to each site. In calculating these schedules of light exposure, the depth variable z (m) was changed every 15 min based on an initial starting position in the water column and an incremental displacement using the prescribed vertical mixing rate. These schedules defined circular trajectories of movement in the water column and included no random component of vertical motion. It is important to note that these experiments were designed to measure *potential* maximum growth rates, not mean in situ rates. This was done by using that mixing schedule which maximized daily light exposure (typically this meant that incubation bottles were near the surface at solar noon).

Previous estimates of growth rates in San Francisco Bay have been based on carbon production normalized to biomass (Cloern et al. 1985). Other researchers have shown that carbon production and cell division may not be tightly coupled (Pruder & Bolton 1980, Cosper 1982, Reynolds et al. 1985), so we measured both change in cell number and carbon productivity as independent estimates of growth rate.

Experimental procedure. From each site, surface water samples were collected with buckets and screened through 60 μm mesh to remove macrozooplankton. Polycarbonate bottles of 4 l capacity were filled and incubated in situ for 24 h beginning at dawn. Vertical mixing was simulated by manually moving the bottles every 15 min according to the schedule prescribed for each experiment, using irradiance measurements with LiCor quantum sensors (192S) attached to each incubation rack. Instantaneous irradiance was recorded every 15 min and integrated over the day to obtain total irradiance I .

Carbon production was determined using the ^{14}C

acid bubbling technique (Schindler et al. 1972). Following incubation, aliquots (3 ml) from each bottle were placed in scintillation vials. Unincorporated ^{14}C was stripped from the sample and the residual activity measured with a scintillation counter. Duplicate chlorophyll samples were taken at each site, also pre-screened with 60 μm mesh. Chlorophyll *a*, corrected for pheopigments, was determined spectrophotometrically (Lorenzen 1967, Riemann 1978).

Samples for phytoplankton identification and enumeration were preserved with Lugol's solution. Aliquots (150 ml) were collected from each initial sample, each incubated bottle, and a 'dark' bottle (incubated at in situ temperatures and kept in total darkness). At least 300 algal cells were enumerated both at 1000 \times and 80 \times using an inverted microscope. The historical estimate of precision (i.e. average coefficient of variation for triplicate counts) is 8% (Wong & Cloern 1982).

Growth rates (divisions d^{-1}) based on cell division (μ_1) and based on carbon production (μ_2) were calculated as follows:

$$\mu_1 = \log_2[N_t/N_d] \quad (2)$$

where N_t = mean cell density after in situ incubation; and N_d = mean cell density after dark incubation (to correct for cell divisions unrelated to light exposure);

$$\mu_2 = \log_2[(C_i + (C_p - C_d))/C_i] \quad (3)$$

where C_p = production (mg C m^{-3}) during in situ incubation; C_d = carbon assimilation in the dark; and C_i = initial phytoplankton biomass as carbon (mg m^{-3}). Phytoplankton biomass was calculated as the product of the initial chlorophyll *a* concentration and an estimated mean carbon to chlorophyll *a* ratio of 50 (Wienke & Cloern 1987).

RESULTS

The initial conditions for each experiment are shown in Table 1. Salinity was about 3 in the North Bay and 30 in the South Bay; water temperature was 22°C in both

Table 1. Initial experimental conditions

	North Bay		South Bay	
	Channel	Shoal	Channel	Shoal
Salinity	3.5	2.4	30.3	31.1
Temperature (°C)	22.2	—	22.0	—
Chlorophyll <i>a</i> ($\mu\text{g l}^{-1}$)	13.9	18.4	2.3	1.9
DIN ^a ($\mu\text{g-at l}^{-1}$)	5.46	0.43	21.56	1.56
PO ₄ ($\mu\text{g-at l}^{-1}$)	1.90	1.67	11.70	9.30
SiO ₃ ($\mu\text{g-at l}^{-1}$)	130	130	111	105

^a DIN (dissolved inorganic nitrogen) = $\text{NH}_4^+ + \text{NO}_3^- + \text{NO}_2^-$

embayments. Chlorophyll *a* concentrations ranged from $1.9 \mu\text{g l}^{-1}$ at the South Bay shoal site to $18.4 \mu\text{g l}^{-1}$ at the North Bay shoal site. Concentrations of dissolved inorganic nutrients (N, P, Si) at the channel locations exceeded those presumed to limit phytoplankton growth. However dissolved inorganic nitrogen concentration was low ($< 0.5 \mu\text{g-at l}^{-1}$) at the North Bay shoal site (Table 1). As observed historically, diatoms and small cryptophytes were the dominant phytoplankton throughout the estuary.

Fig. 3 details the light exposure of each incubation

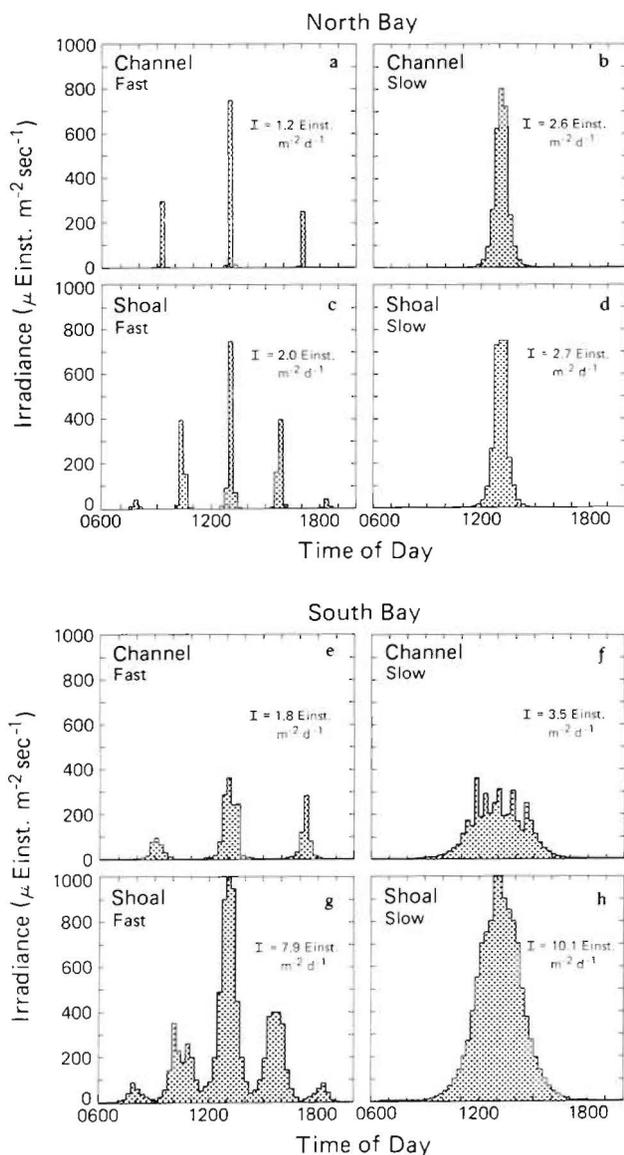

Fig. 3. Light exposure of each incubation bottle during the course of vertical mixing experiments (Irradiance = I_t). Left panels (a, c, e, g) represent high frequency (fast vertical mixing rate) light exposure; right panels (b, d, f, h) represent the light exposure from vertical mixing at the slowest rates. Also shown is total daily irradiance (I) for each incubation bottle

bottle during the course of the 24 h experiments. Both the amount of light received and the timing of the exposure varied with Z_m (i.e. between channel and shoal sites), with Z_p (i.e. between embayments), and with mixing rate. In general, light exposure with the slow mixing rates was characterized by one broad peak centered around solar noon, reflecting the diurnal cycle (e.g. Figs. 3d, h). At the other extreme, rapid vertical mixing generated more variable light exposures such that the incubation bottles were moved between the photic and aphotic zone repeatedly over the photoperiod (e.g. Fig. 3c, g). Total irradiance ranged from 1.2 to $10.1 \text{ Einst. m}^{-2} \text{ d}^{-1}$, which encompasses the range in average water column light intensities found in this estuary (Cloern et al. 1985).

Table 2. Phytoplankton growth rates based on cell division (μ_1) and biomass-normalized carbon production (μ_2) using 2 mixing rates at 4 sites within San Francisco Bay. I : total irradiance (PAR) for each mixing rate. Fast mixing rate (F) = 5 m h^{-1} (channel) or 1.5 m h^{-1} (shoal). Slow mixing rate (S) = 1 m h^{-1} (channel) or 0.5 m h^{-1} (shoal)

	North Bay				South Bay			
	Channel		Shoal		Channel		Shoal	
	F	S	F	S	F	S	F	S
μ_1 (div. d^{-1})	-0.1	0.5	0.4	0.2	0.8	1.2	1.9	1.8
μ_2 (div. d^{-1})	0.2	0.3	0.2	0.3	0.6	1.1	1.7	1.3
I (Einst. $\text{m}^{-2} \text{ d}^{-1}$)	1.2	2.6	2.0	2.7	1.8	3.5	7.9	10.1

Phytoplankton growth rates differed among the 4 locations, ranging from -0.10 to 1.9 divisions d^{-1} based on cell counts and 0.17 to 1.7 divisions d^{-1} based on carbon production (Table 2). The spatial variation in growth rates tracked the variation in the $Z_p:Z_m$ ratio. The fastest growth rates were found in the shoals of the South Bay where $Z_p:Z_m > 1$, and the slowest growth rates were measured in the channel of the North Bay where $Z_p:Z_m = 0.12$. Because the mixing schedules optimized light exposure to each incubation bottle, these measured growth rates represent upper limits rather than mean growth rates for the given mixing rates and $Z_p:Z_m$ ratios.

In these experiments we used 2 methods to measure phytoplankton growth: one based on cell division and one based on biomass-normalized carbon assimilation. These 2 methods yielded growth rates of similar magnitude (Fig. 4), and the 2 measures were highly correlated ($r^2 = 0.93$). The regression slope (Eq. 4) indicates that cell division was faster ($1.3\times$) than the calculated turnover rate of phytoplankton carbon measured by ^{14}C uptake:

$$\mu_2 = 0.04 + 0.76\mu_1 \quad (4)$$

Asynchrony between cell division and photosynthesis has been demonstrated in the laboratory with culture

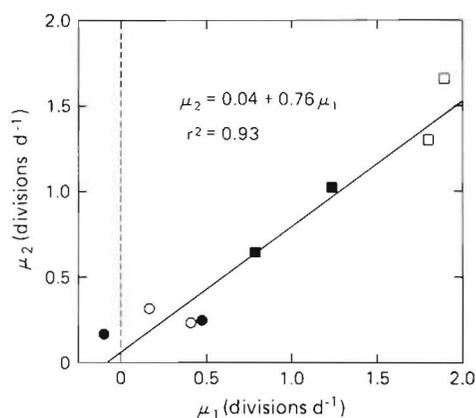

Fig. 4. Regression of μ_2 (growth rate based on carbon production normalized to biomass) against μ_1 (growth rate based on changes in cell numbers). Symbols represent the stations as in Fig. 1

experiments (e.g. Pruder & Bolton 1980, Langdon 1987). However generalities about cell division occurring more rapidly than carbon production, from field studies such as this, should be made with caution. Estimates of μ_2 (from productivity) are based on an assumed ratio of phytoplankton carbon:chlorophyll *a*, which was specified here as 50. However the 2 methods would yield identical mean growth rates (regression slope of 1) given a carbon:chlorophyll *a* ratio of 38, which is within the range expected for natural phytoplankton populations (e.g. Malone 1977, Cullen 1982, Welschmeyer & Lorenzen 1984).

DISCUSSION

Because the 2 methods for measuring phytoplankton growth rate agreed well, we conclude that the traditional approach of estimating μ_1 from productivity:biomass is reasonable. Results of these experiments further demonstrate that estuarine phytoplankton populations have the potential to increase biomass very quickly (i.e. 2 divisions d^{-1}) where the photic depth is large relative to the mixed depth. Conversely, we found small or negative growth rates in the turbid channel of the North Bay where $Z_p:Z_m$ is small. These results support our hypotheses that phytoplankton growth rates can be highly variable spatially, rapid in clear shallow waters (e.g. South Bay shoals) and extremely slow in turbid deep waters (e.g. North Bay channel).

Among others, Cole & Cloern (1987) have shown that phytoplankton productivity is controlled largely by light availability in a wide range of estuarine environments. An objective of this study was to test the hypothesis that variations in phytoplankton growth rate are similarly controlled largely by variations in

light availability. Our results demonstrate a quantitative relationship between growth rate and light exposure. Over a range of light exposure frequencies (Fig. 3), measured growth rates increased with total daily light exposure and fit a hyperbolic function (Fig. 5) that predicts a maximum specific growth rate of about 2 divisions d^{-1} as daily irradiance *I* approaches 10 $Einst. m^{-2} d^{-1}$. A similar hyperbolic relation between growth and irradiance has been observed by Langdon (1987), who measured both particulate organic carbon increase and cell division rate in cultures. Our results also follow the pattern demonstrated by many others (e.g. Bannister 1974, Platt & Jassby 1976, Malone & Neale 1981, Peterson et al. 1987) for the relation between photosynthesis and irradiance. This function also predicts zero growth rate when $I < 1.4$ $Einst. m^{-2} d^{-1}$. Hobson & Guest (1983) have reported daily compensation irradiance (I_{comp}) values between 0.08 and 1.9 $Einst. m^{-2} d^{-1}$ for neritic phytoplankton. Our results are also within the range (0.06 to 1.76 $Einst. m^{-2} d^{-1}$) that Langdon (1987) found in a laboratory study of 3 phytoplankton species: a diatom, a chrysophyte and a dinoflagellate.

Given the protocol of experiments described here, we conclude that an apparent minimum irradiance of about 1.4 $Einst. m^{-2} d^{-1}$ is required to sustain phytoplankton population growth in San Francisco Bay. By knowing this minimum irradiance value (i.e. $I_{comp} = 1.4$ $Einst. m^{-2} d^{-1}$) and substituting it for *I* in Eq. (5), which gives the mean irradiance in a totally absorbing water column, we can estimate the critical $Z_p:Z_m$ ratio needed to sustain growth:

$$I = (I_0 \times Z_p:Z_m) / 4.61 \quad (5)$$

For an average summer day (surface irradiance $I_0 = 40$ $Einst. m^{-2} d^{-1}$) we calculate that the critical $Z_p:Z_m = 0.16$, which is consistent with the critical $Z_p:Z_m$ ratio for photosynthesis (Cloern 1987). This implies that when

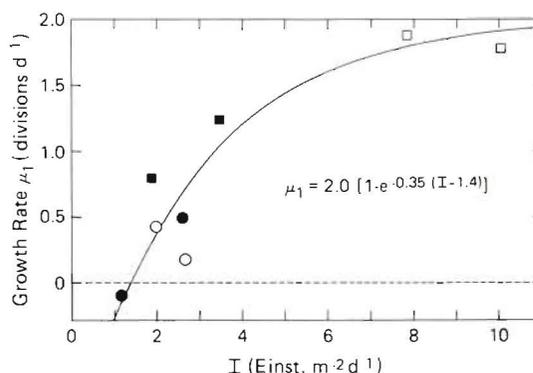

Fig. 5. Phytoplankton growth rate as a function of irradiance during simulated vertical mixing. Measurements were made at 4 sites (see Fig. 1) during September 1984 using 2 vertical mixing rates per site

the photic depth is less than approximately 16 % of the mixed depth, phytoplankton growth cannot be sustained.

Our results demonstrate that phytoplankton population dynamics can be strongly influenced by the ratio $Z_p:Z_m$ in estuaries, as in lakes (e.g. Harris et al. 1980, Horn & Paul 1984, Grobbelaar 1985). We can measure Z_p accurately but do not yet have an equivalent capability to quantify the mixed depth Z_m , particularly when density gradients are present in the water column. Even if Z_m is well defined, it remains difficult to use physical properties (e.g. vertical density or velocity gradients) to infer trajectories of movement, and therefore mean light exposure, of phytoplankton populations. Experimental results such as those presented here emphasize the need for collaborations between phytoplankton ecologists and physical scientists to better characterize the vertical motions of phytoplankton, and thus enhance the utility of empirical functions (e.g. Fig. 5) to estimate phytoplankton growth rates in nature.

SAN FRANCISCO BAY CONSERVATION AND DEVELOPMENT COMMISSION

455 Golden Gate Avenue • Suite 10600 • San Francisco, California 94102 • (415) 352-3600 • Fax: (415) 352-3606 • www.bcdc.ca.gov

May 23, 2014

TO: Commissioners and Alternates

FROM: Lawrence J. Goldzband, Executive Director (415/352-3653 lgoldzband@bcdc.ca.gov)
Joe LaClair, Chief Planning Officer (415/352-3656 joel@bcdc.ca.gov)

**SUBJECT: Staff Recommendation on Comments on the Bay Delta Conservation Plan
Environmental Documents**
(For Commission consideration on June 5, 2014)

Staff Recommendation

Staff recommends that the Commission direct staff to submit the following comments on the Bay Delta Conservation Plan (BDCP) Environmental Impact Report/Statement (EIR/S) with any revisions from the Commission.

The Commission received a briefing from Paul Helliker from the Department of Water Resources (DWR) on the BDCP at its February 20, 2014 meeting, and held a panel discussion on the BDCP at its May 1, 2014 meeting. At these briefings, Commissioners raised several questions about how the proposed project may directly affect the San Francisco Bay and Suisun Marsh. The BDCP is undergoing state and federal environmental review. Commission laws and policies call for adequate fresh water inflows from the Delta to Suisun Marsh and the Bay to maintain proper salinity levels and water circulation patterns, to flush pollutants, and to maintain related ecosystem functions. Based on Commissioner comments and questions, and staff review of the environmental documents prepared for the BDCP, staff prepared the following proposed comments on these environmental documents. Attached to this report is a memo from Paul Helliker providing some additional information on the BDCP issues raised at the Commission's briefings.

Staff Report

Bay-Delta Conservation Plan Project Description. The Bay-Delta Conservation Plan (BDCP) is being prepared to meet the requirements of the federal and state Endangered Species Acts. It is the first attempt in the nation to prepare a habitat conservation plan that includes aquatic habitats. The plan lays out a framework for conserving certain species, both listed and non-listed, and authorizes take of listed species under certain circumstances. Regulated entities (DWR and the US Bureau of Reclamation, state and federal water contractors, other users of Delta water) and resource agencies (California Natural Resources Agency, state and federal fishery agencies) and non-governmental organizations developed the plan.

BDCP's long-term goal is to preserve, restore and enhance aquatic, riparian and associated terrestrial natural communities and ecosystems that support a wide range of species of concern. It intends to provide a stable regulatory environment for water projects, standardize mitigation and compensation requirements, and provide a less costly and more efficient approach to conservation than project-by-project and species-by-species reviews.

The BDCP Environmental Impact Report/Statement (EIR/S) evaluates sixteen project alternatives, including fifteen that vary over different project components. These variations include: four different water conveyance configurations; different intake locations and alignment options; four different diversion capacities ranging from 3,000 to 15,000 cubic feet per second (cfs); eight various operational scenarios based upon guiding water supply parameters, diversion flows, operational demands, and water quality requirements; and, three different habitat restoration plans ranging from 113,000 to 163,000 acres. The alternatives have varying implications for biological resources, hydrology, and interactions with the human environment. Alternative 4, the proposed project of the BDCP, includes using a pipeline/tunnel system to convey water from the Sacramento River over forty miles south, under the Delta, to the California Aqueduct system, which supplies much of the state's water. The comment period on the BDCP draft EIR/S ends June 13, 2014.

Project Impacts. Potential effects of the BDCP on water bodies downstream of the Delta were analyzed and the EIR/S states that the project may affect the following downstream resources:

- Flow;
- Sediment inputs;
- Food;
- Temperature; and
- Dissolved oxygen.

The analysis in the EIR/S concludes that there would be no significant adverse effects on San Francisco Bay. Therefore, areas downstream of the Delta (e.g., San Pablo Bay, San Francisco Bay south to the Golden Gate Bridge and Bay Bridge) were considered, but were not included as a part of the BDCP's analysis.

Staff Comments

Staff would like to commend the authors for this ground-breaking plan. As the first ever aquatic Habitat Conservation Plan/Natural Communities Conservation Plan (HCP/NCCP), in one of the most ecologically, legally and culturally complex areas in the world, the BDCP represents an incredible first effort at crafting a solution to many of the complex Delta issues. We believe there are some pieces missing, and our comments address those. As a responsible agency under CEQA, BCDC should comment on the EIR/S. The Commission will need to issue permits or consistency determinations for the conservation measure projects located in the Suisun Marsh or San Francisco Bay. Based on Commissioner comments and questions, the Commission's laws and policies, and staff review of the EIR/S prepared for the BDCP, staff prepared the following proposed comments on these environmental documents. The relevant, applicable policies are quoted in the following section.

San Francisco Bay and Suisun Marsh Effects. The EIR/S states that there would be no significant effects on San Francisco Bay. Commissioners, staff, other state agencies and members of the public raised concerns about possible project impacts west of the Delta in the Suisun Marsh and downstream in the San Francisco Bay. Some of these effects would be significant. Potential significant impacts could include effects on salinity, sediment supply, and the consequences (intended and unintended) of various restoration programs, and further impacts

on Bay habitats and species. The Delta Stewardship Council's (DSC) Independent Science Board (ISB) concluded that more research and analysis is needed on areas west of the Delta in order to get a more complete picture of the cumulative effects of the BDCP. The ISB noted that "the hydrodynamic modeling needs to capture the entire domain of effects. The current Effects Analysis does not consider the influence of shifting timing of withdrawals on San Francisco Bay circulation patterns and ecology. This is a significant omission with ecologically important implications."

The ISB also noted that the BDCP evaluates "three geographic regions: upstream of the Delta, the legal Delta, and the State Water Project (SWP) and Central Valley Project (CVP) service areas. Areas downstream of the Delta (i.e., San Francisco Bay) were not included even though the National Research Council (NRC) scientific review specifically stated that this area should be included. Adequate justification for lack of consideration of impacts to San Francisco Bay was not provided ... in the document, although there are potential impacts. For example, the expected reduction in sediment supply has the potential impacts of: (1) tidal marshes in the Bay could be less resilient to sea level rise and; (2) increased water clarity in the Bay could render it more responsive to nutrient inputs." The EIR/S should better assess the potential effects on the Marsh and the Bay, and identify potential impacts on salinity, sediment delivery and Bay species as potentially significant, and evaluate strategies to avoid or mitigate these effects.

Water Quality and Salinity. Biological opinions from the National Marine Fisheries Service and the US Fish and Wildlife Service determined that habitat degradation in the Marsh for multiple sensitive species is due, in part, to reduced freshwater inflows from the Delta. Current Delta fresh water outflows seem inadequate to support or recover endangered species. Studies project that the salinity in San Francisco Bay could increase by 0.30-0.45 practical salinity unit (psu) per decade due to the compounding effects of decreasing freshwater inflow and rising sea level (projected by Cloern et al. 2011 to rise approximately 4 inches per decade). Climate change will affect future Bay salinity and the restoration and conservation measures proposed in the EIR/S. Higher salinity in the Suisun Marsh due to high diversion years would affect managed wetlands, and the Bay's native species, such as the Dungeness Crab, that use the lower salinity of the Bay as a nursery. However, these species are not included in the BDCP's analysis. Also, waterfowl that rely on the lower salinity/freshwater of the Marsh as breeding habitat may be at risk, as higher salinity levels have been shown to be dangerous to ducklings.

The EIR/S states that the BDCP would be implemented using a "decision tree process, a focused form of adaptive management that will be used to determine at the start of new operations, the fall and spring outflow criteria that are required to achieve the conservation objectives of the BDCP for delta smelt and longfin smelt and to promote the water supply objectives of the BDCP. Other BDCP-covered fish species, including salmonids and sturgeon, may also be affected by outflow. Their outflow needs will also be investigated as part of the decision tree process." The EIR/S should clarify how the proposed pipelines will be managed in the long term (e.g., 50 years), if there are recurring droughts that require changes in future flow regimes. The BDCP should evaluate flow scenarios that provide greater freshwater flows to the Bay beyond the requirements of D1641¹ to recover declining fish populations. Decreased reliance on Delta freshwater diversions may become necessary for the protection of sensitive and threatened species. Scenario F (Alternative 8: pipeline/tunnel alignment, dual conveyance, intakes at 2, 3 & 5, with 9,000 cfs diversion) would increase Delta outflow up to 1.5 million acre-feet annually. A project alternative that provides for greater Delta outflows is likely necessary to meet the policy objectives in the *San Francisco Bay Plan* (Bay Plan) and the *Suisun Marsh*

¹ D1641 refers to a State Water Board water rights Decision of 2005 that set water quality (salinity) standards for various monitoring stations in the Bay and Delta and amends certain water rights by assigning responsibilities to the persons or entities holding those rights to help meet the salinity objectives.

Protection Plan (Marsh Plan). Also, the EIR/S should evaluate potential impacts on non-listed Marsh and Bay species that rely on salinity levels characteristic of the Bay and the Marsh as required by current X2 standards.

Conservation Measures. Most Conservation Measures are discussed at a programmatic level, rather than at a project level in the EIR/S. The ISB noted that, "the difference in level of detail [of restoration project analyses] presented effectively treats the co-equal goals unequally. We are concerned that the merely programmatic analysis of habitat restoration provides too little basis for decision-making by the Delta Stewardship Council and other parties. Furthermore, the benefits of habitat restoration are assumed when a beneficial cumulative impact is concluded under NEPA or a less than significant cumulative impact is concluded under CEQA. Achieving beneficial conservation measures requires understanding limiting factors, ecosystem processes, sequencing, adaptive management responses, thresholds for certain actions, and interactions and other consequences of these actions...to describe how major uncertainties will be resolved." Also, the Effects Analysis recognizes that suspended sediment has been declining in the Sacramento River, but no analysis of the potential for corresponding increased algal blooms is addressed.

Specific locations for habitat improvements are not discussed in the restoration opportunity areas, including those in the Suisun Marsh. The EIR/S would benefit from further analysis of restoration patterns in the Marsh to determine how they affect salinity patterns in the Marsh and Delta. This may help focus the restoration efforts to specific regions of the Marsh to limit salinity intrusion. There is little discussion in the EIR/S of the effects of climate change on conservation measures. Some Conservation Measures that involve habitat restoration or enhancement should be addressed at a project level of detail in the EIR/S so that they can be implemented early in the project cycle, in timeframes consistent with Conservation Measure 1. Also, additional conservation measures may be needed to address project effects on the Marsh and the Bay, particularly those related to sediment management.

Sediment. The BCDP EIR discusses a potential reduction in suspended sediment transport to the Suisun Marsh and San Francisco Bay of approximately eight to ten percent. The EIR/S does not characterize this change as a significant impact. The ISB report to the Delta Stewardship Council raises this as a significant issue. USGS researchers have observed a steep reduction in Bay suspended sediment concentrations and characterize San Pablo Bay as erosional. With projected sea level rise, further reduction in Bay sediment inputs should be considered significant, given Bay wetland restoration targets, current subsided diked-baylands, and the overall Bay-Delta sediment budget. Given sediment settling in the new northern forebay, the relocation of flows from channels into underground pipes, new pumping regimes and proposed restorations together and separately will alter sediment transport, delivery, and rate of deposition downstream. Reduced suspended sediment in the Bay will exacerbate nutrient loading problems caused from the sewage treatment plants discharging into the Bay.

Construction of restoration projects, which are highly desirable in the Delta upstream of the Bay, will likely create sediment sinks, thus further reducing sediment flows to the Marsh and San Francisco Bay. The cumulative impacts analysis should consider this, using science-based thresholds of significance.

Cumulative Effects. There are several related projects that, cumulatively, could exacerbate effects of BDCP and adversely affect the Bay and the Marsh that are not addressed in the EIR/S. These projects include, but are not limited to, dredging the Baldwin Ship Channel (between San Pablo Bay and the Port of Stockton) that may include constructing a sill in the Carquinez Strait; proposals to construct seasonal drought barriers or gates in the Delta; and several proposed water storage projects on existing dams and reservoirs. The issue of storage should be addressed within BDCP, particularly planned projects. The EIR/S should address cumulative impacts of all relevant related projects.

Next steps. The authors of the EIR/S will review the comments from the many agencies, organizations and members of the public providing input and will determine whether to recirculate a draft or prepare a final environmental document, in either case, that responds to the comments provided. If a draft EIR/S is circulated, then another round of comments will follow, before a final document is prepared, or a final document will be prepared and issued later this year or early next year.

BCDC's Relevant Policies and Related Agreements

Bay Plan Findings and Policies. The Commission's Bay Plan recognizes the tremendous ecological value of the Bay-Delta estuary and the importance of fresh water inflows from the Delta to the survival of fish and wildlife in the Bay and Suisun Marsh.

Bay Plan findings on Tidal Marshes and Tidal Flats state, in part, that "San Francisco Bay is a substantial part of the largest estuary along the Pacific shore of North and South America and is a natural resource of incalculable value" and that "the sheltered waters of estuaries support unique communities of plants and animals specially adapted for life in the region where rivers meet the coast."

Bay Plan findings and policies recognize the importance of fresh water inflows to the ecosystem of the Bay. Bay Plan findings on Fish, Other Aquatic Organisms and Wildlife state, in part, that "conserving fish, other aquatic organisms and wildlife depends, among other things, upon availability of ...proper fresh water inflows, temperature, salt content, water quality, and velocity of the water." Fresh Water Inflow Finding A states that "[f]resh water flowing into the Bay, most of which is from the Delta, dilutes the salt water of the ocean flowing into the Bay through the Golden Gate....This delicate relationship between fresh and salt water helps to determine the ability of the Bay to support a variety of aquatic life and wildlife in and around the Bay."

Bay Plan findings and policies also recognize the impact of pollutants passing through the Delta into the Bay. Bay Plan findings on Water Quality state, in part, that "water from approximately 40 percent of California drains into San Francisco Bay carrying with it pollutants from point and nonpoint sources" and that "harmful effects of pollutants reaching the Bay can be reduced by maximizing the Bay's capacity to assimilate, disperse, and flush pollutants by maintaining and increasing...the volume and circulation of water flowing in and out with the tides and in fresh water inflow."

The Bay Plan's Fresh Water Inflow policies require limits on water diversions, preservation of the Suisun Marsh, and cooperation with the State Water Board to ensure adequate fresh water inflow. Policy 1 states that "[d]iversions of fresh water should not reduce the inflow into the Bay to the point of damaging the oxygen content of the Bay, the flushing of the Bay, or the ability of the Bay to support existing wildlife." Policy 2 states that "[h]igh priority should be given to the preservation of Suisun Marsh through adequate protective measures, including maintenance of fresh water inflows." Finally, Policy 3 states, in part, that the "Bay Commission should cooperate with the State Board and others to ensure that adequate fresh water inflows to protect the Bay are made available."

Suisun Marsh Preservation Act. The Nejedly-Bagley-Z'berg Suisun Marsh Preservation Act of 1974 directed BCDC and the California Department of Fish and Game (CDFG) to develop the Suisun Marsh Protection Plan, which was codified into law as the Suisun Marsh Preservation Act of 1977. The Act recognizes the important role of the Suisun Marsh in providing wintering habitat for waterfowl using the Pacific Flyway and critical habitat for other wildlife, including rare and endangered species.

The Suisun Marsh, where salt and fresh water meet and mix, contains approximately 85,000 acres of tidal marsh, managed wetlands, and waterways in southern Solano County. It is an important part of the Bay-Delta ecosystem and requires adequate fresh water inflows to maintain its fish and wildlife habitat.

Section 29003 of the Act finds that continued wildlife use of Suisun Marsh requires, among other things, “[p]rovision for future supplemental water supplies and related facilities to assure that adequate water quality will be achieved within the wetland areas.”

Section 29010 finds that “[w]ater quality in the marsh is dependent on the salinity of the water in sloughs of the marsh, which depends in turn on the amount of fresh water flowing in from the Delta.”

Suisun Marsh Protection Plan. The Plan recognizes that Suisun Marsh contains “the unique diversity of fish and wildlife habitats characteristic of a brackish marsh.” The Plan emphasizes the need to maintain adequate fresh water inflows to preserve this unique habitat.

Water Supply and Quality Finding 2 of the Plan states, in part, that “[t]he most important source of fresh water inflow to the Suisun Marsh is the outflow from the Sacramento-San Joaquin River Delta.”

Finding 9 states, in part, that “[t]he State Water Resources Control Board in its Delta Decision, and the Environmental Protection Agency and the Regional Water Quality Control Board in the Water Quality Control Plan for the San Francisco Bay Basin, have set water and soil salinity standards for the Marsh.”

Finding 10 states, in part, that “[a]ssuring that sufficient quantities of fresh water will be available to the Marsh to meet the standards and marsh management requirements is as important as determining appropriate water quality standards for the Marsh.”

Water Supply and Quality Policy 1 states, in part, “there should be no increase in diversions by State or Federal Governments that would cause violations of existing Delta Decision or Basin Plan standards.”

Policy 2 states, “Adequate supplies of fresh water are essential to the maintenance of water quality in the Suisun Marsh. Therefore, the State should have the authority to require the Bureau of Reclamation to comply with State and Federal water quality standards for the Delta and the Marsh. This should be accomplished through Federal legislation if necessary.”

Policy 4 states, in part, that “[w]ater quality standards in the Marsh should be met by maintaining adequate inflows from the Delta.”

Suisun Marsh Preservation Agreement. In 1987, DWR, CDFG, the Bureau, and the Suisun Resource Conservation District signed the Suisun Marsh Preservation Agreement to mitigate impacts on Marsh salinity from the CVP, SWP, and other upstream diversions. The objectives of the agreement are:

- To assure that the Bureau and DWR maintain a water supply of adequate quantity and quality for managed wetlands within the Marsh. This is to mitigate adverse effects on these wetlands from operation of the CVP and SWP as well as a portion of the adverse effects of other upstream diversions;
- To improve Marsh wildlife habitat on these managed wetlands;
- To define the obligations of the Bureau and DWR necessary to assure the water supply, distribution, management facilities, and actions necessary to accomplish these objectives; and
- To recognize that water users in the Marsh (i.e., existing landowners) divert water for wildlife habitat management within the Marsh.

In 2005, the Revised Suisun Marsh Preservation Agreement was signed to make its water salinity requirements consistent with water quality standards adopted in 1999 (see “Bay-Delta Beneficial Uses” in Bay-Delta Management section below) and to replace proposed large scale water management facilities with landowner water and management activities to meet the Agreement objectives in the western Marsh.

X2 Water Quality Standards. X2 refers to the salinity level of 2 parts per thousand, which corresponds to the mixing zone of fresh and salt water. Maintaining X2 within Suisun Bay between February and June is considered beneficial for the reproductive success and survival of the early life stages of many estuarine species, including Delta smelt. The CCMP recommended the adoption of these standards, which became an element of the 1994 Bay-Delta Accord.

The US Fish and Wildlife Service listed the Delta Smelt as threatened under the federal Endangered Species Act in 1993, and designated portions of the Delta as critical habitat for the smelt in 1994. The US Environmental Protection Agency and FWS established the X2 water quality standards in 1995. The standards require X2 to be maintained at particular locations within the Delta between February and June depending on the amount of precipitation.

To: BCDC Commissioner and Alternates

From: Paul Helliker, Deputy Director, California Department of Water Resources

Subject: Summary Responses to Issues Raised at the May 1, 2014 Meeting and BDCP Panel Discussion

Relationship to the Suisun Marsh Plan

- The BDCP would restore up to 11,500 acres in Suisun Marsh to tidal wetlands over 50 years; the Suisun Marsh Plan (SMP) calls for 5,000-7,000 acres over 30 years.
- The BDCP would preserve and enhance 8,100 acres of managed wetlands.
- The BDCP can help implement the SMP restoration component.
- SMP and BDCP modeling show that location of restoration is one of the most important factors in managing salinity in the Marsh.

Sediment

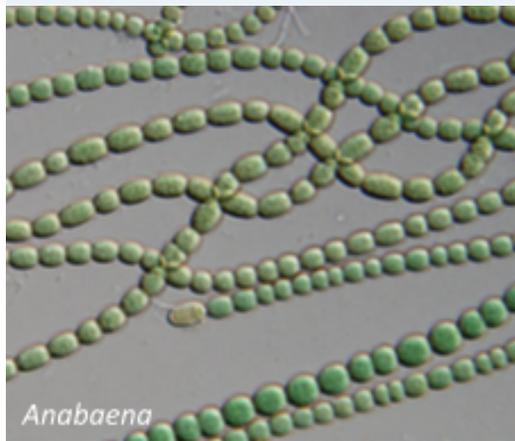

- The BDCP North Delta Intake would reduce the sediment load into the Plan Area (Delta) by around 8-10%. However, that material could be reintroduced into the Plan Area for restoration or other beneficial uses. The actual net reduction in sediment is likely to be less than 8-10%.
- Specific hydrodynamics and restoration locations and designs will dictate how suspended sediments move, including if areas will be sediment sinks or sources.
- Recent work by McKee et al. (2013) using updated methods to improve sediment load estimates beyond previous efforts suggests that, despite their small watershed area (5% of total area) and fluvial flow (7% of total flow), the smaller urbanized and tectonically active tributaries to San Francisco Bay are the major contributors (61% of total) of sediment load into San Francisco Bay compared to upstream sources that are affected by SWP and CVP operations (remaining 39% of sediment load). For San Pablo Bay, which is farther upstream, the proportional contribution of sediment load from upstream was estimated by Schoelhamer et al. (2008) to be approximately 50%.

Inflows

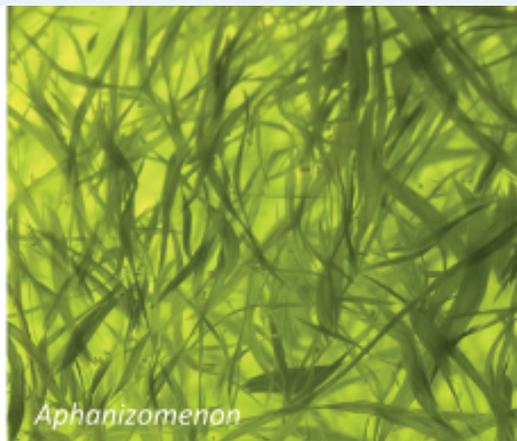

- According to the *Delta Atlas* (DWR 1995), average historical tidal flow through the Golden Gate Bridge is 2,300,000 cubic feet per second (cfs) and average historical tidal flow at Chipps Island is 170,000 cfs. According to BDCP CALSIM modeling, the greatest mean monthly reduction in Delta outflow due to BDCP (compared to a baseline that includes the Fall X2 standard [EBC2]) would be 5,613 cfs during September under the low outflow scenario (LOS), which would not include the Fall X2 standard. This equates to 0.2% and 3% of average tidal flow at the Golden Gate Bridge and Chipps Island, respectively.
- Under all outflow scenarios, the BDCP would comply with D-1641. Under the high outflow scenario, spring and fall outflows would be greater than D-1641.

EXECUTIVE SUMMARY

A world-wide increase in the incidence of toxin-producing, harmful cyanobacterial blooms (cyanoHABs) over the last two decades has prompted a great deal of research into the triggers of their excessive growth. Massive surface blooms are known to decrease light penetration through the water, cause depletion of dissolved oxygen following bacterial mineralization of blooms, and cause mortality of aquatic life following ingestion of prey with high concentrations of toxins. Additionally, humans coming in contact with the water may develop digestive and skin diseases, and it may affect the drinking water supply.

The Central Valley Regional Water Quality Control Board (Water Board) is developing a science plan to scope the science needed to support decisions on policies governing nutrient management in the Delta. Blooms of cyanoHABs are one of three areas, identified by the Water Board, that represent pathways of potential impairment that could be linked to nutrients. The Water Board commissioned a literature review of the factors that may be contributing to the presence of cyanoHABs in the Delta. The literature review had three major objectives:

- 1) Provide a basic review of biological and ecological factors that influence the prevalence of cyanobacteria and the production of cyanotoxins;
- 2) Summarize observations of cyanobacterial blooms and associated toxins in the Delta;
- 3) Synthesize literature to provide an understanding of what ecological factors, including nutrients, may be at play in promoting cyanobacterial blooms in the Delta.

This review had four major findings:

#1. Five principal drivers emerged as important determinant of cyanobacterial blooms in a review of the global literature on factors influencing cyanobacteria blooms and toxin production. These include: 1) Water temperature, 2) Water column irradiance and water clarity, 3) Stratified water column coupled with long residence times, 4) Availability of N and P in non-limiting amounts; scientific consensus is lacking on the importance of N: P ratios as a driver for cyanoHABs, and 5) Salinity regime.

#2. Existing information is insufficient to fully characterize the threat of CyanoHABs to Delta ecosystem services because cyanoHABs are not routinely monitored. Based on existing data, the current risk to Delta aquatic health is of concern and merits a more thorough investigation. This observation is based total microcystin levels found in Delta fish tissues that are within the range of sublethal effects to fish as recently reviewed by the California Office of Environmental Health Hazards (OEHHA 2009), and dissolved toxin concentrations that occasionally exceed both the OEHHA action level and the World Health Organization (WHO) guideline of 1000 ng L⁻¹ in certain “hotspots” of the Delta.

#3. Comprehensive understanding of the role of nutrients vis-à-vis other environmental factors in influencing cyanoHAB presence in the Delta is severely hampered by the lack of a routine monitoring program. Drawing on available information on the five factors influencing cyanoHABs, we can conclude the following:

- Temperature and irradiance appear to exert key roles in the regulation of the onset of blooms. Cyanobacteria require temperatures above 20°C for growth rates to be competitive with eukaryotic phytoplankton taxa, and above 25°C for growth rates to be competitive with diatoms. In addition, they require relatively high irradiances to grow at maximal growth rates.
- It appears that N and P are available in non-limiting amounts in the Delta; moreover, concentrations, or ratios, do not change sufficiently from year-to-year in order to explain year-to-year variation *Microcystis* biomass or occurrence. Therefore the initiation of *Microcystis* or other cyanoHAB blooms are probably not associated with changes in nutrient concentrations or their ratios in the Delta. However, as with all phytoplankton blooms, once initiated, cyanoHABs cannot persist without an ample supply of nutrients.
- Salinity is controlling the oceanward extent of cyanobacteria blooms in the Delta, but salinity gradients do not explain the spatial distribution of cyanoHABs in the Delta. Notably, salinity regime is not a barrier to toxin transport, as cyanotoxins have been detected in SF Bay.
- Turbidity, low temperatures, and higher flows during most of the year are likely restricting cyanobacteria blooms to the July-August time period.

#4. Climate change and anthropogenic activity associated with land use changes have the potential to alter cyanoHAB prevalence in the future. Climate change will likely result in warmer temperatures and increased drought, the latter of which could result in reduced flows, increased residence time and water column stability leading to higher light availability in the Delta. Both temperature and reduced flows would presumably result in a greater prevalence of cyanoHABs. It's noteworthy that phytoplankton biomass and primary productivity are depressed relative to available nutrients in the Delta, so it's unclear what the effect of modifying nutrient loads will have on frequency and intensity of cyanoHAB occurrence in the future.

Given these findings, two major science recommendations are proposed:

R1: Implement Routine Monitoring of CyanoHABs. DWR is currently conducting a monitoring program which routinely samples many of the variables of interest known to influence cyanoHABs. Comprehensive cyanoHAB monitoring should be added as a component to this program. To begin, a work plan should be developed which specifically scopes the needed changes in the program to comprehensively monitor cyanoHABs. This report details specific components that should be considered in this workplan. The workplan should also consider monitoring needed to develop and calibrate an ecosystem model to further investigate controls

on primary productivity and phytoplankton assemblage (see R2 below). The workplan should be peer-reviewed by subject matter experts. After an initial period of 3-5 years, the monitoring data should be used to comprehensively report on the status and trends of cyanoHABs and the factors that favor bloom occurrence in the Delta.

R2: Develop an Ecosystem Model of Phytoplankton Primary Productivity and HABs Occurrence to further Inform Future Risk and Hypotheses on Factors Controlling

CyanoHABs. Because nutrients are not currently limiting cyanobacterial blooms, it is critical that an improved understanding is gained of the factors that are controlling phytoplankton primary productivity in the Delta, since increased phytoplankton growth could lead to increased risk of cyanoHAB blooms. To inform management action moving into the future, an ecosystem model of phytoplankton primary productivity and HABs occurrence should be developed. This model should have the capability to provide information on primary productivity and biomass as well as planktonic food quality and transfer of carbon to higher trophic levels. To step into model development, three actions should be taken: 1) examine existing models already available to determine suitability for this task, 2) utilize existing data to explore, to the extent possible, the relationships between chlorophyll a, phytoplankton composition, climate variables *et al.* factors. This analyses should inform hypotheses that can be tested through model development as well as potential future scenarios, and 3) a work plan should be developed that lays out the modeling strategy, model data requirements, and implementation strategy.

1. INTRODUCTION, PURPOSE AND ORGANIZATION OF THE REVIEW

1.1 Background and Context

The Sacramento–San Joaquin River Delta, is an inland river delta and estuary approximately 1300 square miles in size, found in Northern California. Formed at the western edge of the Central Valley by the confluence of the Sacramento and San Joaquin Rivers, the Delta is a key component of the State’s water resource infrastructure and a region that is rapidly urbanizing, yet serves as critical habitat for fish, birds and wildlife. Water from the 45,000 square mile Delta watershed fuels both local and statewide economies, including important agricultural commodities. The Delta is widely recognized as in “crisis” because of human effects on the environment and competing demands for the Delta’s resources. The consequences of these competing demands include point and non-point discharges, habitat fragmentation and loss, modified flow regimes, introduction of non-native species, all of which combine to threaten ecosystem health, including the continued decline of threatened and endangered species

In 2009 the California legislature passed the Delta Reform Act creating the Delta Stewardship Council. The mission of the Council is to implement the coequal goals of the Reform Act and provide a more reliable water supply for California while protecting, restoring, and enhancing the Delta ecosystem. The Council wrote and adopted a Delta Plan in 2013 to implement these goals. Chapter 6 of the Delta Plan deals with water quality and contains recommendations to implement the coequal goals of the Delta Reform Act. Recommendation # 8 states, in part, “...the State Water Resources Control Board and the San Francisco Bay and Central Valley Regional Water Quality Control Boards (Water Board) should prepare and begin implementation of a study plan for the development of objectives for nutrients in the Delta ... by January 1, 2014. Studies needed for development of Delta... nutrient objectives should be completed by January 1, 2016. The Water Boards should adopt and begin implementation of nutrient objectives, either narrative or numeric, where appropriate, in the Delta by January 1, 2018. Potential nutrient related problems identified in the Delta Plan for evaluation are:

- 1) Decreases in algal abundance and shifts in algal species composition,
- 2) Increases in the abundance and distribution of macrophytes, including water hyacinth and Brazilian waterweed,
- 3) Increases in the magnitude and frequency of cyanobacterial blooms

To provide better scientific grounding for the study plan, the Water Board commissioned two literature reviews centered on these three potential areas of impairment. This document provides a synthesis of literature on cyanobacterial blooms in the Delta. Technical Advisory Group and Stakeholder comments on the review are provided in Appendices B and C, respectively.

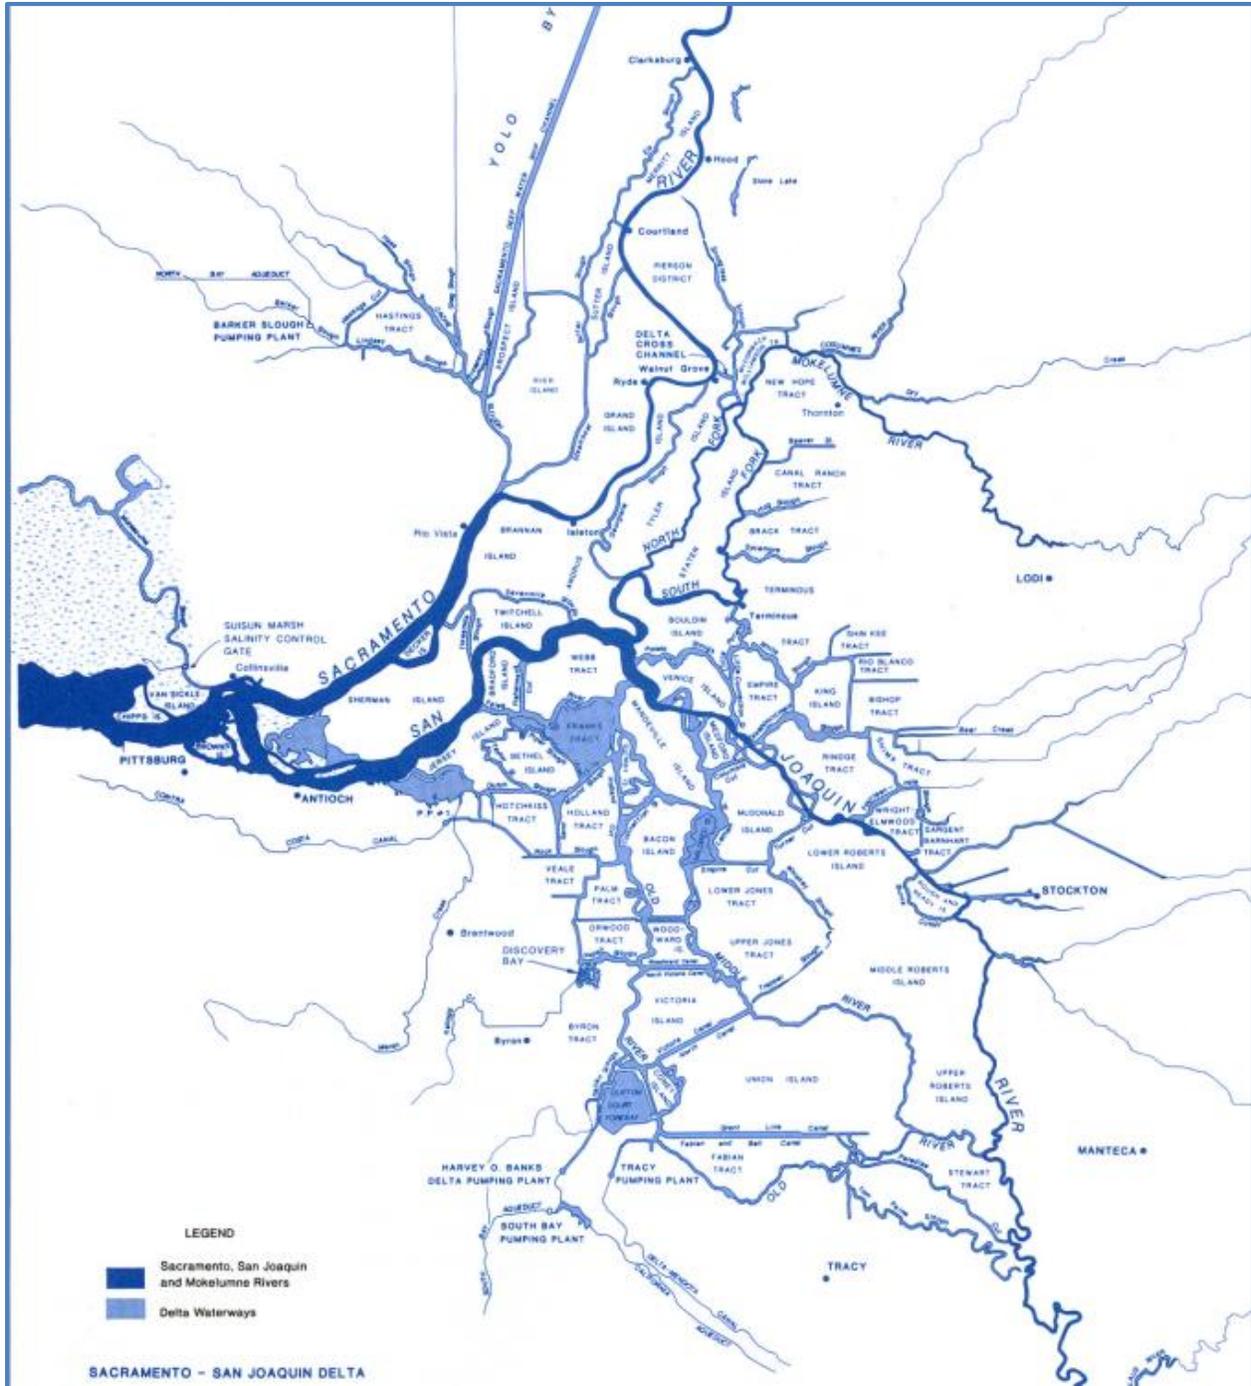

Figure 1.1. The Sacramento-San Joaquin Delta Region.

1.2 Goal and Organization of Cyanobacterial Literature Review

The goal of the cyanobacterial literature review is to synthesize available information to provide insight into cyanobacterial blooms in the Delta. The review had three major objectives:

- 1) Provide a basic review of biological and ecological factors that influence the prevalence of cyanobacteria and production of cyanotoxins;
- 2) Summarize observations of cyanobacteria blooms and associated toxins in the Delta;
- 3) Synthesize literature to provide an understanding of what ecological factors, including nutrients, may be at play in promoting cyanobacteria blooms in the Delta.

This review, and the recommended next steps, will contribute to a science plan to determine whether or how to proceed with the development of nutrient objectives for the Delta. The document is organized as follows:

Section 1: Introduction, Purpose and Organization of the Review

Section 2: Basic Biology and Ecology of Cyanobacteria

Section 3: Factors Influencing Cyanobacterial Blooms and Toxin Production

Section 4: Prevalence of CyanoHABs and Potential for Effects on Ecosystem Services in the Delta

Section 5: Synthesis of Factors Influencing CyanoHABs Presence and Toxin Production in the Delta

Section 6: Recommendations

Section 7: Literature Cited

2. BASIC BIOLOGY AND ECOLOGY OF CYANOBACTERIA

2.1 Overview

Cyanobacteria are a versatile group of bacteria that were the ancient colonizers of Earth and the photosynthetic ancestors of chloroplasts in eukaryotes such as plants and algae. As pioneers of photosynthesis, cyanobacteria were responsible for oxygenating Earth's atmosphere 2.5 billion years ago. In addition to being photosynthetic, cyanobacteria can differentiate into specialized cell types called heterocysts and fix nitrogen (N), exhibit gliding mobility, and tolerate a wide range of temperatures as evidenced by their ability to thrive in hot springs and ice-covered Antarctic lakes. Cyanobacteria also produce an array of bioactive compounds, some of which possess anti-microbial, anti-cancer and UV protectant properties. However, a subset of these bioactive compounds is highly toxic to humans and wildlife.

Blooms of cyanobacteria that produce these toxins, collectively known as harmful cyanobacterial algal blooms (cyanoHABs), has garnered a great deal of attention due to their increased occurrence in recent decades (Chorus and Bartram 1999, Carmichael 2008, Paerl and Huisman 2008, Hudnell 2010). The geographical distribution of these blooms has also increased with blooms appearing in areas previously unaffected (Lehman *et al.* 2005, Lopez *et al.* 2008). CyanoHABs can have major negative impacts on aquatic ecosystems. Toxins produced by cyanobacteria can lead to mortality in aquatic animals, waterfowl and domestic animals (Havens 2008, Miller *et al.* 2010). Moreover, toxins in drinking water supplies can pose a variety of adverse health effects and therefore require expensive treatment options such as filtration, disinfection, and adsorption with activated carbon (Cheung *et al.* 2013). In addition to the threat of toxins, oxygen depletion due to organic matter decomposition following the die-off of blooms can result in massive fish kills. CyanoHABs can also lead to revenue losses and impact local economies by reducing business in affected water bodies during the peak of tourism season. Considerable costs are associated with mitigation of blooms and lake restoration (Dodds *et al.* 2009).

The San Francisco Bay Delta is an area where cyanoHABs were previously undetected but have become commonplace since early 2000 (Lehman *et al.* 2005). In addition to providing a home for several species of pelagic fish and other wildlife, the Delta serves as a critical source of drinking water, and freshwater for irrigation of farms, to communities locally as well as farther south including the Los Angeles Metropolitan Water District. In concert with the occurrence of cyanoHABs, concentrations of the toxins they produce have been detected in the water and in higher trophic levels including zooplankton and fish (Lehman *et al.* 2010). The purpose of the following sections summarizes the basic biology of cyanobacteria beginning with classification, light harvesting, carbon metabolism, buoyancy regulation, nitrogen metabolism, cellular N:P ratios and toxin production, in order to build fundamental concepts that are later utilized in the review.

2.2 General Characteristics

2.2.1 Classification, Distribution and Akinete Production

Classification

Traditionally, morphological traits have been used to subdivide the cyanobacteria into five subgroups (Rippka *et al.* 1979). The major division is between cyanobacteria that are single celled and/or colonial and those that grow filaments (Table 2.1). Each category contains a mixture of marine and freshwater species. In the former category are the Group I Croococcales including the freshwater *Microcystis* and *Synechocystis*, and the marine *Synechococcus* and *Prochlorococcus*. Group II Pleurocapsales include *Pleurocapsa* and *Xenococcus* (Table 2.1). The filamentous algae, Groups III, IV, and V, are further subdivided into the Oscillatoriales that produce only vegetative cells, including the freshwater planktonic *Planktothrix* species, the benthic *Oscillatoria* and *Lyngbya* species, as well as the marine *Trichodesmium* sp. (Table 2.1). Group IV, the Nostocales, contain filamentous algae that differentiate into heterocysts and fix N₂. This group includes *Aphanizomenon*, *Anabaena*, *Nostoc* and *Cylindrospermopsis* (Table 2.1). Additionally, the Nostocales is known for differentiation into resting cells called akinetes during unfavorable conditions. Group V, the Stigonematales include species with filaments that grow in complex branching patterns.

Table 2.1. Cyanobacterial groupings based on morphological traits. Adapted from Rippka *et al.* 1979.

Croococcales Unicellular, reproduce by binary fission		GROUP 1	<i>Gloeotheca</i> (N) <i>Microcystis</i> <i>Prochlorococcus</i> <i>Prochloron</i>	<i>Synechococcus</i> <i>Synechocystis</i>
Pleurocapsales Unicellular, reproduce by multiple fission		GROUP 2	<i>Pleurocapsa</i> <i>Staniera</i> (N) <i>Xenococcus</i> (N)	
Filamentous chain (trichome) forming; reproduce by random trichome breakage, hormogonia, germination of akinetes	Trichome composed of vegetative cells	Oscillatoriales 1 plane division GROUP 3	<i>Lyngbya</i> (N) <i>Oscillatoria</i> (N) <i>Phormidium</i> <i>Prochlorothrix</i> <i>Trichodesmium</i> (N)	
	In the absence of fixed N, trichome contains heterocysts; some produce akinetes	Nostocales 1 plane division GROUP 4	<i>Aphanizomenon</i> <i>Anabaena</i> <i>Cylindrospermum</i> <i>Nodularia</i> <i>Nostoc</i>	
		Stigonematales Division in more than 1 plane GROUP 5	<i>Chlorogleopsis</i> <i>Fisherella</i>	

It was originally thought that N₂ fixation primarily existed in the Nostocales which had the ability to differentiate into heterocyst cells. More recent investigations tracking the *nifD* and *nifH* gene diversity has uncovered that N₂ fixation occurs in a range of unicellular, non-filamentous cyanobacteria dispersed throughout the five original groups first proposed by Rippka *et al.* (1979). These species are indicated by an (N) after their name in Table 2.1. Depending on which functionality of the cyanobacteria is emphasized, recent gene-based groupings of cyanobacteria have created as many as ten different sub-categories (Turner *et al.* 1999, Tomatini *et al.* 2006). However, there appears to exist no general consensus over the best manner in which to categorize the cyanobacteria based on functionality and marker genes. Most cyanobacteria are planktonic and are dispersed throughout the five groups. The benthic cyanobacteria are found mainly in the Oscillatoriales subgroup. The toxic cyanoHAB-forming cyanobacteria are mostly freshwater planktonic species dispersed throughout groups I, III and IV and include the N₂ fixing genera *Anabaena*, *Aphanizomenon*, *Cylindrospermopsis*, and *Nodularia*; the benthic N₂ fixing genera *Lyngbya* and some *Oscillatoria*; and the non-N₂ fixing genera *Microcystis* and *Planktothrix* (Paerl and Paul 2012).

Akinete formation

Akinetes are the resting cells produced by the Nostocales in order to survive adverse environmental conditions such as cold and desiccation (Tomatini *et al.* 2006). Akinete cells maintain low levels of metabolic activity (Thiel and Wolk 1983, Sukenik *et al.* 2007), are dispersed in sediments (Baker 1999, Kim *et al.* 2005, Rucker *et al.* 2009), and are distinguishable from vegetative cells by their larger size (Figure 2.1). They germinate in response to improved environmental conditions such as light and temperature (Baker and Bellifemine 2000, Karlsson-Elfgren *et al.* 2004, Yoshimasa and Nakahara 2005, Kaplan-Levy *et al.* 2010) and provide an inoculum of Nostocales vegetative cells to the water column from the sediments where the akinete “seed bank” may remain viable for decades (Stockner and Lund 1970, Livingstone and Jaworski 1980). Therefore, eradication of Nostocales from a system once it has become “infected” is very difficult.

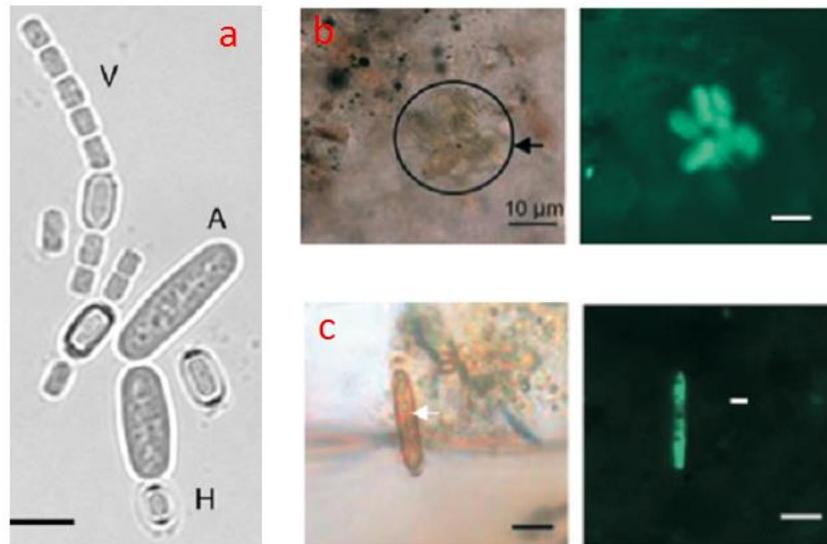

Figure 2.1. Akinetes of a) *Anabaena cylindrica* culture grown in medium without nitrogen; A=akinete; H=heterocyst; V=vegetative cell (picture from Tomatini *et al.* 2006), b) *Anabaena lemmermanni*, and c) *Cylandrospermopsis raciborskii* in lake sediments under light microscopy and hybridized with probe under fluorescence microscopy; scale bar is 10µm (pictures from Ramm *et al.* 2012).

2.2.2 Light Harvesting, Photosynthesis and Carbon Fixation

Cyanobacteria are distinct from all other algae in that most of them possess two light harvesting systems (as opposed to one). Maintaining two light harvesting system is costly in terms of protein and N requirements and manifests strongly in their cell biology. For example, the extra protein requirement means that cyanobacteria have a high tissue nitrogen:phosphorus (N:P) ratio and a high N requirement for growth (discussed below). Despite this, light harvesting is necessary in photosynthetic organisms to 1) collect light energy from the sun and 2) convert it to chemical energy in the form of electrons and ATP that can be used to power carbon fixation.

Light harvesting pigments and photosynthesis

Light harvesting is performed by chlorophyll *a* (Chl *a*) pigment molecules that are associated with two photosystems (PSI and PSII) that comprise the centers of the photosynthetic process which starts with the liberation of an electron from the splitting of water and ends with the production of ATP. Sitting in each of the photosystems is a specialized Chl *a* molecule that initiates the flow of electrons through the electron transport chain that eventually powers ATP synthesis. The other Chl *a* molecules, 40 and 90, together with 12 and 22 carotenoid pigment molecules, in PSI and PSII respectively, funnel light energy to the reaction core (DeRuyter and Fromme 2008). This complex of Chl *a* and carotenoid pigment molecules, coordinated by a large number of proteins, is very similar in its structure to the light-harvesting complex (LHC)

embedded into the thylakoid membranes of vascular plants and eukaryotic phytoplankton (Fromme *et al.* 2001, 2002).

What makes the cyanobacteria unique is that they have a second light harvesting antenna complex peripheral to the thylakoid membrane that is water soluble (e.g. not membrane bound). This pigment complex, comprised of pigmented proteins arranged in rods fanning out from a core attached to the thylakoid membrane, called the phycobilisome (PBS), is what gives cyanobacteria their name (Grossman *et al.* 1993, Grossman 2003). Similar to the carotenoid pigments mentioned above, the PBS chromophores absorb light inbetween the Chl *a* absorption peaks of 440nm and 670nm (Grossman *et al.* 1993). Interestingly, the PBS proteins are not exclusive to cyanobacteria; they also occur in photosynthetic eukaryotes.

Up to 50% of cyanobacterial cellular protein content is bound in the PBS complex taking a large proportion of the cell's resources, particularly its nitrogen (N) allocation. Therefore, under stress condition such as N starvation, the entire PBS can be degraded within a few hours and the N can become reused within the cell (Sauer *et al.* 1999). When conditions improve, the PBS will be re-synthesized and re-assembled (Collier and Grossman 1994, Grossman *et al.* 2001).

Carbon fixation

The ATP produced and the electrons liberated during photosynthesis are used to power the fixation of carbon into sugars in the Calvin Cycle. They are also used to reduce oxidized sources of N to ammonia during N assimilation (discussed below). The primary and rate-limiting enzyme in carbon fixation is Rubisco which catalyzes the first step in the Calvin Cycle. To deal with the rate-limiting nature of Rubisco, cyanobacteria have evolved specialized structures called carboxysomes. In addition to housing Rubisco, the carboxysomes contain a number of other enzymes that help concentrate CO₂ in its vicinity to speed its reaction rate (Kaplan and Reinhold 1999). Cyanobacteria fix carbon to provide the skeletons needed to assimilate N into amino acids and build protein and cellular biomass; fixed carbon can also be used to accumulate carbohydrate storage products (carbohydrate ballasting) in order to make the cell heavier during buoyancy regulation.

2.2.3 Buoyancy Regulation

One distinct advantage of many cyanobacterial genera such as *Microcystis*, *Planktothrix*, *Anabaena* and *Aphenizomenon* is their ability to regulate their buoyancy by a combination of producing gas vesicles and carbohydrate storage products (Oliver 1994, Beard *et al.* 1999, Brookes *et al.* 1999). The former renders them positively buoyant whereas the latter does the opposite (Walsby 1994, 2005). The carbohydrate storage products are derived from C-fixation and the amount produced varies depending on the species and on irradiance (Howard *et al.* 1996, Visser *et al.* 1997, Wallace and Hamilton 1999). At an irradiance that is specific to each species and strain, the amount of carbohydrate storage product will perfectly balance the upward lift

created by the gas vesicles and the cyanobacteria will become neutrally buoyant (Walsby *et al.* 2004). In addition to producing and storing the carbohydrates, cyanobacteria also consume the storage products to produce energy.

By regulating the amount of carbohydrate storage products consumed, cyanobacteria control their vertical position in the water column (Thomas and Walsby 1985, Konopka *et al.* 1987, Wallace and Hamilton 1999). Models demonstrate that filamentous cyanobacteria can sink or float at speeds up to 0.3 m per day in order to position them at a depth where irradiance is such that it maximizes their growth potential (Walsby 2005). These speeds are only achievable for filaments of a certain size and weight; picocyanobacteria and small filaments do not have enough momentum to respond by vertical repositioning to changes in irradiance (Walsby 2005). Of course, carbohydrate production, therefore buoyancy regulation, is affected by nutrient availability; nitrogen starved cells have excess carbohydrate stores and tend to lose buoyancy more easily than nutrient sufficient cells (Klemer *et al.* 1982, Brookes *et al.* 1999, Brookes and Ganf 2001).

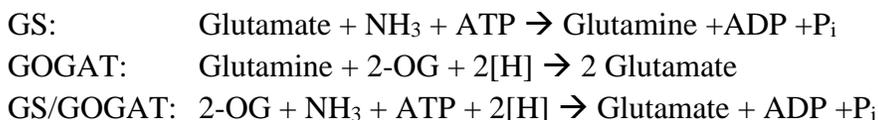

2.2.4 Nitrogen Metabolism

Cyanobacteria use a wide variety of N sources for growth including ammonium (NH_4^+), nitrate (NO_3^-), nitrite (NO_2^-), urea, amino acids, cyanate, and several species are also capable of dinitrogen gas (N_2) fixation to satisfy their cellular N demand. Below we discuss the pathways of N transport, metabolism and assimilation, and their regulation.

Ammonium transport and assimilation of N into amino acids

Being a charged molecule, NH_4^+ cannot diffuse freely into the cell and has to be transported via active transport. Transport of NH_4^+ into cyanobacteria (as well as in eukaryotic algae) occurs via the Amt family of transporters. These transporters are either expressed constitutively or differentially depending on external N concentrations. At environmental concentrations, most of the NH_4^+ is transported into the cell via the high-affinity transporter Amt1 encoded by the gene *amt1* (Muro-Pastor *et al.* 2005).

Before it can be assimilated, all N sources, whether N_2 , NO_3^- or organic N containing molecules, first have to be converted to NH_4^+ . The NH_4^+ is then assimilated into amino nitrogen through the GS/GOGAT pathway. The primary NH_4^+ assimilating enzymes in cyanobacteria (as well as in vascular plants and eukaryotic algae) are glutamine synthetase (GS) and glutamate synthase (also called glutamine-2-oxoglutarate-amido transferase, GOGAT) acting in concert to aminate 2-oxoglutarate (2-OG). Photosystem I (PSI)-reduced ferredoxin (Fd_{red}) is typically used as a reductant in this reaction:

An alternate route of NH_4^+ assimilation involves the enzyme glutamate dehydrogenase (GDH) but it's postulated that this occurs only during select conditions such as stationary growth:

In all photosynthetic cells the link between the carbon (C) and N cycles in the cell occurs at the GS/GOGAT reactions because the two key ingredients in N assimilation is 1) 2-OG derived from carbon fixation, and 2) Fd_{red} derived from PSI. GOGAT (and also GDH) will not proceed without their presence, which avoids wasteful consumption of glutamine, and ensures that even in the presence of excess N, assimilation will not proceed unless an adequate supply of C skeletons is available (Flores and Herrero 2005, Muro-Pastor *et al.* 2005).

Nitrate transport and reduction to NH_4^+

As NO_3^- is also a charged molecule it's transported into the cell via active transport. Cyanobacteria use two different transport systems. Most freshwater species, including *Anabaena*, *Synechocystis* and *Gloebacter*, use the high affinity ATP-binding cassette (ABC) transporter NrtABCD (Flores *et al.* 2005). Most marine species (*Synechococcus* and others) take up NO_3^- and NO_2^- via the major facilitator superfamily transporter NrtP, also a high-affinity transporter (Flores *et al.* 2005). Some species also have a NO_2^- -specific transporter NIT (Maeda *et al.* 1998). Nitrate uptake is tightly regulated by the external concentration of NH_4^+ ; when NH_4^+ becomes available, cells cease NO_3^- uptake and switch to use NH_4^+ which is preferred. This process is regulated at the level of NO_3^- uptake (Flores and Herrero 1994). In addition, CO_2 -fixation (regulated by irradiance) is required to maintain active NO_3^- uptake, a regulatory link that ensures that the product of NO_3^- reduction (ammonium) can be incorporated into carbon skeletons (Luque and Forchhammer 2008).

Reduction of NO_3^- to NH_4^+ is a two-step process catalyzed by the enzymes nitrate reductase (NR) and nitrite reductase (NiR). The power for the reduction reaction, in the form of 2 electrons for NR and 6 electrons for NiR, is provided by Fd_{red} via PSI providing a strong link between the light reactions and NO_3^- use by the cell (Flores *et al.* 2005).

In cyanobacteria, the genes encoding NR, narB, and Nir, nirA, and the NO_3^- transporter NrtP, are typically clustered in the same operon. An operon is a unit that tells the cells to transcribe a sequence of genes simultaneously. In cyanobacteria, the transcription of operons associated with N metabolism is tightly regulated by the transcription factor NtcA (discussed below).

The only cyanobacteria discovered to date that is not able to use NO_3^- is *Prochlorococcus* which lives in the open ocean. While it was initially thought that some species could assimilate NO_2^- , sequencing of their genomes demonstrates that they all lack the *nirA* genes and therefore cannot reduce NO_2^- (Garcia-Fernandez *et al.* 2004).

Urea transport and metabolism

Many, but not all, cyanobacteria can use urea as a source of N for growth. Because urea is not a charged molecule it diffuses freely into the cell; however, environmental concentrations are not such that diffusion can supply the needed concentration of urea for the urease enzyme (based on its K_m). Both in freshwater and marine cyanobacteria, an ABC-type active transport system specific for urea has been identified (Valladares *et al.* 2002). The subunits of this transporter are encoded by the five genes *urtA-E*. In *Anabaena*, the urea transporter genes are in the same NtcA-activated promoter and subject to metabolic repression by NH_4^+ (Valladares *et al.* 2002). Urea is metabolized to two molecules of NH_3 and CO_2 by the enzyme urease, also called urea amidohydrolase (Mobeley *et al.* 1995). The urease enzyme is well-conserved throughout the bacteria and eukaryotic organisms and consists of two small and one large subunit encoded by at least seven genes, three which encode the structural subunits (*ureA*, *ureB*, *ureC*) and the other four (*ureD*, *ureE*, *ureF*, *ureG*) encoding accessory polypeptides required for the assembly of the nickel metallocenter (Collier *et al.* 1999, Palinska *et al.* 2000).

Amino acid transport

All cyanobacteria tested to date have at least one transport system for amino acids. These transporters appear to have broad specificity (i.e. they can transport more than one type of amino acid) and different species have different combinations of transporters (Herrero and Flores 1990, Montesinos *et al.* 1997). For example, freshwater *Synechocystis* sp. has four different amino acid transporters, including the ABC transporter Nat for glutamine and histidine, the ABC transporter Bgt for basic amino acids, and two glutamate-specific transporters GHS and Gtr (Quintero *et al.* 2001). Once in the cell, cyanobacteria possess a variety of deaminase enzymes that can deaminate the amino acids to NH_3 which then enters the GS/GOGAT pathway.

Cyanate transport and metabolism

Cyanobacteria, including freshwater and marine species, can use cyanate (a toxin) as a N source for growth since they have the genes encoding a transporter (*cynA*, *cynB*, *cynC*) and the gene encoding the cyanase enzyme (*cynS*) which hydrolyzes cyanate to NH_3 and CO_2 (Kamennaya and Post 2011). In freshwater cyanobacteria, these genes are repressible by NH_4^+ suggesting that they are under NtcA regulation.

Nitrogen fixation

Arguably the most expensive (energetically speaking) source of N for cyanobacteria is molecular dinitrogen gas (N_2). Nitrogen fixation, the process of reducing N_2 to NH_3 , is catalyzed by the nitrogenase enzyme. The nitrogenase has two subunits. The first is the dinitrogenase subunit which catalyzes the reduction of N_2 to NH_4^+ , composed of the NifD and NifK polypeptides encoded by the *nifD* and *nifK* genes. The dinitrogenase contains an iron-molybdate active site and two iron-sulfur clusters. The second is the dinitrogenase reductase subunit (NifH polypeptide

encoded by the *nifH* gene) which contains a central iron-sulfur cluster whose function it is to donate electrons derived from ferredoxin to dinitrogenase. Reduction of N₂ to NH₃ requires 8 electrons and 15 molecules of ATP in the following reaction:

It was recently discovered that under conditions of molybdate limitation, some *Anabaena* species express an alternative nitrogenase containing a vanadium-iron cofactor instead of the molybdate-iron cofactor (Thiel 1993, Boison *et al.* 2006). Both these variants require iron cofactors to function and N₂ fixation cannot proceed under iron-limiting conditions.

The nitrogenase enzyme is very sensitive to oxygen (O₂), and O₂ is evolved as a byproduct of the water-splitting reactions at photosystem II (PSII), requiring the nitrogenase enzyme to be kept separate from PSII. Accordingly, freshwater cyanobacteria have evolved heterocysts (Wolk *et al.* 1994). These are specialized cells where PSII is inactivated, the PBS antenna proteins are degraded, and energy to power the cell is derived from cyclic electron flow around PSI. Rates of respiration in these cells are also high to scavenge any O₂. The ATP and reductant needed for N₂ reduction is generated by carbohydrate metabolism inside the heterocyst. The carbohydrate is synthesized in the non-heterocyst, vegetative cells flanking the heterocyst and transported inside. In turn, NH₃ produced inside the heterocyst is exported to the vegetative cells in the form of amino acids (Wolk *et al.* 1994). However, many species of cyanobacteria that fix N₂ do not form heterocysts; these species either separate N₂ fixation from photosynthesis in time (e.g. by fixing N₂ at night such as *Lyngbya aestuarii* and *Crocospaera watsonii*) or in different regions of filaments as is hypothesized to be the case for *Trichodesmium* sp. (Frederiksson and Bergman 1997).

Because nitrogen fixation is such an energy expensive process, from the formation of the heterocysts to the reduction of N₂, it is tightly regulated by NtcA and is only induced under N starvation and in the absence of any other fixed N source (Herrero *et al.* 2004).

Regulation of nitrogen metabolism

As evident from the preceding sections, the transcription factor NtcA (encoded by the gene *ntcA*) regulates most of the cyanobacterial genes associated with nitrogen uptake and assimilation, and is therefore considered the master regulator of N metabolism (Herrero *et al.* 2004). NtcA binds to and activates the operons for heterocyst differentiation, N₂ fixation, NO₃⁻ uptake and reduction, urea uptake and hydrolysis, and glutamine synthetase to mention a few. In other words, none of the genes related to N metabolism are transcribed and their enzymes synthesized unless NtcA binds to their promoter in the genome (Luque *et al.* 1994, Wei *et al.* 1994, Forchammer 2004, Luque and Forchammer 2008). The exception to this rule are some NH₄⁺ transport proteins which are not under NtcA control and are transcribed constitutively, i.e.

always “on” (Herrero *et al.* 2001). NtcA also controls signaling proteins that fine-tune cellular activities in response to fluctuating C/N conditions (Herrero *et al.* 2001).

NtcA is under negative control by NH_4^+ , meaning that when NH_4^+ is detectable by the cell, *ntcA* gene transcription is repressed (Herrero *et al.* 2001, Lindell and Post 2001). There is an inverse relationship between NH_4^+ concentration and *ntcA* expression in all cyanobacteria tested to date, with basal levels of *ntcA* expression observed in the presence of high external NH_4^+ concentrations and maximal levels of *ntcA* expression observed under N starvation (Frias *et al.* 1994, Lindell *et al.* 1998, Lee *et al.* 1999, Sauer *et al.* 1999, Lindell and Post, 2001). Ammonium regulates expression of *ntcA* via 2-OG which is synthesized in the Calvin cycle and consumed in the GS/GOGAT cycle. Thus 2-OG is at the crossroads between C and N metabolism and is ideally suited to “sense” NH_4^+ concentrations (Vazquez-Bermudez *et al.* 2002, Tanigawa *et al.* 2002, Forchhammer 2004).

The repression of *ntcA* expression by NH_4^+ places NH_4^+ at the top of the hierarchy of N substrates utilized and assimilated by cyanobacteria. The order in which N substrates other than NH_4^+ is assimilated differs depending on species. For example, in N_2 fixing cyanobacteria, NH_4^+ represses both N_2 fixation and NO_3^- assimilation. Nitrate, in turn, represses N_2 fixation. Therefore N_2 fixation is at the bottom of the hierarchy in some cyanobacteria (Ramasubramanian *et al.* 1994). But in others such as marine *Trichodesmium* sp., NO_3^- does not repress N_2 fixation genes and the process of N_2 fixation is on a more even footing with NO_3^- assimilation (Post *et al.* 2012).

2.2.5 Cellular Nitrogen:Phosphorus (N:P) Requirement

In 1958 Redfield published his discovery that phytoplankton particulate matter was composed of N and P in a molar ratio of 16, similar to the ratio of dissolved N:P in the water (Redfield 1958). Redfield suggested that the ratio of dissolved N:P in the ocean was driven by the remineralization of phytoplankton particulate matter, a theory which has since taken hold (Falkowski 2000, Geider and LaRoche 2002). Given that the average N:P ratio was discovered to be 16 in phytoplankton, it was deduced that under nutrient limiting conditions phytoplankton would become limited by N at dissolved N:P less than 16 and limited by P at dissolved N:P ratios greater than 16.

Shortly after Redfield’s discovery of the universality of the N:P ratio of 16, investigators turned to phytoplankton cultures to examine how closely phytoplankton cellular N:P ratios varied around 16. Parsons *et al.* (1961) published the first investigation demonstrating variability in cellular N:P ratios depending on the phytoplankton species. Subsequent investigations noted that diatoms and dinoflagellates tended to have cellular N:P ratios below 16 whereas chlorophytes and cyanobacteria typically had ratios above 25 (Geider and LaRoche 2002; Ho *et al.* 2003; Quigg *et al.* 2003; Klausmeier *et al.* 2004; Hillebrand *et al.* 2013; Figure 2.2). This difference

among the taxa stems from slight variations in macromolecular composition of the phytoplankton, principally in their ratio of protein, the largest store of N in the cell, to nucleic acids, the largest store of P in the cell (Terry *et al.* 1985, Falkowski 2000, Elser *et al.* 2000, Geider and LaRoche 2002). As mentioned above in section 2.2.2, cyanobacteria have two light-harvesting complexes requiring a greater association of proteins with the light-harvesting pigments compared with eukaryotic cells which only have one light harvesting complex (Raven 1984, Geider and LaRoche 2002). The “excess” protein associated with the peripheral phycobilisomes substantially increase the cellular N:P ratios of cyanobacteria. Once it was realized that there were significant departures in the cellular N:P ratio depending on taxa, it also became clear that the ratio of N:P uptake differed with respect to taxa and that this was a major basis of resource-based competition among taxa (Rhee 1978). That phytoplankton take up N:P in proportion to their tissue composition was subsequently confirmed in culture experiments (Droop 1974, Elrifi and Turpin 1985, Tett *et al.* 1985, Quigg *et al.* 2003, Leonardos and Geider 2004). In other words, phytoplankton do not take up nutrients according to the ratio that occurs in water, but rather the ratio dictated by the macromolecular composition of their tissues.

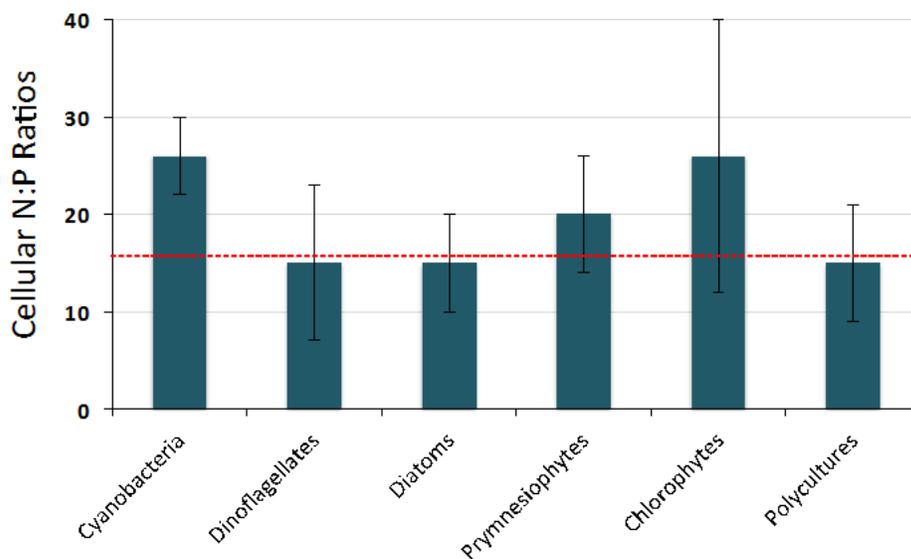

Figure 2.2. Cellular N:P ratios (mole:mole) in different phytoplankton taxa. Dashed red line indicates the average phytoplankton cellular N:P ratio of 16, also called the Redfield ratio. Data from Hillebrand *et al.* 2013.

Tissue N:P composition is not a fixed trait and phytoplankton are able to adjust it, within certain limits, in order to keep growing when environmental conditions change for the suboptimal. When limited for a nutrient, uptake of the non-limiting nutrient can proceed for a while skewing cellular ratios. But, severe limitation by one nutrient will eventually prevent the uptake of the other, non-limiting nutrient, even when the other is present in excess. This quirk of nature

constrains the extent to which cellular ratios vary (Droop 1974, Tett *et al.* 1985, Leonardos and Geider 2004, Hillebrand *et al.* 2013). For example, a summary of nearly 50 phytoplankton studies demonstrates that the N:P ratio of P-limited phytoplankton converge around 28 and the N:P ratio of N-limited phytoplankton converges around 16 (Hillebrand *et al.* 2013).

Irradiance may also change the cellular N:P ratio through its influence on the cellular protein content (LaRoche and Geider 2002). Pigments (Chl *a* and light harvesting antenna pigments) are bound in pigment-protein complexes rich in N that increase as irradiance decreases, and decrease under high light as cells reduce the size of the light harvesting complex to avoid photodamage (Wynne and Rhee 1986, Falkowski and LaRoche 1991, Nielsen 1992, Leonardos and Geider 2004). The irradiance-dependent change in N:P ratios is even more pronounced among cyanobacteria due to the greater association of protein with the phycobilisome than in the eukaryotic light harvesting complex (Raven 1984, Geider and LaRoche 2002).

In contrast with limiting nutrient concentrations or changes in irradiance, changes in the medium N:P ratio when nutrient concentrations are in excess of demand was found not to affect cellular N:P ratios in phytoplankton in early experiments (i.e. Tilman *et al.* 1982, Tett *et al.* 1985, Reynolds 1999, Roelke *et al.* 2003, Sunda and Hardison 2007) and has not been pursued by the scientific community.

2.2.6 Toxin Production

Cyanobacteria produce a large variety of toxins with a number of different actions in animals and humans leading to significant health risks and drinking water issues globally (c.f. Chorus and Bartram 1999, Chamichael 2008, Cheung *et al.* 2013). The toxin-producing cyanobacteria, and the suite of different toxins that each species produces, is discussed below.

Toxin-producing taxa

The cyanobacterial toxins were named according to the species that they were originally discovered in and isolated from. For example, microcystin was discovered in *Microcystis aeruginosa* and anatoxin was originally isolated from *Anabaena*. However, most cyanobacteria produce several different types of toxins, with the exception of nodularin which is only produced by *Nodularia spumigena*.

The toxin most widely produced by different cyanobacterial taxa is the recently discovered neurotoxin Beta-N-methylamino-L-alanine (BMAA, Cox *et al.* 2005). This is followed by the microcystins which are produced by nine different taxa (Table 2.2). Chief among the microcystin producing taxa are *Microcystis* (the toxin was originally isolated from *Microcystis aeruginosa*), followed by *Planktothrix* and *Anabaena*. Another widely distributed toxin is anatoxin-a, which is produced by eight different cyanobacterial taxa, principally *Anabaena*, the genus from which the toxin was originally isolated.

Table 2.2. Toxins produced by cyanobacteria. Based on data from Cox *et al.* 2005, Sivonen and Borner 2008, Cheung *et al.* 2013.

	Microcystin	Nodularin	Cylindro-spermopsin	Anatoxin-a	Anatoxina(S)	Saxitoxin	Dermatotoxin	BMAA
<i>Microcystis</i>	X							X
<i>Planktothrix</i>	X			X		X		X
<i>Anabaena</i>	X		X	X	X	X		X
<i>Nostoc</i>	X							X
<i>Anabaenopsis</i>	X							
<i>Radiocystis</i>	X							X
<i>Synechococcus</i>	X							X
<i>Phormidium</i>	X			X				X
<i>Oscillatoria limosa</i>	X			X				
<i>Oscillatoria</i>				X			X	
<i>Nodularia</i>		X						X
<i>Cylindro-spermopsis</i>			X			X		X
<i>Aphanizomenon</i>			X	X		X		X
<i>Raphidiopsis</i>			X	X				X
<i>Cylindro-spermum</i>				X				X
<i>Lyngbya</i>						X	X	X
<i>Shizothrix</i>							X	
<i>Umezakia natans</i>			X					

Anabaena species, including *flos-aquae/ lemmermannii/ circinalis*, may be the most toxically versatile of all the cyanobacteria as they can produce all the toxins, including BMAA, microcystins, cylindrospermopsin, anatoxin-a, anatoxin-a(S) and saxitoxins, save nodularin (Table 2.2). Nodularin is only produced by *Nodularia spumigena*. Another versatile toxin producer is *Aphanizomenon flos-aquae* which produces BMAA, cylindrospermopsin, anatoxin-a and saxitoxins (Table 2.2). *Planktothrix* also produces four different toxins including BMAA, microcystins, anatoxin-a and saxitoxins. The cyanobacteria *Cylindrospermopsis raciborskii* from whence cylindrospermopsin was originally isolated also produces saxitoxins (Table 2.2). Benthic cyanobacteria are also versatile when it comes to toxin production. For example, *Oscillatoria limosa* can produce microcystins as well as anatoxin-a while *Lyngbya wollei* can produce saxitoxins and dermatotoxins (Table 2.2).

Toxin types and their biosynthetic pathways

The toxins produced by cyanobacteria can be divided into three main groups: hepatotoxins that damage the liver of the organisms ingesting them, neurotoxins that cause respiratory arrest, and dermatotoxins that cause rashes and inflammations. Each is discussed separately below.

Hepatotoxins. The most well-known hepatotoxins are microcystins and nodularin which are serine/threonine protein phosphatase inhibitors (Table 2.3). A large variety of different microcystins (close to 80) have been identified, with the most toxic being microcystin-LR. These cyclic heptapeptides contain seven amino acids, including a unique beta amino acid ADDA (MacKintosh *et al.* 1990, Yoshizawa *et al.* 1990). In contrast with microcystins, only a few varieties of nodularin have been identified (Yoshizawa *et al.* 1990). The toxicity of cyanobacterial toxins is typically measured by injecting them into mice and calculating the lethal dosage to half the population (LD₅₀; Table 2.3).

Biosynthesis of the microcystin and nodularin peptides occurs by non-ribosomal peptide synthases (NRPS) and polyketide synthases (PKS) found mainly in bacteria (Welker and von Dohren 2006). Both of these enzyme classes are needed for both the microcystin and nodularin biosynthesis pathways which have been sequenced from a number of cyanobacterial species including *Microcystis*, *Planktothrix* and *Anabaena* (Borner and Dittman 2005). For example, the *mcyA*, *mcyB* and *mcyC* genes encode the NRPS that synthesize the pentapeptide portion of microcystins. The *mcyD*, *mcyE*, *mcyF* genes encode the PKS which synthesize the ADDA amino acid unique to microcystins. Finally, the *mcyF*, *mcyG*, *mcyH*, *mcyI*, *mcyJ* genes encode the proteins that tailor and transport specific microcystins (Table 2.3). Similarly, the *nda* gene cluster specific to nodularin encode the NRPS and PKS synthases as well as the tailoring and transport proteins (Table 2.3). Although not verified through functional investigations, the cylindrospermopsin gene cluster, encoding the genes *cyrA*, *cyrB*, *cyrC*, has recently been characterized in *Aphanizomenon flos-aquae* (Stuken and Jakobsen 2010).

Table 2.3. Common cyanobacterial toxins. ND: Not determined.

Toxin	Chemical Class	Action	Effect	LD ₅₀	Reference	Gene Name	Gene Reference
Micro-cystins	Cyclic heptapeptides; 80 variants; microcystin-LR is most toxic	Serine/threonine protein phosphatase (1 and 2A) inhibitors	Hepatotoxin; damages liver	50 µg kg ⁻¹	MacKintosh <i>et al.</i> 1990, Yoshizawa <i>et al.</i> 1990	<i>mcyA-I</i>	Tillett <i>et al.</i> 2000, Christiansen <i>et al.</i> 2003
Nodularin	Cyclic pentapeptide; only a few variants identified	Serine/threonine protein phosphatase 1 and 2A inhibitor	Hepatotoxin; damages liver	50 µg kg ⁻¹	Yoshizawa <i>et al.</i> 1990	<i>ndaA-I</i>	Moffitt and Neilan 2004
Cylindrospermopsin	Cyclic guanidine alkaloid	Protein synthesis inhibitor	Hepatotoxin/Cytotoxin; affects liver as well as kidney, spleen, thymus and heart	200 µg kg ⁻¹ at 6 days 2000 µg kg ⁻¹ at 24 hrs	Runnegar <i>et al.</i> 1994, Terao <i>et al.</i> 1994, Ohtani <i>et al.</i> 1992	<i>cyrA-C</i>	Stuken and Jakobsen 2010
Anatoxin-a	Alkaloid	Competitive inhibitor of acetyl choline	Neurotoxins: causes death by respiratory arrest	200-250 µg kg ⁻¹	Devlin <i>et al.</i> 1977, Carmichael <i>et al.</i> 1990, Skulberg <i>et al.</i> 1992	<i>ana</i>	Mejean <i>et al.</i> 2010
Anatoxin-a(S)	Phosphate ester of cyclic N-hydroxyguanine	Anticholinesterase	Neurotoxins: causes death by respiratory arrest	20 µg kg ⁻¹	Carmichael <i>et al.</i> 1990	<i>ana</i>	Mejean <i>et al.</i> 2010
Saxitoxins	Carbamate alkaloids; the most potent are saxitoxins and neosaxitoxins	Sodium channels blocker	Neurotoxin	10 µg kg ⁻¹	Sivonen and Jones 1999	<i>stxA-Z</i>	Kellmann <i>et al.</i> 2008
BMAA	Non-protein amino acid		Neurotoxin: linked with neuro-degenerative diseases (e.g. Parkinson's Dementia Complex)	ND	Cox <i>et al.</i> 2005	ND	
Dermato-toxins	Aplysiatoxins	Protein kinase C activators	Dermatotoxin: tumor promoters; dermatitis and oral/gastrointestinal inflammations	ND	Mynderse <i>et al.</i> 1977, Fujiki <i>et al.</i> 1990	ND	

Neurotoxins. By far the most potent toxins are the neurotoxin saxitoxin that causes paralytic shellfish poisoning (PSP) syndrome and respiratory arrest in humans and animals. This neurotoxin is produced both by cyanobacteria and dinoflagellates and is an alkaloid that acts as a sodium channel blocker. Another alkaloid neurotoxin, anatoxin-a, competitively inhibits acetyl choline, and a variant, anatoxin-a(S), acts as an anti-cholinesterase (Devlin *et al.* 1977, Mynderse *et al.* 1977, Carmichael *et al.* 1990, Sivonen and Jones 1999). The LD₅₀ of these toxins vary from 200-250 µg kg⁻¹ in the case of anatoxin-a, 20 µg kg⁻¹ in the case of anatoxin-a(S), to 10µg kg⁻¹ in the case of saxitoxins (Table 3). The gene clusters encoding the saxitoxin biosynthesis and anatoxin biosynthesis pathways were very recently elucidated via functional homology and each contains 20 or more genes (Kellmann *et al.* 2008, Mejean *et al.* 2010). The recently discovered neurotoxin BMAA, a non-protein amino acid that is potentially linked to neurodegenerative diseases such as Parkinson Dementia Complex (PDC), is produced in almost all cyanobacteria tested to date (Cox *et al.* 2005).

Dermatotoxins. Benthic cyanobacteria, including *Lyngbya*, *Oscillatoria* and *Schizothrix*, produce a number of different toxins including aplysiatoxins, debromoaplysiatoxins and lyngbyatoxin-a. These toxins are protein kinase C activators that cause dermatitis and oral and gastrointestinal inflammations, and can also promote tumor formation (Mynderse *et al.* 1977, Cardellina *et al.* 1979, Fujiki *et al.* 1990). The pathways and genes involved with the production of the dermatotoxins have yet to be elucidated.

Potential functions of toxin production

Interestingly, researchers have not been able to determine the purpose of toxin production in cyanobacteria, or under what conditions toxins are most likely to be produced (Sivonen and Borner 2008). Moreover, under environmental conditions cyanobacteria that produce toxins co-exist with cyanobacteria of the same genus that do not produce toxins; it's unclear whether the possession of, or lack of, the toxins confers an ecological advantage (Sivonen and Borner 2008, Baxa *et al.* 2010).

Despite these complications, several explanations for the potential function of toxin production exist. Originally it was thought that cyanotoxins acted as allelochemicals and that their secretion into the surrounding water would suppress the growth of competitors (Keating 1977, Keating 1978, Flores and Wolk 1986, Klein *et al.* 1995). But, when the distribution of toxins, such as microcystins, was compared between cells and the surrounding medium using immunodetection combined with electron microscopy, most of the toxin was found to be cell-bound (Rapala *et al.* 1997, Wiedner *et al.* 2003, Tonk *et al.* 2005, Gerbersdorf 2006). Because, live (i.e. non-lysed) cyanobacteria do not secrete the toxins they produce it is doubtful that they act as allelopathic chemicals. Consistent with this notion, most investigations that demonstrate allelopathic effects do so at concentrations of extracted toxins far above what is ecologically relevant, leading

investigators to conclude that the ability of cyanobacterial toxins to work as allelopathic chemicals appears unlikely (Babica *et al.* 2006, Berry *et al.* 2008, Holland and Kinnear 2013).

One explanation that is gaining ground is that the primary role of toxins is probably not to be toxic (Llewellyn 2006). Rather, investigators are hypothesizing that toxins may be produced to protect the cells from abiotic stresses. For example, microcystins are produced during all phases of growth but the greatest accumulation typically occurs under conditions that support optimal growth, including growing under optimal light levels (Sivonen and Jones 1999, Wiedner *et al.* 2003). Several lines of evidence point towards increases in irradiance as being a trigger for microcystin production. These include accumulation of intracellular microcystin-LR with increased irradiance, the association of intracellular microcystins with the thylakoid membranes, and increased microcystin gene expression with increased irradiance (Kaebernick *et al.* 2000, Tonk *et al.* 2005, Borner and Dittman 2005, Gerbersdorf 2006). As such, it makes sense that microcystins are produced across a number of cyanobacterial taxa, such as *Microcystis*, *Anabaena*, and *Planktothrix*, that grow well in high-light environments (Paerl and Paul 2012).

Microcystins may also be implicated in preventing iron-stress by acting as siderophores to scavenge iron (Utkilen and Gjolme 1995, Lyck *et al.* 1996), an idea supported by the discovery that the iron-regulator factor Fur binds to the genes that produce microcystins in cyanobacteria (Martin-Luna *et al.* 2006). As such, microcystin production may provide an advantage to cyanobacteria in early stages of iron-limiting conditions (Alexova *et al.* 2011, Holland and Kinnear 2013) vis-à-vis eukaryotic competitors (Molot *et al.* 2014).

Another potential role for cyanotoxins is to act as a grazing deterrent (Burns 1987, Gilbert 1996). However, recent research using *Microcystis aeruginosa*, has demonstrated that it's not the toxic microcystins that deters *Daphnia* from grazing *M. aeruginosa* but other substances it produces. In other words, the substances causing toxicity and deterrence are not identical and the non-toxic substances may be much important in terms of grazing deterrence (Rohrlack *et al.* 1999, 2003).

While the toxic substances are by far the most well-known, there are hundreds of other, secondary metabolites similar in structure to the toxins that are produced by cyanobacteria. Just as the toxins, these cyclic or linear peptides may not be needed for growth but may serve protective functions. For example, the grazing deterrents discussed above belong to a class of depsipeptides called microviridins (originally isolated from *Microcystis viridis*) and has since their isolation been found in a range of cyanobacteria (Rohrlack *et al.* 2003). These secondary metabolites may also have important pharmacological applications. An alkaloid produced by *Nostoc*, called nostocarboline, is a cholinesterase inhibitor which has an effect comparable to galanthamine, a drug approved for Alzheimer's disease (Becher *et al.* 2005). Also isolated from *Nostoc* is a compound called cyanovirin-N which has antiviral activity and is under development as an antiviral agent against HIV (Boyd *et al.* 1997, Bolmstedt *et al.* 2001).

3. FACTORS INFLUENCING CYANOBACTERIAL BLOOMS AND TOXIN PRODUCTION

The world-wide increase in the incidence of cyanoHABs such as the N₂ fixing genera *Anabaena*, *Aphanizomenon*, *Cylindrospermopsis*, and *Nodularia*; the benthic N₂ fixing genera *Lyngbya* and some *Oscillatoria*; and the non-N₂ fixing genera *Microcystis* and *Planktothrix* has prompted a great deal of research into the conditions that favor the growth of these species (Chorus and Bartram 1999; Carmichael 2008; Paerl and Huisman 2008; Hudnell 2008, 2010; O'Neill *et al.* 2012; Paerl and Paul 2012). These conditions typically include favorable salinity, ample supply of nutrients, calm water and stratified conditions, plenty of irradiance and warm water temperatures (Figure 3.1). In contrast, the most successful strategies to mitigate blooms of cyanoHABs include reducing the supply of nutrients, increasing the flow of water to promote mixing and destratify the water column (Figure 3.1). In the following sections, we will focus on the conditions that are favorable for the growth of the cyanoHAB genera.

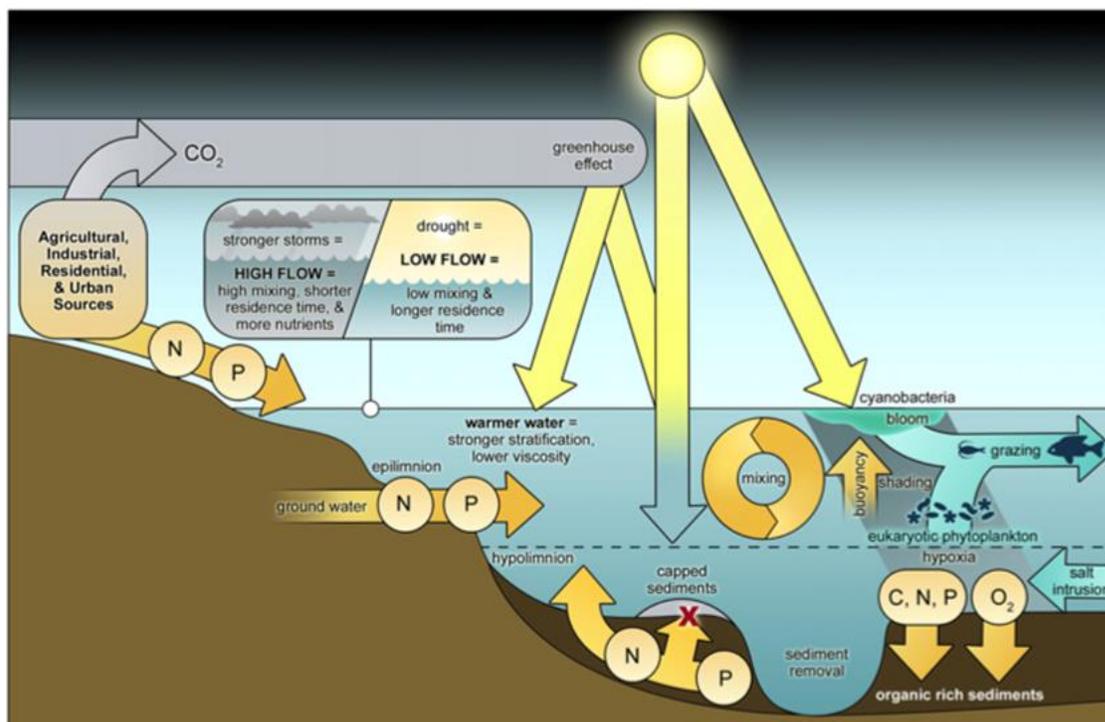

Figure 3.1. Conceptual model of factors affecting cyanobacteria blooms including warmer water, drought and decreased flow, decreased mixing, increased residence time, and increased N and P inputs from agricultural, industrial and urban sources. From Paerl *et al.* 2011.

3.1 Salinity

Most harmful algal bloom-forming and toxin-producing cyanobacteria (cyanoHABs) are freshwater species. In contrast, marine cyanobacteria such as *Prochlorococcus*, *Synechococcus* sp. and *Trichodesmium* sp. are not toxic and do not form cyanoHABs. However, laboratory investigations of freshwater cyanoHAB species demonstrate that these have quite wide salinity

tolerance ranges. For example, the least tolerant, *Cylindrospermopsis* only thrives up to 2.5 ppt salinity, but the most tolerant, *Anabaenopsis* and *Nodularia* spp., thrive at salinities from 5-20 ppt (Moisander *et al.* 2002). *Microcystis aeruginosa* tolerates up to 10 ppt salinity without a change in its growth rate compared to that on freshwater (Tonk *et al.* 2007). What these studies suggest is that given optimal growth conditions, these species could also bloom in brackish-water regions. Indeed, recent decades have witnessed a spread in the geographical extent of these species into the mesohaline (5-15 ppt) reaches of coastal systems (Paerl and Paul 2012). For example, blooms of *Microcystis aeruginosa* have occurred in the Baltic Sea (Maestrini *et al.* 1999) and the San Francisco Estuary (Lehman *et al.* 2013) suggesting 1) that factors other than salinity are regulating their geographical distribution and that 2) those factors are currently changing to allow cyanoHAB growth to occur in regions where they previously did not exist. In summary, salinity may not be the strongest “barrier” in terms of restricting the occurrence and geographical distribution of toxic cyanoHABs.

3.2 Nutrient Concentrations and Ratios

As with other photosynthetic phytoplankton, given optimal temperatures and irradiance, cyanobacterial biomass accumulation is directly proportional to the amount of nutrients (N and P) available in the water column. Therefore, strategies to reduce the accumulation of cyanoHAB biomass and severity of their blooms frequently focus on reductions of nutrient concentrations (Paerl 2008).

3.2.1 Influence of N and P Loadings and Concentrations in Stimulating Cyanobacterial Growth

Cyanobacterial growth in freshwater systems (rivers and lakes), which tend to become limited by P sooner than by N, is frequently linked with excessive P loading (Likens 1972, Schindler 1977, Edmondson and Lehman 1981, Elmgren and Larsson 2001, Paerl 2008, Schindler *et al.* 2008). In contrast with freshwater systems, estuarine and marine systems tend to be more sensitive to N loading (Figure 3.2), and eutrophication due to cyanobacterial growth is frequently linked with excessive N loading (Ryther and Dunstan 1971, Nixon 1986, Suikkanen *et al.* 2007, Paerl 2008, Conley *et al.* 2009, Ahn *et al.* 2011).

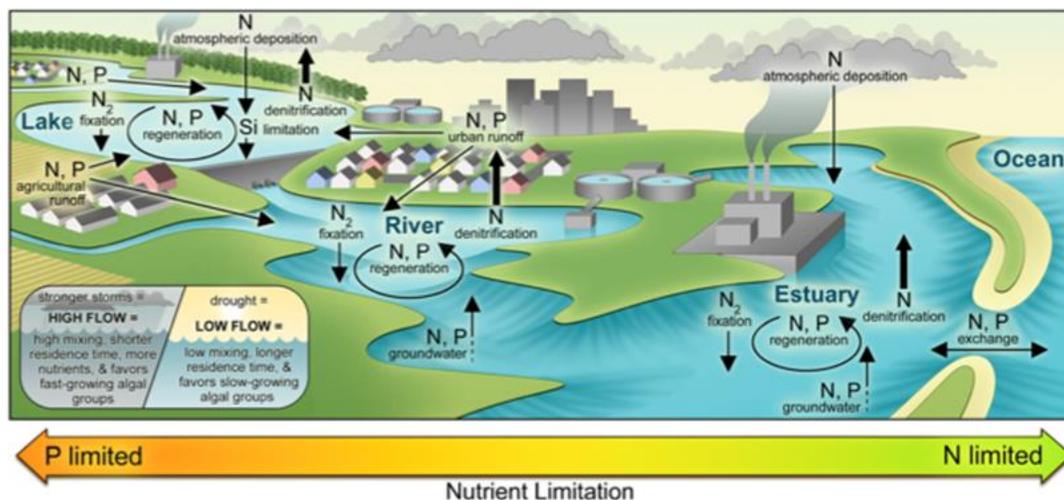

Figure 3.2. Conceptual diagram of interaction of nutrient inputs, cycling processes, and limitation of primary production along the freshwater to marine continuum. From Pearl *et al.* 2014b.

However, both non-point and point source nutrient contributions, such as agriculture and wastewater effluent, tend to increase N and P concentrations simultaneously (Paerl and Paul 2012, Paerl *et al.* 2014b). For example, human population growth-induced intensification of wastewater discharge and agriculture has led to hypereutrophication of China's third largest lake, Taihu (Qin *et al.* 2007). Increased nutrient loads, combined with low water column depth and increased water temperatures, has led to an explosive growth of cyanobacteria and a change in total phytoplankton community composition from being mainly diatom-dominated to being dominated by *Microcystis aeruginosa* (Qin *et al.* 2010, Paerl *et al.* 2014a). Bioassay experiments during summer months when cyanobacterial biomass is at its maximum, and nutrient concentrations at a minimum, demonstrate that N and P exert equal control over biomass accumulation in this system (Paerl *et al.* 2014a).

In general, dominance of both N₂-fixing and non-N₂ fixing cyanobacteria such as *Aphenizomenon flos aquae*, *Nodularia spumigena*, *Microcystis aeruginosa* and *Cylindrospermopsis raciborskii*, have increased world-wide in concert with increased loads of both N and P (Chapman and Schelske 1997, Jacoby *et al.* 2000, Gobler *et al.* 2007, Burford *et al.* 2006, Burford and O'Donahue 2006, Hong *et al.* 2006, Suikkanen *et al.* 2007, O'Neill *et al.* 2012).

3.2.2 Influence of Changes in N:P Ratios on Stimulation or Limitation of Cyanobacterial Growth

At low and intermediate nutrient loadings, reduction in only N or P may be sufficient to control blooms of cyanobacteria. But with elevated loadings of both N and P, reduction of only one type of nutrient can lead to an imbalance in the N:P ratio of the water column potentially leading to a

worsening of the cyanoHAB problem, or even lead to a eukaryotic HAB problem (Smith 1983; Paerl 2008; Pearl *et al.* 2011, 2014b).

Low nutrient concentrations

Pioneering studies by Smith (1983, 1990) predicted that phytoplankton community composition would be dominated by cyanobacteria when N:P ratios were < 15 , and by eukaryotic phytoplankton when N:P ratios > 20 . This was because many nuisance freshwater cyanobacteria that fix N_2 were hypothesized to thrive at very low ambient concentrations of fixed N, therefore at N:P < 15 . In comparison, growth rates of eukaryotic phytoplankton that could not fix N_2 were predicted to slow down at N-limiting concentrations, resulting in eukaryotic species becoming outcompeted at N:P < 15 . At N:P > 20 , growth rates of eukaryotic phytoplankton would not be limited by N and therefore they could dominate phytoplankton community composition (Smith 1983, 1990). These predictions suggested that one could control growth of cyanobacteria by increasing the dissolved N:P ratio above 20. Consequently, many investigators who study lakes with low to intermediate nutrient loadings advocate for reductions in “P only” as a way to control cyanobacterial growth (Schindler 1977, Schindler *et al.* 2008). However, increasing the dissolved N:P ratio > 15 becomes less important as a way to control cyanobacterial growth at high concentrations of nutrients, for a number of reasons, including: 1) nutrient concentrations are high relative to biomass and non-limiting; 2) the prevalence of N_2 fixation in N_2 -fixing cyanobacteria is not as great as initially hypothesized; 3) the cellular N:P ratio of cyanobacteria, and their N requirement, is high; 4) analysis of lake data by several investigators have demonstrated that absolute concentrations of N and P are more important in supporting blooms of N_2 fixing cyanobacteria rather than specific ratios of dissolved N:P.

High and non-limiting nutrient concentrations

In order for changes in nutrient ratios to affect phytoplankton growth, nutrient concentrations must be so low (relative to the phytoplankton biomass) that either P or N will eventually limit their growth rates. In the last decades, both N and P loadings have increased to the point that they exceed the assimilative capacity of the resident phytoplankton in many systems (Chapman and Schelske 1997, Jacoby *et al.* 2000, Burford *et al.* 2006, Burford and O’Donahue 2006, Hong *et al.* 2006, Gobler *et al.* 2007, Suikkanen *et al.* 2007, Paerl 2008, Paerl *et al.* 2011, Dolman *et al.* 2012, O’Neill *et al.* 2012, Paerl and Paul 2012, Paerl *et al.* 2014a). Therefore, changes in the N:P ratio have little effect on the growth of any of the phytoplankton taxa present in the water column (Paerl 2008, Davidson *et al.* 2012, but see also Glibert *et al.* 2011 with respect to diatoms).

Prevalence of N_2 fixation

An assumption that must be met in order that N_2 fixing cyanobacteria dominate the community at low N:P ratios (and N limiting conditions) is that they mostly use N_2 gas rather than fixed N for growth. However, investigations demonstrate that the proportion of the N demand of N_2

fixers that is met by N₂-fixation is typically less than 25% (Levine and Lewis 1987, Findlay *et al.* 1994, Laamanen and Kuosa 2005). For example, in Baltic Sea phytoplankton communities dominated by the N₂ fixers *Aphanizomenon flos aquae* and *Nodularia spumigena*, less than 20% of N utilization is due to N₂ fixation under N-limiting conditions (Sorensen and Sahlsten 1987; Berg *et al.* 2001, 2003; Laamanen and Kuosa 2005). As mentioned in section 2.2.4, N₂ fixation is repressed in the presence of NH₄⁺; culture studies of the N₂ fixing cyanobacterium *Cylindrospermopsis raciborskii* demonstrate that N₂ fixation is shut down in the presence of NH₄⁺ and that it's competitive for fixed N (Sprosser *et al.* 2003, Moisander *et al.* 2008). Based on a wide range of investigations, the assumption that most of the N demand of cyanobacteria is met by N₂ fixation does not hold.

Cellular N:P composition

As discussed above (Section 2.2.5), the cellular N:P requirement of cyanobacteria is greater than any other eukaryotic group due to the large protein demand of the peripheral light harvesting antennae. At N-limiting conditions, cyanobacteria would need to provide most, if not all, of their N demand by N₂ fixation in order to meet their high tissue N demand. This would lead to a sharp divide in the distribution of genera that fix N₂ from those that do not; the latter group would be much better suited to dominate high N:P ratio (>25) than low N:P ratio environments. On the flip side, many genera of eukaryotic phytoplankton, such as diatoms and dinoflagellates, have relatively high tissue P requirements and have cellular N:P ratios <16 (Geider and LaRoche 2002, Quigg *et al.* 2003, Hillebrand *et al.* 2013) rendering them better suited for environments with N:P <16 (Arrigo *et al.* 1999, Mills and Arrigo 2010). Based on their cellular N:P ratios, cyanobacteria are better suited to dominate high N:P ratio systems (>25) and some eukaryotes low N:P ratio systems (<16) which is opposite of the conclusions reached by Smith (1983).

Confounding factors

Because the height of a phytoplankton bloom, including blooms of N₂ fixers, frequently coincides with a depletion in N and N:P <15, it is often assumed that the major control on the cyanobacteria is the nutrient ratio, rather than the other way around. Additionally, there may be time lags between nutrient uptake and increased biomass such that a correlation between the two variables at a given point in time may not imply causality. Blooms of N₂ fixers also coincide with a warm, stratified water column coupled with adequate or high irradiance. Because all these parameters (warm water, high irradiance, stratification, depletion of N, overall increase in Chl *a*) occur in concert, it's difficult to separate out the impact of nutrients from other co-occurring environmental variables in order to quantify the most important effect on increases in cyanobacterial biomass. Investigations that separate out the effect of changes in absolute concentrations from ratios, find that changes in absolute concentrations of nutrients, or changes in total Chl *a* biomass, are more strongly related to changes in cyanobacterial biomass than changes in the ratio of N:P (Trimbee and Prepas 1987, Downing *et al.* 2001, Dolman *et al.* 2012).

Meta analyses of Lake Studies

Consistent with the problems of assigning shifts in phytoplankton community composition to changes in N:P ratios described above, Trimbee and Prepas (1987) and Downing *et al.* (2001) demonstrated that changes in cyanobacterial biomass was more strongly associated with changes in the absolute concentrations of N and P than with changes in the dissolved N:P ratio in 99 different freshwater systems. In a study of 102 lakes in Germany, Dolman *et al.* (2012) found that the more enriched in both N and P the lakes were, the greater was their total cyanobacterial biomass. The cyanobacterial taxa that responded most to nutrient enrichment included *Planktothrix agardhii*, *Microcystis* and *Anabaenopsis*. Moreover, differences between cyanobacterial taxa were not consistent with the hypothesis that N fixing taxa were favored in low N:P conditions as the greatest biomass of *Aphaenizomenon* and *Cylindrospermopsis raciborskii* were found lakes with the greatest N:P ratios (Dolman *et al.* 2012).

3.2.3 Influence of Type of N on Growth of Cyanobacteria

As previously mentioned, NtcA is central in cyanobacterial N regulation and is under negative control by NH_4^+ (Section 2.2.4). Other than NH_4^+ -transporters, transcription of all N related enzymes requires binding of the NtcA transcription factor in order to be transcribed. Therefore, uptake and metabolism of sources other than NH_4^+ does not take place unless NH_4^+ is at limiting concentrations (Lindell and Post 2001, Lindell *et al.* 2005). In contrast, NH_4^+ transporters are constitutively expressed, or always “on”, regardless of external concentration of NH_4^+ (Berg *et al.* 2011). In addition, the *amt1* NH_4^+ transporter gene is one of the most highly expressed in cyanobacterial genomes. In the marine cyanobacteria *Synechococcus* and *Prochlorococcus*, *amt1* is expressed on par with, or at a greater level, respectively, than the gene encoding the C-fixation enzyme Rubisco (Berg *et al.* 2011). Considering the countless other critical processes happening within cells, it is noteworthy that the protein responsible for NH_4^+ uptake is one of the most abundant proteins in cyanobacteria.

Given that NH_4^+ exerts such a strong control over the use of other N sources in cyanobacteria, is the preference for NH_4^+ reflected in different rates of growth on different N sources? There is no clear answer to this question. From a theoretical perspective it should not be the case because the magnitude of reductant and ATP needed for carbon fixation dwarfs the energetic costs of N assimilation, even assimilation of “expensive” sources such as NO_3^- or N_2 gas (Turpin 1991). The type of N should not affect the rate of growth other than under conditions of very low irradiance where assimilation of NO_3^- may compete with carbon fixation for reductant and ATP, thereby lowering the growth rate (Turpin 1991). Culture investigations appear to bear this out as faster rates of growth are typically not observed when cyanobacteria are grown on NH_4^+ versus NO_3^- (i.e. Berman and Chava 1999, Hawkins *et al.* 2001, Post *et al.* 2012, Saker and Neilan 2001, Solomon *et al.* 2010). Differences in growth rates when growing on NO_3^- versus on NH_4^+ are frequently detected for individual strains (i.e. Saker and Neilan 2001), but there is no pattern that can be generalized with respect to cyanobacteria as a whole. Even within the same species,

some strains may be growing faster on NH_4^+ and some on NO_3^- , but the difference with N source in most cases is smaller than the difference in growth rate among different strains (Figure 3.3). Therefore, observations of fast growth of cyanobacteria using NH_4^+ in the field are most likely due to 1) factors that promote fast growth of cyanobacteria generally (i.e. high temperature and high irradiance) combined with 2) high enough availability of NH_4^+ such that NtcA is repressed and only NH_4^+ is taken up and utilized by the cell.

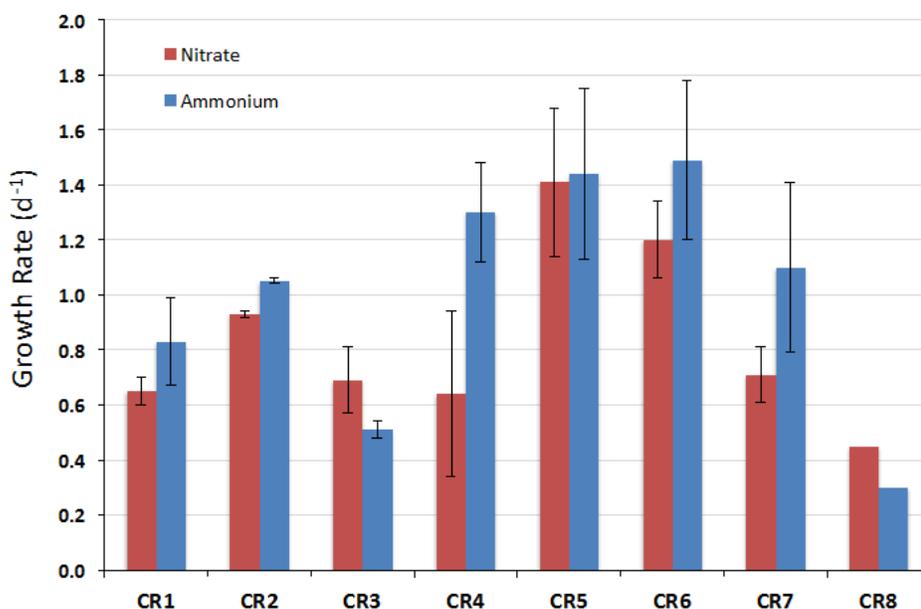

Figure 3.3. Difference in growth rates of *Cylindrospermopsis raciborskii* when growth on NO_3^- (red bars) versus NH_4^+ (blue bars) for eight different strains. Data from Saker and Neilan 2001 and Stucken *et al.* 2014.

3.3 Irradiance and Water Clarity

Cyanobacteria have a distinct advantage with respect to other photosynthetic organisms in the amount of carotenoid pigments per cell volume (Section 2.2.2). These pigments serve a photoprotective function by dissipating excess light energy when required allowing cyanobacteria to be exposed to high irradiances without experiencing photoinhibition (Paerl *et al.* 1983, 1985). Recent investigations also demonstrate that the toxic peptides produced by cyanoHAB species accumulate in the thylakoid membranes potentially serving a role in photoprotection of the cells (Kaebernick *et al.* 2000, Borner and Dittman 2005, Gerbersdorf 2006). Interestingly, many cyanoHAB species are not strong competitors for light in a well-mixed environment due to their poor light absorption efficiency (Huisman *et al.* 1999, Reynolds 2006). Among the cyanoHAB species tested to date, *Microcystis* appears to possess the least efficient rate of photosynthesis for a given light intensity (Figure 3.4). The upshot of these traits

is that cyanobacteria grow ineffectively at low and mixed light, but very effectively when exposed to high light, particularly the toxic peptide-producing varieties (Huisman *et al.* 2004, Reynolds 2006, Carey *et al.* 2012).

Aided by their positive buoyancy, cyanobacteria such as *Microcystis*, can grow very close to the surface by tolerating irradiance levels that are inhibitory to other members of the phytoplankton community. As a result, these cyanobacteria can increase their cell densities past the point where they would ordinarily become light-limited by self-shading. Growing close to the surface can also help cyanobacteria avoid light limitation if there is a high concentration of suspended sediment matter in the water. In contrast, phytoplankton that are not positively buoyant can become shaded by the cyanobacteria growing at the surface (Carey *et al.* 2012).

In contrast with *Microcystis* and *Aphanizomenon*, other cyanoHAB species such as *Cylindrospermopsis raciborskii* and *Planktothrix* sp. are good competitors at low light. Cultures of *C. Raciborskii* can grow at optimal rates at very low irradiances (Briand *et al.* 2004, Dyble *et al.* 2006, Wu *et al.* 2009) and it grows well in deep water columns where it's exposed to fluctuating light levels as it mixes from the surface to the bottom (McGregor and Fabbro 2000, Burford and Donohue 2006, O'Brien *et al.* 2009). Not only is the rate of photosynthesis in *C. raciborskii* efficient at low irradiances, it's also efficient at high irradiances, making this a very versatile cyanoHAB species (Figure 3.4).

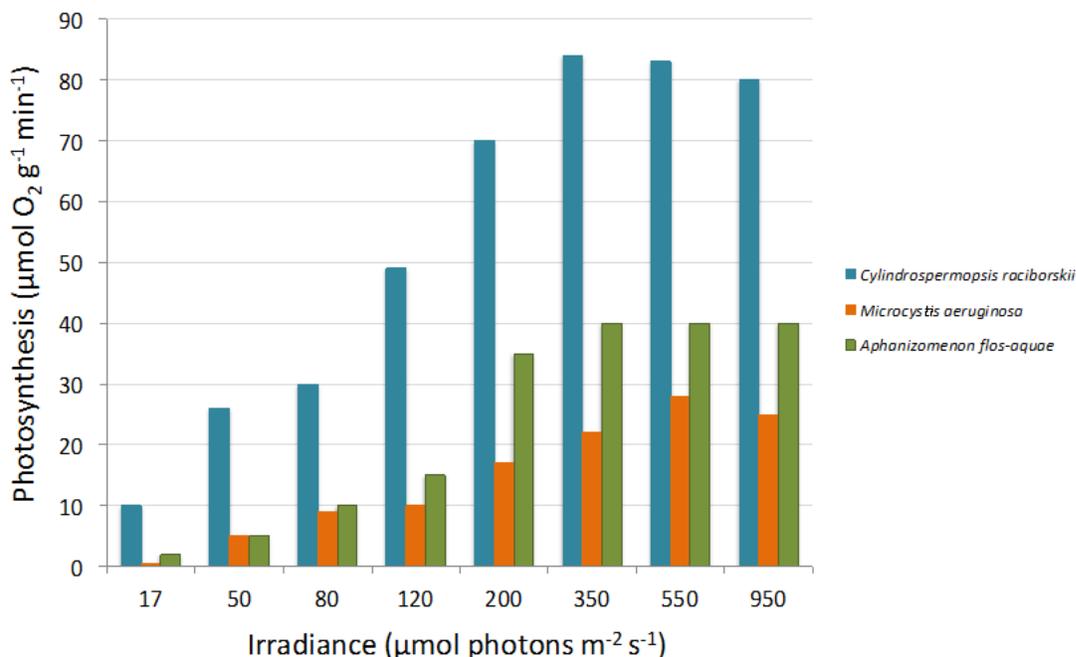

Figure 3.4. Photosynthesis as a function of irradiance in three cyanoHAB species. Data from Wu *et al.* 2009.

3.4 Factors Impacting Toxin Production and Degradation

While a large number of different toxins are produced by cyanoHAB species, the literature is heavily tilted towards investigations of factors impacting the production and degradation of microcystins. Therefore the information presented here is focused on microcystin-LR.

3.4.1 Toxin Production

Just as there is substantial discussion surrounding the purpose of toxin production in cyanobacteria, the conditions under which toxin production is enhanced is also vigorously debated. Previous studies have concluded that the greatest intracellular toxin concentrations are detected under favorable growth conditions, including high irradiance as discussed above, with maximal toxin production occurring at maximal rates of cell division and in late log phase (Watanabe and Oishi 1985, Orr and Jones 1998, Sivonen and Jones 1999, Van Der Westhuizen and Eloff 1985).

Investigations specifically focused on changes in nutrient concentrations and ratios, demonstrate that microcystin content reaches a maximum under maximum growth rates, regardless of medium N:P ratio, but that the microcystin content of the cells correlates with total cellular N and protein content (Lee *et al.* 2000, Vezie *et al.* 2002, Downing *et al.* 2005). These results make sense as the toxins, being peptides, require ample N in order to be synthesized. Consistent with this, total toxin production per cell decreases at N-limiting concentrations (Tonk *et al.* 2008).

Not only does toxin concentration per cell vary in strains that produce toxins (i.e. are toxigenic), but natural populations are typically comprised of a mix of toxigenic and non-toxigenic strains of the same species. It is also of interest to know whether the proportion of toxigenic:non-toxigenic strains within a population changes with nutrient concentrations or ratios. Laboratory culture investigations comparing growth of toxigenic and non-toxigenic strains of *Microcystis* demonstrated that toxigenic strains of *Microcystis* grew faster than non-toxigenic strains at N concentrations of 6000 $\mu\text{moles L}^{-1}$ and at N:P ratios $\gg 200$ (Vezie *et al.* 2002). The reason for this is not clear, but could include microcystin conferring protection from NO_3^- toxicity in the toxin-producing strains at such unnaturally high concentrations of NO_3^- .

While results obtained with unnaturally high nutrient concentrations and ratios do not easily translate to natural systems, a nutrient enrichment bioassay investigation has demonstrated that toxigenic strains within a *Microcystis* population were promoted to a greater degree with N (and P) additions than non-toxigenic strains (Davis *et al.* 2010). However, the pattern of selective stimulation of toxigenic strains with increased nutrient concentrations is not evident in natural communities which typically exhibit a high degree of variability across small spatial scales in the proportion of toxigenic:non-toxigenic strains within a population. This variability appears not to be related to nutrient concentrations or ratios which do not exhibit the same spatial variability (Vezie *et al.* 1998, Baxa *et al.* 2010, Mbedi *et al.* 2005, Dolman *et al.* 2012).

3.4.2 Toxin Degradation

Together with labile dissolved organic carbon, toxins are rapidly degraded by the natural microbial community following sedimentation (and subsequent release of cellular material) of a cyanobacterial bloom (Jones *et al.* 1994, Rapala *et al.* 2005). In addition to non-specific degradation by the whole community, specific degradation of toxin peptides occurs due to bacteria belonging to the *Sphingomonadaceae* family (Bourne *et al.* 1996, 2001), and other more recently discovered families (Rapala *et al.* 2005, Yang *et al.* 2014). Bacteria that degrade microcystins may also degrade nodularin (Rapala *et al.* 2005). The predominance of these specialized bacteria in the microbial community may determine the length of time it takes (i.e. lag period) before bacterial degradation of toxins takes place. For example, Rapala *et al.* (1994) found the lag time decreased in waters with previous cyanobacterial blooms, compared with no previous cyanobacterial blooms, presumably due to a greater proportion of toxin-degradating bacteria in the former environment. Once degradation of toxin commences, it proceeds rapidly and toxin concentrations typically decrease in an exponential fashion (Figure 3.5), with a loss rate of 0.5 to 1 d⁻¹, corresponding to a half-life of only one day (Christoffersen *et al.* 2002, Jones and Orr 1994). While 95% of the toxins may be degraded within the first 3 days, a more recalcitrant fraction may remain for 20 days or more (Jones and Orr 1994). Other sinks for microcystin-LR include UV degradation (Tsuji *et al.* 1995), and adsorption onto clay particles (Morris *et al.* 2000). In the absence of bacteria, clay particles and UV light, microcystins are very stable in the environment and degrade slowly. At temperatures below 40°C the half-life of microcystin toxin increases to 10 weeks; this conservative estimate is used by the Office of Environmental Health Hazard Assessment to determine the risk of the toxin to wildlife (OEHHA 2009). Because there probably exists a great deal of variation in the relative importance of biological, chemical and physical processes in the degradation of microcystins depending on location, accounts in the literature regarding the half-life and recalcitrance of cyanoHAB toxins tend to be conflicting (i.e. Jones and Orr 1994, Gible and Kudela 2014). Added to this uncertainty is the difference in toxin concentrations obtained using different methods of measurements (See Section 4.2.3 below).

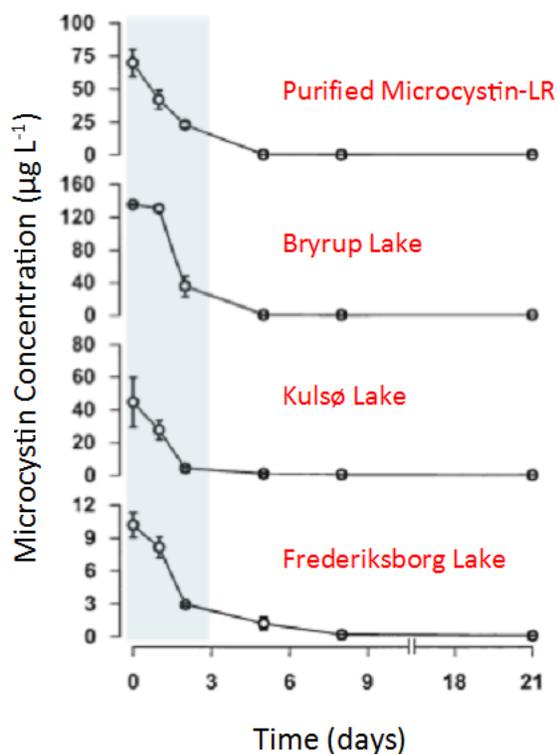

Figure 3.5. Concentration of dissolved microcystin-LR equivalents in bioassays as a function of time after addition of purified microcystin (top panel) or lysed bloom material (bottom 3 panels) to lake water containing natural microbial assemblages. Shaded area corresponds with time period of degradation of 95% of original microcystin concentration. Data from Christoffersen *et al.* 2002.

3.5 Temperature

Perhaps one of the most important factors in controlling the growth rate of cyanobacteria is temperature (Robarts and Zohary 1987, Butterwick *et al.* 2005, Reynolds 2006, Paerl and Huisman 2008). Cyanobacteria isolated from temperate latitudes (i.e. excluding polar regions) typically have temperature growth optima between 25 and 35°C (Reynolds 2006, Lurling *et al.* 2013). For example, in a survey of eight cyanobacteria the growth optima of two *Microcystis aeruginosa* strains were 30-32.5°C and that of *Aphanizomenon gracile* was 32.5°C. Lower growth temperature optima were observed in *Cylindrospermopsis raciborskii* and *Planktothrix agardhii*, both at 27.5°C while *Anabaena* sp had an optimum of 25°C (Lurling *et al.* 2013). The optima of these freshwater HAB-forming cyanobacteria are greater than for marine cyanobacteria which typically have growth temperature optima ranging from 20-27.5°C (Breitbarth *et al.* 2007, Boyd *et al.* 2013).

Compared with other phytoplankton taxa, cyanobacteria typically demonstrate lower growth rates at colder temperatures and higher growth rates at higher temperatures. For example, diatoms typically have a 6-fold higher growth rate at 15°C, 3-fold higher growth rate at 20°C and

a similar growth rate at 25°C, compared with cyanobacteria (Figure 3.6). Growth rates of dinoflagellates typically peak at 25°C. Above 25°C both chlorophytes and cyanobacteria have faster growth rates than diatoms and dinoflagellates (Figure 3.6). The difference in the optimum growth temperatures of the various phytoplankton taxa is hypothesized to become increasingly important in determining phytoplankton community composition as global temperatures continue to increase above 20°C (Lehman *et al.* 2005, Paerl and Huisman 2008). For example, the acceleration of growth rate with a 10°C increase in temperature (Q_{10}) commonly varies from 1-4 for cyanobacteria and 1-3 for chlorophytes (Reynolds 2006). However, it varies from 4-9 for *M. aeruginosa*, the highest recorded for any phytoplankton (prokaryotic or eukaryotic) species (Reynolds 2006). These data suggest that in a mixed phytoplankton assemblage, all else being equal, cyanobacteria will be able to grow faster and outcompete other phytoplankton taxa as the temperature increases. With continued climate change and global warming, there's an increased risk that cyanoHABs will become increasingly competitive vis-à-vis diatoms which often dominate community composition in temperate regions.

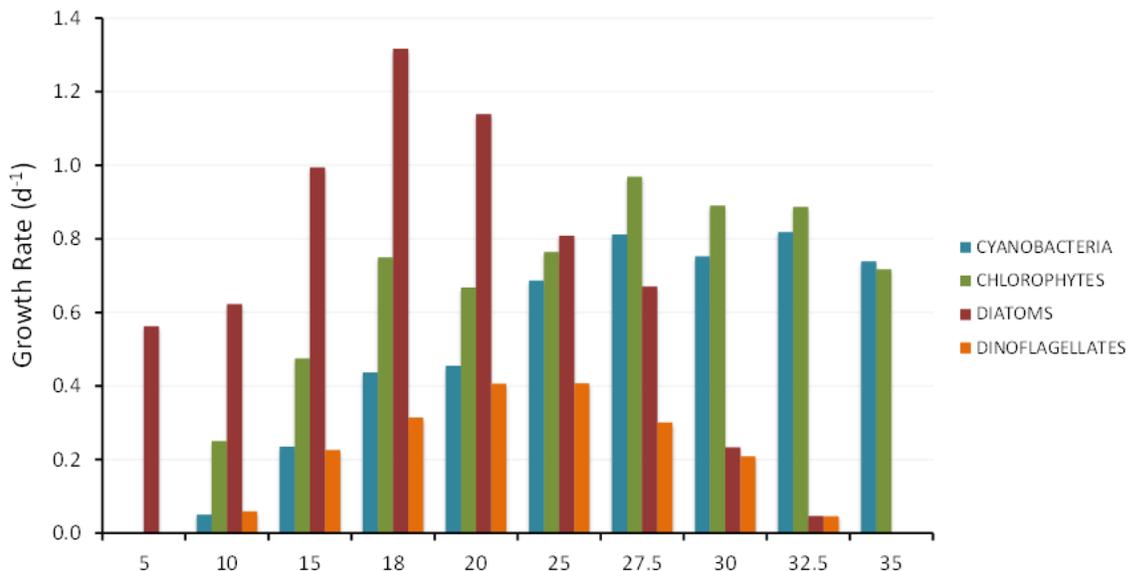

Figure 3.6. Changes in growth rate with temperature for diatoms (red ± 0.35 d⁻¹, $T_{opt}= 20 \pm 1.8$ °C), Chlorophytes (green ± 0.21 d⁻¹, $T_{opt}= 29 \pm 3.8$), Cyanobacteria (cyan ± 0.13 d⁻¹, $T_{opt}=29 \pm 4.5$) and dinoflagellates (orange ± 0.1 d⁻¹, $T_{opt}= 21 \pm 2.8$). Data from Kudo *et al.* 2000, Butterwick *et al.* 2005, Yamamoto and Nakahara 2005, Boyd *et al.* 2013, Lurling *et al.* 2013.

3.6 Stratification and Residence Time

3.6.1 Stratification

CyanoHAB blooms tend to occur during times of calm, stratified water columns (Huber *et al.* 2012). The degree of stratification and water column stability increases with increased temperature, therefore stratification and temperature are closely linked (Paerl and Huisman

2008). The reasons that stratified conditions promote blooms of cyanobacteria are at least three-fold. First, growth rates will increase as a result of the increase in the temperature in the top layer of the water column. Second, cyanobacteria will remain in the top layer of the water column where irradiance is greater, and not become mixed down to the bottom and into lower light, allowing them to maintain higher growth rates. Third, stratification may be a sign of increased residence times (reduced flushing rates), which minimizes loss of cyanobacterial biomass from the system and allows cyanobacteria to use all the nutrients available in the water column (Jeppesen *et al.* 2007). In other words, it's likely that stratification does not directly promote cyanobacterial blooms, but rather it promotes blooms indirectly through increased temperatures, irradiance and reduced loss rates (Elliott 2010).

3.6.2 Residence Time

Because residence time is determined by the flushing rate, the direct effect of increased residence time is to decrease the loss rate of cyanobacteria (Romo *et al.* 2013). Indirect effects of residence time are the same as those for stratification; this is because residence time and stratification typically covary such that stratification is maximal when residence time is minimal, and vice versa. Studies that report on the effect of residence time suggest that cyanobacterial abundance, cell size and toxin concentration are positively related to increased residence time (Elliott 2010, Romo *et al.* 2013).

3.7 Other Factors

Additional to the above-mentioned factors, a number of others may influence cyanobacterial blooms including grazing by higher trophic levels and exposure to toxic compounds such as herbicides and pesticides. Grazing in the Delta region is dominated by *Corbicula fluminea* (Jassby 2008). It is not known to what extent *C. fluminea* impacts cyanoHAB species versus the rest of the phytoplankton community in the Delta. The same is true for grazing by zooplankton. Another factor that may differentially impact cyanoHAB species versus the rest of the phytoplankton community is resistance to herbicides and pesticides. Investigations demonstrate substantial variability in sensitivity to herbicides of cyanobacteria compared with other phytoplankton such as green algae and diatoms (Peterson *et al.* 1997, Lurling and Roessink 2006)

4. PREVALENCE OF CYANOHABS AND POTENTIAL FOR EFFECTS ON ECOSYSTEM SERVICES IN THE DELTA

The Sacramento-San Joaquin Delta (hereafter Delta) is formed at the intersection of two of California's largest rivers, the Sacramento and the San Joaquin Rivers, and contains 700 miles of sloughs and waterways that drain 47% of the runoff in the State of California (Figure 1.1). The land surrounding the waterways is composed of 57 leveed island tracts, many of which provide wildlife habitat. In the Delta, freshwater from the rivers mix with saltwater from the San Francisco Bay; together the Bay and the Delta form the West Coast's largest estuary.

4.1 Ecosystem Services

The Delta region has many ecosystem services including agriculture, drinking water supplies, and wildlife habitat, all of which translate directly to the beneficial uses designated in the Water Board Basin Plan (Appendix A). The population surrounding the Delta region, numbering 500,000 people, is principally engaged in agriculture and produce crops that bring in revenues exceeding \$500 million annually. While there is some local demand on the water from the Delta, most of the water is distributed via the State Water Project and Federal Central Valley Projects to the Central Valley to irrigate farmland and to provide drinking water to Southern California (<http://www.water.ca.gov/swp/delta.cfm>). According to the California Department of Water Resources, about two thirds of Californians and millions of acres of irrigated farmland rely on the Delta for their water. Besides acting as a source of drinking water, the Delta is a popular recreation spot and many people use it for sport fishing.

In addition to the human demand, the Delta supplies critical habitat to a large wildlife ecosystem and intersects migration paths for several fish species, including salmon, traveling between the Pacific Ocean and the Sacramento River and beyond. This habitat is in a fragile state with close to 20 of its endemic species listed as endangered. A recent and unexpected decline in four pelagic fish species including the endangered Delta Smelt and the Longfin Smelt, as well as juvenile-Striped Bass and Threadfin Shad, has caused concern among resource managers and renewed calls for conservation of the fragile Delta ecosystem (Sommer *et al.* 2007).

Set against this backdrop of competing resource use by human populations and wildlife, a new threat to Delta ecosystem services and designated beneficial uses is emerging in the form of toxic cyanoHABs. The impact of toxic cyanobacteria on the aquatic ecosystem differs widely depending on whether their density is low or high. At low concentrations, they are not dense enough to affect light penetration or dissolved O₂ concentration; therefore, they do not affect the growth of other members of the aquatic community. However, even at low concentrations toxins released (upon death and cell lysis, or by grazing) can accumulate in tissues of higher trophic levels (Lehman *et al.* 2010). At high densities, cyanoHABs increase the turbidity of the water column to the point where light penetration is severely restricted suppressing the growth of other

phytoplankton, macrophytes, and benthic microalgae (Jeppesen *et al.* 2007, Paerl and Paul 2012). CyanoHABs also can cause night-time dissolved oxygen depletion via bacterial decomposition and respiration of dense blooms which results in fish kills and loss of benthic fauna (Paerl 2004, Paerl and Fulton 2006). At dense concentrations, mortality to aquatic animals such as sea otters, birds and seals may result from liver failure following ingestion of prey with high concentrations of toxin, or coming into physical contact with the toxin (Jessup *et al.* 2009, Miller *et al.* 2010). Humans coming in contact with the water may develop digestive and skin diseases (Section 2.2.6) and it may affect the drinking water supplies (Cheung *et al.* 2013). In the following sections, cyanoHAB abundance and toxin levels in the Delta vis-à-vis published guidance on alert levels are summarized in order to place the threat of cyanoHABs in the Delta into context.

4.2 Prevalence and Trends of CyanoHABs in the Delta

Since 1999 blooms of the toxin producing cyanobacteria *Microcystis aeruginosa* in the Delta have been observed by the Department of Water Resources (DWR), and have been reported in the scientific literature. In the beginning, only blooms of *Microcystis* were observed; these were documented visually appearing as little flakes of lettuce in the water (Lehman and Waller 2003). Later investigations (post 2005) employing microscopic enumeration and molecular characterizations have documented blooms comprised of a mix of *Aphanizomenon* sp. and *Microcystis*, with *Anabaena* sp. also present in much smaller densities (Lehman *et al.* 2010, Mioni *et al.* 2012).

While environmental indicators such as salinity, turbidity, temperature, total phytoplankton biomass (as Chl *a*), and phytoplankton species composition are monitored on a monthly basis by DWR, surface concentrations of cyanobacteria and cyanotoxins, which require special sampling, are not routinely monitored. As such, the information on the chronology of cyanoHAB occurrences presented here is taken from a handful of publications and reports, and varies somewhat in geographical extent according to where the authors sampled. Because *Aphanizomenon* and *Anabaena* densities have only been documented for two time points, the following sections will focus on *Microcystis* biomass and microcystin toxin concentrations. Additionally, these sections will focus on aquatic health rather than human health whose risks may be better evaluated from sampling of surface scums.

4.2.1 Spatial Distribution of *Microcystis* throughout the Delta

The Central Delta, between Antioch and Mildred Island, is typically the region with the highest surface *Microcystis* and *Aphanizomenon* concentrations. In 2003, the stations with the greatest recorded abundance of Chl *a* due to *Microcystis* (as determined by horizontal surface tows with a 75- μ m mesh plankton net) were Jersey Point (D16), Mokelumne River Mouth and Navigation Marker 13 in the San Joaquin River, followed by San Mound Slough, Mildred Island, (D29) and Rancho del Rio (D28) in Old River (Figure 4.1). In following years, greatest abundance of

Microcystis has repeatedly occurred in the same areas in the San Joaquin and Old Rivers (Lehman *et al.* 2008, Mioni *et al.* 2012, Lehman *et al.* 2013). In 2012, abundant *Microcystis* colonies were also observed in the South-East Delta region in the Turning Basin of the Stockton Shipping Channel (Spier *et al.* 2013). Moving west from Antioch into Suisun Bay, *Microcystis* abundance decreases substantially to almost non-detectable by Chipps Island (Lehman *et al.* 2005, 2008, 2010). The same holds true when moving north where abundances detected at Antioch decline to almost zero by Collinsville at the entrance of the Sacramento River (Figure 4.1).

Whether or not the spatial distribution of *Microcystis* and other cyanoHAB species is affected favorably or unfavorably by concentrations of herbicides entering the Delta as run-off, or from the Sacramento and San Joaquin Rivers is not known. Recent reports suggest that a broad swath of herbicides and fungicides associated with agriculture is present at concentrations high enough to affect aquatic life (Orlando *et al.* 2014). As such, the impact of herbicides common to the Delta in selectively promoting certain phytoplankton species, including possibly cyanoHAB species, may deserve greater attention.

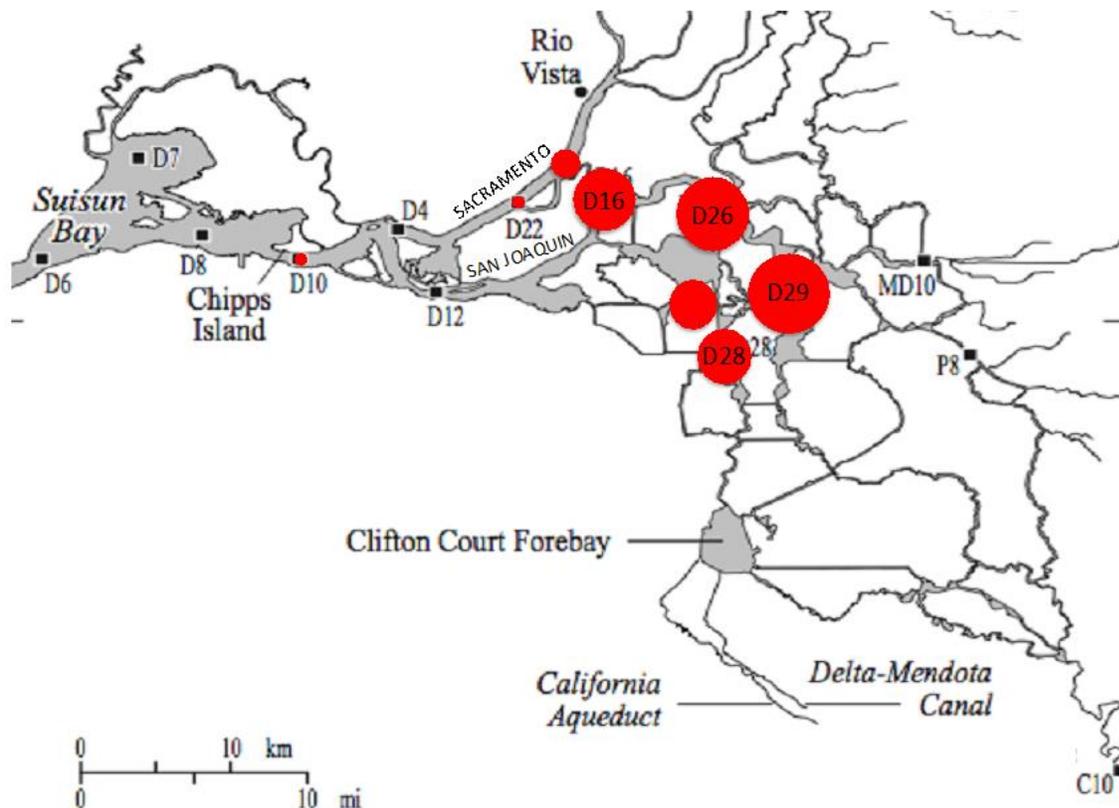

Figure 4.1. The Sacramento-San Joaquin Delta Region. Red bubbles mark locations with greatest *Microcystis*-associated surface Chl a concentrations (largest bubble= $0.55 \mu\text{g Chl a L}^{-1}$). Data from Lehman *et al.* 2005.

4.2.2 Interannual variability in *Microcystis* biomass in the Delta

Since 2003, *Microcystis* cell abundance in depth-integrated surface waters has varied from $4\text{--}40 \times 10^3$ cells mL^{-1} in the Delta (Lehman *et al.* 2008). The biomass (as surface Chl *a*) has also varied approximately 10-fold (Figure 4.2). Not only is *Microcystis* biomass patchy between years, its distribution in the years that it blooms is also variable. Even within a station, the distribution of *Microcystis* colonies is patchy, as evidenced by the low concentration of surface Chl *a*, sampled with horizontal net-tows normalized to total towed volume, which to date has not been above $0.6 \mu\text{g Chl } a \text{ L}^{-1}$ (Figure 4.2). In the years following 2005, *Microcystis* was also present in the phytoplankton community together with *Aphanizomenon flos-aqua*, and to a lesser extent *Anabaena* sp. (Lehman *et al.* 2008, Mioni *et al.* 2012).

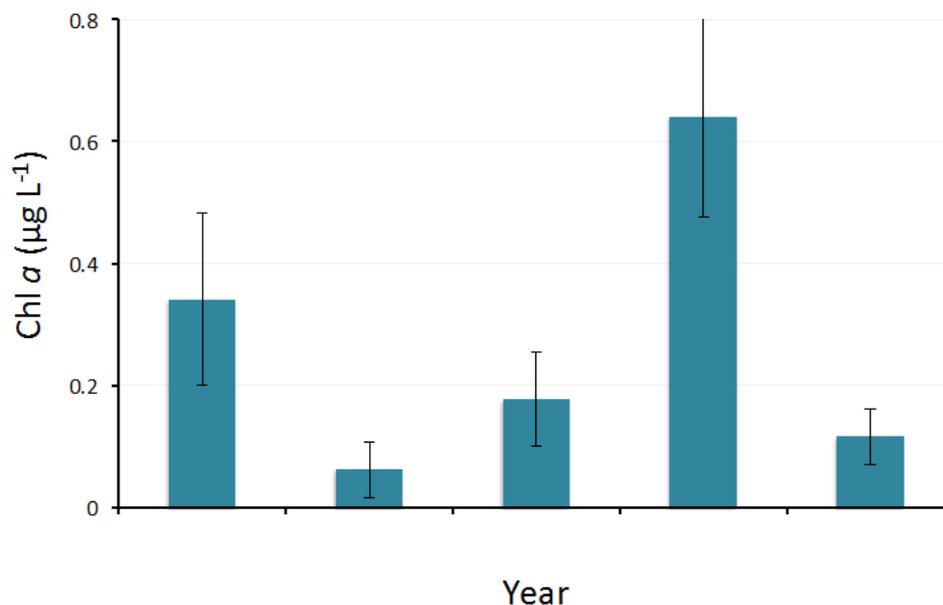

Figure 4.2. Interannual changes in surface Chl *a* due to abundance of *Microcystis* colonies. Means and standard deviations of 9 different stations in the San Joaquin River (Antioch (D12), Jersey Point (D16), Frank's Tract (D19), Potato Point (D26), Prisoners Point (D29), San Joaquin River at Turner Cut, Sand Mound Slough, Mildred Island, and Old River at Rancho del Rio (D28). Data from Lehman *et al.* 2005, 2013.

In addition to a high degree of horizontal variability, *Microcystis* cell densities and biomass also varies vertically in the water column, decreasing from the surface to almost zero at 1 m depth. The density of *Microcystis* in surface waters at the Central Delta Stations does not affect phytoplankton community composition in a measurable way. For example, at four stations where *Microcystis* dominated abundance of phytoplankton at the surface, the communities at 1m depth was a variable mix of different species of phytoplankton that was equally variable at stations containing no *Microcystis* in the surface. Rather than decreasing, the biomass of other

phytoplankton taxa increased in tandem with increasing *Microcystis* biomass (Lehman *et al.* 2010).

Compared with lakes widely recognized for severe CyanoHAB problems, *Microcystis* (and other cyanoHAB species) biomass appears low. For example, in Clear Lake spring and early summer Chl *a* concentrations average $11.5 \pm 8 \mu\text{g Chl } a \text{ L}^{-1}$ but increase to $352 \pm 295 \mu\text{g Chl } a \text{ L}^{-1}$ in the summer once *Microcystis* starts to bloom (Figure 4.4). Here, *Microcystis*-associated Chl *a* concentration is a factor of 100 to 1000 greater than it is in the Delta (Figure 4.4). One important caveat with respect to determining surface Chl *a* concentrations is that it depends on the method used to collect the surface Chl *a*. The difference between using a surface net tow (akin to what is used in Lehman *et al.* 2013) and a grab sample from the middle of a patch (akin to Mioni *et al.* 2012) can be close to be 100-fold, i.e. $0.2 \mu\text{g Chl } a \text{ L}^{-1}$ versus $20 \mu\text{g Chl } a \text{ L}^{-1}$, respectively. This is because the former is an integrated measure and the latter is not, suggesting that the “coverage” of *Microcystis* colonies in surface waters of the Central Delta is around 1%. This is in sharp contrast with Clear Lake where surface Chl *a* is uniformly high (above $150 \mu\text{g Chl } a \text{ L}^{-1}$) at all stations during a bloom (Richerson 1994, Mioni *et al.* 2012).

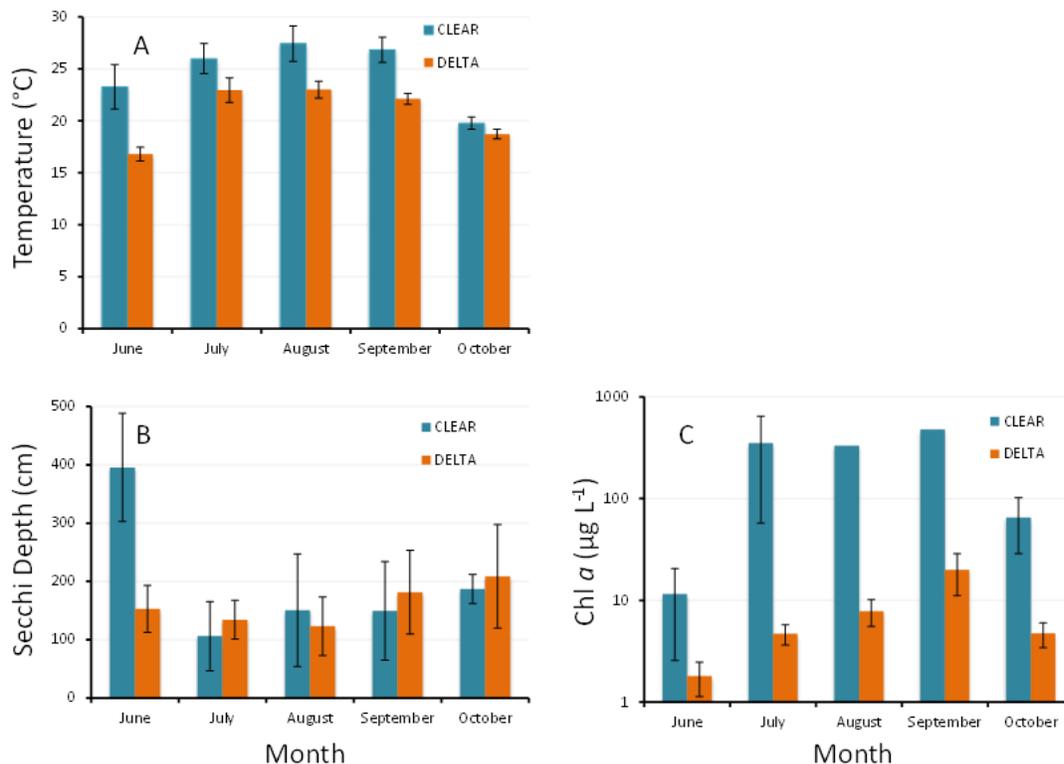

Figure 4.3. Comparison of environmental variables and Chl *a* in Clear Lake (Cyan) and the Delta (orange) using in-patch grab samples during the summer months of 2011. (A) Temperature, (B) Secchi disk depth, (C) Chl *a*. Data from Mioni *et al.* 2012.

4.2.3 Microcystin toxin concentrations in the Delta and San Francisco Bay

Given the number of different toxins produced by each cyanoHAB species, and the number of different genera present in Central California, one would expect a number of different toxins to be present in the water column. However, toxins other than microcystin are not frequently encountered (Kudela pers. com, Gibble and Kudela 2014). Based on the data available for the Delta, this section describes total microcystin concentrations and how they relate to *Microcystis* cell abundance.

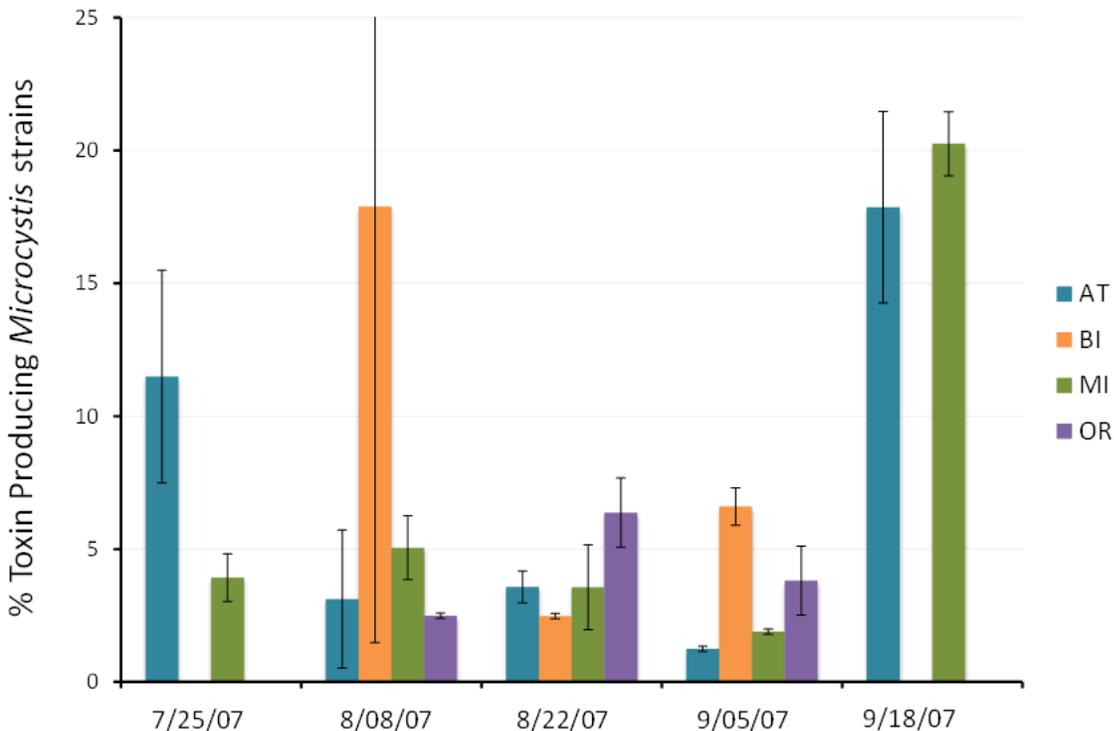

Figure 4.4. Percent toxin-producing strains in *Microcystis* assemblage at stations AT, Antioch (D12); BI, Brannan Island (D23); MI, Mildred Island; and OR, Old River at Rancho del Rio (D28). Data from Baxa *et al.* 2010.

Microcystis produces approximately 100-400 ng microcystin per μg Chl *a* in toxin producing strains (Sivonen and Jones 1999). Just as with other regions where *Microcystis* occurs, the strains that occur in the Delta are a mix of toxigenic and non-toxigenic strains (Baxa *et al.* 2010). Toxigenic strains generally comprise 2-20% of the total number of *Microcystis* strains present. This variation in the proportion of toxigenic strains is observed everywhere (i.e. at every station) and at all times (Figure 4.4). No single station stands out as consistently producing a greater proportion of toxigenic strains compared with other stations (Figure 4.4). Accordingly, total microcystin concentrations reflect total *Microcystis* cell abundance, typically varying from 10-50 ng L^{-1} (Lehman *et al.* 2008). However, in 2012 concentrations approaching 2000 ng L^{-1} were detected in the Stockton shipping channel during a *Microcystis* event (Spier *et al.* 2013).

In the Sacramento River, intermediate concentrations of total microcystins have been detected at a station close to Rio Vista (Brannon Island) where *Microcystis* cell abundance is low to non-detectable (Lehman *et al.* 2008, 2010). This station is connected via a channel to the San Joaquin River and the Frank's Tract area. Physical mixing of water directly from the San Joaquin River with brackish water at this station situated at the entrance to the Sacramento River may bring toxins but establishment of *Microcystis* populations may be prevented by the conditions in the Sacramento River including colder water, greater flow rates, mixing down to the bottom, and lower water clarity (Lehman *et al.* 2008).

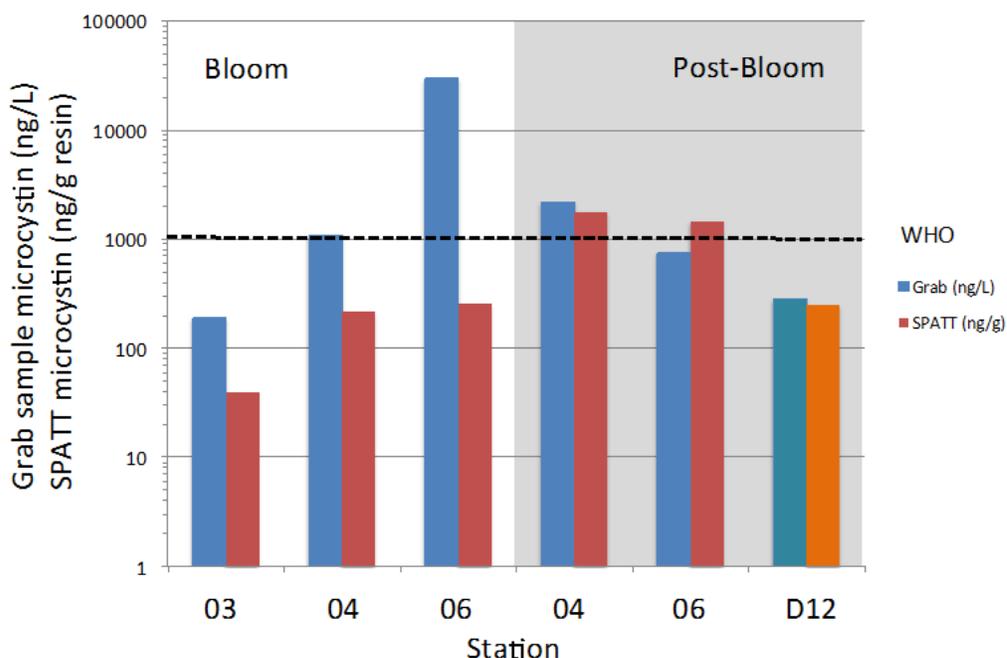

Figure 4.5. Microcystin toxin concentrations determined with grab samples (blue/cyan) and with SPATT resin (red/orange) at three stations in Clear Lake, during and after a *Microcystis* bloom, and at one station (D12, Antioch) in the Delta. Data from Mioni *et al.* 2012.

Microcystin toxin has also been detected at low concentrations throughout the Delta and the San Francisco Estuary using the novel Solid Phase Adsorption Toxin Tracking (SPATT) technique which integrates exposure of dissolved toxins over longer time spans (Kudela 2011). While valuable to indicate a potential for exposure to cyanotoxins, the comparison of SPATT to existing guidelines for human and aquatic health is problematic because SPATT detected concentrations are not directly comparable to traditional, instantaneous grab samples. For example, in Clear Lake microcystin detected with SPATT (ng/g resin) was 5-115 times lower than grab samples (ng/L) taken the last day of the SPATT deployment during the height of a *Microcystis* bloom (Figure 4.5). Post bloom, microcystin detected with SPATT was either comparable to, or double, levels measured in grab samples (Figure 4.5). While microcystin was

detectable both with SPATT and with grab samples in Clear Lake, microcystin was detectable with SPATT in the Delta, at similar levels as in Clear Lake, but not with grab samples. In the former system *Microcystis* was very abundant and in the latter it was not. The above example illustrates that given longer equilibration times, SPATT becomes more sensitive than grab samples at lower concentrations of toxins. Although difficult to “translate” directly into effects on aquatic life (i.e. Echols *et al.* 2000), SPATT detection may be a very useful system for identifying regions at risk for harm to aquatic life from toxin exposure (Gibble and Kudela 2014).

4.2.4 Potential for CyanoHAB Risk to Delta Beneficial Uses

Characterization of the risk of cyanoHABs to Delta beneficial uses is generally poor. While no guidelines for toxicity of cyanotoxins to aquatic life have been established for California, total microcystin levels found in the Delta are within the range of potential impacts to aquatic health, as recently reviewed by the California Office of Environmental Health Hazards (OEHHA 2009). For example, microcystins are acutely toxic to fish at concentrations as low as a fraction of a microgram per liter (OEHHA 2009). Chronic exposures can also be problematic; embryos and larval fish appear to be very sensitive to chronic exposures to microcystins, resulting in oxidative stress, reduced growth, developmental defects, and lethality; exposures as low as 0.25 µg/L resulted in oxidative stress to zebrafish embryos (OEHHA 2009).

Consumption of prey items with body burdens of cyanotoxins can also be a potential pathway of impact. Lehman *et al.* (2010) traced increasing concentrations of microcystins from the water (25-50 ng L⁻¹) to zooplankton (0.4-1.5 µg g dry wt⁻¹) to striped bass muscle tissue (1-3.5 µg g dry wt⁻¹) at Central Delta Stations. These values are within the range of sublethal microcystin doses to fish (2.5 µg g dry wt⁻¹; OEHHA 2009). The striped bass caught at stations where *Microcystis* cells comprised 100% of the surface Chl *a* had tumor lesions in their liver tissue, consistent with the sublethal effects caused by microcystin-LR toxin (OEHHA 2009, Lehman *et al.* 2010). This is consistent with fish feeding studies which demonstrate that microcystin-LR spiked diets result in lesions of the liver (Deng *et al.* 2010; Acuna *et al.* 2012a,b).

Zooplankton are also acutely sensitive to *Microcystis aeruginosa* cells; diets consisting of 50% toxigenic and non-toxigenic *Microcystis* strains result in 100% mortality in the copepods *Eurytemora affinis* and *Pseudodiaptomus forbesi* (Ger *et al.* 2010). Interestingly, when fed diets containing only 10-25% *Microcystis* cells, both copepods demonstrate significantly greater survival on the toxigenic strain than the non-toxigenic strain, suggesting that bioactive compounds other than the microcystin toxin exert a greater adverse impact on the zooplankton (Ger *et al.* 2010). This is consistent with a number of the studies of the effect of cyanoHABs on zooplankton mentioned in Section 2.2.6.

Determination of risk to human health in the Delta is problematic because cyanoHABs monitoring has been focused on aquatic health (depth-integrated sampling) rather than human

health (via surface-scum sampling). With this caveat, toxin concentrations of 10-50 ng L⁻¹ (Lehman *et al.* 2008) are 16-80 times lower than the Office of Environmental Health Hazard Assessment (OEHHA) Action Level for human health (Table 4.1), but the 2012 concentrations approaching 2000 ng L⁻¹ in the Stockton shipping channel (Spier *et al.* 2013) exceed both the OEHHA Action level and the WHO guideline of 1000 ng L⁻¹ (Table 4.1).

Table 4.1. Action levels developed by OEHHA (2009) for human health exposure to cyanotoxins compared with the WHO guidance level for microcystins and the EPA 10-day average exposure threshold.

Toxin	OEHHA Recreational Use (µg/L water)	OEHHA Consumption Level (ng/g fish)	WHO recreational Use (µg/L water)	EPA 10-day average (µg/L)
Microcystins	0.8	10	1.0	0.3
Cylindrospermopsin	4	70		
Anatoxin-a	90	5000		

4.2.5 Summary of Potential for Adverse Effects on Delta Beneficial Uses

A thorough characterization of the risks for adverse effects on Delta beneficial uses is hindered by the fact that cyanoHAB prevalence and toxin concentrations are currently not routinely monitored in the Delta; moreover, sampling has been focused on aquatic health and does not include sampling for human health risks. Determination of risk to human health is not possible at this time because surface scums are not currently being monitored. The current risk to Delta aquatic health is of concern and merits a more thorough investigation. This observation is based on total microcystin levels found in Delta fish tissues that are within the range of sublethal effects to fish as recently reviewed by the California Office of Environmental Health Hazards (OEHHA 2009). In addition, dissolved toxin concentrations (10- 50 ng L⁻¹) that are generally 16-80 times below the OEHHA action level, occasionally exceed both the OEHHA action level and the WHO guideline of 1000 ng L⁻¹ in certain “hotspots” of the Delta. Whether or not these hotspots are expanding is currently not known and merits further investigation and monitoring.

5.0 SYNTHESIS OF FACTORS INFLUENCING CYANOHABS PRESENCE AND TOXIN PRODUCTION IN THE DELTA

The charge of the cyanobacterial workgroup, as outlined in the Delta Nutrient Management Charter, is to “assess whether observed increases in the magnitude and frequency of cyanobacterial blooms in the Delta is the result of long-term changes in nutrient concentrations and whether management of nutrient loads can remedy the problems associated with cyanobacteria.” The best way to characterize the relationship between the extent and frequency of bloom occurrence and nutrient concentrations is by regression analysis. Ideally, this type of analysis ought to be performed in multiple locations for longer time scales. Given that temperature, irradiance and water column clarity are such powerful triggers of blooms, stepwise multiple regression analysis to test the influence of several environmental indicators simultaneously on cyanoHAB cell densities would be even more useful in order to ascertain key triggers of the blooms in the Delta region.

While environmental indicators such as salinity, turbidity, temperature, total phytoplankton biomass (as Chl *a*), and phytoplankton species composition are monitored on a monthly basis by DWR, surface concentrations of phytoplankton, which requires special sampling, are not routinely monitored in this program. Therefore, the statistical analyses needed to answer the charge of the cyanobacterial working group cannot be performed at this time. Instead, this section focuses on summarizing factors known to favor cyanobacterial prevalence (from Section 2) and synthesizing available literature on the extent to which those factors may also be at play in the Delta.

5.1 Present and Future Factors associated with cyanoHAB prevalence in the Delta

5.1.1 Flow and mixing

Environmental and population drivers that promote growth of cyanoHABs in freshwater bodies around the world also play key roles in regulating growth of cyanoHABs in the Delta (Table 5.1). Chief among these is low flow. For example, Lehman *et al.* (2013) noted that increased abundance of *Microcystis* is associated with up to a 50% reduction in flow of water in the San Joaquin River. In 2004, *Microcystis* only appeared in the Central Delta when stream flow was 1-35 m³ s⁻¹ (Lehman *et al.* 2008). In addition to direct effects of decreased flow such as increased stratification of the water column, changes in flow and mixing also impart indirect effects that may influence cyanobacterial growth. These include changes in turbulence, sediment resuspension (therefore turbidity), chemical constituents, and water temperature to mention a few. Changes in these parameters typically cannot be separated from that of flow to determine their relative importance. For example, in the Delta, reduction in flow is accompanied by a 50% reduction in turbidity and volatile suspended solids. Decreased flow also leads to increased water temperatures. Conditions of decreased flow occur more predictably in dry years (Lehman *et al.*

2013). Within the summer season, reduced flows typically occur in the July-August time frame (Figure 5.1) and set the stage for the two factors necessary for bloom initiation, including increased water column temperature and water column clarity (decreased turbidity). While decreased flow may increase the abundance of *Microcystis*, increasing rates of flow decrease its abundance because of the negative effects of water column mixing, such as light limitation, on its growth. Artificial mixing is even used as a strategy to mitigate blooms of harmful cyanobacteria in lakes and reservoirs (Reynolds *et al.* 1983, Burford and O'Donohue 2006). In the Delta, natural mixing rates may be sufficient to restrict the abundance of *Microcystis* to 10-15% of the total phytoplankton community.

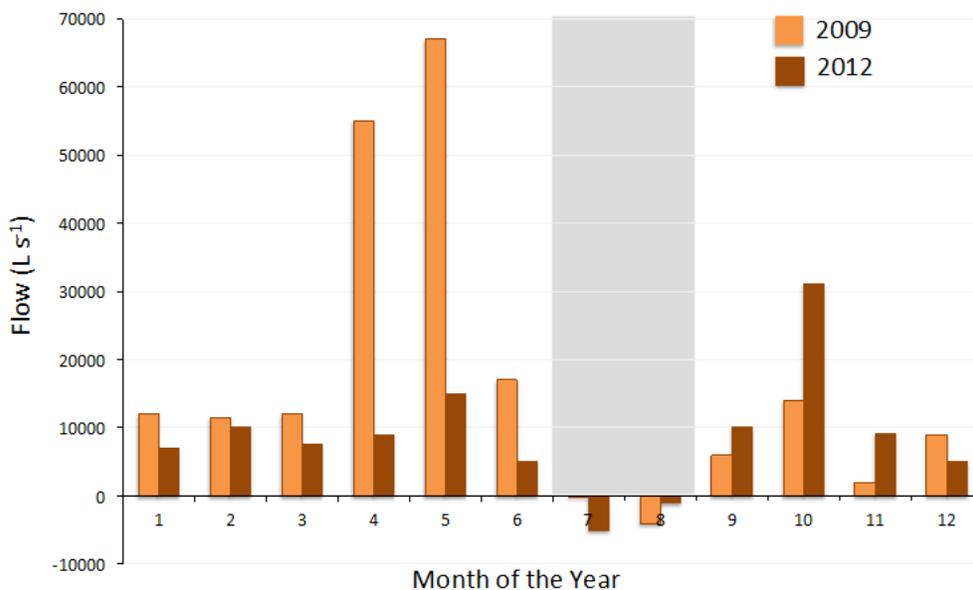

Figure 5.1. Variation in flow at Brandt Bridge in the Delta (years 2009 and 2012) illustrating the low- and reverse-flow window in July-August (shaded grey). Data and plot from Spier *et al.* 2013.

5.1.2 Temperature

Aside from the rate of water flow, water temperatures have increased globally over the last few decades as a result of global warming (Gille 2002, Hansen *et al.* 2005). In the Central Delta, a change from mainly negative deviations in the water temperature from the long-term mean to positive deviations occurred in 1999 (Figure 5.2). This local change in the water temperature may be part of the larger-scale global patterns and/or the Pacific Decadal Oscillation weather pattern which also changed sign in the same year (Cloern *et al.* 2007).

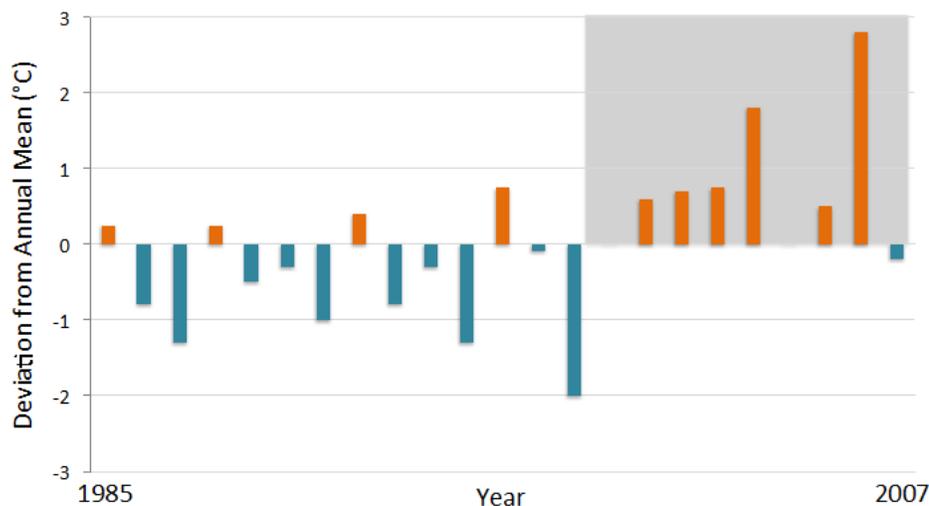

Figure 5.2. Deviation from the annual mean of maximum water temperatures at Stockton in the Central Delta. Grey shaded area indicates period from 1999 onwards with increased positive temperature deviations. Data from Brooks *et al.* 2011.

The interesting question with respect to changes in water temperatures is whether they are great enough to affect competition between cyanobacteria and other members of the phytoplankton community in the Central Delta. Presently, 40-75% of the phytoplankton community in the Delta is comprised of diatoms, followed by chlorophytes (15-30%), cyanobacteria (15-40%), cryptophytes (5-10%) and flagellates (0-10%), including dinoflagellates (Lehman 2007). In order for cyanoHAB species to grow faster than diatoms and displace diatoms as the dominant member of the phytoplankton community, they would have to be able to accelerate their growth rates up to 2-3 fold. Alternatively, a scenario where the growth rate of diatoms would decrease and cyanobacteria would increase is necessary. Examining variation in growth rates with changes in environmental data, temperature appears the most likely candidate for bringing about such a change. Data from Figure 3.6 indicates that a doubling in cyanobacterial growth rates occurs with an increase in temperature from 20-27°C, whereas diatom growth rates decrease over the same temperature range. Therefore, a rise in temperature is a scenario under which cyanobacteria are able to outcompete diatoms.

This scenario is consistent with differences in temperature between a system, such as Clear Lake, where cyanoHABs dominate community composition, and the Delta. Comparing the 2011 environmental variables from Clear Lake and the Central Delta, two pre-bloom (June) differences become immediately clear. One is that the water temperature in Clear Lake is 7°C degrees warmer than the Delta (Figure 4.3). The other is that the Secchi disk depth is 2.6-fold greater in Clear Lake compared with the Delta (Figure 4.3). This difference in water clarity disappears in July when the *Microcystis* bloom takes off in Clear Lake, increasing Chl *a* 35-fold and decreasing the water clarity (Figure 4.3). Lehman *et al.* (2013) also predicted that the two

factors that potentially would make the greatest impact on accelerating the growth of *Microcystis*, and increase the frequency and duration of blooms in the Delta, would be increased water temperatures and increased water column clarity. The earlier in the growth season that these increases would occur the greater the window of opportunity for growth would become (see also Peeters *et al.* 2007).

5.1.3 Water Clarity

The Central Delta is highly turbid due to large amounts of sediments transported into the upper estuary via the Sacramento River as well as due to sediment resuspension. However, as more and more of the sediment load is being caught behind dams, sediment transport is on the decline and the upper estuary is becoming less turbid (Schoellhamer *et al.* 2012). Since 1975, turbidity at Stations D26 and D28 has declined by on average 2 and 4% per year, respectively (Jassby 2008). These average declines are accentuated by declines in turbidity of up to 50% during the low flow months (Lehman *et al.* 2013). If these present declines in turbidity in the Central Delta continue into the future, they may substantially promote growth of cyanoHAB species.

5.1.4 Nutrient Concentrations

If water temperatures did not increase above the summer-time average of 18-20°C, could there be a 2-fold acceleration in cyanobacterial growth rates with changes in N source, or with N:P ratio, at non-limiting nutrient concentrations that would enable them to outcompete diatoms and become dominant? To answer this question, we can 1) look to growth results from culture investigations and 2) investigate how nutrient ratios differ between a system that is overwhelmed by *Microcystis* (such as Clear Lake) compared with the Delta.

- 1) Culture investigations demonstrate that there is no significant, or consistent, change in growth rates with change in N source, or N:P ratios, at nutrient concentrations in excess of demand (Tilman *et al.* 1982, Tett *et al.* 1985, Reynolds 1999, Saker and Neilan 2001, Roelke *et al.* 2003, Sunda and Hardison 2007).
- 2) Comparing the ratios of dissolved N:P between the Delta and Clear Lake, 3.6 ± 0.6 and 2.9 ± 0.8 , respectively, it's clear that these are essentially the same (Mioni *et al.* 2012). Nutrient ratios also do not vary from pre-bloom to bloom in the Delta, indicating that nutrients are in excess of phytoplankton demand for the entire summer season (Lehman *et al.* 2008, Mioni *et al.* 2012). Moreover, nutrient concentrations, or ratios, do not change sufficiently from year-to-year in order to explain year-to-year variation *Microcystis* biomass or occurrence. For example, since 1994 there has been no change in concentrations or ratios of nutrients in the Central Delta (Appendix A).

Therefore, the initiation of *Microcystis* blooms around 1999 in the Delta was probably not associated with changes in nutrient concentrations or their ratios. However, as with all

phytoplankton blooms, once initiated, cyanoHABs cannot persist without an ample supply of nutrients. It is important to keep in mind that while nutrient reduction may not limit the onset or frequency of bloom occurrence, it will limit bloom duration, intensity and possibly also geographical extent. If, in the future, nutrient concentrations were to decrease to the point where they start to limit phytoplankton biomass, then the magnitude of the nutrient pool, as well as seasonal changes in the magnitude, would impact cyanoHAB concentration, distribution and bloom duration.

Interestingly, the long-term record for station D26 demonstrates that a decline in Chl *a* and corresponding increases in nitrogen concentrations (NH_4^+ and NO_3^-) and N:P ratios occurred in the period from 1985-1994 (Appendix A). Jassby (2008) reported similar changes in Chl *a* (decrease) and nitrogen (increase) at Central Delta Stations D16 and D28 between the years 1985 and 1994. Van Nieuwenhuysse (2007) hypothesized that the changes in N:P ratios and Chl *a* were driven by a decrease in phosphorus loadings to the Sacramento River that occurred in 1994; however the step change in P loading that year does not explain the gradual decrease in Chl *a* that started prior to 1994 (Appendix A).

Gradual decreases in Chl *a* concentrations may have been brought about by relative changes in flow and benthic grazing, leading to a new and lower Chl *a* equilibrium by the mid-1990's (Lucas and Thompson 2012). According to Lucas and Thompson (2012) the areas of the Delta where benthic grazing typically overwhelms phytoplankton growth rates are the same as those where *Microcystis* tends to bloom (Figure 4.1; Lehman *et al.* 2005). Because *Microcystis* floats at the very surface, it may avoid being grazed by clams in contrast with other phytoplankton that are distributed throughout the water column. It's important to bear in mind that large-scale (temporal and spatial) variation in environmental factors such as flow and grazing by clams may have a more profound impact on phytoplankton standing stocks, and competition among different phytoplankton taxa, compared with many of the autecological adaptations discussed in this review.

5.2 Summary

In the review of the global literature on factors influencing cyanobacterial blooms and toxin production, five principal drivers emerged as important determinants:

- 1) Water temperatures above 19°C
- 2) High irradiance and water clarity
- 3) Availability of N and P in non-limiting amounts; scientific consensus is lacking on the importance of N:P ratios and nutrient forms (e.g. ammonium) as a driver for cyanoHABs
- 4) Long residence times and stratified water column
- 5) Low salinity (<10 ppt) waters

Comprehensive understanding of the role of nutrients vis-à-vis other environmental factors in influencing cyanoHAB presence in the Delta is severely hampered by the lack of a routine monitoring program. The DWR monitoring program currently measures many of the environmental factors of interest, except cyanobacterial abundance and toxin concentration, which require a different approach than that used in standard phytoplankton monitoring. Drawing on the five factors influencing cyanoHABs, we can conclude the following:

- Because of the large effects of temperature and irradiance on accelerating, and decelerating, the growth rates of cyanoHABs, these two factors appear to exert key roles in the regulation of the onset of blooms. Cyanobacteria require temperatures above 20°C for growth rates to be competitive with eukaryotic phytoplankton taxa, and above 25°C for growth rates to be competitive with diatoms (Table 5.1). In addition, they require relatively high irradiance to grow at maximal growth rates. This is in contrast with diatoms that are able to keep near-maximal growth rates at irradiances limiting to cyanoHABs in the Delta, e.g., 50 $\mu\text{mol phot m}^{-2} \text{ s}^{-1}$ (Table 5.1).
- It appears that N and P are available in non-limiting amounts in the Delta; moreover concentrations, or ratios, do not change sufficiently from year-to-year to explain year-to-year variation in *Microcystis* biomass or occurrence. Therefore, the initiation of *Microcystis* blooms and other cyanoHABs are probably not associated with changes in nutrient concentrations or their ratios in the Delta. However, as with all phytoplankton blooms, once initiated, cyanoHABs cannot persist without an ample supply of nutrients. As long as temperatures, flow rates and irradiance remain favorable for growth, the size of the nutrient pool will determine the magnitude and extent of cyanoHAB blooms.
- Salinity is controlling the oceanward extent of cyanobacterial blooms in the Delta, but salinity gradients do not explain the spatial distribution of cyanoHABs in the Delta (Table 5.1). Notably, salinity regime is not a barrier to toxin transport, as cyanotoxins have been detected in San Francisco Bay.
- Higher flows, turbidity and lower temperatures during most of the year are likely restricting cyanobacterial blooms to the July-August time period.

Climate change and anthropogenic activity associated with land use changes have the potential to alter cyanoHAB prevalence in the future. Climate change will likely result in warmer temperatures and increased drought, the latter of which could result in reduced flows, increased residence time and water column stability leading to higher light availability in the Delta. Both higher temperatures and reduced flows would presumably result in a greater prevalence of cyanoHABs. It's noteworthy that phytoplankton biomass and primary productivity are depressed relative to available nutrients in the Delta, so it's unclear what the effect of modifying nutrient loads will have on frequency and intensity of cyanoHAB occurrence in the future.

Table 5.1. Summary of general physiological drivers of cyanobacterial growth, how they are manifested in population growth and competition with diatoms, and how they compare with environmental drivers observed to be operating in the Delta.

Physiological Driver	Population Driver	Observations in the Delta
Growth significantly slower below 20°C, and greater above 25°C, compared with eukaryotic phytoplankton taxa	Requires temperatures above 25°C for growth rates to be competitive with diatoms	Not observed at temperatures <19°C
Cyanobacteria have greater cellular N:P ratios than diatoms due to two light harvesting systems and peptide toxin production	At non-limiting nutrient concentrations, changes in ratios of nitrogen substrates or N:P does not affect competition among species or taxa	Nutrient concentrations, nitrogen speciation, and dissolved N:P ratios have not changed in the Delta over the last 25 years
Production of bioactive peptide compounds (toxic and non-toxic) results in high N demand of cells	Toxin production per cell is greatest at maximal growth rates; linked with external N concentrations and decrease at N limiting conditions; cyanoHABs do not secrete toxin	Inorganic N and P concentrations are at non-limiting concentrations for growth and toxin production; Variation in toxin produced per cell or in number of toxigenic vs non-toxigenic strains is not related to any specific environmental condition
Inefficient photosynthesis, low alpha; efficient at dissipating excess light energy via high concentration of carotenoid pigments in photosystems (<i>Microcystis</i>, <i>Anabaena</i> and <i>Aphanizomenon</i>)	CyanoHABs (<i>Microcystis</i> , <i>Anabaena</i> and <i>Aphanizomenon</i>) require high irradiance to grow; diatoms able to keep near-maximal growth rates at irradiances limiting to cyanoHABs (e.g. 50 $\mu\text{mol phot m}^{-2} \text{s}^{-1}$)	High rate of water flow and mixing most of the growing season restricting blooms to low-flow periods (July-August), when turbidity is < 50 NTU, flow is <30 $\text{m}^3 \text{s}^{-1}$ and irradiance > 50 $\mu\text{mol phot m}^{-2} \text{s}^{-1}$ (Central Delta 2004-2008)
Growth optimal at salinities <10 ppt for most cyanoHAB species	CyanoHABs generally restricted to freshwater habitats and estuaries with salinities <10 ppt (Baltic Sea, San Francisco Delta, North Carolina)	Does not proliferate outside the Delta in the Sacramento River (freshwater) or Suisun Bay (mesohaline) suggesting that the primary agent restricting its spread is not salinity

6.0 RECOMMENDATIONS

The goal of this review is to synthesize available information to provide insight into cyanobacterial bloom occurrence in the Delta. The review has three major objectives:

- 1) Provide a basic review of biological and ecological factors that influence the prevalence of cyanobacteria and the production of cyanotoxins;
- 2) Summarize observations of cyanobacterial blooms and associated toxins in the Delta;
- 3) Synthesize literature to provide an understanding of what ecological factors, including nutrients, may be at play in promoting cyanobacterial blooms in the Delta.

This review found that the lack of a routine monitoring of cyanoHAB occurrence in the Delta greatly hindered our ability to summarize, with confidence, the status and trends of cyanoHABs in the Delta (Objective 2), and to what extent nutrients versus other factors were controlling their occurrence (Objective 3). Given this finding, our recommendations are focused on two principal actions:

- 1) Strengthening routine monitoring; and
- 2) Development and use of an ecosystem model, coupled with routine monitoring and special studies, to 1) understand controls on primary productivity and phytoplankton assemblage in the Delta and 2) test hypotheses regarding factors promoting or curtailing growth of cyanobacteria.

R1: Implement Routine Monitoring of CyanoHABs

DWR is currently conducting a monitoring program that routinely samples many of the variables of interest known to influence cyanoHABs. Comprehensive cyanoHAB monitoring should be added as a component to this program to fully evaluate risk to human and aquatic health as well as better understand linkages to factors that may be promoting or maintaining blooms.

To begin, a work plan should be developed which specifically scopes the needed changes in the program to comprehensively monitor cyanoHABs. Monitoring should include enumeration of major cyanobacterial species (e.g. *Microcystis*, *Aphanizomenon* and *Anabaena*). Sampling of toxins should include water column concentrations as well as mussel tissue concentrations or other important taxa that represent sentinels for bioaccumulation in the food web. Analyses of toxin concentrations should be expanded to include the six major cyanotoxins of concern identified in the OEHHA guidance in year 1 then adjusted based on the most commonly encountered toxins thereafter. In addition, selective sampling for analysis of concentrations of herbicides and fungicides commonly encountered in the Delta should be considered. The workplan should also consider monitoring needed to develop and calibrate an ecosystem model to further investigate controls on primary productivity and phytoplankton assemblage (see R2 below).

After an initial period of 3-5 years, the monitoring data should be used to comprehensively report on the status and trends of cyanoHABs and the factors that favor bloom occurrence in the Delta.

R2: Develop an Ecosystem Model of Phytoplankton Primary Productivity and HAB Occurrences to further Inform Future Risk and Hypotheses on Factors Controlling CyanoHABs

The Delta is at an advantage with respect to management of cyanoHABs in that naturally occurring high rates of flow and turbulence act to keep cyanobacteria in check. Despite this, future increases in temperature and residence time associated with climate change, increasing the degree and duration of stratification events, may substantially degrade the effectiveness of the Delta's breaking mechanism and increase the risk of cyanoHAB occurrences. Because nutrients are not currently limiting cyanobacterial blooms, it is critical that an improved understanding is gained of the factors that are controlling phytoplankton primary productivity in the Delta, since a relaxation of those factors followed by increased growth of phytoplankton could lead to increased risk of cyanoHABs.

To inform management actions moving into the future, an ecosystem model of phytoplankton primary productivity and HAB occurrences should be developed. This model should have the capability to provide information on primary productivity and biomass as well as planktonic food quality and transfer of carbon to higher trophic levels. Moreover, such a model could be used to assess the relative importance of environmental factors such as benthic grazing, flow, water column stability, temperature, to mention a few, at various times and locations in the Delta, on cyanobacterial growth. To step into model development, four steps should be taken: 1) examine existing models already available to determine suitability for this task, 2) utilize existing data from the Central Delta to explore, to the extent possible, the relationships between Chl *a*, phytoplankton composition, climate variables and other factors at stations where cyanoHABs are known to occur (e.g. D26, D28 and turning basin in the Stockton Shipping Channel). 3) Develop hypotheses regarding the environmental conditions in those areas that promote cyanoHABs. In addition, develop hypotheses regarding conditions needed to curtail cyanoHABs; including the effect of reducing nutrient loads on the entire phytoplankton community (including cyanobacteria) and on the transfer of carbon to higher trophic levels. These hypotheses can subsequently be tested through model development as well as potential future scenarios, and 4) a work plan should be developed that lays out the modeling strategy, model data requirements, and implementation strategy.

APPENDIX A

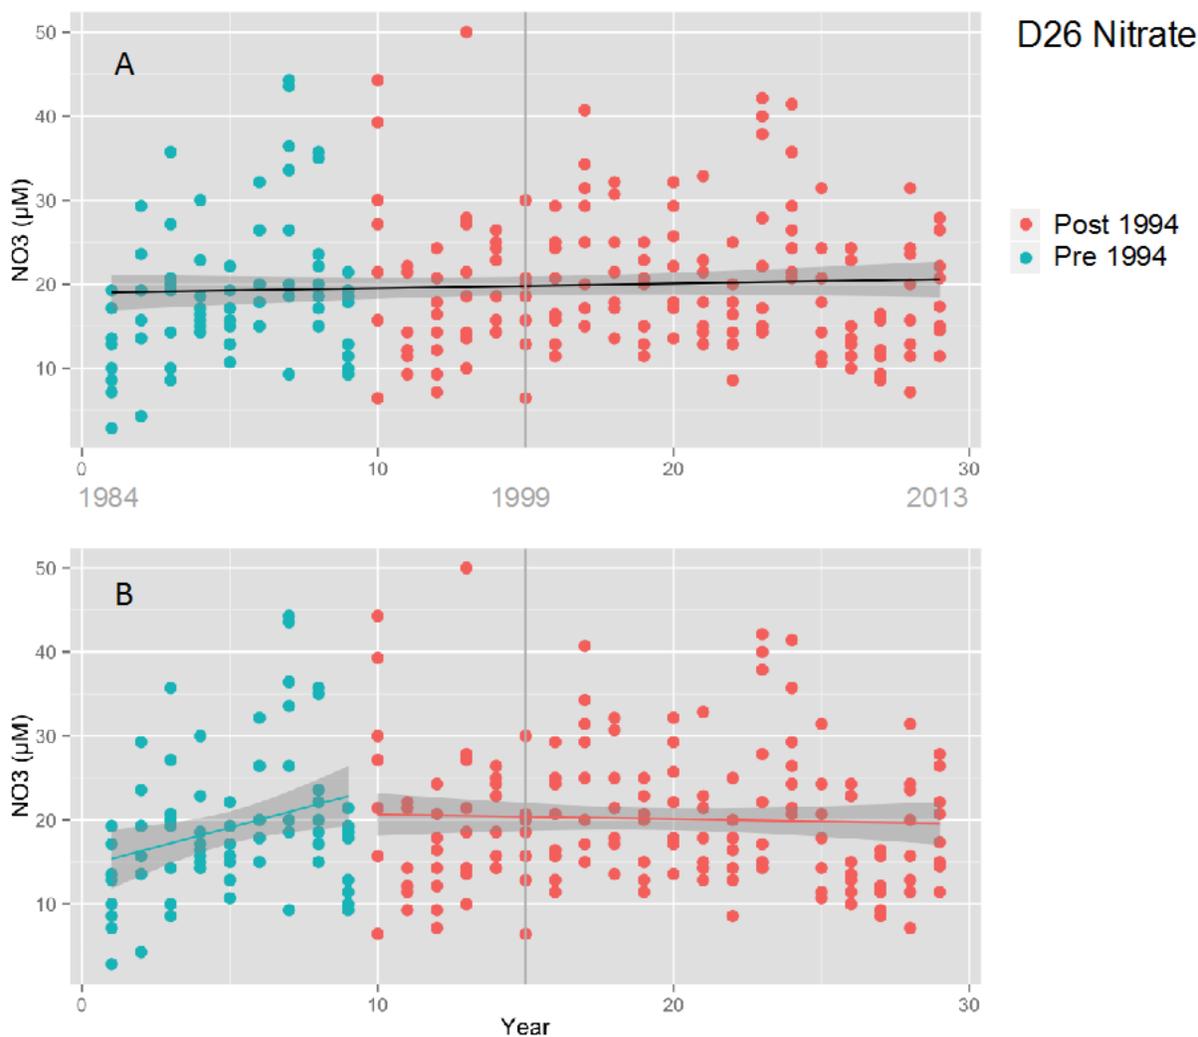

Figure A-1. Changes in the concentration of nitrate (NO_3^-) over time (1985-2013) at station D26 in the Delta. Green filled circles denote period before 1994 and red filled circles denote the period after 1994. Vertical grey line denotes the year 1999 when *Microcystis* started occurring. A) Regression of NO_3^- versus time for the period 1985-2013 (black line) with 95% confidence interval in grey. B) Regression of NO_3^- versus time for the period 1985-1994 (green line) and the period 1994-2013 (red line). Slopes significantly different from zero in bold in regression table:

Nitrate	1985-2013	1985-1994	1994-2013
Slope	0.09066	1.374	-0.02962
Probability	0.226	0.00149	0.832
multi- R^2	0.00424	0.09127	0.0001988

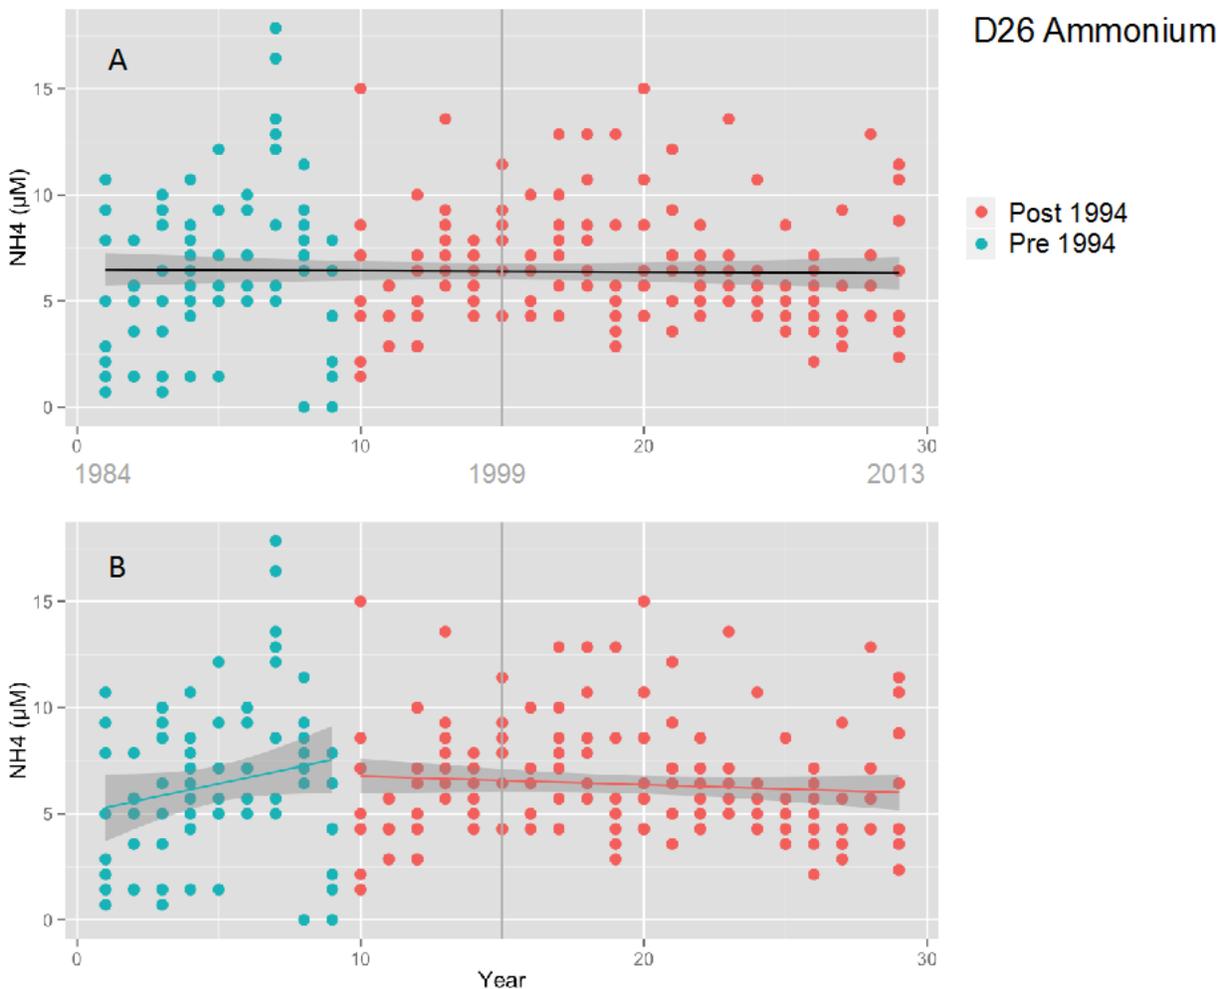

Figure A-2. Changes in the concentration of ammonium (NH_4^+) over time (1985-2013) at station D26 in the Delta. Green filled circles denote period before 1994 and red filled circles denote the period after 1994. Vertical grey line denotes the year 1999 when *Microcystis* started occurring. A) Regression of NH_4^+ versus time for the period 1985-2013 (black line) with 95% confidence interval in grey. B) Regression of NH_4^+ versus time for the period 1985-1994 (green line) and the period 1994-2013 (red line). Slopes significantly different from zero in bold in regression table:

Ammonium	1985-2013	1985-1994	1994-2013
Slope	-0.038	0.3801	-0.03525
Probability	0.108	0.023	0.358
multi- R^2	0.007448	0.04779	0.00374

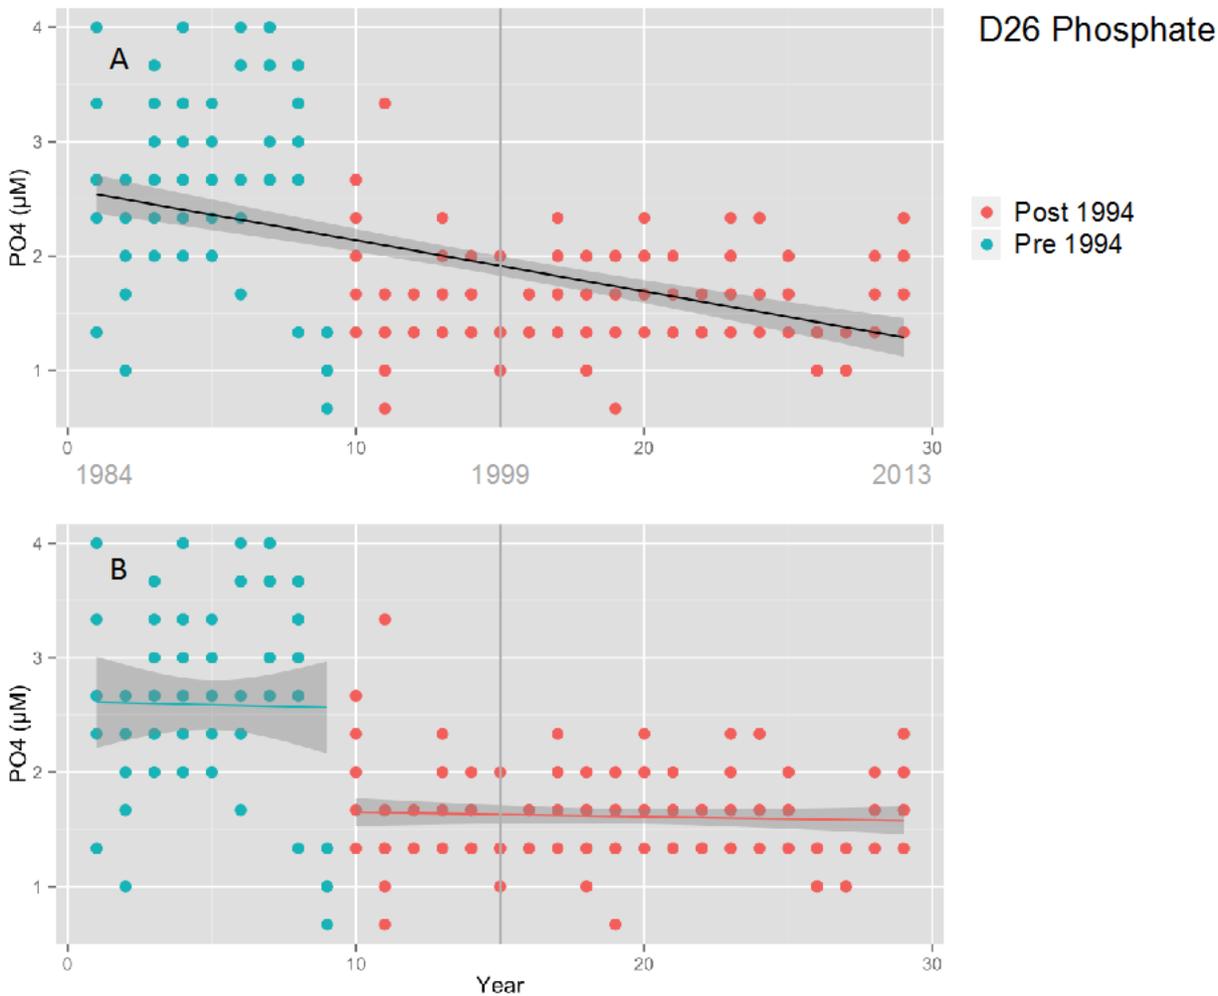

Figure A-3. Changes in the concentration of phosphate (PO_4^{3-}) over time (1985-2013) at station D26 in the Delta. Green filled circles denote period before 1994 and red filled circles denote the period after 1994. Vertical grey line denotes the year 1999 when *Microcystis* started occurring. A) Regression of PO_4^{3-} versus time for the period 1985-2013 (black line) with 95% confidence interval in grey. B) Regression of PO_4^{3-} versus time for the period 1985-1994 (green line) and the period 1994-2013 (red line). Slopes significantly different from zero in bold in regression table:

Phosphate	1985-2013	1985-1994	1994-2013
Slope	-0.048906	0.03673	-0.008772
Probability	2.00E-16	0.263	0.157
multi- R^2	0.2594	0.01183	0.008855

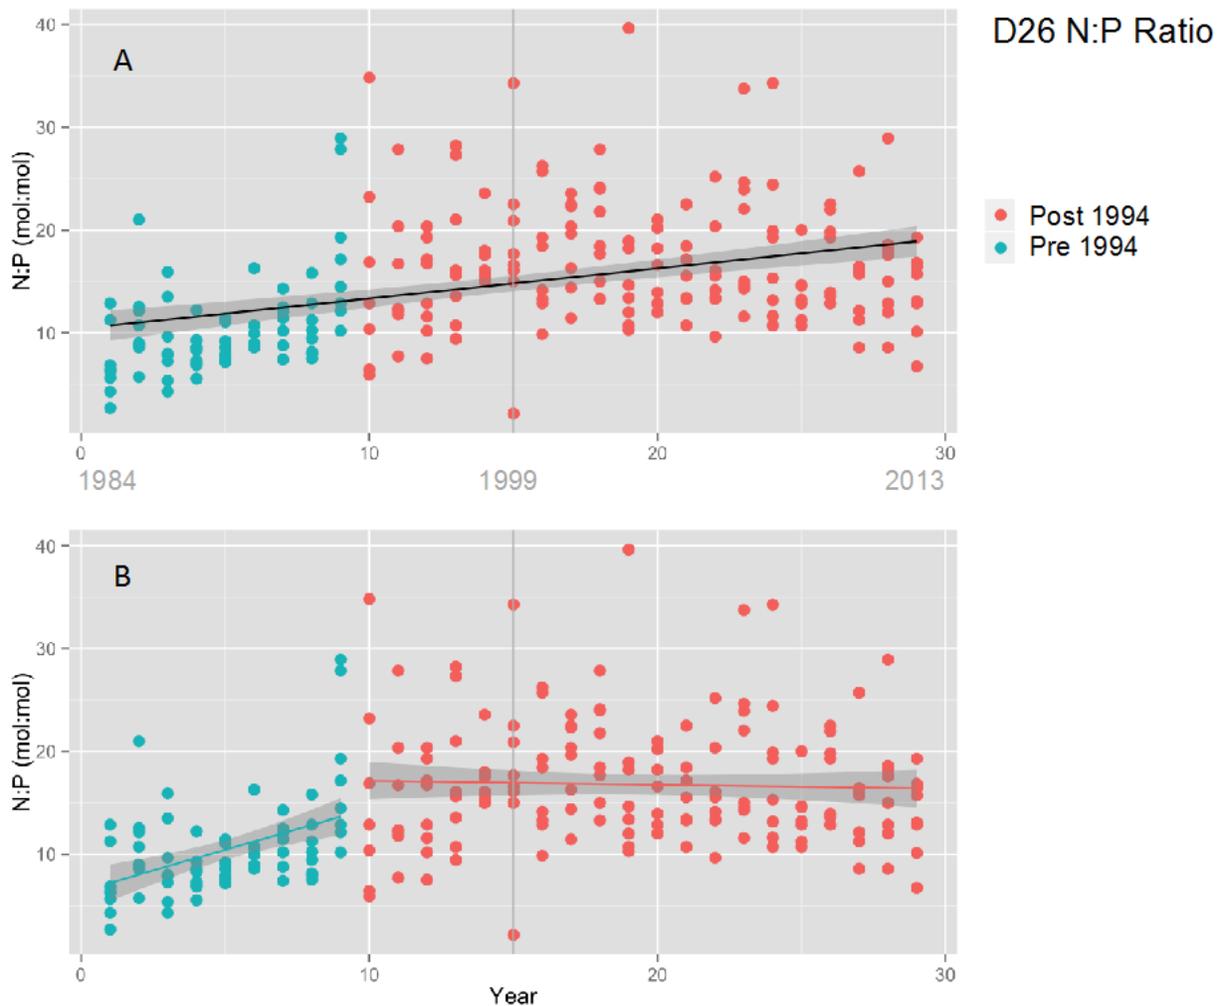

Figure A-4. Changes in the N:P ratio (mol:mol) over time (1985-2013) at station D26 in the Delta. Green filled circles denote period before 1994 and red filled circles denote the period after 1994. Vertical grey line denotes the year 1999 when Microcystis started occurring. A) Regression of N:P ratio versus time for the period 1985-2013 (black line) with 95% confidence interval in grey. B) Regression of N:P ratio versus time for the period 1985-1994 (green line) and the period 1994-2013 (red line). Slopes significantly different from zero in bold in regression table:

N:P Ratio	1985-2013	1985-1994	1994-2013
Slope	0.3726	0.6236	0.02932
Probability	3.79E-16	0.000572	0.736
multi- R ²	0.1747	0.1064	0.0005047

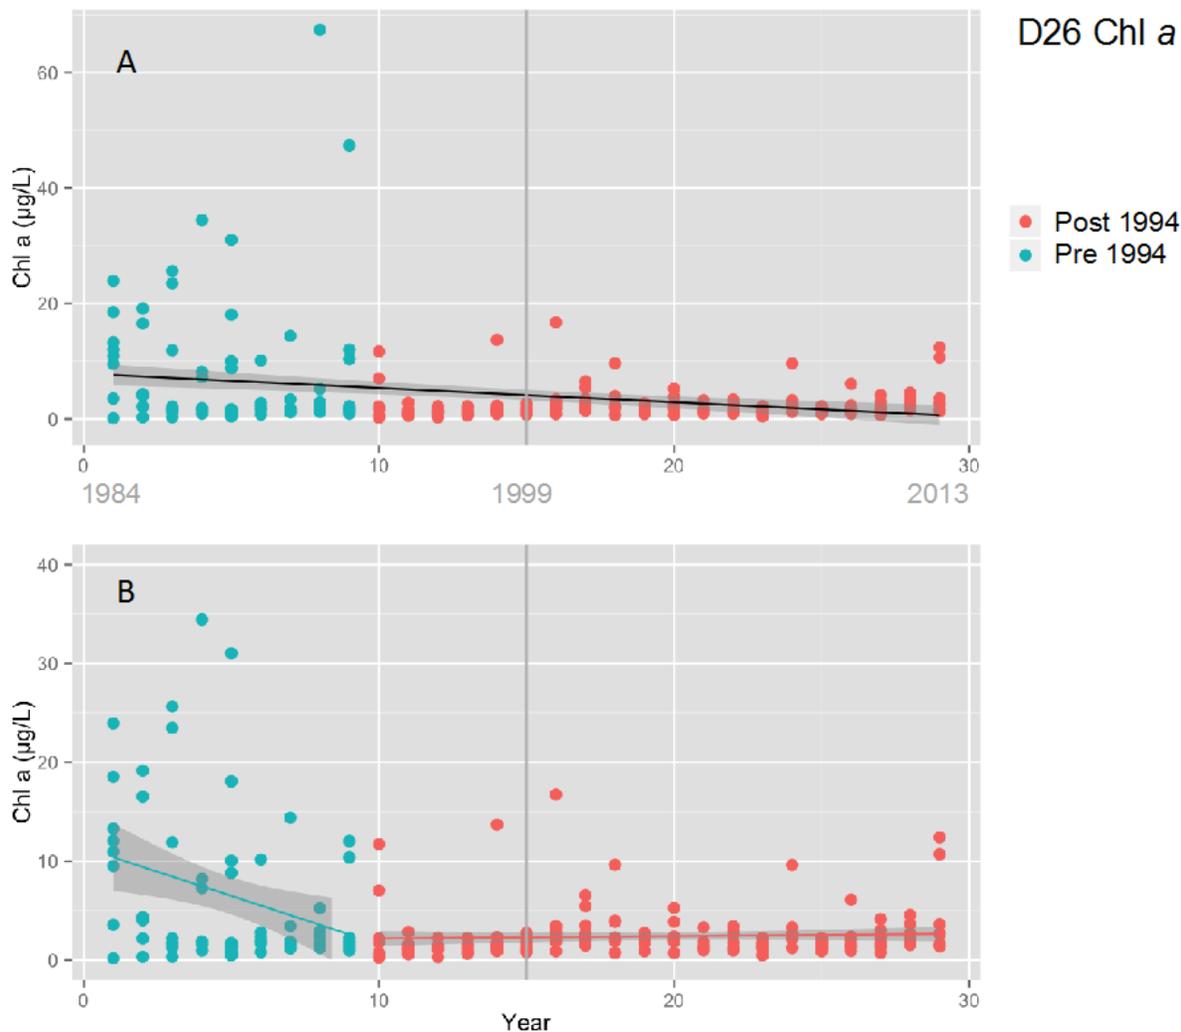

Figure A-5. Changes in the concentration of Chlorophyll a (Chl a) over time (1985-2013) at station D26 in the Delta. Green filled circles denote period before 1994 and red filled circles denote the period after 1994. Vertical grey line denotes the year 1999 when Microcystis started occurring. A) Regression of Chl a versus time for the period 1985-2013 (black line) with 95% confidence interval in grey. B) Regression of Chl a versus time for the period 1985-1994 (green line) with two of the high values from 1994 removed, and the period 1994-2013 (red line). Slopes significantly different from zero in bold in regression table:

Chl a	1985-2013	1985-1994	1994-2013
Slope	-0.1676	-0.7386	0.03936
Probability	2.87E-05	0.00759	0.1148
multi- R ²	0.05143	0.07266	0.01116

APPENDIX B

Comments from the Scientific Working Group and responses from the authors.

Author	Page	Comment	Response
Anonymous	iii	Under Finding #3, second bullet, regarding ratios of N and P in Delta: I'm reading this to mean ratios of total N and total P (including various forms of each). I don't know that enough research has been done to determine if the ratios of the different forms can be an important driver.	Ratios of N:P are important drivers when one nutrient is in limiting supply and slows the growth rate down. Ratios of different forms of the same nutrient are important if a certain form produces a lower growth rate than the other; research on this topic is discussed under section 3.2.3 p24.
Foe	11	Under section 2.2.5, first paragraph, last sentence: Add something like this to last sentence on page 11, "it was deduced that <i>under nutrient limiting conditions</i> phytoplankton would become ..."	Done
Foe	19	On pages 19, 22, and 38 you note that nutrient concentrations are one factor constraining the accumulation of cyanoHAB biomass. Can you estimate either from information from the delta or other waterbodies what range of N and P concentrations would be needed to limit cyanoHAB biomass and toxin levels below a low or moderate probability of human and wildlife health effects? Presumably there are a number of complicating factors including the fact that cyanoHABs co occur with blooms of other algal species which would also pull down nutrient levels. I understand that your estimate is likely to be fairly gross. Would it be possible to refine the range through a series of laboratory and/or field experiments? Could this be considered an information gap? Maybe discuss this somewhere around page 37?	I tried to do this in the original version where based on measurements of microcystin toxin that was harmful to aquatic life (0.8 µg/L) I calculated the amount of Microcystis-associated surface Chl a needed to produce that amount (7 µg/L). Because the science group did not like this estimation I've removed it from the paper. However, using 7 µg/L surface Chl a as a rough estimate, you would need greater or equal to 7 moles N/L to sustain such a level; this is not discussed in the current version
Foe	29	Second paragraph: You might note that Ger <i>et al.</i> , 2010 found that both toxin producing and non-toxin producing strains of Microcystis reduced the survival of both <i>Eurytemora affinis</i> and <i>Pseudodiaptomus forbesi</i> in 10 day lab bioassays. This suggests that the presence of other microcystis metabolites also contribute to overall toxicity.	A new section (4.2.4) on p39 entitled "Potential for CyanoHAB Risk to Delta Beneficial Uses" has been where the Ger (2010) paper and additional papers mentioned by Peggy Lehman are discussed
Foe	32	Under section 4.2.3, second paragraph: Brannan Island is located inside the legal boundary of the delta.	This sentence has been changed to read "Sacramento River" instead
Foe	35	Under section 4.2.4 under potential adverse effects on Delta beneficial uses: What can be concluded about the potential toxicity of cyanoHABs to aquatic organisms including zooplankton and larval fish in the Delta? Presumably there is the possibility of both direct and indirect effects. See Ger et al 2010 for an example of direct toxicity and Acuna et al (2012) and Deng et al (2010) for examples of bioaccumulation related effects. Peggy gave citations for all these papers. If uncertainty exists about the extent of	These effects and papers are discussed in a new section (4.2.4) on p39 entitled "Potential for CyanoHAB Risk to Delta Beneficial Uses". I think uncertainty exists regarding 1) whether the organisms reflect concentrations that are in the water column or 2) they bioaccumulate the toxin 3) what affects the zooplankton - toxic or non-toxic cells

		potential toxicity, then should this be listed as an information gap? What information is most important to collect first?	
Foe	38	Figure 5.2 shows nutrient trends at station D26 in the delta between 1994 and 2014. The conclusion is that nutrients concentrations are not changing. Longer term nutrient analysis suggest otherwise. Nutrient concentrations, N speciation, and dissolved N:P ratios have changed in the delta over the last 40 years. More DIN, more NH4, less SRP and an increase in the N:P ratio (Jassby 2008; Glibert, 2010 ³ ; Van Nieuwenhuyse, 2007 ⁴) ³ Reviews in Fishery Science, 18:211-232 ⁴ Canadian journal of fisheries and aquatic science 64:1529-1542	I reanalyzed the nutrient data going back to 1985. My new interpretation is in section 5.1.4 on p43. I included the Van Nieuwenhuyse and Jassby citations. Appendix A provides plots of NO3, NH4, PO4, N:P, and Chl a from station D26. I demonstrate that one can draw different conclusions from these data depending on whether they are broken into separate time periods or analyzed as one long time course.
Foe	39	Around page 39. You note that cyanoHAB growth rates are a positive function of water clarity. The Delta has become clearer. The delivery of suspended sediment from the Sacramento River to the Delta has decreased by about half during the period between 1957 and 2001 (Wright and Schoellhamer (2004) ¹ and this has resulted in a statistically significant -2 to -6 percent decrease per year in SPM between 1975 and 2005 (Jassby, 2008) ² . Of course, it is uncertain whether the trend will continue. Might this increase in clarity also increase the frequency and magnitude of cyano blooms in Delta and make other factors like nutrients more important? ¹ San Francisco Estuary and Watershed Science, 2004 volume 2, issue 2 ² San Francisco Estuary and Watershed Science, 2006 volume 6, issue 1	This is true and I've added a new section (5.1.3) entitled Water Clarity (p 43) where this additional information is discussed.
Joab	ii	Second paragraph, second sentence. Add "the" between "by" and "Water Board".	Done
Joab	ii	Under Finding #2, item 1), change "e.g." to e.g.,"	Removed
Joab	1	Under section 1.1, first sentence. Add "in" between "found" and "Northern California".	Done
Joab	1	Last paragraph, first sentence regarding the commissioning of literature reviews: Actually we only commissioned two white papers (to date) on cyano	Changed to "two"

		and macrophytes. We are working on commissioning the third.	
Joab	4	Under section 2.1, first paragraph, fourth sentence. In sentence, "Cyanobacteria also produce and array..." Change "and" to "an".	Done
Joab	5	In Table 2.1, under the Nostocales (Group 4), is <i>Cylindrospermum</i> the correct name?	It is the correct name; however, I could just as easily have mentioned <i>Cylindrospermopsis</i> which is a more recognizable species.
Joab	6	Second paragraph, second sentence. You identify Group 5 as having toxic cyanoHAB-forming cyanobacteria: Don't you mean Group 4 based on the species identified in Table 2.1? Also, which group is <i>Planktothrix</i> in? I did not see them identified in the table - can they be added?	I did mean Group 4; it's been changed. I've also indicated in the text which subgroup <i>Planktothrix</i> belongs to
Joab	8	Under Ammonium transport section, third paragraph. Change "alterate" to "alternate".	Done
Joab	8	Under Nitrate transport and reduction section, last sentence regarding nitrate uptake: What concentrations of ammonia are relevant? Are these concentrations in the cells or the water column?	External; sentence changed to reflect this
Joab	9	First paragraph, first sentence: Carbon fixation seems to be very important in the nutrient uptake process. What controls carbon fixation? Is there some way to reduce their carbon fixation?	Irradiance controls CO ₂ fixation; this has been mentioned
Joab	9	Fourth paragraph, last sentence. Remove "have" between "their genomes" and "demonstrates".	Done
Joab	10	Under Nitrogen fixation, second paragraph, last sentence relating to n ₂ fixation under iron-limiting conditions: What is the iron-limiting condition? Do we know?	Where iron is not enough to support cell division
Joab	10	Under nitrogen fixation, last paragraph, seventh sentence. Correct the spelling of "heterocyst".	Done
Joab	11	First paragraph: What are the conditions for N starvation?	When N concentration is not enough to support cell division of available biomass
Joab	19	In Figure 3.1, step 6 states to add grazers: Are their cyanobacteria grazing fish and zooplankton?	This figure was very busy and included many processes not discussed in the White Paper; I've substituted a new and simpler figure
Joab	38	Under section 5.2, first paragraph, first sentence: This citation is now 8 years old. Is there any recent information to suggest if these percentages have changed significantly?	Not that I'm aware
Joab	39	First paragraph: Correct the spelling of "cyanoHABs" to "cyanoHABs". Do global search in document to check spelling of cyanoHAB.	Done
Joab	39	Second full paragraph: In sentence, "In Clear Lake, Both N and P..." delete capital B and make lowercase.	Sentence changed

Joab	41	In Table 5.1, Observations in the Delta "temperatures above 25° C rarely occur." - Temperatures in the San Joaquin River near Stockton have over the past 3 years (2012-2014) reached over 25°C from June through October, most likely due to this persistent drought and overall increase in temperature.	Sentence has been removed
Kudela	31	Figure 4.2. I think this is an issue with Peggy's original figure, because I remember seeing it before, but the chlorophyll units don't make much sense. 0.1 ng/L is barely detectable under the best of circumstances.	Y-axis corrected to µg/L
Kudela	N/A	The toxin table is very thorough, but it might be worth pointing out that, based on available information, Central California seems to be dominated by microcystins. We have all of those genera present but we don't very often see saxitoxins or anatoxin-a. Admittedly we don't look that often either, but we have tested some samples from Clear Lake, SF Bay, and Pinto Lake. We very rarely get low levels of STX, and one low hit for anatoxin-a in Clear Lake. We did see low levels of anatoxin-a in Lake Chabot also, and if you go further north, anatoxin-a becomes dominant in the Eel River basin. This supports Mine's decision to focus on microcystins in the report, but the implication of that section is that we could see a wide variety of toxins, and we usually don't.	This has been pointed out in the first paragraph of section 4.2.3
Kudela	N/A	Temperature. While I completely agree with Mine's summary, bear in mind that we do see toxin at low temperatures (this is documented in Kudela 2012 and Gibble and Kudela 2014). We were not tracking species, but it seems likely that it's related to a shift in composition to more cold-tolerant species such as Planktothrix. We tend to get two peaks of toxicity—one at lower biomass and cooler temperatures, and the second (larger) when Microcystis is dominant.	I was not aware of the Gibble Kudela paper; would like to add appropriate discussion
Kudela	N/A	Marine toxins. I'm not sure I completely believe it but there is a recent article (which I can't find right now—looking for it) that documents presence of microcystins in marine waters, from marine cyanobacteria.	Noted

Kudela	N/A	I'd be very supportive of developing an ecosystem model, but for CHABs in particular you probably need a fairly complex model that can parameterize both end-members (riverine and marine). A good hydrodynamic model would be a great place to start. I'm not sure how easy or difficult it would be to add a biological model on top of that, or whether you'd need two models, etc. It's probably my own bias but I would start with assembling all the available data and run statistical analyses on that (Peggy's done quite a bit of this already) to see what variables emerge as most important. Cecile Mioni has been attempting that with the Bay/Delta data and it's been interesting, in that there are no clear physical drivers related to cell abundance or toxicity. She looked at all the usual ones, temperature, salinity, nutrients, etc. suggesting that either there's not enough data (a real possibility) or that it's not a simple relationship. That of course leads back to the need for more monitoring and modeling.	Noted
Mussen	iii	Under Finding #4, third sentence regarding increased nutrient loading: With continued regulatory controls on nutrient loads into the system, we should not necessarily expect nutrient loading to increase substantially in the future.	This has been removed
Mussen	1	Under section 1.1, in fourth sentence "The Delta is widely recognized as in "crisis" because of competing demands..." Add "human effects on the environment and" between "because of" and "competing".	Done
Mussen	4	Last paragraph, second sentence. Add "in local communities" between "irrigation of farms" and "as well as". Plus, remove the words "drinking water to" after the words "as well as".	Sentence has been revised
Mussen	7	Under Carbon Fixation, fifth sentence. Add "near" between "concentrate CO2" and "its vicinity".	Sentence has been revised
Mussen	28	Under section 4.1 Ecosystem Services, second paragraph, third sentence: Change "Striped Bass" to "juvenile-Striped Bass".	Done
Mussen	29	First paragraph, fourth sentence: "At high densities...(Paerl 2004, Paerl and Fulton 2006)" is a repeat from text in the paragraph above on page 28.	Noted; the repeat text has been removed
Mussen	29	First paragraph, sixth sentence "At dense concentrations..." - If low nutrient concentrations can be used to limit the magnitude of future cyanoHAB blooms, the effects of lower nutrient concentrations must also be considered for all other plant and algae species growing in the system (this is especially important for the period followin onset of a future cyanoHAB blooms where nutrients in the area would be fully depleted).	Noted; this point has been brought up in the recommendations section (6.0) in conjunction with hypotheses development

Mussen	38	Under section 5.2, second paragraph, first sentence referring to growth of cyanoHABs versus diatoms: Without nutrient limitation, growth rates may not determine which phytoplankton species is dominant in the system. Other factors such as light availability, buoyancy, temperature, salinity and grazing pressure may determine the dominant species.	This sentence, presently in section (5.1.4) has been revised to clarify point
Mussen	40	Under second bullet, third sentence concerning blooms not persisting without ample supply of nutrients: Once a bloom consumes the available nutrients, would nutrient remineralization be able to sustain some lower concentration of cyanoHABs presence throughout the remainder of the growth season? Could cyanoHABs persist at harmful levels in this manner?	I think typically not; harmful levels require a certain level of biomass to be sustained
Mussen	40	Under second bullet, third sentence: Add "flow rates," between "temperatures," and "and irradiance".	Done
Mussen	40	Under second bullet, third sentence: Remove "s" from word "remains".	Done
Mussen	40	Last paragraph, fourth sentence starting with "Increase nutrient loading...": Please see my comment above on increased nutrient loading.	This has been removed
Mussen	42	Under R1, second paragraph discussing enumeration of cell counts: What about the inclusion of "and average biomass?"	Controversy regarding how it is to be measured; could be discussed under recommendations
Mussen	43	Under R2, first paragraph, second sentence: Replace "higher chlorophyll a" with "increased phytoplankton growth in the Delta".	Done
Mussen	43	Last paragraph, first sentence concerning informing management actions: It is also important to model expected nutrient levels with levels of reduced loading. The time required for a reduction and the amount of nutrient regeneration in a system can be highly variable.	Section expanded in order to note this point
Mussen	43	Last paragraph, first sentence. Add "s" to "action" making it "actions".	Done
Mussen	43	Last paragraph, second sentence regarding modeling primary productivity and biomass: CyanoHAB growth rates under ideal conditions (which may be used as the basis for a model design) can be quite different from their growth rates at near-limiting nutrient conditions. Do we know what low nutrient concentrations (thresholds) would be necessary to prevent the overgrowth of different cyanoHABs? How would other plants and algae in the system be affected by low nutrient concentrations? With limited nutrients, can we predict which phytoplankton species would be dominant in the system, and how the dominant species may change with climatic factors such as temperature, flow, and turbidity, or with differing grazing rates?	Section expanded in order to note this point

Orr	iii	Under #3, first bullet - During the last meeting lower temperatures (18°C) were discussed. Are there references for the blooms at lower temperatures in the delta?	None that I'm aware of
Orr	28	For the last sentence on page 28 under section 4.1. Ecosystem Services, "CyanoHABs also can cause night-time dissolved oxygen depletion via bacterial decomposition and respiration of dense blooms which results in fish kills and loss of benthic fauna (Paerl 2004, Paerl and Fulton 2006) - Does this occur in the Delta or is flow mixing sufficient to prevent the issue?	This is an example of an adverse effect noted in other systems
Orr	29	In the second paragraph, the sentences starting with "At low concentrations...(Lehman <i>et al.</i> 2010)" are already in the preceding paragraph. Consider removing.	This has been removed
Orr	29	Regarding the third sentence at the top of the page, "However, even at low concentrations, toxins released (upon death and cell lysis, or by grazing) can bioaccumulate in higher trophic levels (Lehman <i>et al.</i> 2010) - There is some disagreement on this topic in the literature. Based on the Lehman paper alone it seems unclear whether the toxins bioaccumulate or simply occur in tissue at concentrations that are not greater than the surrounding environment. In other systems it depends on the particular toxin and species in question. I recommend removing the "even at low concentrations" to make a more conservative statement. Another option would be to state they have been observed in higher trophic levels in the delta and leave the bioaccumulation to be addressed in recommendations or further research.	This sentence has been modified
Orr	32	Under section 4.2.3, last sentence in first paragraph "Using the relationship 115 ng microcystin μg surface Chl a^{-1} (Figure 4.4), <i>Microcystis</i> -associated surface Chl a concentration of 7 $\mu\text{g L}^{-1}$ (sampled using a horizontal net tow) would produce enough microcystin (800 ng L^{-1}) to reach the OEHHA Action Level, and constitute an action level for the Delta." I am concerned with the concept of using Chl a to determine actions levels. While Chl a and microcystin levels are related the correlation is not linear and does not take other cyanotoxins into account. Whether or not chl a correlates with other toxins would be an interesting question.	This can be discussed further; to be on the safe side I removed Figure 4.4 and the calculation of a surface Chl a level that could potentially constitute an action level

Orr	36	Under section 5.1, last half of paragraph relating to flow and turbidity - Is there data to suggest that increased turbidity reduces risk of HABs in the delta that is independent of flow rate or temperature? HABs are common in other water bodies with high turbidity. The observation the HABs are controlled by turbidity may be an artifact of higher flows and lower temps. In low flows and turbid water could buoyancy regulating species stay near the surface to receive the necessary light intensity?	Yes, I do think that the effect of turbidity cannot be separated from the effect of flows in the Delta; whether turbidity alone has the same effect is not clear. I have revised this statement to reflect that the two covary
Orr	42	Under R1, second paragraph discussing monitoring - Consider not listing species. If the plan is long term the species of concern may change or expand.	Adaptive management strategies should take care of that; the species are listed as an example
Orr	42	Under R1, last sentence in first paragraph, correct the misspelling of "calibrate".	Done
Orr	N/A	The introductory sections have a broad perspective regarding toxigenic algal species. However, the discussion of factors influencing cyanobacterial blooms appears to focus on microcystins as a model for all blooms. I think the discussion of other species should be increased.	The literature is heavily tilted towards microcystins therefore the white paper as well. However, Kudela noted in his comments that cyanobacterial toxins other than microcystins are almost not detected in the Delta; a statement to this effect has been added in the first paragraph of section 4.2.3
Orr	N/A	I am concerned about how turbidity is discussed. If data is available I recommend discussing it separately from flow and temperature. If turbidity related data is not available avoid general assumptions regarding its influence on blooms.	I have repeated previously published statements regarding turbidity and Microcystis in the Delta; the assumptions in the published work are stated. A new section (5.1.3) on water clarity in the Delta has been added.
Orr	N/A	It was unclear to me what the end goal of the monitoring program is. If a clearer question(s) can be developed I encourage adding a more specific monitoring plan.	To be discussed at the next meeting
Orr	N/A	I heard some monitoring questions from the group and am interested in how common these questions are among the group. I suspect there will be some disagreement about the hypothesized answers but the questions seemed shared. (See 4 questions below)	Noted
Orr	N/A	1. When and where do we reach the required surface temperatures for a bloom? (microcystis exclusively?) a. What is the appropriate depth to measure temperature?	Noted
Orr	N/A	2. Do nutrient limited conditions occur during blooms in the delta? Presumed not to. a. Does this occur in some areas but not others? b. Are we close enough for this to occur in near future? c. Is this question species or nitrogen source dependent in a non-limited system?	Noted
Orr	N/A	3. Spatially where are both temperature and nutrients high and do we need more spatial resolution?	Noted

Orr	N/A	4. Is chlorophyll a the right parameter to be measuring? a. Does it correlate with microcystin concentrations?	Noted
Taberski	iii	Delete "already exists" under the section R1, first sentence.	Done
Taberski	1	Add "of" under section 1.1, 4th sentence "...Delta is widely recognized as in "crisis" because of competing demands..."	Done
Taberski	1	Delete "d" in word "declined" under section 1.1, last sentence "...including the continued declined of ..."	Done
Taberski	22	The paragraph under sub-section "Confounding factors:" is not clear, particularly the last sentence is confusing.	This sentence has been revised
Taberski	29	In the 5th sentence at the top of the page, insert a space in the word "watercolumn".	Done
Taberski	32	In table 4.1, I think you should also include the OEHHA thresholds.	Table below has OEHHA thresholds
Taberski	39	Under the last paragraph for section 5.2, the last sentence "...nutrients are unlikely to play a role in the onset or frequency of bloom occurrence in the Delta." - I agree. Nutrient concentrations would play a role, though, in the magnitude (concentration) and duration of a bloom. If nutrients were lower, they would be depleted more quickly and the bloom would crash. This was stated in the Summary bullet #2. That clarification should be added to this paragraph.	This has been added
Taberski	40	Under the second bullet, in the third sentence, correct the misspelling of "initiated".	Done
Taberski	40	In the last paragraph, in the second sentence, put a space in the word "watercolumn".	Done
Taberski	40	In the last paragraph, in the third sentence, change the sentence to read as "Both <i>higher</i> temperatures and reduced ..."	Changed
Taberski	42	Under R1, first sentence, delete the wording "already exists".	Done
Taberski	N/A	A section should be added on risk to aquatic life.	Done
Taberski	N/A	Historical data should be analyzed based on driving factors to evaluate risk (areas with high temperatures/low turbidity/long residence time)	Example analysis of nutrient concentrations at station D26 performed; included in Appendix A
Taberski	N/A	Recommended monitoring should be based on specific management questions related to status and trends, hotspots, risks to humans, animals and aquatic life, and directing management actions.	Noted
Taberski	N/A	Monitoring information should be collected on processes and projections needed for modeling cyanoHABs and directing management actions. The SF Bay RMP's management questions could be used as a model for developig management questions for cyanoHABs. The RMP's management questions are:	Noted

Taberski	N/A	<p>1. Are chemical concentrations in the Estuary at levels of potential concern and are associated impacts likely?</p> <p>a. Which chemicals have the potential to impact humans and aquatic life and should be monitored?</p> <p>b. What potential for impacts on human and aquatic life exists due to contaminants in the Estuary ecosystem?</p> <p>c. What are appropriate guidelines for protection of beneficial uses?</p> <p>d. What contaminants are responsible for observed toxic responses?</p>	Noted
Taberski	N/A	<p>2. What are the concentrations and masses of contaminants in the Estuary and its segments?</p> <p>a. Do spatial patterns and long-term trends indicate particular regions of concern?</p>	Noted
Taberski	N/A	<p>3. What are the sources, pathways, loadings, and processes leading to contaminant-related impacts in the Estuary?</p> <p>a. Which sources, pathways, and processes contribute most to impacts?</p> <p>b. What are the best opportunities for management intervention for the most important contaminant sources, pathways, and processes?</p> <p>c. What are the effects of management actions on loads from the most important sources, pathways, and processes?</p>	Noted
Taberski	N/A	<p>4. Have the concentrations, masses, and associated impacts of contaminants in the Estuary increased or decreased?</p> <p>A. What are the effects of management actions on the concentrations and mass of contaminants in the Estuary?</p> <p>B. What are the effects of management actions on the potential for adverse impacts of humans and aquatic life due to Bay contamination?</p>	Noted
Taberski	N/A	<p>5. What are the projected concentrations, masses, and associated impacts of contaminants in the Estuary?</p> <p>A. What patterns of exposure are forecast for major segments of the Estuary under various management scenarios?</p> <p>B. Which contaminants are predicted to increase and potentially cause impacts in the Estuary?</p>	Noted
Thompson	ii	You only have four, not five, major findings identified in the Executive Summary section	Corrected
Thompson	iii	Under Finding #3, first bullet, second sentence relating to temperature for growth: Should we specify the time frame over which the temperature is measured? e.g., instantaneous, daily average, daily max or min. This will matter more when we get to modeling phytoplankton dynamics.	Save for the modeling

Thompson	19	Under section 3, first sentence: Correct spelling of word "prompted" by adding a "p" between "m" and "t".	Done
Thompson	20	Under section 3.1, in sentence "Indeed, recent decades has witnessed..." Replace word "has" with "have".	Done
Thompson	20	Under section 3.2.1, first paragraph, reference Edmondson and Lehman 1981 was not included in the reference section.	Done
Thompson	21	Under Cellular N:P composition section: Reference Mills <i>et al.</i> was not included in the reference section and date missing in citation.	Corrected; citation added
Thompson	22	Under Confounding Factors, third sentence: Should we introduce the concept that there may be time lags between nutrient uptake and increased biomass, such that a correlation between two variables at a given point in time may not imply causality?	Good idea; sentence added under confounding factors on page 23 of revised manuscript.
Thompson	22	Under Confounding Factors, third sentence discussing parameters: Is there a diagram from a paper or textbook that we could borrow and reference, that shows the patterns of these variables over time before, during and after a bloom? (e.g., temperature, nutrient concentration, nutrient uptake rate, phytoplankton biomass). Something to show phytoplankton biomass peaking as nutrients draw down.	I found one diagram that showed a dinoflagellate peaking as nutrients were drawn down but nothing for cyanobacteria; after looking for the same pattern for cyanobacteria for half day I gave up
Thompson	27	Last paragraph under section 3.6 on stratification and residence time: Suggest adding a brief discussion of the potential role of ferrous iron. See Molot <i>et al.</i> 2014. A novel model for cyanobacteria bloom formation: the critical role of anoxia and ferrous iron. <i>Freshwater Biology</i> 59:1323-1340. The article mainly deals with lakes but there is a section on page 1330 that mentions shallow, nearshore regions of lakes, including harbors, inshore areas of Lake Erie, and embayments of Georgian Bay (Lake Huron). [Text from Introduction shown on next line.]	The potential role of toxins acting as siderophores and aiding cyanobacteria with iron uptake providing an advantage in competition with eukaryotes is discussed in a new expanded paragraph on p. 19 and the Molot <i>et al.</i> citation has been added to this section.

		<p>Here's some text from the Introduction:</p> <p>"We cannot predict with any certainty when a cyanobacteria bloom will begin once temperatures are warm enough to support growth or the duration of a bloom except through empirical observations from previous years. Nor do we know why the problem is worsening in some mesotrophic systems."</p> <p>"Clearly, the predictive state of cyanobacteria science is unsatisfactory. This dissatisfaction may have contributed to the recent debate challenging the supremacy of the P paradigm in eutrophication management. Wurtsbaugh, Lewis, Paerl, and their colleagues argue that N plays a major role alongside P in promoting cyanobacteria blooms and that both N and P should be controlled (refs). This argument has been vigorously challenged in return by Schindler and his colleagues who claim that controlling N to control cyanobacteria will not work because N-fixation by cyanobacteria will compensate to a large extent for induced N shortages (refs). The outcome of this on-going debate can be expected to influence the direction of billions of dollars in public expenditures to remedy nutrient loading."</p> <p>"Our purpose here is to present a novel model that does not supplant the important roles of P and N as major macronutrients, but instead weaves additional ideas into older ones to create a novel and more comprehensive conceptual framework with much more explanatory power that spans the range of conditions where cyanobacteria blooms have been observed."</p>	
Thompson	27		Noted
Thompson	28	Under section 4.1 Ecosystem Services, second paragraph, Reference Sommer <i>et al.</i> 1997 not included in reference section.	Citation added
Thompson	30	Figure 4.1 - Can we get a higher resolution version of this map? It was blurry in the original Word version, prior to becoming a Google doc.	Will investigate
Thompson	36	Under section 5.0, first paragraph, last sentence: Should we specify that the variables may need to be time-lagged in order for the correlations to be apparent?	I actually prefer to be vague in case entirely different statistics are needed
Thompson	38	Under section 5.2, first paragraph, second sentence referring to Microcystis and Aphanizomenon becoming more common: Is the reference for this statement the Lehman 2007 paper? I think it would be worth referencing it again at the end of this sentence, or adding an additional reference as necessary.	This is based on Lehman's 2008 paper and the Mioni <i>et al.</i> 2012 report; these citations have been added
Thompson	38	Under section 5.2, second paragraph, second and fourth sentence referring to Figure 2: I think this is now [Figure] 3.3. Check Figure number.	Corrected: now figure 3.6

Thompson	39	Second full paragraph, reference to Figure 4.5: This information is not shown in this figure. Check your Figure number.	Correct, the reference to this figure has been deleted
Thompson	39	Second full paragraph, last sentence related to culture investigations: It would strengthen the point to reference (re-reference) some key papers here.	Done
Thompson	41	In Table 5.1, Observations in the Delta "when turbidity is <50 NTU, flow is <30 m ³ s ⁻¹ and irradiance >50 μmol phot m ⁻² s ⁻¹ ": Please briefly state where in the Delta this was measured, and over what spatial and temporal scale.	Done
Ward	N/A	<p>Comment 1: Of the five questions the Work Group is tasked with answering, the first is to determine whether the principal physical and biological factors promoting cyanobacteria blooms and toxin production in the Delta have been identified. My reading of the current work in this area leads me to conclude that these factors have not yet been adequately characterized. More importantly, the critical task of accurately gauging the relative weight of various factors that are known to influence/control the formation of toxigenic (or other) blooms still seems beyond our capability at present, whether in the Delta or in other waterbodies for which some relevant data is available. These deficiencies are particularly problematic for the development of a model that has practical utility.</p> <p>The field work and laboratory studies on Delta water quality and Delta species involved with the Pelagic Organism Decline that were cited in the draft white paper and/or distributed to the Work Group are largely "Microcystis-centric" and "microcystin-centric". There is, in my view, a very large risk in attributing (1) all significant microcystin production to Microcystis in the Delta, and; (2) focusing on microcystin(s) to the exclusion of the effects of other possible toxigenic genera and other cyanotoxins. Dr. Berg's draft white paper duly notes the existence of many other toxigenic genera and other cyanotoxins, but it seems the Delta-specific research on these possibilities may not yet be available for review.</p>	Noted; Please see new comment under section 4.2.3 on toxin data available from Central California demonstrating that very few detections of toxins other than microcystins have been made in the Delta

Ward	N/A	<p>Comment 1 continued: This is not a trivial point: for example, various Aphanizomenon strains can produce saxitoxin, microcystin(s), cylindrospermopsin, BMAA, and anatoxin-a (Paerl & Otten, 2013), and Lehman <i>et al.</i> have noted the presence of this genus in the estuary, bay and/or Delta. Though it is quite possible that I have overlooked Delta-specific studies on Aphanizomenon strains which examined the possibility that one or more of these toxins is present, if it is true that these studies have not been conducted yet, it would be ill-advised to presume that microcystin(s) are some sort of "model" toxin that can be regarded as a generic equivalent of all of the others in a subsequent modeling exercise, especially given their chemical and toxicological heterogeneity. Similarly, the diazotrophic cyanobacteria such as Aphanizomenon may respond rather differently to "nutrient limitation" (of nitrogen) than the non-diazotrophic genera such as Microcystis. If both genera produce microcystins, then microcystin production per se may continue in a water body as nitrogen becomes more limiting for Microcystis.</p> <p>Comparisons of diazotrophic cyanobacteria with non-nitrogen fixing cyanobacteria to nitrogen-limited conditions tend to show the following pattern: diazotrophs (e.g., Aphanizomenon) tend to produce toxins such as microcystin under nitrogen-limited conditions, whereas non-nitrogen fixers such as Microcystis and Planktothrix increase toxin production under non-limiting conditions.</p>	Not necessarily; please see Dolman 2012 citation for patterns of abundance of various species and toxin production in over 100 lakes in Germany under different N:P scenarios described in "Meta analyses of Lake Studies" on page 24.
Ward	N/A	<p>Comment 1 continued (references): Holland, A., Kinnear, S. Interpreting the possible ecological role(s) of cyanotoxins: compounds for competitive advantage and/or physiological aide? <i>Marine Drugs</i> 2013, 11(7), 2239-2258 http://www.mdpi.com/1660-3397/11/7/2239 Paerl, H. Otten, T. Harmful Cyanobacterial Blooms: Causes, Consequences, and Controls. <i>Microbial Ecology</i> 2013 May;65(4):995-1010 http://www.unc.edu/ims/paerllab/research/cyanohabs/me2013.pdf Leao, P. <i>et al.</i> The chemical ecology of cyanobacteria. <i>Natural Products Reports</i>, 2012 Mar;29(3):372-91 http://www.ncbi.nlm.nih.gov/pmc/articles/PMC4161925/pdf/nihms-599340.pdf</p>	
Ward	N/A	<p>Comment 2: Given my time limitations for reviewing more recent work on how/whether nutrient management can reduce the magnitude and frequency of cyanobacteria blooms and toxin formation, I was unable to conduct the review I had originally anticipated on this question.</p>	Noted

Ward	N/A	<p>Comment 3: I believe the draft white paper correctly examines and compares the relative significance of various factors in controlling the growth and development of toxigenic blooms based on the limited data now available on this subject that is “Delta-specific”. However, as stated in answer to Question 1 (above), I also believe the factors considered, while appropriate, are nevertheless an incomplete list. At our meeting I mentioned the apparent role of competition for iron as a factor in bloom formation and dominance in freshwater ecosystems, and provided a citation for this. Other factors which should be considered include the differences in sensitivity to herbicides between cyanobacteria and other phytoplankton that are being reported in studies conducted elsewhere, and the role of allelopathy in bloom formation, dominance, and senescence. Allelopathy is also discussed in references provided in answer to Question 1. For pesticides – in this case, I focused on herbicides – please refer to references provided below.</p>	<p>Allelopathy was discussed in the original version of the White paper under "Potential Functions of toxin production" on page 18. Two new references have been added to the previous references on allelopathy in this section.</p>
Ward	N/A	<p>Comment 3 continued (references): The USGS maintains an online geo-referenced database which charts the most commonly-used pesticides in CA as they have continued to change in recent years that is current through 2012: http://water.usgs.gov/nawqa/pnsp/usage/maps/compound_listing.php Lurling, M., Roessink, I. On the way to cyanobacterial blooms: Impact of the herbicide metribuzin on the competition between a green alga (<i>Scenedesmus</i>) and a cyanobacterium (<i>Microcystis</i>). <i>Chemosphere</i>, 2006, 65:4, 618-626. Peterson, H. <i>et al.</i> Toxicity of hexazinone and diquat to green algae, diatoms, cyanobacteria and duckweed. <i>Aquatic Toxicology</i>, 1997, 39(2), 111-134. Arunakumara, K. <i>et al.</i> Metabolism and degradation of glyphosate in aquatic cyanobacteria: a review <i>African Journal of Microbiology Research</i>, 2013 Vol. 7(32), pp. 4084-4090. http://www.academicjournals.org/article/article1380269900_Arunakumara%20et%20al.pdf</p>	<p>The potentially important influence of herbicides and fungicides on the prevalence of cyanobacteria vis-à-vis other phytoplankton is discussed in a new Section 3.7 on p. 31 and again under Section 4.2.1 p 33. Because concentrations of herbicides in the Delta have been demonstrated to be quite high, a recommendation has been added that selective sampling for herbicides and pesticides be instituted in the Delta.</p>
Ward		<p>Comment 4: In answer to this question, please see the additional references supplied in answer to Questions (1) and (3).</p>	<p>A citation by Holland and Kinnear (2013) has been added on the benefits of toxin production under iron limiting conditions as mentioned in previous comments.</p>

<p>Ward</p>	<p>N/A</p>	<p>Comment 5: Overall, I agree with the draft recommendation put forward regarding monitoring of CyanoHABs (Recommendation 1), but would place more emphasis on monitoring for more immediate threats to public health e.g., intakes for drinking water treatment plants either within the bloom-prone areas of the Delta. The waterboard’s drinking water program staff has informed me that some public water supply systems are struggling to successfully contend with this issue elsewhere in California, and this may also be a recurrent problem for smaller communities in the Delta. With perennially limited resources, public health protection should be given the highest priority, followed closely by protection of beneficial uses such as threatened/endangered species already impacted by the Pelagic Organism Decline, and a (seasonal?) surveillance program for areas of the Bay/Delta which experience periods of frequent and prolonged recreational uses water-contact uses, fishing, etc.</p> <p>With respect to Recommendation 2, I am unclear as to what the model being described is intended to accomplish: will it, if properly deployed, facilitate successful toxigenic bloom “forecasting”? Will use of whatever model results from this development process be of assistance, say, to managers of local public water supplies whose intakes are situated in the Delta? Having worked on this issue for ten years, I am concerned that our scarce resources are not being directed at immediate (& often seasonally recurrent) cyanotoxin hazards, and that local public health officials and water system managers have too few resources to respond effectively, and in a timely manner, when these episodes occur.</p>	<p>Noted</p>
-------------	------------	--	--------------

<p>Ward</p>	<p>N/A</p>	<p>Comment 5 continued: As an example, last year the public water supply system for 400,000 people in the greater Toledo area were shut down, causing a public emergency and immediate potable water shortage for the entire population, when a microcystin-producing <i>Microcystis</i> bloom swamped the treatment plant's capacity to remove it in the "finished" drinking water. The National Guard was called-up to help deliver potable to this large urban population, and the problem did not abate for several days. Prior to this episode, NOAA had been doing quite a bit of modeling, bloom-forecasting, and other scientific investigations on these recurrent toxigenic blooms on western portion of Lake Erie where Toledo area residents obtain their public water supplies. The NOAA investigations remain on-going, and no doubt have provided much useful information on the role of various environmental factors in bloom formation: their "mission", however, is not to protect specific public water supplies from catastrophic events such as this episode. http://www.washingtonpost.com/news/post-nation/wp/2014/08/04/toledos-water-ban-and-the-sensitivity-of-our-drinking-systems/</p>	<p>Noted</p>

APPENDIX C

Comments from the Stakeholder and Technical Advisory Group (STAG) members and responses from the authors.

Author	Page	Comment	Response
Lee	N/A	Overall Comment: The findings expressed in the draft white papers are consistent with our many years of experience investigating nutrient-related water quality, our findings in investigating Delta nutrient impacts and control of excessive aquatic plants, as well as with the findings expressed in presentations made at the CWEMF Delta Nutrient Modeling Workshop discussed below.	Noted
Lee	N/A	There remains little ability to quantitatively and comparatively describe the role of nutrients (N and P) in controlling the excess fertilization of the Delta waters.	Noted
Lee	N/A	There is considerable misinformation in the professional arena on the relative roles of N and P concentrations and loads, and the ratios of N to P in affecting water quality in the Delta; some of the information presented on nutrient/water quality issues is biased toward preconceived positions.	Noted
Lee	N/A	Based on the results of the US and international OECD eutrophication study and our follow on studies of more than 600 waterbodies worldwide (lakes, reservoirs, estuarine systems) the planktonic chlorophyll levels in the Central Delta are well-below those that would be expected based on the phosphorus loads to the Delta.	Noted
Lee	N/A	There is a lack of understanding of the quantitative relationship between nutrient loads and fish production in the Delta.	Noted
Lee	N/A	The Delta Stewardship Council's timetable for developing Delta nutrient water quality objectives by January 1, 2016, and to adopt and begin implementation of nutrient objectives, either narrative or numeric as appropriate, in the Delta by January 1, 2018 is unrealistically short.	Noted
Lee	N/A	There is need for substantial well-funded, focused, and intelligently guided research on Delta nutrient water quality issues over at least a 10-yr period in order to develop the information needed to generate a technically sound and cost-effective nutrient management strategy for the Delta.	Noted
Lee	N/A	As discussed in our writings, some of which are noted below, it will be especially difficult to develop technically valid and cost-effective nutrient control programs for excessive growths of macrophytes in the Delta.	Noted

Mioni	3	#2: pH may also be important (I see some correlations and I think Raphe mentioned a report). I believe some cyanobacteria can be more competitive when pH increases due to CO ₂ concentrating mechanism. I think Alex Parker did some research on the Delta pH... Also, the residence time may be affected by the pumping station located near the EMP Old River D28 station (a station with typically high Microcystis abundance).	Noted
Mioni	13	last paragraph: Please talk to Anke Mueller-Solger. I believe Microcystis was there before 2000 but was simply not monitored as closely or did not cause such bloom.	Noted
Mioni	16	Carbon fixation: I would include a few reference to the cyanobacteria carbon concentrating mechanism.	Noted
Mioni	16	Table 2.3: Microcystin LD50 varies depending on the variant	Noted
Mioni	20	typo "preceding"	Noted
Mioni	21	N:P ratio: I would cite Hans Paerl as well. I believe he has shown (in Lake Taihu?) that the N:P ratios were not so fixed for cyanobacteria.	Noted
Mioni	29	Salinity: I think Pia Moissander did phylogenetic studies in the SFBD and has shown that there were two types of Microcystis, one of those was associated with higher salinity.	Noted
Mioni	31	I agree that absolute concentrations of nutrients is more relevant than N:P ratios with regards to cyanobacteria. I believe Hans Paerl also demonstrated this (Nature paper? I can't recall the exact source).	Noted
Mioni	37	last paragraph: typo "water column"	Noted
Mioni	39	Old River stn (D28) usually has the highest abundance based on my monitoring. Antioch also has a high abundance of Microcystis. Pia Moisaner's paper show that there may be two different strains (different requirements?) between antioch and other stations. It varies between years at other stations (see attached examples but please do not use as this is for the paper I am writing...)	Noted

Mioni	40	<p>It really depends on the year. Aphanizomenon was very sporadic before 2011 and I focused on enumerating Microcystis which was the dominant cyanoHAB. But in 2011, Aphanizomenon was pretty significant. The tricky part here is that the Aphanizomenon cells are much larger than Microcystis so even if Aphanizomenon doesn't reach the cell density of Microcystis, it doesn't mean they are not dominating the bloom (e.g. 2011, it would clog my filters pretty quickly at some stations)... In 2012, Microcystis abundance was higher than in 2011 but Apha was still pretty abundant. I think that the "bloom" classification based on cell density should be revised to take into account the biovolume... Cell counts can be misleading.</p>	Noted
Mioni	44	<p>There is definitely variations explained by the method but there are also variations due to heterogeneity, patchiness and temporal variation. In Clear lake, while on station (within maybe 30min or less), we could see the scum moving very quickly with the wind. Also, the two net samples mostly applies to colonial forms of Microcystis although it occurs also as single cells and microcolonies. Another bias is the cell count. Prior to do my cell counts, I was homogenizing the samples by dislocating the colonies physically (based on prior research and comparison). I suspect that not dislocating the colonies prior to do the cell count may result in bias as the person enumerating the cells may not be able to count accurately as colonies can be more 3D than 2D (I hope it makes sense)... Although there is a bias in all methods, I do not think I ever collected samples in the same time than Peggy and at the same location. Thus, the comparison is a little puzzling to me. We never did intercomparison of the cell enumeration from the same samples. It would be more relevant to compare methods for the toxicology work since we did intercomparison of methods for the same samples.</p>	Noted
Mioni	48	<p>"colonial Microcystis have been more common", see my comments regarding the bias of tow net sampling versus grad raw water samples...</p>	Noted

Mioni	4 & 35	#3 and page 35, temperature: Lenny Grimaldo generated a logistic model based on my CALFED data (see attached) which shows that Microcystis bloom probability raises to 50% when surface water temperature reaches 25C. Also, I suspect there is a minimum temperature that would need to be sustained for several days if not week for a bloom to initiate.	Noted
Mioni	42-43	I think the SWAMP report could be cited, especially for the SPATT results.	Noted
Mioni	Fig 4.5	Figure 4.5: the axis are not labelled and I have trouble understanding this figure.	Noted
Mioni	48	I could not find the figure 2 mentioned here...	Noted

Factors Controlling Submersed and Floating Macrophytes in the Sacramento-San Joaquin Delta

The authors of this document wish to thank the members of the Submersed and Floating Macrophyte Science Working Group and Stakeholder and Technical Advisory Group for review and input. This report was produced under California State Water Board contract to the Southern California Coastal Water Research Project (Agreement Number 12-135-250).

DRAFT

This report should be cited as:

Boyer K and Sutula M. 2015. Factors Controlling Submersed and Floating Macrophytes in the Sacramento-San Joaquin Delta. Southern California Coastal Water Research Project Technical Report No. XXX. XXXX 2015.

Executive Summary

The Central Valley Regional Water Quality Control Board (Water Board) is developing a plan to generate the science needed to support decisions on policies governing nutrient management in the Delta. Non-native, invasive floating and submersed aquatic vegetation (SAV) are one of three areas, identified by Water Board, that represent pathways of potential ecosystem impairment that could be linked to nutrients. The Water Board commissioned a literature review of the factors that may be controlling the prevalence of floating and SAV. This literature review addresses three major questions:

- 1) How do submersed and floating aquatic vegetation support or adversely effect ecosystem services and related beneficial uses?
- 2) What is known about the spatial and temporal trends in submersed and floating aquatic vegetation in the Delta?
- 3) What is the relative importance of nutrients versus other factors in promoting observed trends in submersed and floating aquatic vegetation in the Delta?

This review had seven major findings:

#1. Native submersed and floating vegetation are beneficial components of the Delta; however, non-native species have been found to adversely affect Delta ecosystem services and associated beneficial uses at the high densities at which they typically occur. Adverse effects include: 1) changes to water chemistry including diurnal swings in pH and dissolved oxygen, 2) changes to physical properties of water including flow and turbidity 3) outcompetition of native SAV, phytoplankton, and other benthic primary producers, 3) changes to the food web, 4) impedece of navigation and obstruction of industrial intake pipes and 5) poor aesthetics.

#2. Two invasive species, *Egeria densa* (Brazilian waterweed, a submersed species) and *Eichhornia crassipes* (water hyacinth, a floating species) are widely recognized as problematic in the Delta, and appear to be increasing in abundance despite control efforts. *E. densa* coverage was estimated at ~2000 hectares in 2007 and 2900 hectares in 2014. *E. crassipes* covered ~200 hectares between 2004-2008 and 800 hectares in 2014.

#3. Additional invaders may also have reached high enough abundance to be considered problematic, especially *Ludwigia* spp. (water primrose). *Ludwigia* spp. (unknown proportion of *L. peploides* and *L. hexapetala*, and possibly *L. grandiflora*) are now equal in floating coverage to water hyacinth (800 hectares each estimated in 2014), whereas the native pennywort was much more common than *Ludwigia* during the period of 2004-2008. *Ludwigia* spp. are not part of a control program in the Delta at this time.

#4. Data on spatial and temporal trends in invasive aquatic plants have been collected only sporadically in space and time and without adequate detail. Remote sensing may be adequate to estimate of coverage of floating vegetation, but submersed vegetation requires a much greater, field-

based effort to distinguish species. Both types of vegetation require estimates of biomass or preferably primary production if we are to understand patterns in abundance and rates of turnover.

#5. Existing scientific literature has documented a number of environmental and management-related factors that have control over the growth of invasive aquatic plants worldwide. These include: 1) light, 2) temperature, 3) salinity, 4) dissolved inorganic carbon (for SAV), 5) nutrients, 6) flow and residence time, 7) interaction with other species, and 8) control efforts.

#6. Studies have documented the importance of a subset of these factors in the Delta, but insufficient evidence exists to determine the relative importance of nutrients versus other factors in promoting the expansion of these species. Drawing on available information, we can conclude the following:

- Conditions in the Delta, including seasonal low flow, low turbidity, warm temperatures, and a freshwater (low salinity) regime, appear to favor the establishment and growth of invasive macrophytes.
- Aquatic plants require macronutrients (nitrogen, N and phosphorus, P) for growth. N and P are available in relatively high concentrations in the Delta ($\sim 0.5 \text{ mg l}^{-1}$ dissolved inorganic N, DIN, and 0.05 mg l^{-1} DIP), and available nutrients may not limit growth. However, it is difficult to discern the relative influence of nutrients versus other factors, making uncertain the effect that nutrient management could have on growth and persistence of these invasive aquatic plants. Recent rapid expansion of invasive macrophyte acreage, despite evidence that concentrations of NH_4^+ , NO_3^- , PO_4^+ , and ratios of N:P within Delta waters have been steady over the last decade, suggest other factors besides nutrients are contributing to the extensive plant growth at the scale of the whole Delta.

#7. Climate change and anthropogenic activity associated with land use changes have the potential to further increase the prevalence of invasive macrophytes. Climate change will likely result in warmer temperatures, reduced frequency of frost, and increased drought, the latter of which could result in reduced flows, increased residence time and water column stability in the Delta. These factors would provide a favorable environment for increased prevalence of *E. densa* and *E. crassipes*, and perhaps other invaders. However, increased salinity intrusion into the west Delta would favor native species of aquatic vegetation, in particular the pondweed *Stuckenia pectinata*.

Given these findings, three major science recommendations are proposed:

R1: Implement routine monitoring of invasive floating and submersed aquatic vegetation. Routine monitoring of floating and submersed aquatic vegetation should be undertaken to assess trends over time and to support ecosystem modeling of the Delta. Grant-funded efforts have been sporadic and there is no plan for on-going rigorous evaluation of patterns and trends. Monitoring should be comprised of a combination of remotely sensed areal coverage and field-based transects to estimate biomass or, ideally, net primary production (through repeated measures of biomass over time to determine rates of turnover), as well as species composition. Estimates of biomass/production and areal cover should be conducted in combination with measures of the major factors that control growth of

these primary producers, including water column and sediment nutrients. Early actions should include the development of a workplan to lay out the key indicators and cost estimates required for monitoring.

R2: Develop a biogeochemical model of the Delta, focused on nutrient and organic carbon fate and transport. Understanding of factors controlling floating and SAV is critically hampered by the lack of information on nutrient and carbon budgets for the Delta and its subregions. In particular, it is important to quantify the storage in the compartments of the ecosystem (i.e. water, sediment, plant biomass, etc.) and fluxes or exchanges between compartments at varying seasonal and spatial scales and with a variety of water flow and residence time scenarios. This information will provide an understanding of whether management of nutrients is likely to aid in control of floating and SAV. To step into model development, three actions should be taken: 1) examine existing models already available to determine suitability for this task, 2) develop a work plan that lays out the modeling strategy, model data requirements, and implementation strategy, and 3) conduct special studies and other monitoring needed to support model development. This includes special studies that quantify N, P, and organic carbon associated with ecosystem compartments as well as uptake, release and flux rates that characterize different reaches of the Delta. Lab and field experiments that test whether macrophyte growth is limited by nutrients in Delta waters could help inform management and predict problem areas. These analyses and experiments should inform hypotheses that can be tested through model development as well as potential future scenarios. The monitoring and modeling teams should collaborate closely to collect high priority data to inform the models.

Comment [KB1]: Point of discussion: John Madsen said “the authors are assuming that nutrients are limiting plant growth without knowing this. It is doubtful that an ecosystem model will indicate if nutrients are limiting either water hy or egeria. It is far more common to see luxury consumption of nutrients by submersed and floating aquatic plants than nutrient limitation”.

R3. Review current and potential future control strategies for invasive aquatic macrophytes in the Delta, including mechanical, chemical, biological control, and integrated control methods, as well as barriers that reduce movement of vegetation into sensitive areas or those with heavy human use. Depending on the outcome of R2, nutrient management may be ineffective in controlling invasive floating and SAV. While monitoring, modeling and special studies are under way, determine the degree to which control strategies are supporting beneficial uses and nutrient management objectives going forward. This work should begin by evaluating current and planned control strategies to determine effectiveness at both reducing live biomass and minimizing recycling of nutrients from dead material into additional growth in areas with high residence time. A current USDA-ARS program on integrated control methods for both *E. densa* and *E. crassipes* could help to inform the proposed review.

Right: Conceptual model of successional pathways of *E. crassipes* growth and expansion, with effects on other floating and submersed plants. From Khanna et al. 2012..... 40

DRAFT

1. Introduction, Purpose and Organization of the Review

1.1 Background and Context

The Sacramento–San Joaquin River Delta (hereto referred to as “the Delta”), is an inland river delta and estuary approximately 1300 square miles in size, found in Northern California (Fig. 1.1). Formed at the western edge of the Central Valley by the confluence of the Sacramento and San Joaquin Rivers, the Delta is a key component of the State’s water resource infrastructure and a region that is rapidly urbanizing, yet serves as critical habitat for fish, birds and wildlife. Water from the 45,000 square miles of Delta watershed fuels both local and statewide economies, including important agricultural commodities. The Delta is widely recognized as being in a state of “crisis” because of competing demands for the Delta’s resources (Delta Plan 2013). The consequences of these competing demands include point and non-point discharges, habitat fragmentation and loss, modified flow regimes, introduction of non-native species, all of which combine to threaten ecosystem health, including the continued decline of native fish (Delta Plan 2013).

In 2009 the California legislature passed the Delta Reform Act creating the Delta Stewardship Council. The mission of the Council is to implement the coequal goals of the Reform Act and provide a more reliable water supply for California while protecting, restoring, and enhancing the Delta ecosystem. The Council wrote and adopted a Delta Plan in 2013 to implement these goals. Chapter 6 of the Delta Plan deals with water quality and contains recommendations to implement the coequal goals of the Delta Reform Act. Among these include a recommendation to consider development of nutrient objectives for the Delta.

Potential nutrient related problems identified in the Delta Plan for evaluation are:

1. Decreases in phytoplankton abundance and shifts in algal species composition,
2. Increases in the abundance and distribution of macrophytes, including water hyacinth and Brazilian waterweed, and
3. Increases in the magnitude and frequency of cyanobacterial blooms

To provide better scientific grounding for the study plan, the Water Board commissioned two literature reviews centered on the latter two potential areas of impairment. This document provides a synthesis of literature on submersed and floating macrophytes in the Delta.

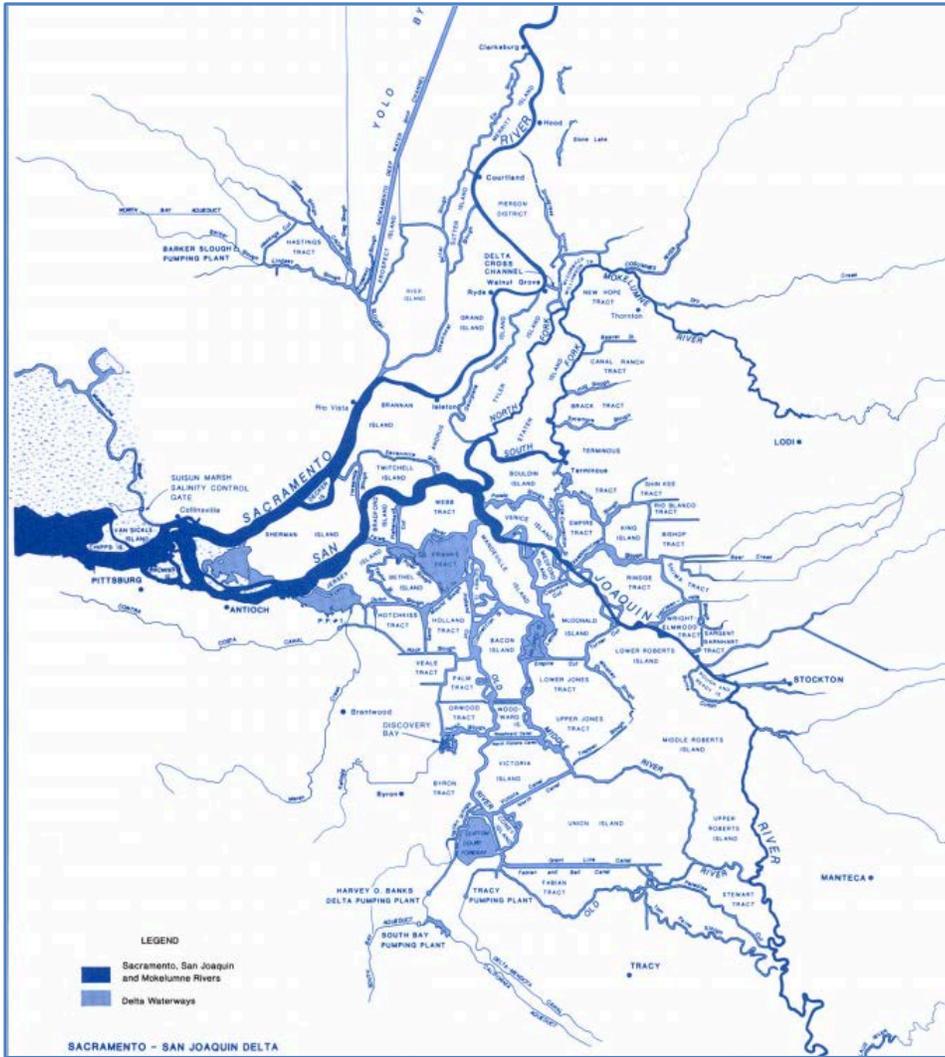

Figure 1.1 | The Sacramento-San Joaquin Delta Region

Comment [KB2]: Consider replacing figure – Shruti said hard to read (and I agree). What was ultimately used in the cyano review?

1.2 Goal and Organization of Macrophyte Literature Review

This review aims to assess whether there is evidence that the perceived increase in the abundance and distribution of submersed or floating aquatic macrophytes in the Delta is the result of long term changes in nutrient or organic matter loading relative to other factors and to ascertain whether management of nutrient loads might be used to remedy the problems associated with these macrophytes. This review will be evaluated and utilized by a Science Working Group to develop recommendations for a research plan to resolve outstanding questions regarding the need for nutrient management to reduce the impacts of invasive aquatic macrophyte species; a Stakeholder and Technical Advisory Group (STAG) will review and contribute to the research plan.

This review addresses the following key questions:

- 1) How do submersed and floating aquatic vegetation support or adversely effect ecosystem services and related beneficial uses?
- 2) What is known about the spatial and temporal trends in submersed and floating aquatic vegetation in the Delta?
- 3) What is the relative importance of nutrients versus other factors in promoting observed trends in submersed and floating aquatic vegetation in the Delta?
- 4) What are the key data gaps and recommended future studies?

The document is organized as follows:

Section 1: Introduction, Purpose and Organization of the Review

Section 2: General Ecology and Trends in the Distribution of Submersed and Floating Aquatic Vegetation in the Delta

Section 3: Role of Submersed and Floating Aquatic Vegetation in Supporting Ecosystem Services

Section 4: Factors Contributing to the Prevalence of Submersed and Floating Aquatic Vegetation in the Delta

Section 5: Recommendations

Section 6: Literature Cited

2. General Ecology and Trends in the Distribution of Submersed and Floating Aquatic Vegetation in the Delta

2.1 Classification of Aquatic Vegetation and Scope of Review

This review pertains to the fully aquatic vegetation in the Delta, including those submersed and rooted plant species in the sediments and those floating on the surface. It does not include emergent species such as sedges, rushes, and broad-leafed forbs that are rooted along the Delta's shores but do not extend across the water surface beyond where they are rooted. The focus is on the most common species and especially the prolific invaders for which management measures leading to a reduction in abundance and distribution, if feasible, would be deemed acceptable and desirable to resource agencies, scientists, and the general public. We consider only the vascular plants; macro- and microalgae are outside of the scope of this review, although they are mentioned in terms of macrophyte effects on them.

2.2 Overview of Species Found in the Delta

There are at least nineteen species of submersed or floating aquatic plants in the Delta (Table 2.1) as identified in the peer-reviewed and grey literature (Anderson 1990, 2011; Jassby and Cloern 2000; Ustin et al. 2007, 2008; Santos et al. 2011; Khanna et al. 2012, Khanna, pers. comm. 2015; Boyer et al. 2012, 2013; Cohen et al. 2014). About half of those species are rooted and submersed beneath the water surface except at low tides. Roughly half of the species are introductions from other regions.

No studies have estimated abundance of all these species Delta-wide, but patterns in relative abundance have been evaluated within particular regions. Two studies focused on submersed species (Santos et al. 2011; Boyer et al. 2013) used a rake method in which the number of tines occupied by each species is used to determine relative abundance (Kenow et al. 2007). *Egeria densa* was by far the most abundant submersed species found in the central Delta study, with detections at 70-90% of sampling points (Santos et al. 2011; Fig. 2.1). Similarly, *E. densa* was detected up to 100% of the time within the submersed vegetation beds sampled at four west Delta locations (Boyer et al. 2013; Fig. 2.2). Recent remote sensing data indicate that submersed vegetation covers ~2900 hectares of the Delta, with *E. densa* dominant among the species (Khanna and Ustin 2014, unpublished data; CA State Parks Division of Boating and Waterways [DBW]). Other submersed, non-native species are typically much less abundant (Fig. 2.1, 2.2), but both *Potamogeton crispus* and *Myriophyllum spicatum* are species of potential concern (see Santos et al. 2011). Distinguishing among submersed species in mixed stands is problematic, leading to concerns about accuracy of coverage estimates, as further discussed below.

Ceratophyllum demersum (coontail) was the most frequently encountered submersed native species within both the central and west Delta studies described above, and was more common than all the introduced species other than *E. densa* (Fig. 2.1, Santos et al. 2011; Fig. 2.2, Boyer et al. 2013). In the same central Delta region that harbored 383 hectares of *E. densa* in fall 2007, *C. demersum* covered 284 hectares (Santos et al. 2011; Fig. 2.1). In 2014, *C. demersum* was found in 45% of all sampled points for

submersed aquatic vegetation with an average cover of 30% (Khanna and Ustin, unpublished data). We know of no Delta-wide estimates of acreage for this species.

Table 2.1. Submersed and floating vegetation in the Sacramento-San Joaquin Delta. N = Native, I = Introduced. * Indicates the most abundant introduced and native species, on which this review is focused.

Species	Common name	Submersed/ Floating	N/I
<i>Cabomba caroliniana</i>	Carolina fanwort	Submersed	I
<i>Egeria densa</i> *	Brazilian waterweed	Submersed ¹	I
<i>Eichhornia crassipes</i> *	Water hyacinth	Floating	I

<i>Myriophyllum aquaticum</i>	Parrot's feather	Floating	I
<i>Myriophyllum spicatum</i>	Eurasian watermilfoil	Submersed	I
<i>Potamogeton crispus</i>	Crisped or curly-leaf pondweed	Submersed	I
<i>Azolla</i> sp.	Water fern	Floating	N
<i>Ceratophyllum demersum</i> *	Coontail	Submersed ³	N
<i>Elodea canadensis</i>	Common waterweed	Submersed	N
<i>Hydrocotyle umbellata</i> *	Pennywort	Floating	N
<i>Lemna</i> sp.	Duckweed	Floating	N
<i>Ludwigia palustris</i>	Water purslane	Floating	N
<i>Potamogeton foliosus</i>	Leafy pondweed	Submersed	N
<i>Potamogeton nodosus</i>	Long-leaf or American pondweed	Submersed ⁴	N
<i>Ruppia maritima</i>	Widgeongrass	Submersed	N
<i>Stuckenia pectinata</i> *	Sago pondweed	Submersed	N

1 *E. densa* is typically rooted but fragments can form floating mats.

2 There is confusion over the identification of native and non-native species of water primrose; this species has been designated as introduced in this review as it has by other authors (e.g., Khanna et al. 2012).

3 *C. demersum* is the one submersed species that is not rooted in the sediment; it is found loose in the water column.

4 *P. nodosus* is rooted in the sediment but its leaves float at the surface of the water.

In addition, the native submersed pondweed *Stuckenia pectinata* was relatively common in the Delta sites (Fig. 2.1, Santos et al. 2011) and is typically the only aquatic plant species found within the open Suisun Bay (Fig. 2.2; Boyer et al. 2012, 2013). Although this species has been referred to as *S. filiformis* based on gross morphology, or *Stuckenia* spp. because of difficulty in identification, recent genetic analyses indicate *S. pectinata* is the correct species identification for a morphologically broad range of samples throughout Suisun Bay and the Delta (Patten and Boyer, unpublished; see below). Because *S. pectinata* occurs in monotypic stands in the open Suisun Bay and the plants are clearly visible from the surface of the water during summer low tides, Google Earth images show the beds well; these were digitized and systematically ground-truthed by boat and were found to very accurately represent the

acreage present (Boyer et al. 2012). Approximately 200 hectares occur within Suisun Bay as determined through this digitizing and ground-truthing activity during 2011-2014 (Boyer et al. 2012, 2015). Such methodology could be effective in open water, high flow regions of the Delta as well, as *S. pectinata* occurs there at 100% relative abundance (Khanna, pers. comm., based on 2014 remote sensing and ground truthing). Estimating acreage remotely becomes much more difficult in semi-enclosed flooded islands and other embayments within the Delta where many more species are present; however, a rough estimate is that another 350 hectares of *S. pectinata* occur within the Delta region (Boyer et al. 2015). *S. pectinata* occurring in island interior sloughs and in Suisun Marsh is not included in these estimates.

Comment [KB3]: Ask Shruti if she can give an estimate

In terms of floating species, *Eichhornia crassipes* (water hyacinth) has become notorious for its role in clogging channels, marinas, and water supply pipes within the Delta (see Literature Cited, Local and Regional Press Reports, for many recent articles centered around the Stockton area). Worldwide, it is ranked as one of the worst invaders (OTA 1993). As of 2014 it covers ~800 hectares, based on remote sensing and ground truthing of point locations (Khanna and Ustin, unpublished). Its prevalence and nuisance effects in areas of high human activity have led to high interest in understanding factors that control it.

Number of detections, relative frequency (in percent) from point samples, area (ha) and percent cover of the submersed aquatic plant species detected in the Sacramento-San Joaquin River Delta (waterways area is 639.89 ha)

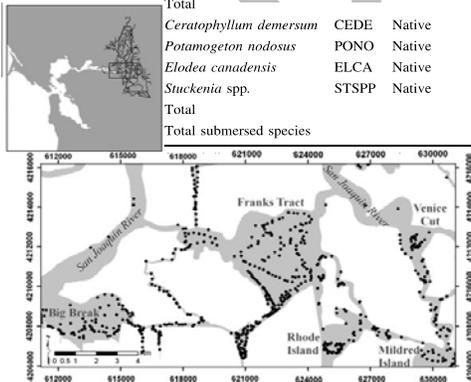

Figure 2.1. Rake detections and other data on abundance of submersed species at sampling points within the central Delta (left). Excerpted from Santos et al. 2011

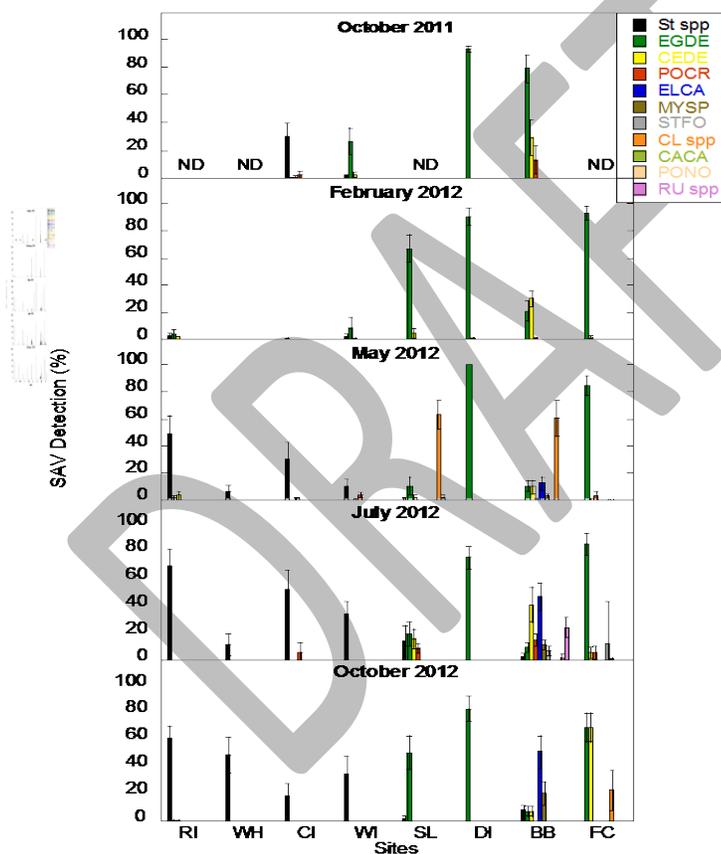

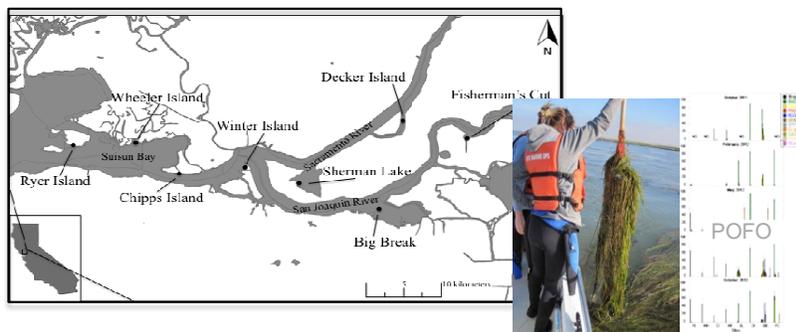

Figure 2.2. Relative abundance of submersed plant species in the west Delta and Suisun Bay (see map inset to interpret site abbreviations from west to east) in 2012 as estimated with a rake sampling method (Kenow et al. 2007). Species abbreviations as in Fig. 2.1, with the addition of the native Potamogeton foliosus (POFO), the green alga Cladophora spp. (CL), and Ruppia spp. (RU). (Figure from Boyer et al. 2013)

Recently, another floating invader, *Ludwigia* spp. (water primrose), has become very common in the Delta as well. As of 2014, it covered about the same acreage as *E. crassipes* (800 hectares; Khanna and Ustin, unpublished data). Rooted at the shoreline, this combination of *L. hexapetala*, *L. peploides*, and perhaps *L. grandiflora* (Khanna and Ustin, unpublished data), has now become a subject of concern, although there is not yet a program to control the plants.

The floating native species, *Hydrocotyle umbellata* (pennywort), was common during recent years and nearly as abundant as *E. crassipes*. Currently, it is much less abundant than both *E. crassipes* and *Ludwigia* spp. (Khanna and Ustin, unpublished data).

These six species, the submersed *Egeria densa*, *Ceratophyllum demersum* and *Stuckenia pectinata* and the floating *Eichhornia crassipes*, *Ludwigia* spp. and *Hydrocotyle umbellata*, will be the primary subjects of this review (Fig. 2.3), with a special focus on the invaders. A botanical description of each of these species is given below (from the Jepson Manual and Flora of North America, plus unpublished genetic work on *Stuckenia pectinata* from San Francisco State graduate student Melissa Patten).

Egeria densa (Brazilian waterweed) is native to warm temperate South America in southeastern Brazil, Argentina, and Uruguay. It grows with trailing stems up to 5 m long, producing roots at intervals along the stem. Although it is typically rooted in the sediment, it can also form mats of detached fragments. The leaves are produced in whorls of four to eight, 1–4 cm long and 2–5 mm broad, with an acute apex. It is dioecious, with staminate and pistillate (sometimes referred to as “male” or female”, respectively) flowers on separate plants; however, all plants outside the native range, including California, are believed to be “male”, with reproduction accomplished only through fragmentation. The flowers are 12–20 mm diameter, with three broad, rounded, white petals, 8–10 mm long.

Ceratophyllum demersum (coontail) is a submersed, native perennial that grows in still or very slow-moving water. The stems reach lengths of 1–3 m, with numerous side shoots making a single specimen appear as a large, bushy mass. The leaves are produced in whorls of six to twelve, each leaf 8–40 mm long, simple, or forked into two to eight thread-like segments edged with spiny teeth; they are stiff and brittle. The flowers are small, 2 mm long, with eight or more greenish-brown petals; they are produced in the leaf axils. The fruit is a small nut 4–5 mm long, usually with three spines, two basal and one apical, 1–12 mm long. *C. demersum* is not rooted; it can be found free-floating beneath the water surface, often among other plant species.

Stuckenia pectinata (sago pondweed) is a monocot, perennial rhizomatous herb native to California, with long stems (2–4 m in summer) and a submersed canopy of thin leaves near the water surface. *S. pectinata* was historically an important food for Canvasback ducks in ponds within Suisun Marsh (Jepson 1905) but was not recorded in the open waters of the San Francisco Estuary until very recently (Boyer et al. 2012, 2015). Morphology of these plants is quite variable, and a form outwardly resembling *Stuckenia filiformis* is common, with little to no secondary branching, leaves frequently > 1.5 mm and often 2–3 mm or more wide (with extremes to 3.7 mm), olive in color and blunt-tipped (fruits are seldom found but should be 2–3 mm in size with style and stigma reduced to a broad flattened disk at the top of fruit).

Figure 2.3. Species central to this review. Left, submersed species: *Egeria densa* (top; photo Katharyn Boyer), *Ceratophyllum demersum* (middle, photo Ron Vanderhoff), and *Stuckenia pectinata* (bottom; photo Katharyn Boyer). Right, floating species: *Eichhornia crassipes* (top; photo Bob Case), *Ludwigia* spp. (center), *Hydrocotyle umbellata* (bottom)

In contrast, a form more closely resembling keys for *Stuckenia pectinata* is also present, and has a forking “zig-zag” (wide branch angle) pattern of branching, multiple orders of very leafy branches, with leaves 1 mm wide or less and seldom exceeding 1.5 mm, brighter green in color with more acutely-pointed leaf tips (fruits are seldom found but should be 2.5-5 mm with pronounced beaks resulting from

persistent styles). Many specimens observed to date do not precisely match keys for either species, and the few fruits available have been intermediate between the two species (large but not beaked) (Boyer et al. 2015); however, recent genetic data (using the CO1 region of the mitochondrial DNA) indicate that samples representing a wide range of morphologies are all *Stuckenia pectinata* (Patten and Boyer, unpublished data). Additional analyses underway using microsatellite data will help to reveal whether there are fine-scale genetic differences across the region within this species that could lead to different observed morphologies, while common garden experiments are examining the degree of phenotypic plasticity that results from variation in flow velocities (Patten and Boyer, unpublished data).

Eichhornia crassipes (water hyacinth) is a free-floating perennial aquatic plant native to tropical and sub-tropical South America. With broad, thick, glossy, ovate leaves, water hyacinth may rise above the surface of the water as much as 1 meter in height. The leaves are 10–20 cm across, and float above the water surface on long, spongy and bulbous stalks. The feathery, freely hanging roots are purple-black. An erect stalk supports a single spike of 8-15 conspicuously attractive flowers, mostly lavender to pink in color with six petals. When not in bloom, water hyacinth may be mistaken for the smaller South American sponge plant (*Limnobium laevigatum*), recently discovered in the Delta (Anderson 2011). One of the fastest growing plants known (a mat of 10 plants can produce 650,000 in one growing season; Penfound and Earle 1948), water hyacinth reproduces primarily by way of runners or stolons, which eventually form daughter plants. Although each plant can produce thousands of seeds each year, these have a low germination rate outside their native range and seedlings grow slowly, taking a full growing season to produce flowers. The stembase can lie under water during winter and initiate rapid growth in the new growing season (Madsen, pers. comm.).

***Ludwigia* spp.** (water primrose) is well known as a noxious weed that invades and clogs waterways. It is perennial herb that grows in moist to flooded areas. The stem can creep over 2 meters long, sometimes branching. It spreads to form mats on the mud, or floats ascending in the water. The leaves are several centimeters long and are borne in alternately arranged clusters along the stem. The flower has 5 to 6 lance-shaped sepals beneath a corolla of 5 or 6 bright yellow petals up to 2.4 centimeters long. The fruit is a hard, cylindrical capsule. In the Delta, *Ludwigia peploides* and *L. hexapetala* are the primary species, but *L. grandiflora* may also be present (Khanna, pers. comm.).

Hydrocotyle umbellata (pennywort) is a perennial herb that is native to California and is also found elsewhere in North America and beyond. It can also be found growing as an introduced species and sometimes a noxious weed on other continents. It can be found creeping or floating with round leaves generally 1–5 cm wide. Its inflorescences are open umbels with up to 60 individual flowers on them.

2.3 Habitat Types in Which They are Characteristically Found

Egeria densa is found throughout the Delta in areas of moderate and low flow, along the margins of larger sloughs and in more protected areas such as smaller sloughs and breached islands (e.g., Sherman Lake, Franks Tract: Fig. 2.4). It can be found as far west as the confluence of the Sacramento and San Joaquin Rivers around Winter Island (Boyer et al. 2013). It grows densely throughout the water column

in waters up to 7 m deep (Parsons and Cuthbertson 1992), but grows nearer to the surface in turbid waters (Bossard et al. 2000; Khanna, pers. comm.). Typically, it is rooted in the substratum throughout its distribution but it can also be found as a free-floating mat (Bossard et al. 2000).

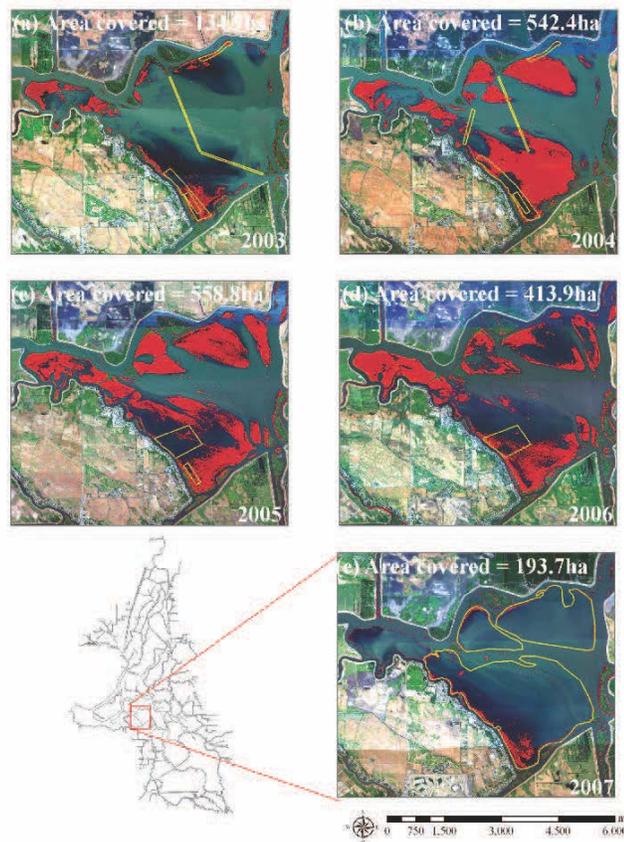

Figure 2.4. Submersed vegetation (primarily *E. densa*) coverage of up to 560 hectares within Franks Tract in the central Delta, 2003-2007 (figure from Santos et al. 2009)

Ceratophyllum demersum has been documented as abundant in the west and central Delta in areas of low flow (Santos et al. 2011; Boyer et al. 2013). This species was found with roughly half the frequency of *Egeria densa* within the central Delta region in one study (Santos et al. 2011). It is free-floating and may benefit from water column stability through co-occurrence with other submerged vegetation; in one survey, it more often occurred along with other species such as *E. densa* than on its own (Santos et al. 2011).

Stuckenia pectinata is less commonly found in the Delta than the other species described above, but still more common than all other native species besides *Ceratophyllum demersum*. It was found at about 25% of the frequency of *C. demersum* in a survey of the central Delta (Santos et al. 2011). With high

salinity tolerance (maintaining its biomass even at a salinity of 15; Borgnis and Boyer, in revision), it forms large beds in the west Delta (e.g., Sherman Lake) and along shoals and island shores throughout much of the open Suisun Bay, as well as in sloughs interior to islands and the Suisun Marsh (Fig. 2.5; Boyer et al. 2015).

Eichhornia crassipes is found throughout the Delta in calm waters, but can be dislodged by boating

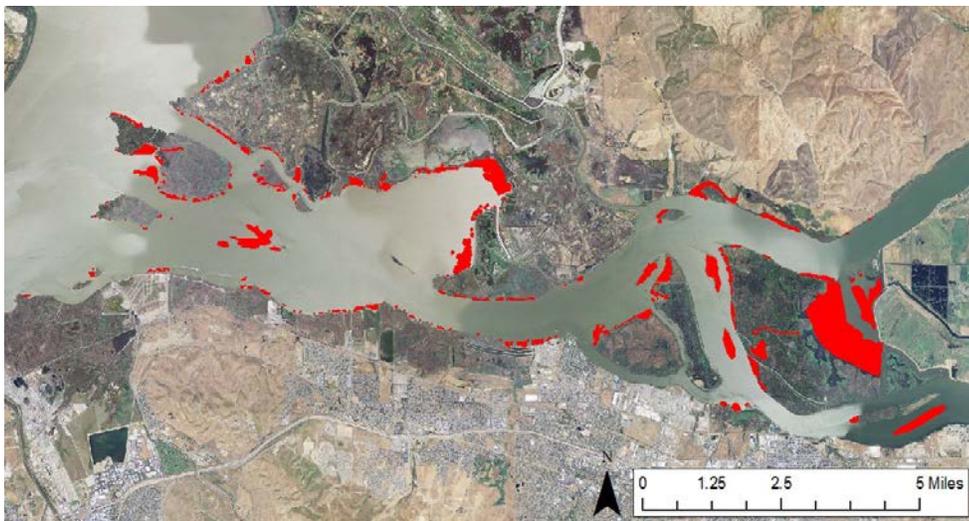

Figure 2.5. Spatial distribution of *Stuckenia* sp. from Ryer Island in Suisun Bay to Sherman Lake in the west Delta, as determined from digitizing and ground truthing aerial imagery (Google Earth), 2012. Coverage is estimated to be ~500 hectares in this region. Image unpublished, based on data in Boyer et al. 2015.

activity, high tides, or wind, and can be seen rafting through open waters with its stout leaves acting as sails (Boyer, pers. obs.). It has been extremely abundant near the city of Stockton in the last several years (see Literature Cited, Local and Regional Press Reports, for many news articles). It has also been very abundant near the Tracy Fish Collection Facility and River's End Marina on Old River (see Literature Cited). It is typically found along channel edges with more stable flow conditions, thus minimizing wash out, or in narrow channels or low flow basins (e.g., marinas, breached island interiors, inside of tule islands) where there is protection from higher velocity flows. Water depth alone is not a limitation, as it does not root in the sediment.

Ludwigia spp. is also found throughout the Delta in calm waters and can be found interspersed with *E. crassipes* and *Hydrocotyle umbellata*. It is typically found in shallow water where it is rooted in the sediment and has creeping stems that reach across the water surface. It often grows in matted stands, with thick white spongy roots at floating nodes. It frequently climbs over other plants.

Hydrocotyle umbellata is found in similar habitats to *Ludwigia* spp., attached to the sediments in shallow water and creeping across the water.

2.4 Spatial and Temporal Trends in their Distribution and Abundance

A regular, comprehensive mapping program for aquatic vegetation does not exist for the Delta region. Several grant-funded efforts to conduct remote sensing have provided valuable information, and have led to improvements in mapping techniques. In particular, recent work to incorporate hyperspectral imagery has aided in the distinction of some of the native submersed species (*Ceratophyllum demersum* and *Potamogeton nodosus*) from non-native ones (*Egeria densa*, *Myriophyllum spicatum*, *Potamogeton crispus*). However, distinction among the non-native species was not well achieved, especially in the western region of the Delta where green algae obscured the spectral signal of *Egeria densa* and *Myriophyllum spicatum* was confused with *E. densa* (Santos et al. 2012). Further, although the native *Stuckenia* sp. (presumed to be *S. pectinata* based on recent genetic work; Patten and Boyer unpublished) had a distinct spectral signature in greenhouse tanks, patches were too small to be detected by remote sensing in the area of the Delta studied (Santos et al. 2012). Mixed species stands are also problematic for remotely determining species presence and extent as described above. Hence, on the ground monitoring of relative abundance, biomass, and preferably, primary production (through multiple biomass estimates over time to estimate turnover) is necessary to complement the remote sensing work.

Below, we summarize what is known of the spatial and temporal extent of each of the six species emphasized in this review, primarily resulting from individual grant-funded efforts that provided a window into the distribution over, at most, a few years at a time.

Egeria densa is thought to have been introduced to the Delta in 1946 (Light et al. 2005) through aquarium dumping and has spread throughout the region (Anderson 1990; Foschi et al. 2004; Santos et al. 2009). It was discussed without signs of alarm in a CA Department of Water Resources report that described water quality conditions over a 30-year period (DWR 1993); however, by 1996, Grimaldo and Hymanson (1999) described thick stands harboring many non-native centrarchid fish. It may have replaced native submersed aquatic plants in much of this area (Lund et al. 2007). In terms of interannual trends, there has been a major expansion in acreage over the last several years. In 2007, submersed vegetation dominated by *E. densa* covered ~2000 hectares (~8%) of Delta waters (Santos et al. 2009) and this number increased to ~2900 hectares (~11%) according to remote sensing and ground-truthing in 2014 (Khanna and Ustin, unpublished data). Application of herbicide (by the California Department of Boating and Waterways, now the CA Department of Parks and Recreation Division of Boating and Waterways, DBW) in areas such as Franks Tract has the potential to reduce acreages locally, especially if conducted in spring (Santos et al. 2009; see Fig. 2.4, acreage was reduced by >50% after fluridone application in April 2007, as opposed to after July 1 in the other years). However, a very small proportion of the Delta is included in the management program, with the most area treated in any year covering only 4-5% of the Delta waterways (DBW 2005). During periods of drought, this species shifts further east into the Delta (Boyer, pers. obs.), as its survivorship is very low at salinities of 5 and above (Borgnis and Boyer, in revision; see Chapter 4). In terms of seasonal trends, one study documented a greater acreage and percent cover in the central Delta in fall (October 2007) than in the summer (June 2008) (Santos et al. 2011, see Fig. 2.1). Though its biomass declines in winter, it maintains aboveground shoots (Pennington and Systma 2009; Santos et al. 2011; Boyer et al. 2013, see Fig. 2.2).

Ceratophyllum demersum was documented to change in abundance seasonally, with greater acreage and percent cover in October 2007 (284 ha, 44% cover of the waterways sampled) than in June 2008 (59 hectares, 9%) within the same central Delta region (Fig. 2.1, Santos et al. 2011). A similar pattern was found at Fisherman's Cut, with rake detections at 70% in October 2012, but little to no presence in February, May, and July 2012 (Fig. 2.2, Boyer et al. 2013). However, its frequency of occurrence at Big Break varied considerably seasonally, with 40, 10, 30, and 5% detection over the four sampling periods in 2012, respectively. In the same study there were no detection at Decker Island, and less than 10% detection at Sherman Lake in any season (Fig. 2.2, Boyer et al. 2013). We found no records of *C. demersum* variation in abundance in the Delta over longer periods of time.

Stuckenia pectinata appears to have increased in acreage over the last several decades (Fig. 2.6, from Boyer et al. 2015). Comparing digitized imagery over time for Suisun Bay, and in doing so assuming that historical stands were essentially monotypic as they are at present, there was little change in acreage between 1993 and 2002. However, there was about a 30% increase in acreage (43 hectares) in the Suisun Bay region between 2002 and 2012, with many new, mostly small beds occurring along nearly every stretch of shoreline and large increases in acreage in the cove on the southwest side of Ryer Island and along the south sides of Simmons and Chipps Islands. In the west Delta, a similar increase in acreage (37 hectares) appears to have occurred over the decade ending in 2012, a 13% increase since 2002; however, this increase is less certain due to the many species present within Sherman Lake that make accurate estimates much more difficult. Still, there appeared to have been large gains in *S. pectinata* acreage in Sherman Lake, offshore and to the west of Sherman Island, and to the west of Winter and Browns Islands (Fig. 2.7). In a 2014 remote sensing survey followed by groundtruthing of point locations, *S. pectinata* was found in 26% of sampled points in the Delta (Khanna and Ustin, unpublished data). In that survey it was found to have an average relative cover of 50%, but 100% in open water areas of the Delta, perhaps suggesting a distinct environmental niche (Khanna and Ustin, unpublished data; Khanna, pers. comm.). It is not clear why *Stuckenia pectinata* acreage would be expanding over the last 20 years, although increased water clarity and thus greater light availability may be partially responsible (Wright and Schoellhamer 2004; Schoellhamer 2011; Hestir et al. 2013; see Chapter 4).

Eichhornia crassipes was introduced to the Sacramento River in 1904 by horticulturalists (Finlayson 1983; Cohen and Carlton 1998; Toft et al. 2003) or perhaps through garden escape (Light et al. 2005). It was estimated to cover 160-300 hectares of the Delta (~1% of the water area) during the period of 2004-2008 (Santos et al. 2009); however, this species has expanded in coverage, with ~800 hectares in 2014, or about 3% of the water area (Khanna and Ustin, unpublished data). This increase in cover may be partly attributable to a delay in chemical treatment over two years (2011 and 2012) owing to permitting issues (Llaban, pers. comm.); however, in general, these control methods seem to have little impact on year-to-year coverage of water hyacinth (Khanna pers. comm., unpublished data). There also seem to have been favorable conditions during the years of rapid increase in cover, including but not limited to a low occurrence of frost in winter (Khanna, pers. comm.). Positions of colonies can shift within a season and from year to year due to drifting and movement on the tides and with wind or other disturbance (Santos et al. 2009).

Comment [KB4]: Ask Shruti if she'd like us to cite the SOTER side bar that has these trends. I have cited the 2014 changes as unpublished data throughout at this point

Ludwigia spp. has expanded greatly in coverage between remote sensing surveys conducted in 2008 and 2014 (Khanna and Ustin, unpublished data). It had low coverage during the period of 2004 to 2008, but is now equal in coverage to *E. crassipes*, with ~800 hectares present in 2014 (Khanna and Ustin, unpublished data).

Hydrocotyle umbellata has declined in coverage between the remote sensing surveys conducted in 2008 and 2014 (Khanna and Ustin, unpublished data). Between 2004 and 2008, *H. umbellata* was comparable in coverage to *E. crassipes*. Considering the large increases in *Ludwigia* spp. seen in 2014, it is possible that *Ludwigia* has a competitive advantage over *H. umbellata* under current conditions.

3. Role of Submersed and Floating Aquatic Vegetation in Supporting Delta Ecosystem Services

Submersed and floating aquatic vegetation are natural components of estuaries, providing benefits in the form of carbon storage, uptake of nutrients, oxygenation of waters, trophic support through direct consumption by grazers or contributions to the detrital food web, provision of surfaces for algal and invertebrate attachment (also providing trophic support), and predation refuge for small fish. Negative effects tend to emerge in the case of non-native species that have invaded large areas and that have characteristics unlike those of the native species (especially when the invaders are at high densities), thus leading to undesirable changes in a number of factors, including nutrient dynamics and food web support. Here we review both the positive and negative effects of submersed and floating vegetation, based on the published literature from other regions as well as local studies where available.

3.1 Conceptual View of Positive and Negative Effects of Submersed and Floating Aquatic Vegetation on Ecosystem Services.

Anderson (2008) proposed a draft conceptual model of the effects of submersed, floating, and emergent vegetation on water quality and fish habitat in the Delta (Fig. 3.1). In general, low to moderate densities or open growth forms of any species may have beneficial functions, including provision of habitat and food web support, but the dense stands typical of the worst invaders tend to produce negative effects. For example, dense canopies of the floating *Eichhornia crassipes* may shade phytoplankton and exclude submersed native plants such as *Stuckenia*. Dense stands of submersed plants (primarily *Egeria densa*) can draw down oxygen at night, increase water temperatures by increasing water residence time, increase pH to the benefit of plants that can utilize bicarbonate as a carbon source (e.g., *E. densa*, see Section 4.1.4), and harbor large non-native fish in the shadows of the canopy, which could possibly lead to predation on smaller adult and juvenile native fish. In contrast, the open water beneath naturally sparse canopies of native submersed species such as *Stuckenia pectinata* may provide a more stable dissolved oxygen setting, accessible invertebrate food resources, and a paucity of large predator hiding places – in all, it has the potential to provide more suitable habitat for native fish species than dense *E. densa* beds (Fig. 3.1). As expected in a conceptual modeling exercise, there is not necessarily data to support all of the effects and feedbacks (e.g., there is no detailed dataset for the composition or abundance of fish species that utilize *Stuckenia* beds); in these cases, the model can be used to identify hypotheses that should be tested with further data collection and experimentation.

Below, we detail a number of adverse effects that may result from introduced macrophyte species when they become dense and widespread in invaded regions. Potential adverse effects include changes to water quality, a decline in phytoplankton and native plants, a change in the physical structure of the habitat, alterations of trophic interactions, impediments to navigation and industry, and visual impacts.

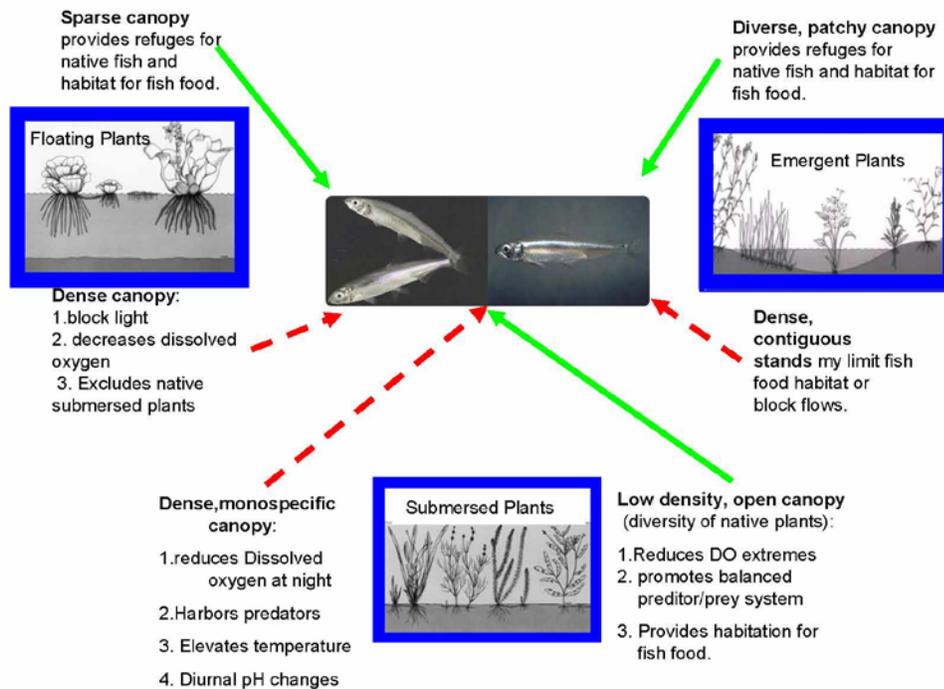

Figure 3.1. Conceptual model of the effects of Delta macrophyte canopy structure on provision of fish habitat. Arrows show direction and primary effect caused by interaction of each "ecological type" of aquatic plant on fish (red, dashed = negative effect, green, solid = positive effect. From Anderson 2008

3.1.1 Changes to Water Chemistry

Dissolved oxygen

Submersed species such as *E. densa* have the potential to greatly draw down dissolved oxygen levels within thick mats (e.g., Getsinger 1982). Dissolved oxygen in plant beds declines at night due to a lack of photosynthetic oxygen production to counter oxygen needs for respiration, and these diurnal swings can be especially pronounced in high density submersed macrophyte beds (Fig. 3.1). Interestingly, *E. densa* was promoted as a way to oxygenate waters for fish during its early introduction period (Cook and Urmikönig 1984).

Dense mats of *E. crassipes* can lead to large reductions in dissolved oxygen through drawdown at night as well as prevention of gas exchange at the water's surface (Madsen 1997; Hunt and Christiansen 2000; Perna and Burrows 2005) and through shading photosynthetic species in the water including phytoplankton and submersed vascular plants (Malik 2007). In the Delta, drawdown of dissolved oxygen has been documented in areas of rapid *E. crassipes* growth, even in places with significant tidal

exchange (Dow Wetland, directly off the mainstem of the San Joaquin River, with 1-2 m tidal variation; Greenfield et al. 2007). Further, decomposition of *E. crassipes* following mechanical treatment can lead to high biological oxygen demand and drawdown of oxygen in areas with low flow, creating unfavorable conditions for fish and invertebrates and even fish kills (dissolved oxygen concentration $<2.3 \text{ mg l}^{-1}$; US EPA 1986). For example, Greenfield et al. (2007) found dead bluegill sunfish and carp during weeks of anoxic waters after an experimental *E. crassipes* shredding operation at the low-flow Lambert Slough. With this in mind, the CA Parks Division of Boating and Waterways must monitor dissolved oxygen levels during weed control, maintaining a minimum of $5\text{-}7 \text{ mg l}^{-1}$, as mandated by the Central Valley Water Quality Control Board (Moran, pers. comm.).

Comment [KB5]: Is there a citation for this?

Notably, decreased oxygen in the sediments can increase mobility of phosphorus, contributing to nutrient loading (Scheffer and Van Ness 2007). In support of this concept, Cornwell found high phosphorus release in soils of submersed macrophyte beds in the Delta; if conditions conducive to phosphorus release develop over time in these beds, they could promote a positive feedback in which phosphorus is supplied to the plants, especially through porewater uptake (Cornwell et al. 2014; J. Cornwell, pers. comm.).

pH

High abundance of submersed macrophytes can lead to increased pH as CO_2 is drawn down during photosynthesis, leading to diurnal swings in pH and to bicarbonate (HCO_3^-) becoming the primary form of dissolved inorganic carbon (DIC) available (Sand-Jensen 1989; Santamaria 2002). This can work to the advantage of species that can use bicarbonate efficiently as their carbon source (e.g., *Egeria*, Cavalli et al. 2012). We are not aware of data on pH within submersed macrophyte beds in the Delta to date, but expect both the changes in pH and these effects on the form of available DIC would be greatest in thick *E. densa* beds and in places with limited water flow.

Nutrients

Both *Egeria densa* and *Eichhornia crassipes* are known for their abilities to take up nutrients and store them for later use (e.g., Gopal 1987; Reddy et al. 1987). *E. crassipes* has been used in a number of regions as a tool to remove nutrients from the water column, both in pilot and demonstration scale projects and in full scale wastewater treatment (reviewed by Malik 2007). Despite this propensity for nutrient uptake, Delta-wide effects of these species on water column nutrient removal could be relatively low considering only about 3% of Delta waters contain *E. crassipes* and 11% contain *E. densa* as of 2014 (Khanna and Ustin, unpublished data). To understand the contribution of these species to nutrient cycling, including in comparison to other producer groups (e.g., ~9500 hectares or 37% of Delta waters contained emergent plant species in 2014; Khanna and Ustin, unpublished), data on productivity rates, sequestration of nutrients within perennial tissues, and recycling within tissues and from the water column and sediments would be needed. One Florida study comparing nutrient removal effects over a range of macrophyte species found *E. crassipes* to rank much higher than many others (including *Hydrocotyle umbellata* and *Egeria densa*) in N removal during summer (Reddy and DeBusk 1985). P removal was also higher in *E. crassipes* than in all other species in summer. Interestingly, in winter, *H.*

umbellata was higher in both N and P removal rates than all the other species (Reddy and de Busk 1985).

In areas of densely growing macrophytes, intraspecific competition can lead to continuous shedding of dead tissues that decompose in place and may serve as a source of remineralized nutrients to the existing plant bed as well as other producers (Carignan and Neiff 1992; Rommens et al. 2003). Seasonal senescence of *Eichhornia crassipes* is generally slow and occurs during fall and winter (Carignan and Neiff 1992; Pinto-Coelho and Greco 1999; Battle and Mihuc 2000; Spencer 2005). *Egeria densa* sheds tissues in winter even though it does not fully senesce within the Delta region (Fig. 2.2, Boyer et al. 2013; Santos et al. 2011). In both cases, natural senescence is likely to result in a slow release of dissolved organic compounds from plants in the water column that may be utilized by the macrophytes or other producers locally, or transported away with water flow. Accumulation of dead organic matter within sediments of the beds appears limited in open water areas; sediment flux measures by Cornwell et al. (2014) in Sherman Lake, Big Break, and Franks Tract (all sites with substantial *E. densa* populations) did not suggest high rates of sediment respiration or nitrogen release, although rates tended to be higher than in non-vegetated areas measured in Suisun Bay. However, rapid deposition of dead macrophyte tissue in low flow areas may be a significant source of nutrients fueling macrophyte growth. For example, control methods that leave large quantities of shredded water hyacinth material in place can lead to increased water column nutrients, especially total P (up to 5-fold increases) and organic P (up to 2-fold increases) and to a lesser extent, total N (3-fold increase at one site) (Greenfield et al. 2007). This elevated nutrient effect was found to be short-lived (<4 days) where there was tidal exchange but water column nutrients were elevated at least several weeks after treatment in a quiescent site (Greenfield et al. 2007) where a related study documented significant quantities of the shredded debris even after six months (Spencer et al. 2006). These studies highlight that water residence time and flow rates at any one location will critically affect the degree to which macrophyte biomass accumulates and releases nutrients within the beds, whether as a result of control efforts or other abrupt changes in conditions (e.g., extended periods of frost for *E. crassipes*, or increased salinity for *E. crassipes* or *E. densa*; see Chapter 4) that cause rapid plant mortality.

3.1.2 Changes to physical properties of water

Flow

In general, dense submersed vegetation has the potential to slow the velocity of water, thereby initiating a positive feedback loop in which the favorable lower flows permit greater growth and spread (e.g., *E. densa*, Roberts et al. 1999). The density of the vegetation throughout the water column influences the degree to which water flow is affected (>40% reduction in dense *E. densa* beds; Wilcock et al. 1999) and varies with both plant morphology and density. Submersed plants may also facilitate the establishment and spread of floating plants through reduction in flow, permitting floating plants to better remain in place and spread locally (see Khanna et al. 2012, and Chapter 4). Dense floating macrophytes also can reduce flow under already moderately low flow conditions (Penfound and Earle 1948).

Light

Dense floating and submersed vegetation greatly reduce light penetration through the water column, shading other plants beneath. However, *E. densa* is also capable of reducing suspended sediment, creating clearer water in the vicinity of the plants (Tanner et al. 1993; Hestir et al. 2013). Grimaldo and Hymanson (1999) found secchi depth increased to 2 m in patches of *E. densa* in Franks Tract (central Delta), up from 0.5-1 m outside of patches.

Temperature

E. crassipes infestations lead to increased water surface temperatures through reduction in water flow (Penfield and Earle 1948). *E. densa*, too, causes increased water temperatures during the day, which helps to reduce heat loss at night (Grimaldo and Hymanson 1999).

3.1.3 Effects on algae and native macrophytes

A number of changes to the local environment by nuisance aquatic macrophytes could impact other species of primary producers, including native vascular plants and algae. First, shading of the water column by dense stands of floating or submersed macrophytes can reduce the light available to native submersed species, which tend to have more sparse growth forms and less potential to shade other species themselves (see Anderson 2008 conceptual model, Fig. 3.1). Shading of phytoplankton and benthic microalgae could also result from dense canopies or mats of aquatic macrophytes such as *Egeria densa* or *Eichhornia crassipes*. *E. densa* can reduce suspended sediment concentrations through baffling of particles out of suspension (Hestir et al. 2013); however, shading from thick mats could minimize any potential positive effects of sediment removal to other submersed primary producers. Second, thick mats of *E. densa* reduce water flow, and although floating vegetation is less likely to reduce water motion, a dense coverage over the water can reduce the generation of wind waves across the water surface. Third, reductions in dissolved oxygen within *E. densa* mats or beneath *E. crassipes* could also limit other producers among or below these plants. Fourth, a number of submersed and floating macrophytes, including *Eichhornia crassipes*, have been noted to have allelopathic effects on algae and microbes (Shanab et al. 2010). Removal of *E. crassipes* may lead to increases in *E. densa* abundance (Khanna et al. 2012), most likely due to increased light, but perhaps due to a combination of factors described above. Chapter 4 further describes the interactions between species that may influence abundance of introduced and native macrophyte species.

Submersed vegetation and the roots of floating vegetation provide surfaces for the growth of epiphytic algae and attachment points for filamentous algae where there is sufficient light (Fig. 3.2). These in turn affect the habitat and food availability to invertebrates and fish, and can influence nutrient cycling; e.g., filamentous algae attached to *Potamogeton crispus* was found to increase phosphorus retention of an experimental pondweed assemblage (Engelhardt and Richie 2002). These algae can also be considered

Figure 3.2. Green filamentous algal mats attached to *Egeria densa* in Sherman Lake, May 2012. Photo, Katharyn Boyer

nuisance species if they become overly abundant. Observations of thick green algal mats attached to *E. densa* have been made in a number of locations within the Delta (Santos et al. 2012; Boyer unpublished, Fig. 3.2; Llaban and DBW staff, pers. comm.).

3.1.4 Trophic support

Macrophyte invasion can lead to changes in structural complexity of the habitat, altering composition and abundance of invertebrates, which can have effects on higher trophic levels (e.g., Toft et al. 2003; Schultz and Dibble 2012). Direction and magnitude of change are difficult to predict in terms of desirable food for fish; however, thick stands of *Egeria densa* are thought to make access to invertebrate food resources difficult for fish, while locally clear water and dark, shadowy hiding places appear to increase predation risk compared to other habitats (Grimaldo and Hymanson 1999; Brown 2003; Nobriga and Feyrer 2007). The degree to which these modifications to food and predator conditions impact native fish in particular is unclear, nor have there been comparable studies in native SAV beds (e.g., *Stuckenia pectinata*) to support the assertion that the typically more open native plant canopies and greater turbidity (expected to be less reduced through baffling of sediment particles out of the water column) create more favorable habitat for native fish (Fig. 3.1). There is evidence that thick stands of *Egeria densa* impede the movement of small (including juvenile) fish, including natives such as salmonids, splittail, and Delta smelt (Brown 2003). It is possible that *E. densa* could be managed to maintain lower densities, and that this would permit increased access to food resources and reduce predation risk as the more open native plant canopies are hypothesized to do (Fig. 3.1).

Eichhornia crassipes may also modify the food resources available to higher trophic levels. Floating macrophyte invasion of open water can increase the surface area available for epiphytic invertebrate colonization (Brendonck et al. 2003). However, when native floating macrophytes are replaced, there can be a large change in species composition of the invertebrate assemblage. For example, in the Delta, large differences in the epiphytic invertebrate assemblage were found on *E. crassipes* versus the native floating species, pennywort (*Hydrocotyle umbellata*) (Toft et al. 2003). Microcrustacean zooplankton can be more abundant with no vegetation than with *E. crassipes* present (Brendonck et al. 2003). A study in Uruguay found calanoid and cyclopoid copepods to be less abundant at sites with *E. crassipes* than with *Stuckenia pectinata* or no vegetation (Meerhoff et al. 2003). Still, the literature on *E. crassipes* effects on zooplankton are inconsistent, perhaps because there are many factors that might interact to affect zooplankton, including the effects of density of *E. crassipes* on predator abundance (Villamagna and Murphy 2010).

In terms of food web support for fish, consumption of *E. crassipes* appears to be minimal, as it is a nutritionally poor diet choice for herbivorous fish (Cox 2003). For carnivorous fish, the presence of *E. crassipes* may change the invertebrate foods available relative to those on the native *Hydrocotyle umbellata* (Toft et al. 2003). Although both assemblages are dominated by amphipods, large drawdowns in dissolved oxygen (see Section 3.1.1) make *E. crassipes* a less favorable location for feeding due to physiological constraints on the fish (Simenstad et al. 1999). In fact, dissolved oxygen under dense or decomposing mats of *E. crassipes* can be dangerously low for fish (lower than 4.8 mg l^{-1} ; reviewed by Villamagna and Murphy 2010). The abundance of *E. crassipes* is linked to the value of the habitat it creates for fish; at some (undefined, and probably site-specific) lower level of abundance, adequate light for phytoplankton production to support zooplankton, surfaces for algae and invertebrate attachment, and dissolved oxygen all support fish presence and diets, while at higher abundance these features are diminished or even threatening to fish (McVea and Boyd 1975; Brown and Maceina 2002).

Similarly, for birds, presence of *Egeria densa* or *Eichhornia crassipes* may benefit certain birds through provision of invertebrate or fish prey attracted to the physical structure; however, access to these prey becomes diminished when canopies become excessively dense (Brendonck et al. 2003), and declines in dissolved oxygen (see Chapter 3) that affect prey would also limit value to birds. Neither of these species is known to be a valuable food source for birds themselves although American coots are known to eat *E. crassipes* (Villamagna 2009). In contrast, *Stuckenia pectinata*, a native species subject to replacement by these two invaders, is a very nutritious food source that was heavily used by canvasback ducks historically (Jepson 1905).

3.1.5 Navigation and industry

Submersed and floating vegetation both have the capacity to clog navigation channels, marinas, intake pipes for potable water supply, industry, and agriculture. Highly productive aquatic plant beds can have devastating effects on local economies and quality of life for recreational users of waterways. Thick mats of *Egeria densa* hinder a wide variety of recreational and commercial activities, including boating, fishing, swimming and water pumping for potable supply and irrigation (Bossard et al. 2000). *Eichhornia crassipes* can grow so densely on the water's surface that it impedes navigation by recreational

motorboats and ships, becomes entrained in water pumps, and chokes irrigation channels (Bossard et al. 2000; Toft et al. 2003). In turn, boating and shipping activities can facilitate spread of these invaders; *E. crassipes* can become dislodged from colonies and drift to other locations, and *E. densa* can be chopped into fragments that can become propagules for establishment elsewhere through water movement.

3.1.6 Aesthetics

Some invasive macrophytes are very attractive, but lose their aesthetic appeal when there is a loss of commercial, industrial, municipal, and recreational use. *Eichhornia crassipes*, in particular, has very showy and attractive purple flowers, a likely reason for its original introduction in many areas of the world.

4. Factors Contributing to the Prevalence of Submersed and Floating Aquatic Vegetation in the Delta

4.1 Conceptual Models of Growth, Propagation and Environmental Characteristics that Enhance or Limit Growth

There are a number of factors known to influence aquatic vegetation in low salinity and fresh regions of an estuary. Anderson (2008) developed a draft conceptual model to describe the ways in which submersed, floating, and emergent species are likely to respond to and modify conditions within the Delta. This effort included a general model for establishment, growth, and dispersal, reprinted here as Fig. 4.1. To briefly review this model, both submersed and floating macrophytes are influenced by light levels, with submersed plants adapted to lower light conditions. Carbon dioxide limits photosynthesis especially for submersed plants in thick stands where drawdown and high pH reduce availability, but many submersed species are capable of substituting bicarbonate as a source of inorganic carbon. Water quality conditions, including nutrient levels, are known to strongly influence growth of these species. Sediment characteristics, including nutrients and grain size distribution affect growth and anchoring of submersed vegetation. Local flow conditions help to maintain floating plants in place and help submersed species to accumulate large quantities of biomass.

Anderson (2008) described “sub models” for submersed and floating species which further detailed important determinants of establishment, growth, and dispersal for each vegetation type. These are reprinted here as Fig. 4.2A and B. Below we review these sub models in detail and the literature supporting each of them.

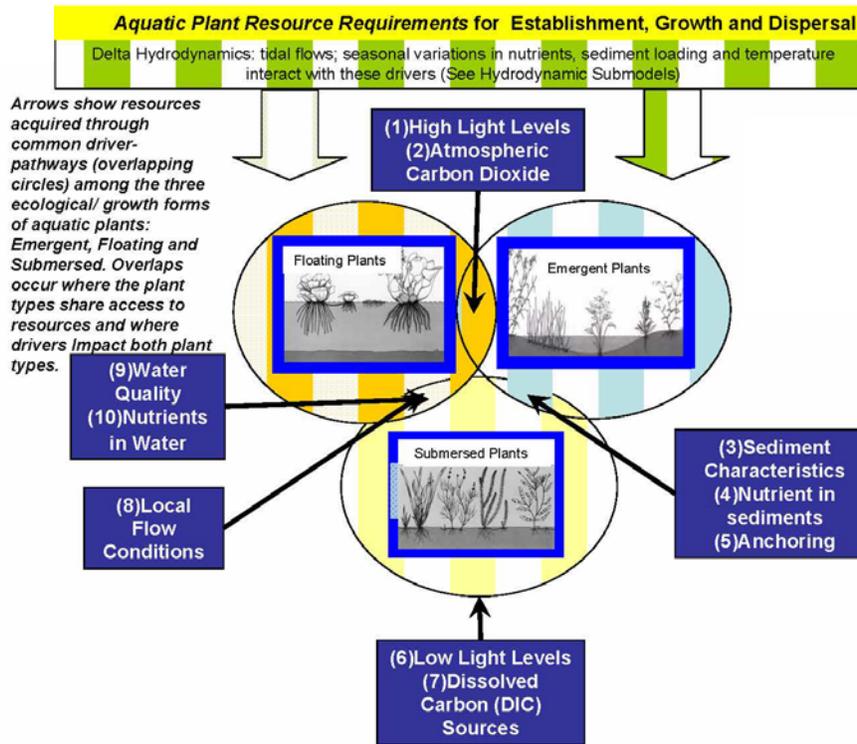

Figure 4.1 Aquatic plant resource requirements for establishment, growth and dispersal, as described in a draft conceptual model by Anderson (2008)

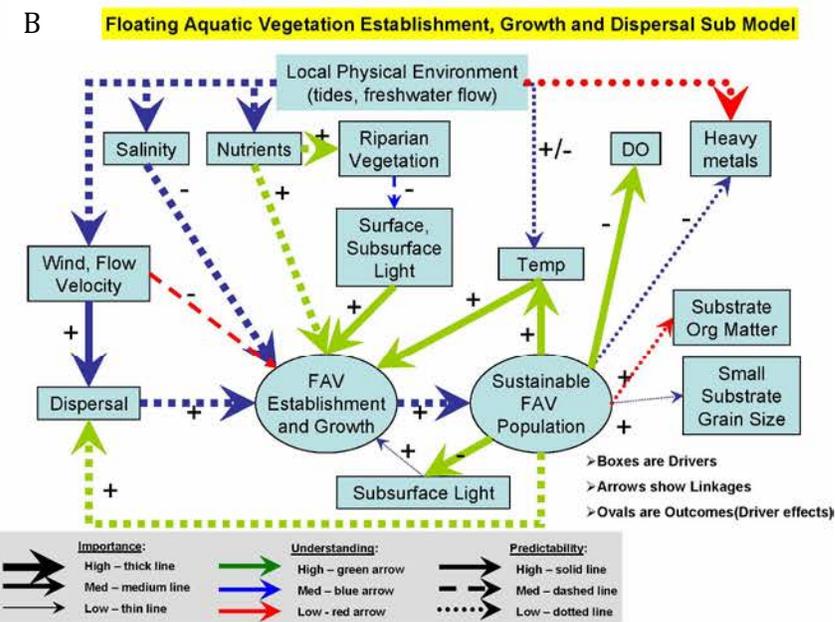

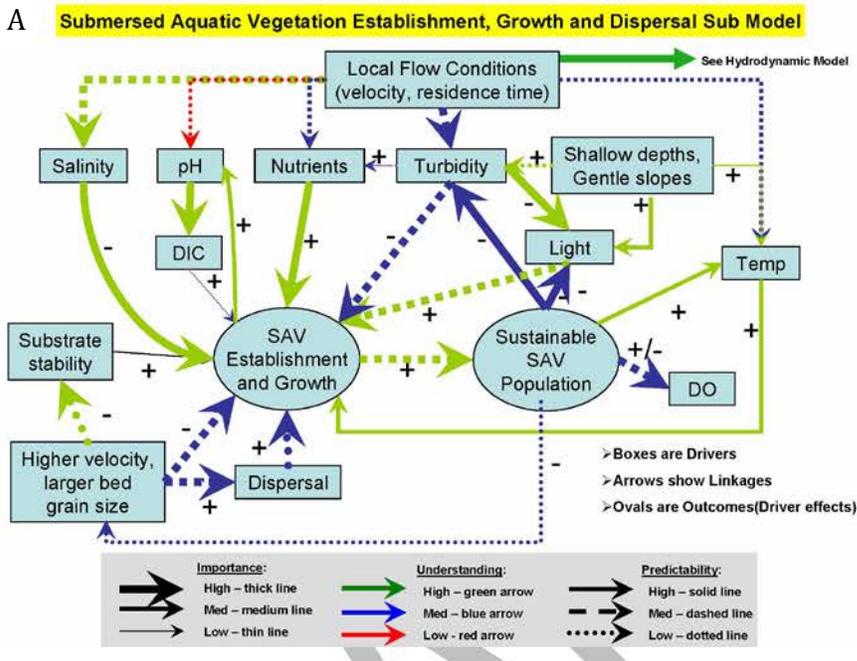

Figure 4.2. Sub models describing important drivers of establishment, growth, and dispersal in submersed (A) and floating (B) aquatic vegetation. From draft conceptual model by Anderson (2008)

4.1.1 Light

Light is essential to photosynthesis in all plants and is generally adequate for floating species such as *Eichhornia crassipes*, although periods of reduced light due to extended cloud cover (during El Niño years) have been implicated in a major decline in this species' vigor and cover in Lake Victoria in Africa (Williams et al. 2005, 2007). Floating species can benefit by shading submerged plants (see Section 4.1.7 below), which frees other resources such as nutrients and favors development of sustainable floating macrophyte populations (Fig. 4.2B).

Submersed species must cope with lower light conditions than floating species due to attenuation of photosynthetically-active radiation (wavelengths of 400-700 nm, PAR) through water. PAR is further attenuated by particles in the water, including sediments and phytoplankton. Light availability is very important to establishment of submersed species at the sediment surface (Fig. 4.2A), whether from seeds, turions, or vegetative fragments, depending on the species. After establishment, dense plant growth can lead to self-shading of tissues lower in the water column. However, *E. densa* reduces turbidity of the water, leading to greater light penetration (Fig. 4.2A; Hestir et al. 2013), which is likely to represent a positive feedback toward greater growth even at depth. *Stuckenia pectinata* has its canopy of leaves within the upper portion of the water column, which provides access to higher light levels near the surface, and its relatively sparse leaf growth minimizes self-shading. This sparse leaf growth does not appear to reduce the turbidity of the water based on measures of PAR inside and outside of *S. pectinata* beds (Boyer unpublished data). However, species-specific effects on light conditions are not well known for this or other species in the Delta.

Studies also support that light is likely to be quite limiting to lower portions of plant tissue in dense *Egeria densa* beds. In one local experiment testing light effects, *E. densa* had 4-fold lower biomass under conditions comparable to those measured in beds in the Delta at 1 m depth ($215.5 \mu\text{M quanta m}^{-2}\text{s}^{-1}$) compared to light levels 2x greater (Borgnis and Boyer, unpublished data). Although Durand (2014) found an ambiguous relationship between turbidity and *E. densa* growth, he found a low probability of establishment at depths below 5 m. In a New Zealand mesocosm study, reduced light (25% reduced from 50% incident level) was found to be a more important factor controlling *E. densa* than was temperature (tested at 20, 26, and 30°C) (Riis et al. 2012). Interestingly, a Brazilian study found the highest rates of elongation for apical shoots of *E. densa* occurred under reduced light conditions ($<30 \mu\text{M quanta m}^{-2}\text{s}^{-1}$), suggesting a mechanism by which *E. densa* may extend its canopy upward through the water column (Rodrigues and Thomaz 2010).

Waters in the Delta have become clearer over at least the last fifty years. The delivery of suspended sediment from the Sacramento River to the Delta has decreased by about half during the period between 1957 and 2001 (Wright and Schoellhamer 2004) and this has resulted in a statistically significant (2 to 6 percent) decrease per year in suspended particulate matter between 1975 and 2005 (Jassby 2008). It is unclear whether this increase in water clarity has increased the biomass and distribution of submerged macrophytes already, or how it will influence other important factors in plant growth, including nutrients.

4.1.2 Temperature

Warm temperatures are expected to favor the establishment and growth of both floating and submersed species and to produce localized warming of waters through reduction in water flow, which in turn should benefit plant growth (Fig. 4.2A-B). However, high water temperatures within the range found currently in the Delta might limit growth of some species, and temperatures are expected to increase with climate warming (Knowles and Cayan 2002; Wagner et al. 2011). A 2012 experiment testing water temperature effects on growth of *E. densa* apical shoot sections in aquaria showed substantial increases over time in aboveground biomass, total shoot length, and mean root length at a water temperature of 22°C (the average measured in the west Delta in summer) in fresh water, with similar effects at 26°C, although much less of a biomass response (Fig. 4.3, Borgnis and Boyer in revision). In contrast, there were great reductions in all these measures at 30°C (Fig. 4.3), which is within the current range of maximum temperatures measured for the west Delta (Borgnis and Boyer, in revision). Further, testing these temperatures at a salinity of 5, which can be found in the west Delta in drought years (e.g., 2012-2014), led to a reduction in root length at all temperatures. At a salinity of 10, the negative effects of high temperature (30°C) were amplified and led to greatly reduced aboveground biomass (Fig. 4.3). As for cold temperatures, we are not aware of any local data; in other regions, night-time freezing, especially in shallow water was found to be highly stressful to *E. densa* (Leslie 1982).

We know of no local experiments testing temperature effects on *Eichhornia crassipes*, *Ceratophyllum demersum*, or *Stuckenia pectinata*. In other regions, *Eichhornia crassipes* has been shown to benefit from warming above ambient conditions within limits. In China, *E. crassipes* rates of relative growth and clonal propagation increased by 15% with an increase in water temperature from 24 to 26-27°C in mesocosms (You et al. 2014). However, at

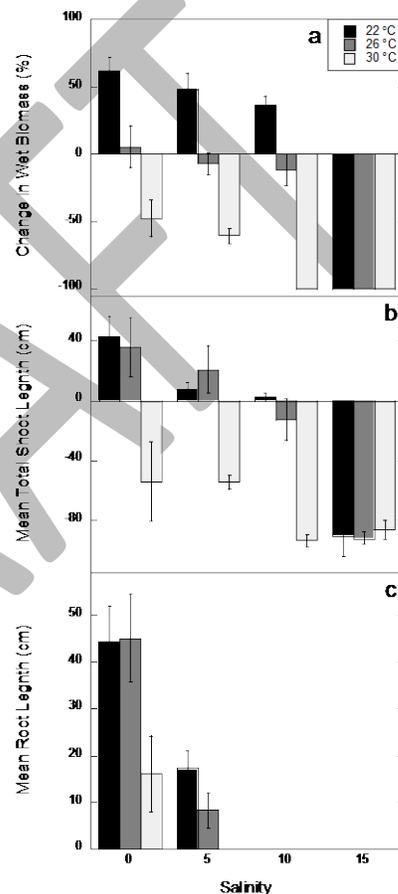

Figure 4.3. Response of *Egeria densa* to a range of temperature conditions applied at increasingly high salinity conditions at the end of 6 weeks in aquaria. From Borgnis and Boyer, in revision

temperatures above 33-34 C, *E. crassipes* loses nutrients from the roots and experiences negative growth (Moran, pers. comm.). *E. crassipes* is also limited by cold temperatures in the range of 10°C (Gopal 1987; Wilson et al. 2005). Frost can cause mortality of leaves and whole plants (Bock 1969; Ueki and Oki 1979; Spencer 2005), although stem bases can survive and serve as propagules for growth in the next year (Spencer 2005). Large rafts of *E. crassipes* have been observed floating seaward from the Delta during periods of freezing night-time conditions, suggesting deterioration of the ability to remain in cohesive mats under these conditions (Foe, pers. comm.). Further, a three-week period of night-time frost in 2007 appeared to have contributed to a significant decline in *E. crassipes* in the next year (Khanna, pers. comm.).

4.1.3 Salinity

In general, species in much of the Delta experience fresh water maintained with little seasonal variation through water management practices to support potable, industrial, commercial, and agricultural uses (Moyle et al. 2010). This is in contrast to the historic condition of seasonal and interannual salinity variation prior to water management practices. In the past several years of drought, late-summer water salinities of 5 or more have reached east to the Sherman Lake region of the Delta. Salinity could further increase in the Delta through several mechanisms stemming from climate change and water management. Sea-level rise and shifts in magnitude and timing of snowmelt events are projected to increase salinity levels by 1-3 in this region by 2090 (Knowles and Cayan 2002). In addition, extended periods of drought could lead to increased salt penetration not counteracted by reservoir releases during the summer months. There is also potential for levee failures through erosion or earthquakes, leading to a higher volume of saline tidal waters reaching up-estuary. Finally, management actions that inadvertently or deliberately reduce fresh water releases during the dry season could increase salinity in this region. Summer and fall salinity has already increased in the last 25 years due to reduction in fresh water releases from water control structures (Knowles and Cayan 2002; Contra Costa Water District 2010). C&H Sugar Refining Company (Crockett, CA) has long tracked salinity in order to access fresh water for its refining process; its data show annual salinity intrusion now occurs much earlier in the year in Suisun Bay (beginning of March) compared to the early 1900s (beginning of July) (Department of Water Resources 2010).

As mentioned, *Egeria densa* is strongly limited by salinity. As in the six-week temperature-controlled aquaria experiment described above, a three-month experiment conducted in large tanks in a greenhouse in 2012 showed *E. densa* negative responses to a salinity of 5, with a 5-fold decrease in biomass relative to the freshwater treatment over the three months (Fig. 4.4, Borgnis and Boyer, in revision). At salinities of 10 and 15, mortality and decomposition occurred within three weeks. This was in contrast to 5-fold increases in shoot biomass in freshwater over the three months, and nearly 10-fold increases in the number of shoots and in root biomass (Fig. 4.4). Tissue nitrogen (N) concentration stayed constant at salinities of 0 and 5; however, tissue phosphorus (P) increased at a salinity of 5 (and thus N:P also), suggesting that P taken up could not be utilized and thus accumulated in the tissues, perhaps another indication of stress at this higher salinity.

Of all aquatic macrophyte species found within the Delta, *Stuckenia pectinata* is expected to have the greatest tolerance for salinity. This assumption is due in part to its nearly monotypic distribution in waters that can reach salinities of 15 within Suisun Bay. Further, in six weeks in greenhouse mesocosms, *S. pectinata* biomass accumulated greatly (~4x initial) at salinities of 0 and 5, doubled at 10, and was unchanged at 15 (Fig. 4.4; Borgnis and Boyer, in revision). Increases in both N and P concentrations in tissues at higher salinities (Fig. 4.4) suggests an inability to utilize all available nutrients, and perhaps the accumulation of N as “compatible solutes” to balance water potential as is common in saline wetland plants.

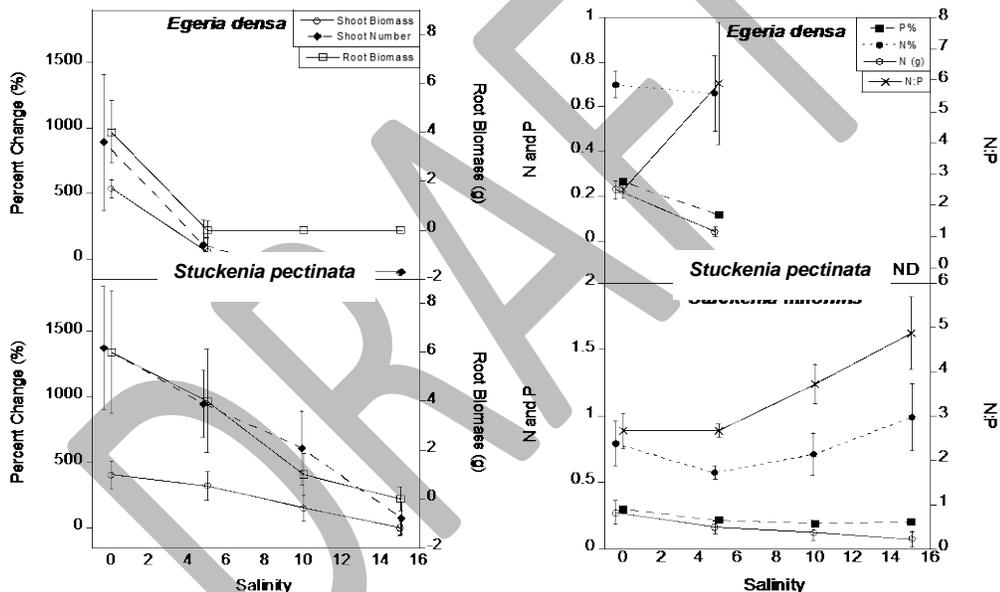

Figure 4.4. Salinity effects on growth characteristics and nitrogen and phosphorus content and ratio of *Egeria densa* and *Stuckenia pectinata* at the end of mesocosm experiment that ran June-August 2012. ND = no data; *E. densa* tissue nutrients could not be measured at the higher salinities due to insufficient tissue availability. From Borgnis and Boyer, in revision

We are not aware of any local studies of salinity tolerance on *Ceratophyllum demersum* or *Eichhornia crassipes*. Studies in other regions have found that *E. crassipes* undergoes stress at salinities as low as 2.5 (Haller et al. 1974) and that salinities above 6-8 are lethal (Muramoto et al. 1991; Olivares and Colonnello 2000).

4.1.4 Dissolved inorganic carbon

Floating vegetation should be able to access adequate carbon dioxide to fuel photosynthesis; however, availability of dissolved inorganic carbon (DIC) can be an important limiting factor to submersed species. The forms of carbon dissolved in the water are determined by pH (Barko and Smart 1981; Sand-Jensen 1989). Although CO₂ is the form of DIC preferred by all autotrophic organisms (Raven 1970), drawdown of CO₂ leads to increased pH. This is because CO₂ in solution is in equilibrium with carbonic acid (H₂CO₃), which becomes more common, leading to removal of protons from the water (thus a higher pH). This, in turn, has an effect on the relative concentrations of the other DIC forms in the water and bicarbonate (HCO₃⁻) becomes the primary form of DIC available (Sand-Jensen 1989; Santamaria 2002). Species that can utilize bicarbonate efficiently should have an advantage in the waters of the Delta. Both *Egeria densa* and *Ceratophyllum demersum* are able to efficiently utilize bicarbonate as a DIC source (Cavalli et al. 2012), which may partly explain their success within the Delta, with the heightened pH in dense beds leading to further advantage over time through positive feedback (Fig. 4.2A). We are not aware of pH measures within macrophyte beds in the Delta, but heightened pH and diurnal swings in both pH and CO₂ would be expected to be greatest within dense beds of *E. densa* and in settings with limited water flow.

4.1.5 Nutrients

The primary nutrients that limit plant growth are nitrogen (N) and phosphorus (P). Limitation is typically determined by adding one or more nutrients to ascertain if the potential rate of net primary production has been achieved (Howarth 1988); in other words, if the plant grows with added nutrients, then it has greater potential for production than what its ambient nutrient environment allows. At temperate latitudes, phosphorus is generally considered the primary limiting element to system primary production in freshwater, and nitrogen is considered the primary limiting element in marine systems, although there is variation in this pattern (Smith 1984). N may be less limiting in freshwater due to a greater importance of N fixation there (Howarth et al. 1995, 1999; Paerl et al. 1995), and a greater efficiency of sediments in sequestering P than in marine systems (Caraco et al. 1990); however, both N and P have been shown to be important in estuaries (McComb et al. 1981; D'Elia et al. 1986) under different conditions and seasonally (Conley 2000).

The San Francisco Estuary is an example of a system replete in both N and P, and yet depauperate in phytoplankton production (Cloern 2001). The annual loading rates of both N and P are higher in San Francisco Estuary than in the Chesapeake, and yet large phytoplankton blooms and mortality common in Chesapeake, followed by large drawdowns in dissolved oxygen concentration, do not typically occur in the San Francisco Estuary (Cloern et al. 2001). Thus, San Francisco Estuary is not considered to be a eutrophic system in terms of algal production; phytoplankton may be limited by high levels of turbidity, abundant consumers including introduced clams (Jassby and Cloern 2000), and possibly by the ratios of species of N available (i.e., ammonium versus nitrate, Wilkerson et al. 2006).

Although adequate nutrient supply is necessary to fuel growth of macrophytes in the Delta, the degree to which nutrients trigger or exacerbate extensive growth of the invasive *Egeria densa* and *Eichhornia crassipes* (and now *Ludwigia* spp. as well) within Delta waters is unclear. Acreage of all these invasive

Comment [KB6]: John Durand said "limited at times in N Delta off Sac plume" – need clarification or reference

macrophytes has expanded in recent years, and especially during the time between two mapping events in 2008 and 2014 (Khanna and Ustin, unpublished data). Although there has been an increase in NH_4^+ and a decrease in the N:P ratio over a 30 year period through 2006, especially in the upper Sacramento River, this trend was not evident in the last decade of that time period (Glibert 2010; Fig. 4.5). A closer look at the last decade (through 2013) shows no trends in any form of inorganic nutrients or N:P ratios in the central Delta region (Berg and Sutula 2015, Figure A-1 through A-4). Thus, it does not seem that overall increasing acreages of invasive macrophytes can be related to changes in ambient dissolved inorganic nutrient concentration, form, or ratios during the same time period.

DRAFT

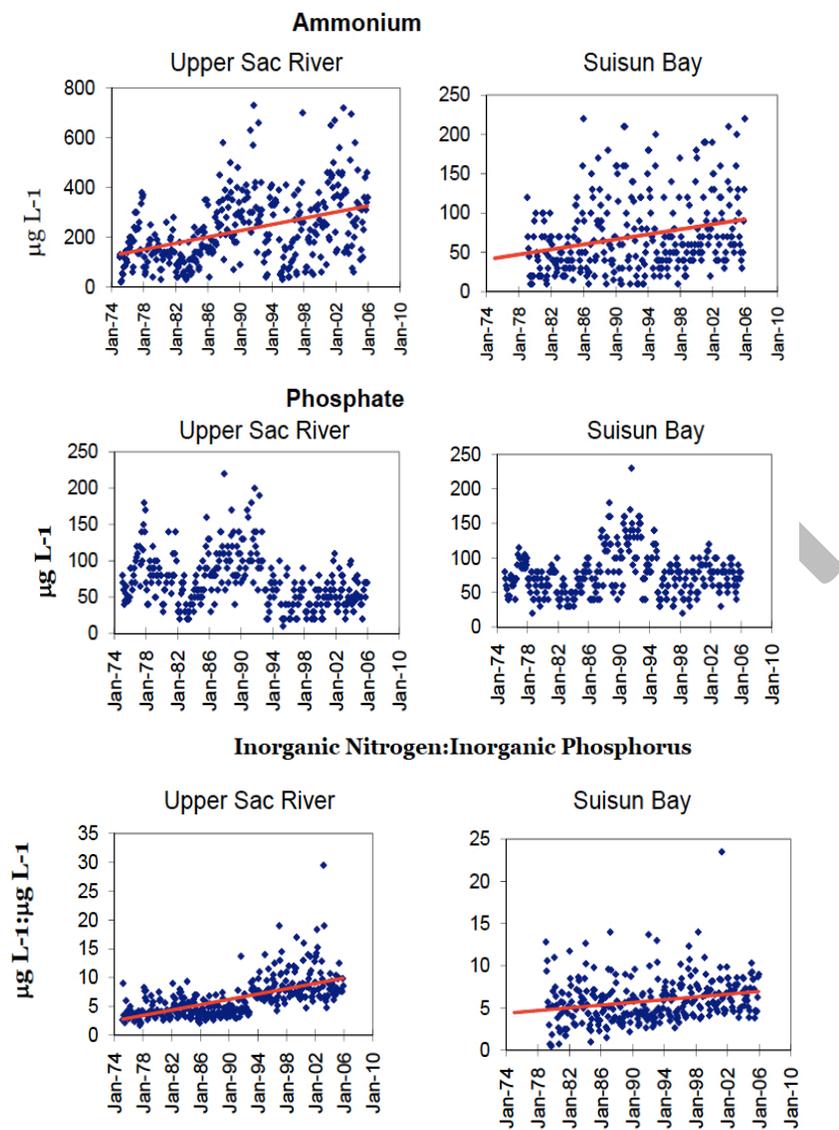

Figure 4.5. Patterns in ammonium, phosphate, and ratios of inorganic N to P over time at two locations, upper Sacramento River and Suisun Bay. From Glibert 2010.

Water nutrient concentrations vary across the geographical extent of these species, with at least a 3-fold difference in all three of the primary inorganic nutrient forms, ammonium (NH_4^+), nitrate (NO_3^-) and phosphate (PO_4^+) from the upper Sacramento River to Chipps Island (Foe et al. 2010; Figs. 4.6, 4.7).

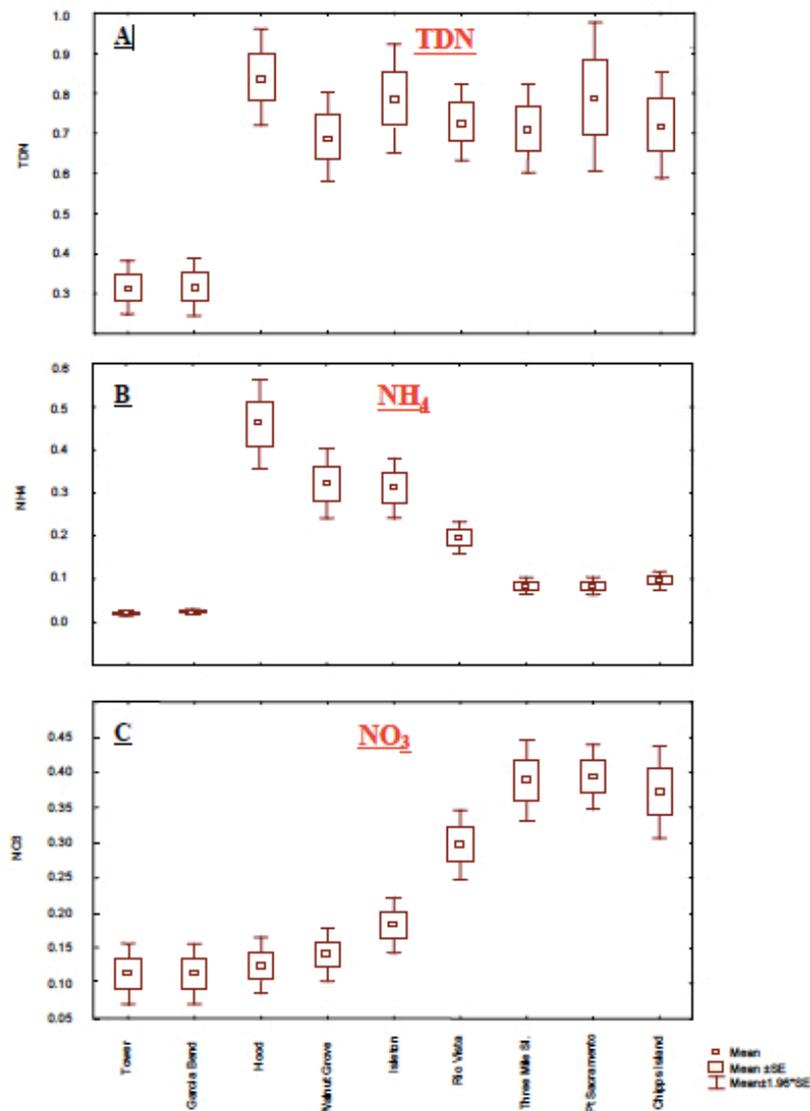

Figure 4.6. Mean annual total dissolved nitrogen (TDN), NH_4 and NO_3 concentrations in the Delta between Tower Bridge (north Sacramento River) and Chipps Island (Suisun Bay) between March 2009 and February 2010. Tower and Garcia Bend sites are above the discharge of the Sacramento River Water Treatment Plant. From Foe et al. 2010.

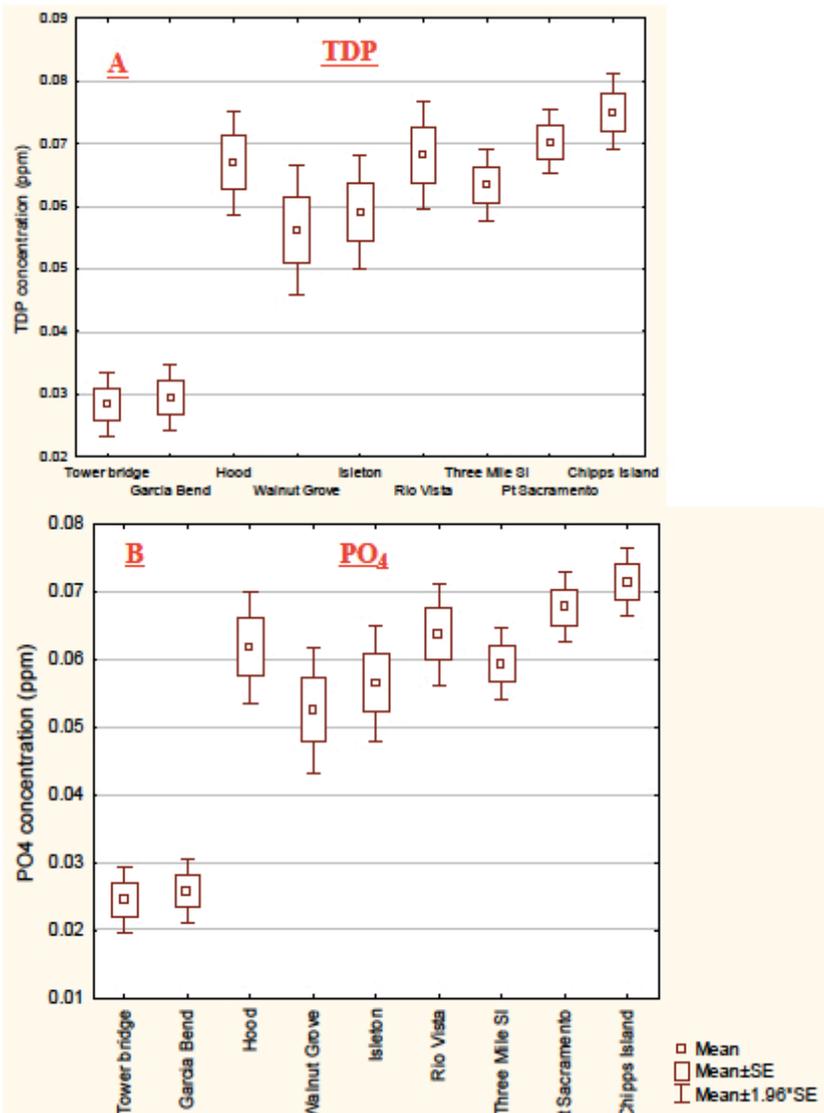

Figure 4.7. Mean annual total dissolved phosphorus (TDP) and PO₄ across sites as in Fig. 4.5. From Foe et al. 2010.

It is possible that acreages of these species could be examined in relation to nutrient supply to determine if there is a correlation between changes in abundance and nutrient patterns at specific locations, but it would be difficult to tease apart other co-occurring patterns in environmental conditions that may vary with nutrients.

Egeria densa is able to take up nutrients through its leaves and roots, thus accessing water column nutrients from both the water column and the sediment. Studies differ on whether it preferentially takes up nutrients from its roots (Barko and Smart 1980) or shoots (Feijoo et al. 2002). *Eichhornia crassipes* accesses nutrients through its roots hanging at the surface of the water column (Klumpp et al. 2002; Rommens et al. 2003). Although many experiments have tested the effects of nutrients on phytoplankton growth under different scenarios of light, temperature and other variables in the Delta (e.g., Wilkerson et al. 2006), we know of no comparable local experiments conducted on aquatic macrophytes.

Researchers in other regions have evaluated nutrient limitation of *E. densa* through experiments in which nutrients were added to test the plant's response. In *E. densa*'s native range in highly enriched Pampean streams in Argentina, biomass and nutrient content were positively correlated with nutrient concentrations (phosphate and ammonium) in the water and in sediments (as total N) (Feijoo et al. 1996). An experiment by that same group found ambient levels of phosphate (0.3 mg l^{-1}) led to significantly greater biomass than phosphate at half of ambient concentrations (Feijoo et al. 2002). In a separate experiment, they found that ammonium was absorbed more readily than nitrate (added at ambient concentrations of 6 mg DIN l^{-1} , separately), leading to higher concentrations of tissue N with ammonium; however, this did not translate to differences in biomass (Feijoo et al. 2002). A comparison across the two experiments found phosphate was more readily absorbed by *E. densa* than nitrogen in either form, and that water column uptake was greater than from sediments (Feijoo et al. 2002). A study in Florida also found *E. densa* to prefer ammonium over nitrate when both were present in the water in equal amounts at concentrations considered to be non-limiting (10.5 mg l^{-1} of each DIN source, plus phosphate at 3 mg l^{-1} , as found in sewage effluent, Reddy et al. 1987). In a separate experiment, these authors varied concentration of ammonium and phosphate (range of $1\text{-}4 \text{ mg N}$ and $0.2\text{ to }0.8 \text{ mg P l}^{-1}$, respectively); although they did not report biomass data, they noted that biomass was *greater* at low nutrient concentrations than at high. N and P removal rates were estimated to be $186\text{-}408 \text{ mg N m}^{-2} \text{ day}^{-1}$ and $122\text{-}228 \text{ mg P m}^{-2} \text{ day}^{-1}$ from the water column (Reddy et al. 1987). *E. densa* uptake of both nutrients was similar in summer and winter experiments. A Florida mesocosm experiment repeated in two different seasons (April-June and October-December) found no effects of fertilizer (N:P:K of 15-9-12 in slow release fertilizer) added to the sediment in a range of concentrations from 0 to 4 kg/g sediment) on *E. densa* biomass (Mony et al. 2007).

Taken together, these studies of *E. densa* suggest that nutrient uptake from water may be preferred over uptake from sediment, that ammonium may be preferred over nitrate, and that phosphate may be more readily absorbed than either form of N. The tests of water column nutrient effects in all the above studies were conducted at very high concentrations, which may explain the limited growth responses. Although concentrations vary among sites in the Delta, typical DIN levels are 0.5 mg l^{-1} and DIP levels are 0.06 mg l^{-1} (annual means of ~monthly sampling in 2009-2010; Figs. 4.6, 4.7; Foe et al. 2010), with an

annual average as high as 1.43 mg l⁻¹ DIN and 0.18 mg l⁻¹ DIP at one site (Foe 2010). However, the studies described in the previous paragraph evaluated *E. densa*'s responses under higher ambient nutrient conditions and thus they tell us little about water column nutrient thresholds for macrophyte biomass expansion in the Delta. In addition, little is understood about the role that dissolved organic nutrients may play in supporting macrophyte growth. Moreover, we suspect rooted species like *E. densa* with the capability of accessing nutrients from both the water column and the sediments would be very difficult to manage by only reducing water column nutrient supply, especially in quiescent areas where dead biomass can accumulate and possibly provide an extended period of remineralizable nutrients. Further, the positive feedback of declines in dissolved oxygen making sediment-bound P more available (see Chapter 3) suggests that this important nutrient will continue to be sourced from the sediments (Cornwell et al. 2014), especially in places where decomposing macrophyte tissues accumulate.

Eichhornia crassipes, with access to nutrients only from the water column, is perhaps a simpler case. A number of studies have shown *E. crassipes* to readily absorb added N (Carignan and Neiff 1994; Heard and Winterton 2000; Reddy et al. 1989, 1990; Moran 2006) and to sometimes be limited by P (Srivastava et al. 1994; but see Moran 2006, who did not find an association between DIP and P uptake). In a mesocosm study on *E. crassipes* in China, nutrient additions to lake water comparable in nutrients to the Delta (0.6 mg l⁻¹ total N and 0.05 mg l⁻¹ total P), raising N to 5 mg l⁻¹ (using NH₄NO₃) and P to 0.5 mg l⁻¹, led to 30% increases in both relative growth rate and clonal propagation rate (You et al. 2014). Notably, the same elevated N level combined with a much higher P enrichment (1.0 mg l⁻¹) led to 150% increases in these measures relative to ambient conditions simulated. In that same study, warming by 2-3 degrees had a much smaller positive effect on growth rate (15%) and some effects of elevated temperature (increased shoot:root and foliar N) were found only when nutrient levels were also elevated (You et al. 2014). A study that explored water N concentration in relation to *E. crassipes* growth rates (Aoyama et al. 1986; see review and modeling by Wilson et al. 2005) suggests that *E. crassipes* growth rates in the Delta could be reduced with lower DIN concentrations than are typically found there (0.5 mg l⁻¹, Foe et al. 2010). This work also estimated that N becomes limiting for *E. crassipes* growth at an N:P ratio in water of <7 (Wilson et al. 2005); assuming 0.5 and 0.06 mg l⁻¹ DIN and DIP in Delta waters on average (Foe et al. 2010), respectively, an N:P ratio of about 8 suggests that N supply is not currently limiting. Although water column nutrients are the only source available to *E. crassipes*, sediment fluxes can supply both N and P (the latter enhanced by low oxygen conditions) to the water column. Hence, while management of water column nutrient supply might seem to be a straightforward solution that could reduce *E. crassipes* abundance, perhaps more easily than for *E. densa*, biogeochemical coupling with the sediments must also be considered.

4.1.6 Flow, residence time, substrate stability, and slope

Flow velocity and residence time of water within a given area are expected to influence both floating and submersed species. Propagules need to be able to stay in place to initiate bed establishment, which succeeds to a greater degree in more protected areas. Two studies found flow rates above 0.3 or 0.49 ms⁻¹ limiting to establishment of *Egeria densa* (Durand 2014 and Hestir 2010, respectively). Substrate stability is necessary for submersed plant establishment and persistence, and larger grain size (sand) can

lead to less stable bed conditions, especially under higher flow regimes. Development of an aquatic plant bed slows flow in the immediate vicinity, a positive feedback loop that further supports bed development. Although the draft conceptual model of Anderson (2008) indicates the importance of substrate stability, it does not indicate the importance of this positive feedback (Fig. 4.2A). Densely growing submersed macrophytes like *Egeria densa* can reduce flow by 40% (Wilcock et al. 1999; Champion and Tanner 2000), favoring their continued presence and spread within the area. However, higher flow is important to dispersal of propagules of all aquatic macrophytes to new areas (Fig. 4.2A) and water movement is essential for growth by bringing nutrients and dissolved carbon to the leaves by mass transport.

Depth and slope of shores can also limit submersed species (Fig. 4.2A). *Egeria densa* can grow to depths of 6 m (Carrillo et al. 2006) and 40% slope, but this seems to be the extreme (in tropical, high elevation lakes). *Eichhornia crassipes* vegetative propagation is not limited by water depth, but propagules accumulate along shores due to greater protection from washing out. Although sexual reproduction contributes little to population growth in the Delta, germination and seedling growth require shallow water over gentle sloping shorelines to maximize light availability (Barrett 1980).

4.1.7 Interactions with other submersed or floating species

A factor not summarized in the draft conceptual models of Anderson (2008) is interaction among species of aquatic macrophytes. Several recent studies suggest these could be quite important in determining the abundance of some species or guilds of species. For example, experimental work in mesocosms suggests that *Egeria densa* has strong negative effects on *Stuckenia* sp. growth under fresh water conditions. When grown together with *Egeria densa* in fresh water, *Stuckenia* sp. produced 75% less biomass than in monoculture, and significantly more nodal roots, suggesting increased nutrient foraging (Fig. 4.5, Borgnis and Boyer in revision). At a salinity of 5, a decline in *E. densa* performance (see above) coincided with a doubling of *Stuckenia* sp. shoot

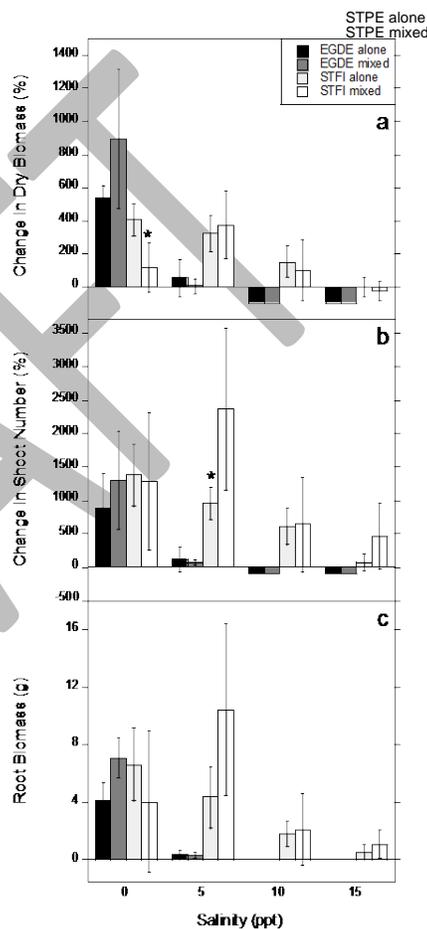

Figure 4.5. Effects of salinity on growth characteristics of *Egeria densa* (EGDE) and *Stuckenia pectinata* (STPE), grown separately and together, at the end of a mesocosm experiment running June-August 2012. From Borgnis and Boyer, in revision

density. These results suggest that *S. pectinata* might be more abundant in the fresh waters of the Delta in places where *E. densa* currently dominates.

There may be other possibilities of important interactions within the submersed plant community. As previously mentioned, *Egeria densa* maintains substantial biomass during the winter, perhaps increasing its competitive ability among species that undergo winter senescence, such as *Stuckeina pectinata*. However *E. densa* may facilitate other species in some cases. In one study, *Ceratophyllum demersum* was found to occur more frequently with other species, especially *Egeria densa*, than it occurred on its own (Santos et al. 2011), suggesting it may derive some benefit from other species.

In addition, remote sensing data tracking changes in the coverage of the floating species *Eichhornia crassipes* indicated a large loss of submersed species with an increase of 25% in *E. crassipes* and conversely a large increase in submersed species with 25% decrease (Fig. 4.6, Khanna et al. 2012). The possibility that one of these invaders will replace the other and vice versa with management is an important issue to consider. In contrast, there were no consistent effects on other floating species: the native *Hydrocotyle umbellata* or the introduced *Ludwigia* spp. (Fig. 4.6). A conceptual model was developed to show the hypothesized relationships between *E. crassipes* and submersed vegetation with succession and treatment (Fig 4.6). An interesting new trend of reduced *H. umbellata* accompanied by large increases in *Ludwigia* spp. suggests that there may be feedbacks between these two species as well (Khanna and Ustin, unpublished data).

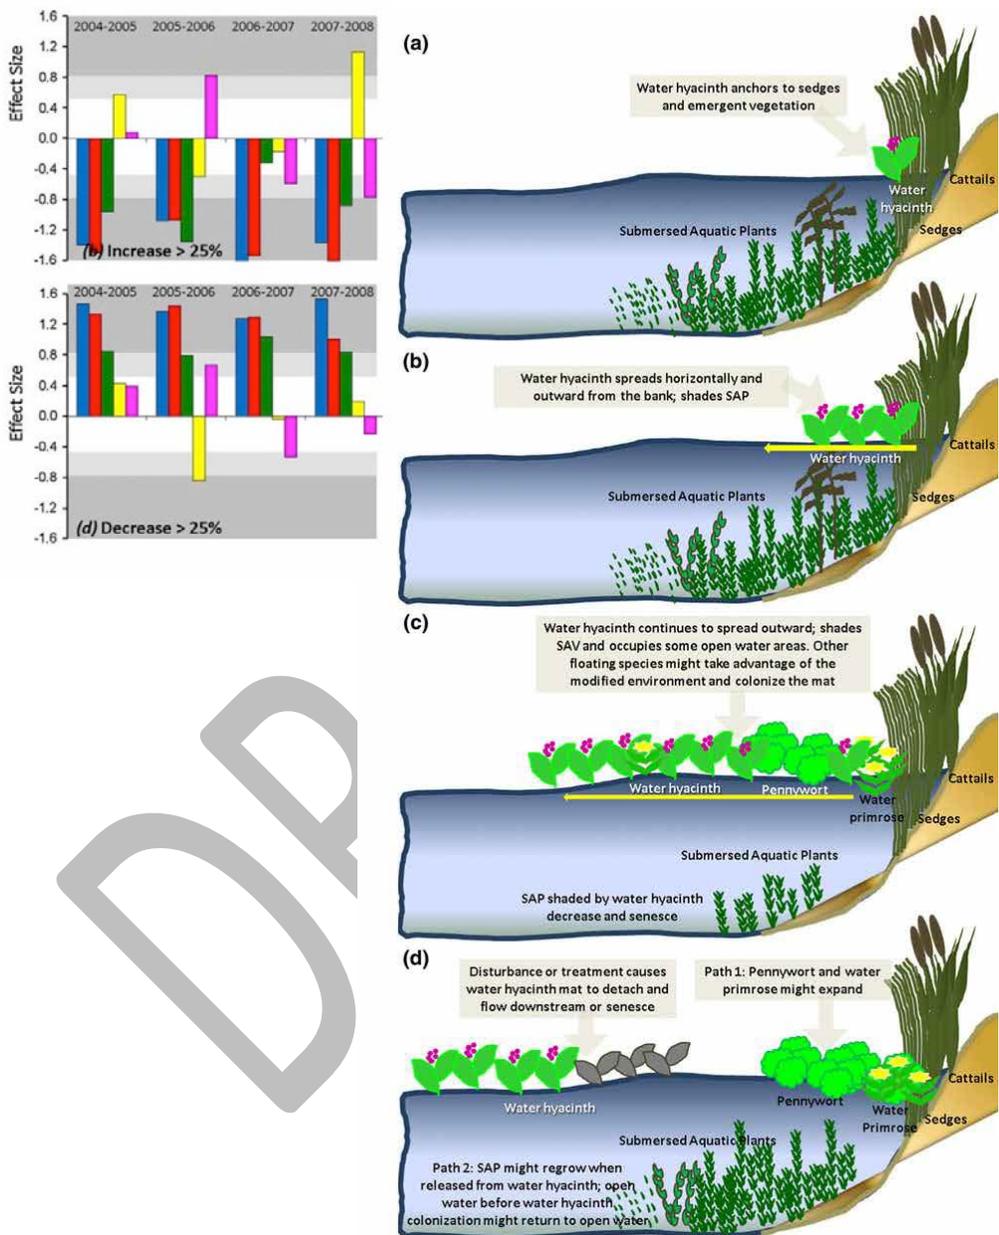

Figure 4.6. Left: Effect sizes reflecting change in coverage with 25% increases or decreases in water hyacinth (*Eichhornia crassipes*) from remote sensing data (dark region of background indicates a strong effect). Changes are shown for water (blue), submersed vegetation (red, predicted to be primarily *Egeria densa*), emergent and senescent plants (green), native pennywort *Hydrocotyle umbellata* (yellow), and introduced water primrose (*Ludwigia* spp., pink). Right: Conceptual model of successional pathways of *E. crassipes* growth and expansion, with effects on other floating and submersed plants. From Khanna et al. 2012

4.1.8 Chemical, mechanical, and biological control

Herbicide application has been the most common means of attempted control for both *Egeria densa* and *Eichhornia crassipes* to date (Anderson 1990, DBW 2005). Legal challenges to herbicide control have led to new permitting and monitoring requirements (Siemering et al. 2005), and a re-evaluation of alternative control methods (Greenfield et al. 2007).

Mechanical removal of *Egeria densa* has been attempted in the Delta, but tends to produce fragments that then can become propagules for further spread locally and in distant locations through water movement (Anderson 2003). Such harvesting also has the potential to remove or damage non-target organisms. Mechanically gathering and harvesting *Eichhornia crassipes* can be effective in limited areas, but it is expensive to remove the heavy masses of plants with very high water content (Gopal 1987). Shredding of this species using shredder boats and leaving the plant material in place may be one option, although the resulting biomass and source of remineralizable nutrients as well as dissolved oxygen implications are both concerns in areas with limited flow (Greenfield et al. 2007; see above). Further, such shredding can leave viable propagules that can survive and regrow (Spencer et al. 2006). Benthic barriers have been used to limit small infestations of *E. densa* around high use areas such as docks, boat launches and swimming areas in other regions but have not been used in the Delta to our knowledge.

There is an extensive literature on the use of biological agents as controls for *Eichhornia crassipes*. There are two commonly used weevil species from the plant's native range in use for biological control, in the genus *Neochetina* (Sosa et al. 2012). Typically, mechanical or chemical treatment is used first, making initial conditions more manageable for biological control (Adekoya et al. 1993). In the Delta, several species intended for biological control of *E. crassipes* were introduced in the early 1980s; of these, the weevil *Neochetina bruchi* has become established but does not appear to have much impact (Stewart et al. 1988). Although this weevil is likely to have its nutritional needs met through adequate plant nutrient levels in the Delta (Spencer and Ksander 2004), its immature stages have poor survivorship during winter conditions (Akers and Pitcairn 2006). The US Department of Agriculture (USDA-ARS) and the California Department of Food and Agriculture (CDFA) are investigating other potential biological control agents, and are beginning to release a planthopper, *Megamelus scutellaris* for *E. crassipes* control (P. Moran, USDA-ARS Exotic and Invasive Weeds Research Unit, Albany, CA, pers. comm.). This planthopper is considered to be sufficiently host-specific in Florida, where it is now widely established, and impact evaluations there are ongoing (Tipping et al. 2014a; Moran, pers. comm.).

To date, besides the above biological control attempts in the Delta on *E. crassipes*, no other introductions have been made for control of other invasive macrophytes. Biological control studies are underway for *E. densa* under lab conditions; an ephydrid fly larva is one species being evaluated (D. Dubose, USDA-ARS, pers. comm.).

Although biological control methods may be desirable to avoid the concerns of non-target species effects of chemical application, the resulting biomass can still be an issue to contend with. *Neochetina* spp. weevils reduce buoyancy of *Eichhornia crassipes*, making it sink to the bottom and decompose (Wilson et al. 2007). As with chemical control or natural causes of plant death (e.g., freezing

Comment [KB7]: Cite – Llaban suggested Biology and Control of Aquatic Plants. A Best Management Practices Handbook

temperatures), if there is mortality and accumulation of dead material, decomposition can lead to a drawdown of oxygen and a release of nutrients, mainly in quiescent areas where the material is not washed out (Greenfield et al. 2007). Further, biological control has been shown to reduce the size of *E. crassipes* plants over several generations, which could reduce the biomass of live plants that can lead to low oxygen conditions beneath the floating mats (Tipping et al. 2014b).

4.2 Relative Importance of Nutrient Subsidies Versus Other Factors in Promoting Observed Trends

Our review indicates that there are a number of important factors that affect the biomass and distribution of nuisance aquatic species. There are a few factors that can lead to large losses of biomass in a short period of time, including increased salinity for *E. densa* and *E. crassipes* and freezing temperatures for the latter. Two papers reported on state shifts resulting from dramatic losses of these two species. As described above, *E. crassipes* suffered a major decline largely attributed to reduced light due to extended cloud cover (during El Niño years) in Lake Victoria in Africa (Williams et al. 2005, 2007). *E. densa* disappeared from a wetland in its native range in southern Chile, probably due to desiccation exacerbated by low rainfall and cold temperatures (Marin et al. 2009). It is possible that there are management actions that could be used in some areas of the Delta to control these species to some degree. For example, water levels could be controlled in some locations, in order to attempt to desiccate *E. densa*, and salinity could be permitted to intrude for brief periods of time if that were politically acceptable (Moyle et al. 2010), which could shift west Delta *E. densa* stands to the native *Stuckenia pectinata*. Species interactions are also worth considering in manipulations; e.g., are there management actions that could shift composition toward native or desirable species? However, there is also the possibility of a “zero sum game” if managing *E. crassipes* leads to further invasion by *E. densa* and vice versa, or other undesirable species are benefitted through a management action.

Nutrients are certainly important to the growth of all plant species and our review suggests that the nutrient levels currently found in the Delta are probably not limiting these plants. Studies of nutrient addition to *Eichhornia crassipes* show clear signs of a direct relationship of water column nutrients to accumulation of biomass as well as clonal propagation, and it may be possible to reduce growth rates through nutrient reductions. However, studies of *Egeria densa* biomass at realistic nutrient levels for the Delta are very limited, and thus do not provide convincing evidence that a reduction in water column nutrients will result in a reduction in *E. densa* production. Further, for both these species, we have very limited understanding of the relative importance of new nutrient supply versus the cycling of nutrients within beds, including the release of P from sediments within macrophyte beds (Cornwell et al. 2014). Finally, have very limited information on the relative importance of nutrients versus other factors in controlling growth and biomass expansion of any of the nuisance invaders within the Delta. The fact that DIN, DIP, and N:P have remained quite steady over the last decade, while there have been great expansions in areal extent of *E. densa*, *E. crassipes* and *Ludwigia* spp. during the latter part of this period, suggest that nutrient management alone will not be sufficient to control any of these species.

5. Recommendations

The goal of this review is to synthesize available information to provide insight into major factors controlling the expansion of invasive floating and submerged aquatic vegetation in the Delta. The review addressed three major questions:

1. How does submersed and floating aquatic vegetation support or adversely affect ecosystem services and related beneficial uses?
2. What is known about the spatial and temporal trends in submersed and floating aquatic vegetation in the Delta?
3. What is the relative importance of nutrients versus other factors in promoting observed trends in submersed and floating aquatic vegetation in the Delta?

This review found that the lack of routine monitoring of aquatic macrophytes greatly hindered our ability to summarize, with confidence, the status and trends of floating and SAV in the Delta (Question 2), and to what extent nutrients versus other factors were controlling their occurrence (Question 3).

Given this finding, our recommendations are focused on three principal actions:

1. Implement routine monitoring of macrophytes as well as the major factors that control them.
2. Develop and use a biogeochemical model, coupled with routine monitoring and special studies, to understand the spatial and seasonal nutrient and organic carbon budgets vis a vis major sources of nutrients fueling floating and SAV growth.
3. Conduct a literature review and a pilot research program in floating and SAV control programs.

R1: Implement Routine Monitoring of Invasive Floating and Submersed Aquatic Vegetation. Routine monitoring of floating and submersed aquatic vegetation should be undertaken to assess trends over time and to support ecosystem modeling of the Delta. Grant-funded efforts have been sporadic and there is no plan for on-going rigorous evaluation of patterns and trends. Monitoring should be comprised of a combination of remotely sensed areal coverage and field-based transects to estimate biomass or, ideally, net primary production (through repeated measures of biomass over time to determine rates of turnover). Despite recent advances in remote sensing to include image spectrometry (i.e., hyperspectral remote sensing), problems with misclassification among non-native SAV as well as poor detection of species that occur in smaller patches (e.g., *Stuckenia* sp.) suggest that transect and quadrat monitoring is also needed to follow trends in species composition in space and time. Estimates of biomass/production and areal cover should be conducted in combination with measures of the major factors that control growth of these primary producers, including water column and sediment nutrients and other standard water quality measures (e.g., temperature, salinity, pH, dissolved oxygen), as well as flow rates. Early actions should include the development of a workplan to lay out the key indicators and cost estimates required for monitoring.

R2: Develop a Biogeochemical Model of the Delta, focused on Nutrient and Organic Carbon Fate and Transport. Understanding of factors controlling floating and SAV is critically hampered by the lack of information on nutrient and carbon budgets for the Delta and its subregions. In particular, it is important to quantify the storage in the compartments of the ecosystem (i.e. water, sediment, plant biomass, etc.) and fluxes or exchanges between compartments at varying seasonal and spatial scales and with a variety of water flow and residence time scenarios. Early actions should include the development of a workplan to lay out the key indicators and cost estimates required for monitoring. This information will provide an understanding of whether management of nutrients is likely to aid in control of floating and SAV. To step into model development, three actions should be taken: 1) examine existing models already available to determine suitability for this task, 2) develop a work plan that lays out the modeling strategy, model data requirements, and implementation strategy, and 3) conduct special studies and other monitoring needed to support model development. This includes special studies that quantify N, P, and organic carbon associated with ecosystem compartments as well as uptake, release and flux rates that characterize different reaches of the Delta. Lab and field experiments that test whether macrophyte growth is limited by nutrients in Delta waters could help inform management and predict problem areas. These analyses and experiments should inform hypotheses that can be tested through model development as well as potential future scenarios. The monitoring and modeling teams should collaborate closely to collect high priority data to inform the models.

R3. Review current and potential future control strategies for invasive aquatic macrophytes in the Delta, including mechanical, chemical, biological control, and integrated control methods, as well as barriers that reduce movement of vegetation into sensitive areas or those with heavy human use. Depending on the outcome of R2, nutrient management may be ineffective in controlling invasive floating and SAV. While monitoring, modeling and special studies are under way, determine the degree to which control strategies are supporting beneficial uses and nutrient management objectives going forward. This work should begin by evaluating current and planned control strategies to determine effectiveness at both reducing live biomass and minimizing recycling of nutrients from dead material into additional growth in areas with high residence time. A current USDA-ARS program on integrated control methods for both *E. densa* and *E. crassipes* could help to inform the proposed review.

DRAFT

7.0 Appendices

7.1 Comment Matrix and Responses to Science Working Group

Author	Page	Comment	Response
Conrad	ii	Executive Summary, first paragraph, second sentence - What type of impairment? Ecosystem?	added word "ecosystem"
Conrad	ii	Executive Summary, first paragraph, last sentence - Only three (major) questions follow (not four).	fixed
Conrad	ii	Executive Summary, Finding#2: Lack of a routine monitoring program hampers our ability to discern recent spatial and temporal trends. - This seems like a recommendation rather than a finding. The finding is that Egeria and water hyacinth dominate the macrophyte community in the Delta and may be expanding. The lack of adequate monitoring is addressed in your recommendations below so I suggest removing this sentence here.	changed the findings section to incorporate this
Conrad	iii	Executive Summary, Finding#5: first sentence - Sea level rise should also be mentioned here, perhaps?	did not mention; much less important to species that can grow in range of depths than other factors
Conrad	1	Under Chapter 1, Section 1.1, fourth sentence: The Delta is widely recognized as in "crisis"... - Incomplete sentence.	fixed
Conrad	3	Under Chapter 1, Section 1.2, Second paragraph - Re-start numbering (of key questions) at #1.	fixed
Conrad	4	Under section 2.1, the first two sentences were highlighted by the commenter but no comment provided.	not sure why highlighted by reviewer either
Conrad	11	Figure 2.5 caption - The caption says that the Google Earth imagery was "digitized and ground truthed." How was the ground-truthing conducted? It seems hard to believe that a species-level determination of submersed vegetation can be done from visual review of Google Earth imagery, especially given that analysis of hyperspectral imagery was not always reliable for species determination of SAV. The reference for this is Boyer et al. 2015, which is not provided in the Google Drive of references. Is it possible to see this information.	additional explanation added. Species level is pretty easy to determine within Suisun Bay, as ground-truthing (visiting all areas) by boat, and performing rake sampling in a subset of these areas confirmed that <i>Stuckenia pectinata</i> is nearly mono-typic there. In the Delta where there are many more species, this methodology does not work well as described by Ustin research group. Yes, all references will be added to the Google Drive.
Conrad	12	4th paragraph, reference to Breiter 2014 - This citation is not provided in the Literature Cited.	fixed

Conrad	13	Second paragraph on <i>Stuckenia sp.</i> , first sentence - See comment above on Fig. 2.5. Was <i>Stuckenia</i> coverage in 1993 and 2002 also ground-truthed?	No, it was not. Additional explanation added that we assumed that <i>Stuckenia</i> was the only species present then as in 2011-2012 time period. The distinct growth form of <i>Stuckenia</i> can be seen in the previous images
Conrad	15	Section 3.1, first paragraph, highlighted sentences from "In contrast, dense canopies... to "...leading to predation on smaller adult and juvenile native fish" - Some of the following paragraph (e.g., highlighted passage) reads as if these conceptual ideas have been well established. Not the case for all of these assertions. Suggest revising the language to be less absolute.	Revised to clearly state where conceptual ideas have not been backed up by data.
Conrad	16	Under section 3.1.1, first paragraph, fourth sentence " <i>E. densa</i> sheds some biomass in winter but does not fully senesce (Fig. 2.2) - Santos et al. 2011 may be another reference to use for this assertion.	Added this reference
Conrad	17	Section 3.1.3 - Consider re-naming this "Effects on hydrodynamic and sediment processes" or some version of this. "Habitat" can mean a lot of things- from substrate to food web to water quality. I expected this section to address vegetation effects on water quality given that it addressed suspended sediment. Also, it seems more intuitive to discuss effects of vegetation on the physical habitat (like water velocity) and water quality before discussing food web effects. Right now the organization discusses food web ("trophic support") in the middle of these physical aspects.	Revised the names and order of the sections in this chapter.
Conrad	17	Under section 3.1.3, third sentence, "Submerged plants may also ..." - I think Shruti Khanna's 2012 paper present a conceptual model that expresses this idea	yes, cited and this is discussed in detail in chapter 4
Conrad	18	Under section 3.1.3, last paragraph on floating vegetation - This is a very short section on habitat alteration by floating vegetation. Check Shruti Khanna's paper for more detail that could be fleshed out here...	additional detail added.
Conrad	18	Under section 3.1.4, first paragraph, first sentence - A useful reference that could be included in this synthesis is: Schultz, R., and E. Dibble. 2012. Effects of invasive macrophytes on freshwater fish and macroinvertebrate communities: the role of invasive plant traits. <i>Hydrobiologia</i> 684:1-14.	thanks, added the reference.
Conrad	19	Under section 3.1.4, Second paragraph under <i>Eichhornia crassipes</i> , 2nd sentence - Awkward sentence, should be revised. Shift invertebrate	sentence revised

		foods available relative to what?	
Conrad	19	Under section 3.1.4 third paragraph under <i>Eichhornia crassipes</i> - This section seems fairly brief, given the amount of published work on the subject. To help readers process the host of effects that aquatic veg can have on water quality, it may be useful to deal with each water quality parameter one by one, and highlight the important results (e.g. subsections for DO, pH, nutrients. And what about temperature? It seems that should be discussed as well if there is literature suggesting the AV may have effects. Examples help too...	Each effect now discussed one by one.
Conrad	19	Under section 3.1.5. Changes in Water Quality, 1st paragraph, first sentence - These effects should be described in more detail here, with citations. I expected the rest of this paragraph to delve into effects on DO, but instead the next sentence shifts gears into nutrients.	More detail and citations added.
Conrad	19	Under section 3.1.5. Changes in Water Quality, 1st paragraph, 2nd sentence - Interesting...is there a citation for this?	yes, added citations
Conrad	20	Under section 3.1.5 2nd paragraph, 1st sentence - Does SAV contribute DO or limit it? There are diurnal swings in DO in dense <i>Egeria</i> beds.	expanded this section and discussed diurnal swings
Conrad	20	Under section 3.1.5, 2nd paragraph, 1st sentence (Meerhoff et al. 2003) - This reference is not listed in the Literature Cited section.	fixed
Conrad	24	Under section 4.1.1 Light, 2nd paragraph, last two sentences - Seems like it's worth noting here that rigorous study of species-specific effects on local water quality conditions (such as turbidity) have not been done- perhaps this is an area worthy of more study?	yes, added this
Conrad	24	Under section 4.1.1. Light, third paragraph, second sentence - The difference between treatments in the study described is unclear in this sentence. 2x greater...depth...light?	clarified in the text
Conrad	24	Under section 4.1.1 Light, third paragraph, last sentence - Again, the conditions tested in this experiment are not completely clear in this sentence. Why not state what the light exposure treatments were?	light exposure treatments now given

Conrad	24	Under section 4.1.2 Temperature, reference for Knowles and Cayan 2002 - This reference is missing in the literature cited section. Also, a more recent reference that projects Delta water (rather than air) temperatures is: 1. Wagner RW, Stacey M, Brown LR, Dettinger M (2011) Statistical models of temperature in the Sacramento-San Joaquin Delta under climate-change scenarios and ecological implications. <i>Estuaries and Coasts</i> 34: 544-556.	added this citation
Conrad	25	Under section 4.1.3 Salinity, first paragraph, first sentence - This first paragraph provides helpful background on how this aspect of water quality responds to current management practices and how it has been changing over time. It also puts the Delta plant life in context. I think this would be nice to do for light (i.e., turbidity) and for temperature as well. There are several papers that discuss a trend of water clearing in the Delta. You already do this to some extent with temperature, but it could be expanded a little (see above comment for an updated reference).	did some expanding of these sections
Conrad	25	Under section 4.1.3 Salinity, first paragraph, sentence related to summer and fall salinity in last 25 years due to management of fresh water - Reduction?	yes, reduction
Conrad	26	Under section 4.1.3 Salinity, second paragraph, reference to Figure 4.4 - I find the axes below of % change a bit confusing. What is the reference condition? What does 1000% change at 0ppt mean?	change from initial conditions over 3 month experiment. Tried to make this more clear in the text.
Conrad	27	Under section 4.1.3 Salinity, first paragraph, second sentence - Similar to (Engle's) above comment: I understand this text, but I don't see this message reflected in Fig. 4.4. It looks like a declining trend in <i>Stuckenia</i> biomass with increasing salinity.	there was no change in biomass at a salinity of 15 over the course of the experiment. There was a great increase in biomass at all lower salinities. Yes, there is a declining biomass with increasing salinity.
Conrad	27	Under section 4.1.3 Salinity, second paragraph - Given that there is little detail above on the distribution of these species, I'm not sure what this surmising is based on.	added citations for tolerances
Conrad	27	Under section 4.1.4, first paragraph, second sentence - And what are primary factors determining pH in the Delta?	did not address this -- out of my scope
Conrad	28	Under section 4.1.5, third paragraph, second sentence - Add a ")" after the words "0 to 4 kg/g sediment"	added

Conrad	29	Under section 4.1.6 Flow, first paragraph, second sentence - Erin Hestir's dissertation includes an analysis of maximum water velocity thresholds for SAV establishment in the Delta (I have a copy if you would like to review): 1. Hestir EL (2010) Trends in estuarine water quality and submerged aquatic vegetation invasion [Dissertation]. Davis: University of California, Davis. 146 p.	edited and added citation
Conrad	31	Under section 4.1.8, second paragraph regarding reference to Santos et al. 2011 - An important result from this paper that I don't see highlighted here is that Egeria sustains its biomass in the fall/winter, giving it a head-start in growth in the following spring compared to other species.	yes, had this elsewhere but added it here
Conrad	35	Under section 5. Recommendations, R2 - More detail of the vision here? See major comment in the accompanying Word File (my general comment #4)	Tried to give more detail for this recommendation. Note that I did not receive a Word file with general comments from Louise
Cornwell	N/A	General Comments: Overall, this is a good analysis of control of invasive/native macrophytes in the Bay/Delta. As a biogeochemist, my comments are focused on nutrient-related regulation of plant success and the effects of invasive plants on Bay/Delta nutrient cycling and balances. My lab's recent publication in sediment biogeochemistry may be of some help, I didn't emphasize macrophyte effects because we also saw large effects of benthic microalgae in areas with submersed vegetation.	Cited Cornwell paper mentioned here and discussed in multiple places in revised paper
Cornwell	N/A	Specific Comment 1. The biogeochemical feedback of increased plant biomass on water quality, especially low dissolved oxygen and higher nutrient remineralization/release is of concern. Often, as in the Hydrilla invasion of the Potomac River, the results can be beneficial for nutrient balances. I think the concern of poor sediment quality, i.e. high rates of respiration/nutrient release/poor habitat for benthos, is perhaps less of a worry. Our sediment flux work (Cornwell et al. 2014) in several locations with (albeit sparse) submersed aquatic vegetation (Sherman Lake, Big Break, Franks Tract) did not suggest extremely high rates of sediment respiration or nitrogen release, although rates tended to be higher than in non-vegetated Suisun Bay environments. The macrotidal nature of much of this estuary might lead to export of decaying macrophyte biomass "downstream", with only a very modest effect on nutrient balances in the plant bed. However, these concerns are easily tested.	Cited this paper and indicated that a sediment pool of decomposing macrophytes probably only contributes to nutrient balances in quiescent areas

Cornwell	N/A	Specific Comment 2. Evaluating the role of nutrients in the spread of invasive macrophytes is a massive challenge. In the Chesapeake, the loss of water clarity from phytoplankton and the proliferation of epiphytes lead to a collapse of grasses; understanding the enhancement of macrophytes by nutrients is more difficult. The hypothesis that enhanced P release from increasing metabolic rates for <i>E. densa</i> is interesting, and in fact we observed high P releases in March 2012 in areas with macrophytes. If plant beds develop conditions conducive to P release over time, with the buildup of organic matter, there may be a strong supply of P, especially from pore water uptake. Thus, there could be a positive feedback.	Agreed, a massive challenge. Cited Cornwell work showing sediment P release in areas with macrophytes
Cornwell	N/A	Specific Comment 3. The absence for routine monitoring of plant biomass, spatial extent, species composition, and relatively standard water quality measures (oxygen, salinity, pH, chlorophyll a, nutrients) in plant beds is the greatest source of uncertainty in the report and an absolute necessity to move forward with modeling and control strategies. This is perhaps the key investment that needs to be made; without this, the extent of the problems will be poorly understood. Any potential investments in more research, modeling, or management suggestions need this basic information.	Yes, beefed up recommendation that a routine monitoring program for the macrophytes should include standard water quality measures
Cornwell	N/A	Specific Comment 4. The suggestion of developing a biogeochemical model of the Delta has been made in this report and from our work, it appears to be a key needed advance. There exist many different models for estuarine ecosystems, and I would suggest that off the shelf models might work well for large scale nutrient cycling and balances. Modeling macrophyte communities remains a huge challenge in estuarine science. The biogeochemical effects of given plant species and biomass are becoming better understood, but models also need to the temporal and spatial patterns of macrophyte abundance.	Yes, emphasized need for information on temporal and spatial patterns in macrophyte abundance needed for modeling efforts
Cornwell	N/A	Overall Comment and Reference: Overall, this is a useful assessment of the state of knowledge regarding Delta macrophytes, with a number of modest caveats from committee members that were expressed at our meeting. The report includes all plausible environmental controls on biomass, as well as biogeochemical feedbacks. Cornwell, J. C., P. M. Glibert, and M. S. Owens. 2014. Nutrient Fluxes from Sediments in the San Francisco Bay Delta. <i>Estuaries and Coasts</i>	Included citation and discussed its findings in several places

		37:1120-1133.	
Durand	iii	Under Recommendation #4, first bullet on conditions in Delta favoring growth: low turbidity?	added
Durand	iii	Under R1: We need routine nutrient monitoring on a finer scale than we have, too.	yes, added to recommendation
Durand	iv	Under R3: Item 2 in last sentence: Suggestions for control strategies: chemical, mechanical, gated restoration planning, etc.	all now included
Durand	1	Under 1.1: first paragraph, last sentence - Typo on declined [change "declined" to "decline"], wording for "threatened and endangered" to native? desirable?	typo fixed. yes, native used instead
Durand	1	Under 1.1, second paragraph - need an end quote on sentence "...the State Water Resources...".	fixed
Durand	1	Under Potential nutrient related problems, item 1. Decreases in algal abundance - Do you mean phytoplankton?	yes, clarified
Durand	1	Under Potential nutrient related problems, item 3. Increases in the magnitude and frequency of cyanobacterial blooms - Do you mean Microcystis?	wording in the Delta Plan is "cyanobacterial blooms" -- probably means Microcystis
Durand	5	Last paragraph, last sentence - I am certain that it has greatly expanded during the drought.	acreage updated using Shruti's 2014 data
Durand	10	Under section 2.3 third sentence on egeria densa related to growth response under red light - ... or conditions with sufficient turbidity to shade out blue light.	revised to say it grows nearer to the surface in turbid water
Durand	12	3rd paragraph on page starting with "egeria densa is thought to have been introduced to the Delta in 1946". - But worth noting that DWR reports from 1993 (Department of Water Resources. 1970-2000. Water Quality Conditions in the Sacramento-San Joaquin Delta. Sacramento, CA.) mention Egeria without alarm; however by 1996 Grimaldo and Hymanson (1999) noted thick stands with lots of alien centrarchids. My point being that some shift in the late century began accelerating the spread of this plant.	Added this
Durand	13	2nd paragraph on Stuckenia sp., first sentence - Louise' (Conrad) comments notwithstanding, this is an interesting way to compare...can you do something like this with Egeria...and how reliable are your estimates?	Can be done with monotypic stands of Stuckenia in Suisun but not in places where Egeria is mixed with other species
Durand	15	Under Chapter 3, first paragraph, second sentence on negative effects - ...usually facilitated by very high densities of alien SAV	yes, clarified

Durand	15	Section 3.1, first paragraph, sentence "In contrast, the open water beneath sparse canopies of native <i>Stuckenia</i> sp. may provide ..." - I am not sure how well these statements are supported by the literature as well. For example, I am not sure if we have any idea that native fish are particularly associated with <i>Stuckenia</i> . Adverse effects of alien SAV on fishes are more consistent with the literature...but even some of that may have been overstated. For example, while high densities of predators may lurk in SAV patches, there is no evidence to suggest that this is responsible for populations effects of vulnerable native fishes like smelt or salmon.	okay, point taken. Tempered this whole section
Durand	16	Under section 3.1.1, first paragraph, fourth sentence " <i>E. densa</i> sheds some biomass in winter but does not fully senesce (Fig. 2.2) - Freezing can make a huge impact. Years (like the last) without a freeze had limited die back. I think Shruti has some documentation or a ref for this.	<i>E. crassipes</i> is greatly affected by freezing. Is this comment referring to <i>E. crassipes</i> or <i>E. densa</i> ?
Durand	18	Under section 3.1.4, first paragraph, second sentence on cascading effects - not sure what you mean by this: trophic cascades are typically top down	took "cascading" out
Durand	18	Under section 3.1.4, first paragraph, fourth sentence on thickly growing stems - But it's reasonable to think about this as a management question, because, as we have said, at intermediate densities it probably provides more food access with limited risk. Also, at reasonable densities, it can provide prey refuge, I suspect. the question I have is: how often does it occur at "reasonable densities" and if so, can we find that as an intermediate ideal?	added a sentence on this
Durand	18	Under section 3.1.4, first paragraph, last sentence with effects on the food web - predation effects	added
Durand	19	Under section 3.1.4 under <i>Eichhornia crassipes</i> first paragraph, 3rd sentence - I wonder how much this matters to predators? Matt Young at UCD has a lot of insight into this. [Matt's email] mjyoung@ucdavis.edu	have not contacted Matt Young at this point. Toft paper discusses this somewhat and I added more detail from it.
Durand	20	Under section 3.1.5, 2nd paragraph, 1st sentence - [In reference to Conrad's comments on DO] ...especially at night.	yes, added
Durand	24	Under section 4.1.1 Light - For what it's worth, my model using Santos' data showed an ambiguous relationship with turbidity, a low probability of establishment at depths below 5 m and a rapidly decreasing probability of establishment with increasing flows.	added this information and cited Durand thesis

Durand	25	<p>Under section 4.1.3 Salinity, first paragraph, second sentence -[In reference to Shruti Khanna's comment] Not sure what you mean Shruti, but the Delta was not necessarily fresher before the 1970's. It had more intra and inter-annual variability than we see now. One of the famous early pieces of evidence for this is the Martinez C&H Sugar plant records which document how far up the Delta they needed to go for freshwater. After project implementation, the Vernalis agreement established a salinity standard, legally prohibiting the intrusion of salinity past a certain point. Clearly, Egeria responds well to the more stable salinity regime.</p> <p>We have recommended salinity variability as a way of controlling a number of alien species. Generally, this has been shot down because of legal implications, in Delta consumptive use and the cost of water.</p>	added more about lowered variability in salinity
Durand	27	Under section 4.1.5, second paragraph, first sentence - But limited at times, in the north Delta, that is, off of the Sac plume.	Not sure what this is referring to; need a reference or more information from JD
Durand	29	Under section 4.1.6 Flow, first paragraph, second sentence - [In reference to Conrad's comments on Hestir's dissertation reference] Hestir found a dramatic decrease at .49 ms ⁻¹ , I found a decrease at around .3 ms ⁻¹ .	added both values to text
Durand	31	Under section 4.1.8, first paragraph, first sentence - [his comments on the words "is interactions"] case	fixed

Durand	34	<p>Under section 5. Recommendations - Are there really no concrete recommendations that we can bring, at least in the form of hypotheses, about management of the two main invasives? The "more research is needed" is understandable, but not really adequate, given the time and money currently invested in research and management of this beast.</p> <p>I believe we can say a number of things about SAV/FAV distributions, even if we have to qualify the recommendations with a certain amount of uncertainty, or state explicitly that some recommendations remain disputed or controversial.</p> <p>For example, restorations with limited flow and shallow water 1 and 5 meters are going to get a lot of Egeria. Small embayments or eddies on the lee side of channels are going to be heavily impacted by E. crassipes.</p> <p>Regions that can utilize flow pulses of water will be able to "reset". Managed wetlands are able to "reset" by draining.</p> <p>Chemical management is not very effective except for short periods, and is quite spotty in terms of its impact.</p> <p>Mechanical harvesting is slow and the effect is only good for short periods (how long?), but the effect is targeted where it is most needed. The waste can be re-used as fertilizer to subsidize the harvest.</p> <p>Etc, etc. I am sure that at this point, we can describe these and other hypo-recommendations either as targeted research questions or for interim management recommendations....</p>	<p>Information about distributions given. If more information is available that this reviewer wants included, please provide additional comment and citations. Have not given these detailed recommendations but considering whether to do so</p>
Durand	34	<p>Under section 5. Recommendations, first listed item #3 - This may not be your charge, but a fourth question worth considering is how aq. veg will affect restoration and how restoration sites can be managed or designed in anticipation of this.</p>	<p>consider this to be outside scope of this review</p>
Durand	34	<p>Under section 5. Recommendations, second paragraph, second listed item #1 - I said this before, but routine monitoring should include continuous water quality monitoring, flow conditions, and nutrient compositions across the estuary. The SFE is really behind in these basic observational elements.</p>	<p>yes, added this to recommendation</p>

Durand	35	Under section 5. Recommendations, R2 - Also a widely available hydrodynamic model, which will be necessary to understand stand development and dispersal	yes, I think this is covered now
Engle	iii	Under R1: Second sentence on monitoring: We have to be able to quantify the net primary production (changes in biomass over small time periods using tagged whole rosettes or internodes) , expected growth increments based on (standing biomass at "Time A")x(measured NPP), and then compare the expected growth increment to standing biomass at next time point (Time B). This provides NPP and turnover rate. Without those you cant know what the carbon or nutrient flux into and out of the plant biomass is. In other words, standing biomass can be absolutely static even while huge quantities of carbon and nutrients are being fixed in tissue and rapidly turning over.	Agreed, added that ideally primary production would be measured to estimate turnover
Engle	3	Under section 1.2, originally item 6) of the following key questions: What is the relative importance of nutrients and organic matter accumulation ... - Not sure that "organic matter accumulation" is meant to be described here as "a factor promoting trends" in the vegetation. At our meeting, it was being discussed as a potential result of vegetation but not the cause of it.	revised accordingly
Engle	5	Last paragraph, first sentence in references (see Literature Cited...) - Rephrase to "Literature Cited, Local and regional press reports"	rephrased
Engle	15	Section 3.1, first paragraph - Floating macrophyte beds also provide a substrate near the water surface for a diverse and large biomass of attached microalgae that can exceed the biomass of phytoplankton in adjacent open water (on a per m2 basis). We may not fully understand how the epiphytic community contributes to production at higher trophic levels. Certainly in my own experience there can be thousands of microcrustaceans and other invertebrates (especially insect larvae) per dry gram of root tissue in floating macrophyte beds. If you would like some references from analogous systems in the Amazon, let me know.	added more on the habitat value of roots and community that develops on it.

Engle	15	Section 3.1, first paragraph, last sentence discussing excessive organic matter accumulation - As we discussed during the meeting, I am not sure if there is accumulation of organic matter in the Delta channels where this stuff grows. I'm sure there is a "rain" of detritus, however - what is the evidence that there is organic sediment build up? It is just as likely that the turnover of biomass yields primarily DOC that is exported downstream. This is the predominant fate of macrophyte-fixed carbon in the Amazon system.	revised to say that it could be a factor where high residence time and minimal export
Engle	16	Under section 3.1.1, first sentence on sediments over time - See my comments above. Are we really getting organic matter build up in Delta sediments? If we are going to emphasize a sediment feedback hypothesis as leading to impairment I would like to see some citations from the Delta confirming that there is organic matter accumulation in the sediments, or this should be couched as hypothesis and a data gap. Also, in a lotic system, nutrients released from sediment into the water column aren't preferentially used by macrophytes...they are available to any primary producer in the downstream environs. In general I find myself wishing for more discussion of fate and transport processes related to elemental stocks in macrophytes since the Delta is a "fluid" system (no pun intended).	greatly reduced this section and discussed likelihood that organic matter fuels nutrient recycling only low flow areas if there is a mechanism of biomass accumulation
Engle	16	Under section 3.1.1, first paragraph, last sentence on page "As aquatic vegetation expands in coverage, this large contribution of organic matter from both natural senescence and management of these abundant plants represents eutrophication. - I really am uncomfortable with this assertion unless we can demonstrate that the macrophyte bed carbon metabolized in adjacent water is causing the Delta waterways to be net heterotrophic.	removed this and reduced whole section it was in
Engle	17	Under section 3.1.2., 1st paragraph, 1st sentence - See my earlier comment regarding macrophyte beds providing a platform for attached microalgae that are maintained near the surface and get plenty of light. In fact, there may be more primary production in attached microalgae being held near the surface than there is in the turbid, mixed water column in adjacent waters.	added this
Engle	19	Section 3.1.5 Changes in Water Quality - Since this paper will be used in a nutrient standard setting purpose, it is important that this section be robust and supported by citations.	increased detail and added citations

Engle	19	Under section 3.1.5 Changes in Water Quality, 1st paragraph, 3rd sentence - The Greenfield citation is about effects of mechanical shredding. Natural senescence is not likely to have the same water quality effects. There ought to be sufficient literature to support a hypothesis about large beds naturally "sinking" - if not, we should leave this out. In my experience, aquatic macrophytes usually lose most of their labile elemental mass while still in the water column as they senesce - which means lots of transport downstream through dissolved organic compounds. You dont usually find hearty masses of decaying stems and other tissues sitting around on the bottom unless there has been a physical disturbance. If massive sinking occur in the Delta in undisturbed beds - it should be backed up with a citation.	point taken. This section heavily edited
Engle	21	Under section 4.1, first paragraph, last sentence - Back in the days when BDCP was generating its conservation measures, they relied heavily on a threshold velocity for Egeria establishment of 0.49 meter per second (m/s) to model the effects of their future operations scenarios on Egeria distribution. This threshold was cited to come from: Hestir, E. L., D. H. Schoellhamer, J. A. Greenberg, T. Morgan-King, and S. L. Ustin. 2010. Interactions between Submerged Vegetation, Turbidity, and Water Movement in a Tidal River Delta. Water Resources Research, (in review) I dont find that this paper ultimately appeared in the literature, but the threshold received lots of publicity in the arena of BDCP-management scenarios and I would like to know if the macrophyte-mavens in the Delta support acknowledgement of this threshold in the white paper. I see further down that this threshold is brought up by other reviewers and came from Hestir's thesis.	incorporated Hestir and Durand findings of thresholds for Egeria establishment. I couldn't find the Hestir paper mentioned so have cited her dissertation
Engle	24	Under section 4.1.2 Temperature - If you take Louise's suggestion about adding water management aspects to the other "factors", you might want to look at the BDCP modeling outcomes for temperature under operations scenarios. They modeled the operations effects on Microcystis (not saying I agree or disagree with their conclusions) by calculating how many days temperature would exceed certain thresholds in the Delta in the future. Cant remember if they published temperature scenarios that include climate change.	Have not reviewed these modeling outcomes at this time

Engle	27	Under section 4.1.3 Salinity, first paragraph, second sentence -Should you let people know you are using PSU, if you are?	Oceanographers I work with insist that salinity has no units and thus psu is not appropriate
Engle	27	Under section 4.1.4, second paragraph - Are there any direct diel measurements of pH inside macrophyte beds in the Delta? If not, this should be acknowledged. I'm skeptical of dissolved-gas mediated changes in water chemistry in lotic settings, although in flooded islands and back sloughs less skeptical.	I have not found direct diel measurements of pH inside macrophyte beds locally. I added a caveat that changes would be greatest in dense beds in quiet waters
Engle	29	Under section 4.1.5, first paragraph on section related to organic loading of sediments - My usual saw...this is highly speculative unless there is evidence that there is continual organic loading of sediments going on in this system (as opposed to rapid export), with subsequent higher release rates of DIN and DIP from sediments where macrophytes are growing.	revised this section to indicate that most organic matter losses are likely to be mostly in dissolved form
Engle	29	Under section 4.1.5, second paragraph on <i>Eichhornia crassipes</i> - I dont have time by today to look into Eichhornia dosing experiments, but its seems that there should be more than 1 citation out there regarding Eichhornia dosing experiments. I suspect Shruti may have provided some resources. Given the "charge" to guide the Central Valley Board regarding whether nutrients are driving macrophytes - this nutrient section should be beefed up with a more thorough literature review - and the experimental conditions placed in context of DIN and DIP concentrations from monitoring stations in the Delta to see if any of them are environmentally relevant.	yes, added more citations
Engle	30	Under section 4.1.7 third paragraph, first sentence - Is there a review paper or two to cite, or even the proceedings of some symposia or another?	added citations
Engle	31	Under section 4.1.8, third paragraph, first sentence - It seemed from our meeting that there is concern that the "niche" occupied by Eichhornia would be occupied by SAV if Eichhornia was effectively managed. This "zero sum game" aspect of the Delta macrophyte issue should be discussed more fully in this white paper, in my view.	yes, this shift in composition was already described but it is more explicitly discussed now

Engle	33	Under section 4.2 - There seem to be only a few examples where a hyacinth or SAV-dominated system experienced a state-change to plankton-dominated. In the cases I am aware of, climatic perturbations seem to be a driver, not nutrient management. One case is the state change to low hyacinth in Lake Victoria in the late 1990s. The explanations for this state change have been debated in the literature (bio-control, meteorologic event like an El Nino?). In addition, there was a regime shift from Egeria dominance to turbid open water in the Rio Cruces wetland in Chile that may have been prompted by a climatic event (Marin et al. - citation was among those posted for the group). I think the white paper should have at least a brief section acknowledging cases where some kind of perturbation actually DID result in disappearance of FAV or SAV - it could be instructive for management debate here.	agreed, added that state shifts have been noted for both species
Engle	33	Under section 4.2, third sentence on accumulation of biomass as well as clonal propagation - But at environmentally relevant concentrations for the Delta?	revised as described in previous sections
Engle	34	Under section 5. Recommendations, R1 - Please see my comment about NNP and turnover measurements in the executive summary	revised as suggested
Engle	39	Reference for Marina, V.H. et al. 2009 - spelling is Marin; This paper is not referenced in the paper, but should be regarding regime shifts having to do with climatic perturbations. I wonder if there are other references here that are not cited in the text?	fixed. Citations updated.
Foe	24	You note that light availability is important for successful colonization of Egeria densa, and maximizing its tissue growth and biomass. The Delta has become clearer. The delivery of suspended sediment from the Sacramento River to the Delta has decreased by about half during the period between 1957 and 2001 (Wright and Schoellhamer (2004) ¹ and this has resulted in a statistically significant 2 to 6 percent decrease per year in SPM between 1975 and 2005 (Jassby, 2008) ² . Of course, it is uncertain whether the trend will continue. Might this increase in clarity also increase the biomass and distribution of submerged macrophytes like E. densa? Could this increase in clarity make other factors like nutrients more important? 1 San Francisco Estuary and Watershed Science, 2004 volume 2, issue 2 2 San Francisco Estuary and Watershed Science, 2006 volume 6, issue 1	discussed under sections on light

Foe	24-25	I have observed large rafts of Eichornia crassipes being tidally moved seaward out of the Delta to San Francisco bay in late fall with the first cold snaps. I assumed that colonies lost their cohesive stability under freezing night time conditions. This seems like a potentially significant biomass loss mechanism. Is this true? Is there any mention of this in the literature?	added a description of effects of cold temps, including this observation
Foe	28	Second paragraph - You say, "High nutrient availability is often cited...." Can you give a reference to support this assertion?	took statement out because hearsay
Foe	29	Redfield ratios are often used in phytoplankton studies to determine which nutrient will become limiting as the nutrient pool is exhausted. Typical phytoplankton N:P Redfield ratios are 7.5:1 (wt:wt) although the number may change somewhat based upon algal growth stage and species. DIN to DIP ratios for Suisun Bay are around 6:1 (Glibert et al 2010). Ratios for the delta are more variable but range between 5 and 10 (Foe et al., 2010). You can get more data from Alex Parker and Dick Dugdale at the Romberg Tiburon Center. N:P ratios are 2 to 3 for Stuckenia sp and E densa in figure 4.4. If so, it seems that macrophytes may have a higher P requirement than phytoplankton and may be more likely to become P limited in the Delta if consuming mostly waterborne nutrients. Can you comment?	added N:P of water thought to be limiting for E crassipes, but otherwise this is still a gap
Foe	29	It would be nice to include a summary table of the key factors controlling macrophytes in the Delta. Left column would be a list of primary macrophyte species and across the top the primary drivers. These might be light, temperature, salinity, DIC, and nutrients. In the cells give the ranges that restrict plant establishment and growth.	I have not done this and most of these numbers could only be very rough with little local data on how the factors work specifically in the Delta.
Foe	34	I think the recommendations are fine but are too general. I suspect that both the monitoring and modelling should be accompanied by special studies to help interpret and inform the results. Maybe under monitoring you could list specific high priority questions in bullet form. For example: Do N and P concentrations limit E. crassipes growth and biomass anywhere in the Delta now? To determine this conduct amendment experiments in the laboratory and/or in field mesocosms to determine growth as a function of nutrient concentrations and compare these with levels found in and around macrophyte beds in the Delta now. What is the limiting nutrient? Are these conclusions robust under different light and temperature regimes typical of	expanded the recommendations to be more detailed, but not as detailed as suggested here

		the delta?	
Foe	N/A	<p>I think the nutrient discussion would be improved by including a paragraph or two on ambient nutrient concentrations and trends over time in the Delta. Annual average DIP and DIN concentrations at key locations in the Delta range between 0.02-0.09 mg/l and 0.13-1.10 mg/l (Foe et al., 2010)¹. Typical DIN and DIP concentrations are 0.5 and 0.05 mg/l, respectively, but talk with dick dugdale from the Romberg Tiburon Center for more information. All the amendment experiments cited in the review paper are at higher concentrations than occur in the delta and this may affect the interpretation of the results. The results obtained by You et al. for E. crassipes are particularly interesting and suggest the possibility of nutrient limitation in the delta now. You et al. increased N and P concentrations above 0.6 and 0.05 mg/l and observed a 30% increase in growth and clonal propagation. If these findings are confirmed by additional experiments, then nutrient management might be an option for reduce the severity of the water hyacinth problem. Please comment.</p> <p>¹ http://www.waterboards.ca.gov/centralvalley/water_issues/delta_water_quality/ambient_ammonia_concentrations/foe_nutrient_conc_bio_effects.pdf</p>	<p>added several figures on nutrient concentrations in the Delta including ones from Glibert and from Foe. Would like to add a figure like what is in the cyano report if I can get those data. Added more on nutrient limitation and that E. crassipes is unlikely to be limited under current conditions.</p>
Foe	N/A	<p>About trends, nutrient concentrations, N speciation, and dissolved N:P ratios have changed in the delta over the last 40 years. More DIN, more NH₄, less SRP and an increase in the N:P ratio (Jassby 2008; Glibert, 2010²; Van Nieuwenhuysse, 2007³). Could these changes in concentrations be partially responsible for the emerging macrophyte problem?</p> <p>² Reviews in fishery Science, 18:211-232 ³ Canadian journal of fisheries and aquatic science 64:1529-1542</p>	<p>Although there has been an increase in NH₄⁺ and a decrease in the N:P ratio over a 30 year period through 2006, especially in the upper Sacramento River, this trend was not evident in the last decade of that time period (Glibert 2010; Fig. 4.5). A closer look at the last decade (through 2013) shows no trends in any form of inorganic nutrients or N:P ratios in the central Delta region -- this comes from the more recent data shown in the Cyano white paper, which I am trying to get.</p>
Foe	N/A	<p>The modelers are going to need specific data to be collected to help inform model development. This paper should note and recommend that there be collaboration between the monitoring and modeling team to collect high priority information to inform the models.</p>	<p>yes noted this</p>

Joab	1	Under 1.1 - In sentence "...critical habitat or fish.." Change "or" to "for".	fixed
Joab	1	Under section 1.1, last paragraph - The Water Board only commissioned two not three literature reviews.	fixed
Joab	3	Under section 1.2, listing for Section 3: Insert "to" between "Contributing" and "the" and capitalize the words "submersed", "floating", "aquatic", and "vegetation" to be consistent in formatting.	fixed
Joab	4	Under section 2.2, first sentence - Only 17 species are identified in Table 2.1, not eighteen. Please correct text or Table 2.1.	19 now with addition of 2 by Shruti
Joab	17	Under section 3.1.1., last sentence - "identified" spelled incorrectly.	
Joab	All	Global Comment: I found numerous references cited in document that were not included in the Chapter 6 Literature Cited. Please compare all references in text and Chapter 6.	fixed
Khanna	iv	Under R3: Item 2 in last sentence: adding information to Durand's comments on control strategies: also biological	added
Khanna	1	Under 1.1 - In sentence, "...45,000 square mile" change "mile" to "miles."	fixed
Khanna	1	Under 1.1, second paragraph - the sentence "Studies needed for development of Delta..." seems incomplete - difficult to understand.	need to pull up the language used in this document to fill this in and make more clear
Khanna	2	Figure 1.1 - Maybe pick a different figure? I can't read any of the text in this figure.	can the water board suggest another figure that would be more clear?
Khanna	4	Heading of section 2.1 - "Classification" is misspelled.	fixed
Khanna	4	Under section 2.2, second paragraph reference to Hestir et al. 2010 - As I remember, this figure actually comes from some other paper that Erin might have cited in her paper. I know she did not herself harvest biomass and determine the % coming from Egeria. Moreover, this original paper is even older. I think the timeline is important. I think when you mention cover, biomass ratios, any information pertaining specifically to the Delta, it is better to mention which year this study comes from. Because the Delta is so dynamic and what was true 10 years ago, might no longer be true. Same goes for the Santos et al. 2009 study.	revised this. Tried to always indicate year that data came from.
Khanna	4	Under section 2.2, last paragraph, first sentence on Coontail being the most frequently encountered native species - In 2014, (coontail) found in 45% of all sampled SAV points. Average cover where sampled - 30%.	added
Khanna	4	Under section 2.2, last paragraph, last sentence - What is the citation for these numbers (284 hectares)?	Santos et al. 2011. cited it again.

Khanna	5	Table 2.1 - There are two more species we have documented which I don't see mentioned here - one is water purslane (which is similar to water primrose and floating - genus Ludwigia), the other is parrotfeather (genus myriophyllum), which is actually a floating species.	added to table
Khanna	5	General comment on figures - for new figures, see total area of floating in the excel sheet I forwarded and divide by half to get appx. water hyacinth area. Other half is water primrose.	included these new estimates from the excel sheet from Shruti throughout
Khanna	10	Under section 2.3, last sentence on egeria densa on range of depths in turbid and clear water - but maybe to a shallower depth in turbid water.	added
Khanna	11	Under section on Stuckenia sp. - 2014 survey: Sago or fineleaf found in 26% of sampled points. Avergae cover where samples: 50%. Especially in the open bay. It is found as 100% cover so it looks like it's niche is at least partially unique from all other submerged species.	added
Khanna	11	Figure 2.5 caption - I agree with Louise's comment. We have not been able to differentiate between SAV species even with hyperspectral data. I'd like to see this reference.	see my clarifications on this, and response to Louise's comment
Khanna	12	Thirrd paragraph, fourth sentence " <i>Egeria</i> coverage expanded during the years between 2003 and 2007" - I haven't read Maria's paper recently but according to the numbers I have (see the xls file), <i>Egeria</i> was abundant until 2006 then decreased quite a bit in 2007 and even more in 2008.	revised to reflect numbers in Shruti's spreadsheet
Khanna	12	Fourth paragraph, second sentence on <i>Eichhornia crassipes</i> , reference to Santos et al 2009 study - Maria's study was hazy about the efficacy of water hyacinth control. My study found that control had no impact on year-to-year cover of water hyacinth. The decline of cover in 2007 was mainly due to a 3 week period of continuous frost nights in Jan 2007. There are several studies that back up the claim that water hyacinth is vulnerable to frost.	added reference to Khanna study on lack of year-to-year change from control efforts. Added references on frost.
Khanna	12	Fourth paragraph, second sentence on <i>Eichhornia crassipes</i> with mention on estimates of acreage - Take estimates from the SOTER report or the xls file. I have a comment on this earlier.	done
Khanna	15	Section 3.1, first paragraph, highlighted sentences from "In contrast, dense canopies..." to "...leading to predation on smaller adult and juvenile native fish" - [Following Louise Conrad's statement] Moreover, doesn't each of these statements require a citation?	greatly revised this section to address concerns of Louise and John D

Khanna	16	Under section 3.1.1, first paragraph, 4th sentence " <i>E. densa</i> sheds some biomass in winter but does not fully senesce (Fig. 2.2) - [In reference to John Durand's comment that Shruti may have references.] Yes, check the annotated bibliographies. There are examples from Florida and Louisiana.	added references
Khanna	17	Under section 3.1.3, fourth sentence "Dense submersed vegetation is ..." - There are a couple of new Hestir et al. papers on the relationship between SAV and turbidity e.g. Hestir, E. L., D. H. Schoellhamer, T. Morgan-King, and S. L. Ustin. 2013. A step decrease in sediment concentration in a highly modified tidal river delta following the 1983 El Niño floods. <i>Marine Geology</i> 345:304-313.	added reference
Khanna	19	Under section 3.1.5 Changes in Water Quality, first paragraph, second sentence - [In reference to Conrad's comments on citations for this section] Yes, many. Kathy, check out the bibliography. If not there, then the Gopal book should have a ton. I think he has a chapter on the use of water hyacinth as a secondary water pollutants purifier.	added references
Khanna	20	Under section 3.1.5, second paragraph, first sentence - [In reference to Conrad's comments on DO] I also seem to remember that <i>Egeria</i> mats can depress oxygen levels.	yes, added
Khanna	20	Under section 3.1.5, second paragraph, third sentence on decomposition of <i>E. crassipes</i> following senescence - Even in a healthy mat, the growth rate of hyacinth is so obscene that there is material constantly dripping from the root system and a thick mat can cause part of its own mat to senesce due to intra-species competition.	agreed, added
Khanna	24	Under section 4.1.1 Light, second paragraph, last two sentences - [In reference to Conrad's comments on these statements] I agree. I think the <i>Stuckenia</i> comment can still stand but maybe instead of <i>Egeria</i> , you can say SAV mats? Especially since <i>Elodea</i> , a native that has increased in the Delta over the past six years, also forms dense canopies identical to <i>Egeria</i> . Also Hestir et al. paper cited in a previous comment.	yes, changed to SAV mats. Added Hestir citation
Khanna	24	Under section 4.1.2 Temperature - For water hyacinth, lower air temperatures can be pretty limiting and this is insufficiently discussed here. I have some references on the subject in the bibliography.	added info and refs on cold temps/frost

Khanna	25	Under section 4.1.3 Salinity, first paragraph, second sentence -This is a matter of debate. The historic delta used to be a lot more of freshwater and the X2 line was much farther away. Only in times of drought would part of the Delta become brackish. And the reason was that the water had a much longer route to take through meandering narrow channels and did not meet with the bay waters as readily. By dredging the Sacramento river and getting most of the water out quickly into the bay, we have reduced the residence time of the water in the Delta thereby ironically increasing the salt intrusion. The thing different in the part was the strong seasonal variability in the salinity - especially more salinity during low-flow. Now the delta is fresh all year long. This is the crucial change. References?? I have a bibliography on the Delta too, I think. I'll send it to you directly.	Durand had conflicting view. Added info about salinity variability being decreased.
Khanna	27	Under section 4.1.3 Salinity, second paragraph - there are many salinity studies for eichhornia and they are all mentioned in my annotated bibliography. Please take a look.	added more citations
Khanna	27	Under 4.1.3 Salinity, second paragraph - [In reference to Conrad's comment on this section] probably field data?	yes, field data but weak so added citations from other regions
Khanna	28	Under section 4.1.5, second paragraph - There are many studies of Eichhornia with nutrients but in a slightly different set of literature - paper on water purification plants. I'm not sure if I have much in my bibliography but if you research use of water hyacinth in water purification, you'll get some good references.	added more citations
Llaban	ii	Under Major Finding #1, first sentence - Native floating aquatic vegetation (i.e. pennywort) can also be a beneficial component (invertebrate habitat and trophic support). Toft et al 2003 found higher insect densities in pennywort vs. hyacinth and that invertebrates associated with pennywort occurred more often in diets of adjacent fish.	yes, added native floating to sentence indicating it is typically beneficial. Toft reference cited in another section to help capture the comment
Llaban	iv	Under R3 - Mechanical removal/harvesting of water hyacinth is already being implemented by DBW in the Delta as a part of an integrated pest management program (Water Hyacinth Control Program).	added this
Llaban	1	Under 1.1, first paragraph, last sentence on Delta Plan - Please include a full reference under literature cited.	need to add
Llaban	3	Under section 1.2 regarding key questions 4-7 - Should these questions be numbered starting from 1?	fixed

Llaban	11	Under Eichhornia crassipes paragraph, first sentence on windy periods- High tides can also cause water hyacinth to dislodge from shores or tule islands and move with the tidal flux. Disturbance from boating activity can also cause water hyacinth to detach and float around. (DBW staff observations)	added
Llaban	11	Under Eichhornia crassipes, paragraph, second sentence regarding abundance - Also has been historically abundant near USBR's Tracy Fish Collection Facility and River's End Marina (Old River) due to hydrodynamics and waterway characteristics. Related news articles at http://www.recordnet.com/article/20121222/A_N_EWS/212220315 http://www.contracostatimes.com/contracosta-times/ci_24673609/state-begins-using-mechanical-harvesters-control-water-hyacinth	added these locations
Llaban	11	Under Eichhornia crassipes paragraph, third sentence regarding channel edges - Also can be found around tule islands in the middle of a channel.	added
Llaban	12	Under Egeria densa paragraph concerning active management spraying - Suggest avoiding the word "spraying" and rephrase to "herbicide application" or "herbicide treatment". Egeria densa treatments are done with application of granular (pellet) formulations of herbicide, rather than spraying of liquid herbicide. In the rest of the paragraph change "spraying/sprayed" to "treatment".	done
Llaban	12	Under Eichhornia crassipes paragraph, second to last sentence regarding "spraying over several years" - Please change the word "several" to "two". 2011 and 2012 were years where there were delays in permitting between DBW and federal agencies.	done
Llaban	15	Under section 3.1, first paragraph, third sentence regarding shading of phytoplankton - Can also decrease dissolved oxygen in water (as depicted in Figure 3.1).	added discussion of DO effects
Llaban	18	Under section 3.1.3, first paragraph, last sentence on west Delta - Also observed by DBW staff in east Delta.	added pers. comm.
Llaban	20	Under section 3.16, third sentence referencing "boating" - In return, boating activity can facilitate spread of egeria densa by production of plant fragments from propeller disturbance.	added
Llaban	24	Under section 4.1.1, third paragraph, last sentence on E. densa expanding more rapidly - Under what conditions? Low light?	yes, fixed

Llaban	27	<p>Under second paragraph, first sentence regarding local studies - Found a report from a UC Berkeley student on salinity effects on water hyacinth.</p> <p>http://nature.berkeley.edu/classes/es196/projects/2004final/Cheng.pdf</p> <p>This is not a peer-reviewed article and appears to be a class project, so I'm unsure if it can be used as a reference.</p>	have not reviewed this report yet to determine appropriateness
Llaban	30	<p>Under section 4.1.7, first paragraph, last sentence - This section should include a description of benthic barriers as an alternative control measure (cultural control) to control small infestations of <i>Egeria densa</i> in or around high-use areas such as docks, boat launches and swimming areas.</p> <p>I'm not aware of use of benthic barriers in the Delta, but it has been used in Emerald Bay to control Eurasian watermilfoil.</p>	added. Still need to search for info from other locations like Emerald Bay.
Llaban	30	<p>Under section 4.1.7, second paragraph, first sentence on mechanical removal - In general, there are concern about impacts to non-target plant species and by catch of non target organisms, that should be addressed in this section. A useful reference: <i>Biology and Control of Aquatic Plants. A Best Management Practices Handbook.</i></p>	added. Have not been able to get this book.
Llaban	30	<p>Under section 4.1.7, second paragraph, last sentence on concerns - Another concern is potential survival and regrowth of cut water hyacinth.</p> <p>Reference: Spencer et al 2006. Evaluation of Waterhyacinth Survival and Growth in the Sacramento Delta, California, Following Cutting. <i>Journal of Aquatic Plant Management</i> 44:50-60.</p>	added to text and cited
Llaban	30	<p>Under section 4.1.7, third paragraph, fifth sentence regarding no biological control methods - USACE released <i>Neochetina bruchi</i> in the Delta in the early 1980s. USDA-ARS also has done some releases of <i>Neochetina</i>.</p>	updated this whole section on biological control
Llaban	32	<p>Figure 4.6 - Left figure is cutoff. Please resize to present the complete 2007-2008 data.</p>	fixed

Llaban	33	<p>Under section 4.1.9, first paragraph, last sentence - Vegetative growth is not limited by depth and bank slope. However, water hyacinth seed germination and seedling establishment can be limited by depth and requires shallow water. Although vegetative reproduction is likely the primary means of reproduction, factors affecting sexual reproduction should be considered.</p> <p>Barret 1980 conducted a study of seed production germination in the Delta near Stockton, Ca. S.C.H. Barrett. 1980. Sexual Reproduction in Eichhornia Crassipes. II. Seed Production in Natural Populations. Journal of Applied Ecology. 17:113-124.</p>	Added and cited.
Llaban	34	Under section 5 Recommendations - Section title is inconsistent with title on pg. 3 - "Section 5: Key Data Gaps and Research Recommendations". Please revise either title for consistency.	fixed
Llaban	36	Under section 6 Literature Cited - Many references within the body of the paper are missing from the literature cited section. Please revise the literature cited to ensure consistency with referenced literature.	done
Madsen	5	Recommendation 1. Aerial remote sensing, whether by satellite or aircraft, provide useful data on water hyacinth distributions, but perform extremely poorly on egeria or any other submersed plant communities. Species discrimination with remote sensing is still insufficient to categorize species composition without significant ground truthing. The recommendation does not indicate how biomass estimates would be derived from transects, nor does what technique is planned for transect.	clarified throughout document. Added more detail on biomass estimates
Madsen	5	Recommendation 2. The authors are assuming that nutrients are limiting plant growth without knowing if this, in fact, is the case. It is doubtful that an ecosystem model will indicate if nutrients are limiting either water hyacinth or egeria. It is far more common to see luxury consumption of nutrients by submersed and floating aquatic plants than nutrient limitation.	Need help from SWG to decide how to address

Madsen	6	Recommendation 3. Why do the authors want to reinvent the wheel on management of invasive species? Why select a management technique that is already known to kill fish – namely, harvesting? USDA ARS has already been doing this research for decades, as has the US Army Engineer Research and Development Center. This recommendation is made, yet no citations of existing best management practices manuals are included in this report. The Journal of Aquatic Plant Management has 2,000 articles on the biology and management of aquatic macrophytes, and has ONE citation in the report. The San Francisco Estuary Institute had a multi-year project to investigate harvesting to replace herbicides for management in the early part of the last decade, and concluded that harvesting was not a replacement for herbicides.	changed this recommendation to suggest a review of existing and planned methods of control with an eye to effectiveness in meeting nutrient objectives and increasing beneficial uses
Madsen	17	Rake methods. Rake methods to “estimate biomass” are poor substitutes for actually measuring biomass.	true, but this is the method that has been done
Madsen	19	Coontail does not “attach to other plants.” It might wrap around other plants. It lies on the surface of the sediment.	fixed
Madsen	22-23	<i>Egeria densa</i> . I realize that, in trying to be understood by non-scientists, many people use the term “male” and “female” plant or flower, but the plant or flower itself is not male or female. The plant or flower is correctly referred to as either “staminate” or “pistillate,” not male or female.	yes, corrected
Madsen	23	Water hyacinth. While water hyacinth does produce a large number of seeds, outside of their native range they have very low germination rates, and the seedlings take exceedingly long to grow. A seedling may not be capable of producing a flower until the end of the year. For overwintering, the importance of the stembase cannot be overstated. The stembase can lie underwater during the cold season, and initiate growth rapidly in the new growing season.	added both these points
Madsen	23	Coontail does not attach to other plants. It is neither epiphytic nor saprophytic.	fixed
Madsen	26	Line 5. <i>M. spicatum</i> is misspelled as <i>spicatam</i> . Repeatedly.	fixed (2 locations)
Madsen	26	Line 23. Submersed herbicide application is inaccurately described as “spraying,” when in fact liquid herbicides for submersed plants are injected beneath the water’s surface using trailing weighted hoses. Since most of the fluridone in the past decade has been applied as a granular formulation, “spraying” is even more inaccurate.	fixed

Madsen	27	Stuckenia distribution. Unless remote sensing is ground truthed, it is not a reliable method for estimating the distribution of submersed plants. More than half of the population will be out of detection, and the amount remaining undetected will vary based on water clarity and other issues.	Stuckenia is well predicted within Suisun Bay where it is nearly monotypic; in Delta this is only true in open water areas according to Shruti
Madsen	N/A	Global Comment. By the way, most of the figures did not download from Google Documents.	True, hopefully he was able to look at original version sent out
Madsen	N/A	Global Comment. About half of the Literature Cited citations are incomplete, making it impossible for me to look up these citations.	fixed
Moran	i	Acknowledgments: Does the author mean this Macrophyte Science Working Group? Or is there a separate Submersed and Floating Macrophyte Technical Advisory Group?	There is a Science Working Group and also a Stakeholder and Technical Advisory Group. This was clarified.
Moran	ii	Executive Summary: Text indicates four major questions, but only three are listed.	fixed
Moran	ii	Executive Summary: Major Finding #2, aquatic weed coverage values are too low -CDBW-CA Parks estimates <i>Egeria densa</i> coverage at 10,000-15,000 acres or 4,050-6,075 ha. -Water hyacinth coverage in the Delta is much more than 200 ha. In 2014, for example, the Division of Boating and Waterways-CA Parks treated 2,617 acres or 1,060 ha. In 2015, they plan to treat close to 3,400 acres or 1,377 ha. DBW estimates at least 5,000 acres or 2,025 ha in the Delta. See comments from Ustin lab for more precise estimates of coverage. Provide information on increase in coverage from mid-2000s to now. [See reference below.]	Updated with Shruti's numbers in excel sheet
Moran	ii	Ustin Ian, UC Davis, estimates 2000 ha, 1/2 Water hyacinth, 1/2 Ludwigia -This study should consider other important aquatic invasive macrophytes for which there is currently no control program, especially Ludwigia spp., which is likely as widespread or more widespread than water hyacinth and equally damaging (and the two weeds co-occur and appear to benefit from each other's presence)	Ludwigia now addressed. Pointed out as a finding that there are additional problematic invasive species that have not received much attention.
Moran	iii	Recommendation R1: (Comment for discussion) Remote sensing data for water hyacinth are being collected by NASA as part of the USDA-ARS Areawide Project for improved control of aquatic weeds in the Delta. R1: Check spelling of "areal" (correct is "arial")	areal was intended -- it means across an area
Moran	iii-iv	Recommendation R2: This should be communicated to the Modeling Work Group. The Macrophyte work Group could identify data requirements.	yes, added this in recommendation

Moran	iv	Recommendation R3: The USDA-ARS Areawide Delta Aquatic Weed Management Project is conducting pilot studies on integrated control.	added that current and planned control methods should be evaluated relative to nutrient objectives
Moran	3	Under Introduction Section 1.2 Goal and Organization of Macrophyte Literature Review - Key Questions: Why are they numbered 4,5,6, and 7?	some kind of auto-formatting--fixed
Moran	5	Information on coverage of water hyacinth, see above and information from Ustin lab on correct coverage estimates.	used estimates provided by Shruti
Moran	10	Under Chapter 2 General Ecology and Trends, Section 2.3 Habitat Types in which they are typically found - <i>Egeria densa</i> some of the information here is redundant with page 8.	fixed
Moran	12	Under Chapter 2 General Ecology and Trends, Section 2.4 Spatial and Temporal Trends in Distribution and Abundance - DBW-CA Parks is treating up to 4-5% of Delta area for <i>Egeria densa</i> .	added this percentage
Moran	13-14	Under Chapter 2 General Ecology and Trends, Section 2.4 Spatial and Temporal Trends in Distribution and Abundance - Are there specific causes of the <i>Stuckenia</i> expansion over the past 20+ years? Describe here or in Section 4.	added text that it could be increased water clarity but that we don't know
Moran	16	Under Chapter 3 Role of Submersed and Floating Aquatic Vegetation in Supporting Delta Ecosystem Services 3.1.1 Organic matter subsidy/accumulation - For more information on seasonal growth and senescence of water hyacinth, see also Spencer, D. 2005. Seasonal growth of water hyacinth in the Sacramento/San Joaquin Delta, California. <i>J. Aquat Plant Manage.</i> 43:91-94.	Added this citation
Moran	17	Under Chapter 3 Role of Submersed and Floating Aquatic Vegetation in Supporting Delta Ecosystem Services 3.1.3 Habitat alteration - Can <i>Egeria densa</i> alter habitat in ways that helps it outcompete <i>Stuckenia</i> and other submersed natives? Refer reader to Section 4.1.8	referred to chapter 4 here
Moran	17	Under Chapter 3 Role of Submersed and Floating Aquatic Vegetation in Supporting Delta Ecosystem Services 3.1.3 Habitat alteration - Water hyacinth and <i>Ludwigia</i> often grow together, although one dominates. Could mention here and refer to Section 4.1.8.	about half each in 2014 -- already mentioned
Moran	18	Under Chapter 3 Role of Submersed and Floating Aquatic Vegetation in Supporting Delta Ecosystem Services 3.1.4 Trophic support - Redundant information in the paragraph about <i>Egeria densa</i> providing hiding habitat for predatory non-native fish.	fixed

Moran	19	<p>Under Chapter 3 Role of Submersed and Floating Aquatic Vegetation in Supporting Delta Ecosystem Services</p> <p>3.1.5 Changes in water quality - Consider more references here and in the more detailed nutrient section later on to support statement of use of water hyacinth to remove nutrients from sewage or other nutrient-rich water.</p> <p>Reddy, K. R., M. Agami and J. C. Tucker. 1989. Influence of nitrogen supply rates on growth and nutrient storage by waterhyacinth (<i>Eichhornia crassipes</i>) plants. <i>Aquat. Moran	30	<p>Section 4.1.7 Chemical, mechanical and biological control - Major errors in fact regarding biological control</p> <p>Continued comment from above: (and Patrick Moran, USDA-ARS Exotic and Invasive Weeds Research Unit, Albany, CA, pers. comm.)</p> <p>-No biocontrol agents have been released for any of the other non-native weeds listed. -Biocontrol using non-native natural enemies is not be an option for control of native aquatic plants that may sometimes be invasive/cause problems, such as coontail and pennywort. Biocontrol using native natural enemies that are reared and released in large numbers (such as a native fungus or a plant-feeding insect) may be an option.</p>	added this info
Moran	30	Gopal 1987 book cited here is not listed in Literature Cited.	fixed
Moran	30	<p>The conclusion that biocontrol poses a unique risk to DO is flawed. Biocontrol of water hyacinth reduces the size of plants over several generations of growth: Tipping, P. W., M. R. Martin, E. N. Pokorny, K. R. Nimmo, D. L. Fitzgerald, F. A. Dray, Jr., and T. D. Center. 2014a. Current levels of suppression of waterhyacinth in Florida, USA. Biological Control 71:65-69. Biocontrol does not cause rapid sinkage that would be associated with DO declines. Also, biomass accumulation in sediments in areas of water hyacinth invasion will occur in either the presence or absence of biocontrol, in areas of low flow; biocontrol will reduce the problems caused by living plants. In any event, biocontrol would not pose any greater DO hazard than herbicidal control, and in fact would pose less of a hazard.</p>	revised text and added citation.
Moran	32	<p>Under Chapter 4 Factors Contributing to the Prevalence of Submersed and Floating Aquatic Vegetation in the Delta</p> <p>4.1.8 Interactions with submersed or other floating species - Fig 4.6 (Left, Bar charts). I assume that Ludwigia is the pink bars after yellow, but this is missing in legend. The figure is partially cut off on the right.</p>	figure placement fixed. Color coding is identified in the caption

Moran	34-35	Under R1, include monitoring of water and plant nutrient content and analysis of their relationships. Also water flow. Possibly also rates of growth.	added
Moran	34-35	R3 is already underway through the USDA-ARS Areawide Project focused on water hyacinth and Egeria densa.	mentioned this
Moran		General Comment on the evaluation factor - All of the major water quality problems caused by the proliferation of water hyacinth and Brazilian waterweed in the Delta have been identified. "Yes"	good
Moran		General Comment on the evaluation factor - All physical and biological factors that influence the abundance and distribution of these invasive aquatic weeds have been identified. "YES, but little quantitative information is provided on the environmental tolerances of the aquatic weeds in terms of salinity, water flow, turbidity, may be other factors such as temperatures. Information could be provided on what is known for the Delta (lots of gaps), and what is known from other areas."	these topics more extensively reviewed now
Moran		General Comment on the evaluation factor - Evidence is presented that ambient nutrient concentrations influence or do not influence the growth, distribution and abundance of aquatic weeds. More quantitative information is needed on typical nutrient levels in the Delta, and nutrient requirements/concentration ranges in the aquatic weeds, and effects on plant growth (not well-studied in the Delta, so would be mostly from other regions).	quite a bit added on this
Moran		General Comment on the evaluation factor - The White Paper findings are fully supported by the literature and there is no additional unreferenced information that either supports or refutes the findings. Additional references have been suggested.	Added many more citations
Moran		General Comment on the evaluation factor - The prioritized list of nutrient recommendations include all questions that need to be resolved before it can be concluded that nutrient management will reduce the severity of the invasive aquatic weed problem in the Delta. NO, the monitoring plan under R1 needs to include water nutrient, plant nutrient, and plant growth information. Also, studies are needed on nutrient changes resulting from control-killed plants being left in place vs removed.	Included

Moran		Additional Questions from the STAG: Is nutrient management necessary for management of macrophytes UNCERTAIN a. Yes or No? b. If so, what level?	okay
Moran		Additional Questions from the STAG: Is nutrient management alone sufficient to control macrophytes? UNLIKELY	okay
Moran		Additional Questions from the STAG: What combinations of management actions (nutrient and non-nutrient) are likely to achieve equal levels of benefit with regard to macrophyte management? What are the likelihoods, costs, and potential unintended consequences of these different strategies?	no comment made
Moran		Additional Questions from the STAG: How do stands of macrophytes affect nutrient dynamics in surrounding waters? Include under R2	done
Moran		Additional Questions from the STAG: How do stands of macrophytes affect higher-level organisms, including POD species? Some studies underway as part of USDA-ARS Areawide Project. Invertebrates in water hyacinth roots before/after chemical herbicide control.	did not discuss at this point

7.2 Comment Matrix and Responses to Stakeholder and Technical Advisory Group

Author	Comment	Response
Bedore	Specific Comment 1. The White Paper provides a general description of the types of impairments that can be associated with macrophyte over-abundance, but there should be greater detail provided on the actual nature of macrophyte-related impairments in the Delta itself. The impairments should be linked to the Beneficial Uses of the Delta as they are described in the Water Quality Control Plan for the Sacramento and San Joaquin River Basins (2011), and the frequency, magnitude, and geographic extent of macrophyte-related impairments should be described for each Beneficial Use. It should also be determined, to the best degree possible, the level of macrophyte management that is necessary to fully achieve these Beneficial Uses.	Did my best to increase the detail in this. Have not linked them to the Beneficial Uses of the Delta document mentioned. I do not have the information on frequency, magnitude and geographic extent of macrophyte related impairments. I don't think we can determine at this time the level of management needed to achieve beneficial uses.
Bedore	Specific Comment 2. A detailed life history for each macrophyte of interest is also recommended to provide context for describing why various physical and biological factors influence their abundance and distribution. Details particular to the life cycles of macrophytes in the Delta would be most helpful.	Life history info has been added, but probably not to the degree desired here. I need to be careful to not exceed my charge or scope.

Bedore	Specific Comment 3. A more thorough review of all known and relevant efforts related to macrophyte management in estuaries should be provided. From this review it could then be determined under what conditions nutrient management or management of other factors (physical removal, herbicide treatments, hydrological controls, etc.) are likely to be successful, and whether control of those factors is possible and/or likely to be effective for the Delta given its unique hydrology and water quality. This information should then be used to rank the probable efficacy of possible macrophyte management options for the Delta.	Added detailed information about management in the Delta. Added a recommendation to review the current and planned control methods with respect to nutrient objectives.
Bedore	Specific Comment 4. Recommendations to expend resources on nutrient/macrophyte-related research should consider the overall probability that nutrient management, relative to other management options, is likely to provide an effective means for addressing the known macrophyte impairments in the Delta.	added more discussion of the fact that there have been massive increases in problematic species during a period when increased nutrients or changes in ratios has not been observed. Suggests that nutrient management may have limited effects compared to other factors controlling the macrophytes.
Lee	Overall Comment: The findings expressed in the draft white papers are consistent with our many years of experience investigating nutrient-related water quality, our findings in investigating Delta nutrient impacts and control of excessive aquatic plants, as well as with the findings expressed in presentations made at the CWEMF Delta Nutrient Modeling Workshop discussed below.	good to hear
Lee	Basically, the water quality/beneficial use of the Delta is seriously degraded by excessive growths of aquatic plants that are caused by excessive nutrient loads to, and within, the Delta.	We have not been able to make the link that excessive nutrient loads are the leading reason for excessive macrophyte growth, although we have not ruled out that they contribute
Lee	There remains little ability to quantitatively and comparatively describe the role of nutrients (N and P) in controlling the excess fertilization of the Delta waters.	that's right
Lee	There is considerable misinformation in the professional arena on the relative roles of N and P concentrations and loads, and the ratios of N to P in affecting water quality in the Delta; some of the information presented on nutrient/water quality issues is biased toward preconceived positions.	do not know what biases are being referred to
Lee	Based on the results of the US and international OECD eutrophication study and our follow on studies of more than 600 waterbodies worldwide (lakes, reservoirs, estuarine systems) the planktonic chlorophyll levels in the Central Delta are well-below those that would be expected based on the phosphorus loads to the Delta.	yes, this is mentioned in the review

Lee	There is a lack of understanding of the quantitative relationship between nutrient loads and fish production in the Delta.	probably true, not sure what the specific comment is here
Lee	The Delta Stewardship Council's timetable for developing Delta nutrient water quality objectives by January 1, 2016, and to adopt and begin implementation of nutrient objectives, either narrative or numeric as appropriate, in the Delta by January 1, 2018 is unrealistically short.	A comment for Chris to address
Lee	There is need for substantial well-funded, focused, and intelligently guided research on Delta nutrient water quality issues over at least a 10-yr period in order to develop the information needed to generate a technically sound and cost-effective nutrient management strategy for the Delta.	A comment for Chris to address
Lee	As discussed in our writing, some of which are noted below, it will be especially difficult to develop technically valid and cost-effective nutrient control programs for excessive growths of macrophytes in the Delta.	okay

DRAFT

2012 South Delta Chinook Salmon Survival Study

Rebecca Buchanan, University of Washington;
Pat Brandes, Mike Marshall, J. Scott Foott, Jack Ingram and David LaPlante,
U.S. Fish and Wildlife Service;
Josh Israel, U.S. Bureau of Reclamation;
Compiled and edited by Pat Brandes, U.S. Fish and Wildlife Service

Introduction

The Vernalis Adaptive Management Plan (VAMP) as part of the San Joaquin River Agreement has been measuring juvenile salmon survival through the Delta since 2000 (SJRG 2013). Prior to 2000, similar south Delta coded-wire-tag (CWT) studies were funded by the Interagency Ecological Program and others (Brandes and McLain 2001). Since 2008, survival of juvenile Chinook Salmon through, or in, the Delta has been measured using acoustic tags. The main objective of the VAMP was to better understand the relationship between Chinook Salmon smolt survival through the Delta and San Joaquin River flows and combined CVP and SWP exports in the presence of the physical head of Old River barrier (HORB). The San Joaquin River Agreement and the VAMP study ended in 2011.

In 2012, the main objective of the Chinook Salmon survival study was to estimate survival through the Delta during the San Joaquin River Flow Modification Project (USBR 2012), during which the Merced River flows were augmented between April 15 and May 15, and compare it to survival, without the flow augmentation (after May 15), in the presence of the HORB. As part of the National Marine Fisheries Service and California Department of Water Resources Joint Stipulation Regarding South Delta Operations during April and May of 2012

(http://www.westcoast.fisheries.noaa.gov/central_valley/water_operations/ocapstip.html; accessed 8/27/15), the physical HORB was installed in 2012. The barrier had eight culverts in 2012, compared to between two and six culverts as in past years. Funding for this study was provided by the restoration fund of the Central Valley Project Improvement Act, the California Department of Water Resources (CDWR) and the U.S. Bureau of Reclamation (USBR).

These salmon studies also estimated route selection at some channel junctions in the south Delta along the main stem San Joaquin River and provided information on how route selection into some reaches influences overall survival through the Delta to Chipps Island. Recent advances in acoustic technology have allowed investigators to evaluate the influence of route selection and reach-specific survival of salmon to overall survival through the Sacramento-San Joaquin Delta (Perry et al. 2010). In this study, the hypothesis focused on the impact of changes in hydrology with the HORB, as the primary factor relative to juvenile salmon survival however we are aware that many other factors also influence survival through the Delta.

Goals and Objectives

The goal of this study was to determine if there were differences in survival resulting from changes in hydrology (i.e. increased flow) with the HORB installed.

Objectives:

1. Determine survival of emigrating salmon smolts from Mossdale to Chipps Island during two time periods (prior to May 15 and after May 15) in the presence of the HORB to determine if there was a benefit from the flow augmentation from the Merced River in the spring of 2012.
2. Assess whether the higher flows resulted in a reduction in travel time; a potential mechanism for why survival may be higher with higher flows.
3. Identify route selection at HOR and Turner Cut under the two periods with varied flows to determine its effect on survival to Chipps Island in 2012.
4. Assess the influence of flow on survival between Mossdale and Jersey Point with the HOR barrier installed in 2012 and compare it to past years to further evaluate if the increased flow from the Merced River flow augmentation likely resulted in higher smolt survival through the Delta.

Background

Survival during the smolt life-stage was assumed to be the link associated with two statistically significant relationships between San Joaquin basin escapement and 1) San Joaquin River flow at Vernalis and 2) the ratio of San Joaquin River flow to Central Valley Project and State Water Project exports, 2 ½ years earlier (Figures 5-20 and 5-21 in SJRGA 2007). It is these relationships between flow and flow/exports and escapement that are the basis for the hypothesis that increasing flow and decreasing exports during the smolt outmigration would increase adult escapement and production in the San Joaquin basin.

The early, pre-VAMP studies compared survival of CWT Feather River Hatchery (FRH) smolts released into upper Old River to those released on the main stem San Joaquin River at Dos Reis. Dos Reis is located on the San Joaquin River downstream of the head of Old River. These studies were conducted between 1985 and 1990 and suggested that survival was higher for salmon smolts released on the main stem San Joaquin River at Dos Reis than for fish released into Old River (Brandes and McLain 2001). The results of these studies were the basis for recommending a rock barrier at the head of Old River (HORB) to prevent juvenile salmon from migrating down Old River where survival appeared to be less.

CWT releases made at Dos Reis were also used to assess the survival of salmon smolts on the San Joaquin River downstream of Old River. Although it is assumed that fish released at Dos Reis migrated downstream via the main stem San Joaquin River, there is the potential for fish released at Dos Reis to have moved upstream into Old River on flood tides, especially during periods of low San Joaquin River flows and high exports or into the interior Delta via Turner or Columbia Cuts or other downstream connections to the interior Delta. Data from 1989 to 1999 indicated that as San Joaquin River flows increased downstream of Old River, survival increased from Dos Reis to Jersey Point (Figure 5-14 in SJRGA 2007). These data provided the basis for the hypothesis that increased flow in the San Joaquin

River would increase salmon smolt survival. However, with the addition of more recent data (2005 and 2006) from recoveries in the trawls (as there were no or limited recovery data from the ocean fishery due to fishery closures in 2008 and 2009), the strength of this relationship appeared to lessen (Figure 5-13 in SJRGA 2007).

With the HORB in place, the majority of the fish migrating downstream would stay on the main stem San Joaquin River at the junction between the San Joaquin River and the head of Old River. With the HORB, a statistically significant relationship between CWT survival in the reach between Mossdale or Durham Ferry and Jersey Point and San Joaquin River flow at Vernalis has been observed ($r^2 = 0.73$, $p < 0.01$; Figure 5-11 in SJRGA 2007), further supporting our hypothesis that increased flow in the San Joaquin River would increase juvenile salmon survival in the Delta.

In 2010, as part of the VAMP peer review, a statistical model was used to model survival through the Delta as a function of flow and exports, based on the CWT releases in the south Delta (Appendix 1). The results of this modeling also suggested survival was generally higher on the San Joaquin River than in Old River and flow tended to improve survival in the San Joaquin River route, but there was a lot of environmental noise (low signal to noise ratio). This modeling also supported our hypothesis that a HORB would improve survival, because it would reduce the number of smolts migrating through Old River.

Conceptual Model

Our hypothesis in 2012 was that survival would increase with increased flow from the Merced River flow augmentation in the presence of the HORB. Flows were an average of 3,543 cfs during the flow augmentation period and 2,327 cfs afterwards. A potential mechanism for increased survival with increased flow is that increased flow results in shorter travel times (i.e. increased migration rates) through the riverine parts of the Delta, and thus reduces the period of exposure to mortality factors such as high water temperature, predation and toxics (Figure 1). Increased flow is also expected to reduce the effect of the mortality factors by 1) decreasing water temperatures to less stressful levels for juvenile salmon, 2) decreasing the impacts of predation due to lower metabolic rates of predators at lower water temperatures and 3) reducing toxicity concentrations through dilution (Figure 1). Survival through the entire Delta (i.e. to Chipps Island) was expected to increase with the higher flows in 2012 as a consequence of higher survival through the riverine portion of the Delta because of these hypothesized relationships.

The higher flows provided by the Merced flow augmentation in 2012 may also have resulted in the tidal prism moving further downstream, because most of the increased flow would have stayed in the San Joaquin River at the head of Old River (HOR) junction with the HORB, in contrast to when there is no HORB and a large majority of the flow moves into Old River at that junction. The shift in the tidal prism's position serves to increase the portion of the Delta that is riverine and the portion of the migration pathway that potentially responds to decreases in travel time in response to increased flow (Figure 1). It is unclear how far the tidal prism would be moved downstream from the increase in flow of approximately 1200 cubic feet per second (cfs) from the Merced flow augmentation in 2012. Additionally, the shifted position of the tidal prism further downstream, which is dependent on the magnitude of the increased flow, could also potentially reduce the proportion of flow and tagged fish

that enter Turner Cut (Figure 1). In summary, survival through the entire Delta was expected to increase as the riverine component of the Delta increased and the proportion of water and fish that were diverted into Turner Cut was reduced from a positional shift of the tidal prism downstream from higher flows.

Once fish enter the interior Delta or into the strongly tidally influenced San Joaquin River, residence times are hypothesized to increase and survival is hypothesized to decrease compared to the river reaches. The increased residence times are anticipated to increase the exposure time of juvenile salmonids to predation or other mortality factors. The incremental increase in flow from the Merced River flow augmentation was not anticipated to decrease water temperatures or dilute toxics in the tidally dominant areas of the Delta as much as the riverine reaches because inflow is a much lower proportion of overall flow in these tidally dominated regions. Lastly, the change to the flow patterns at the HOR from the installation and operation of the HORB was expected to result in fewer tagged fish being salvaged or entrained at the CVP and SWP in 2012 because a low proportion of the San Joaquin flow (~ 5%) and tagged fish enter Old River when the HORB is in place.

Study Design and Methods

This study was conducted in conjunction with a separate, but coordinated study assessing the HORB in 2012 (CDWR, 2015). As part of this HORB assessment, other groups of juvenile salmon were tagged with Hydroacoustic Technology Incorporated (HTI) tags prior to, during, and after the salmon tagging as part of this study (with VEMCO V5 tags). While the methods and results of the HTI study will not be discussed in this report, we have listed when the HTI fish were released with our study fish (Table 1).

Sample Size Analyses

A unique sample size analyses was not conducted for the 2012 study, instead we used information derived from the 2011 VAMP sample size analyses to guide release numbers for the 2012 study (SJRG 2013). For a single release at Durham Ferry it was determined that a sample size of 475 fish would allow estimation of parameters for low route specific survival (0.05), with high detection probability (90-97%) at Chipps Island. To estimate a relative effect of 100%, between two routes (San Joaquin and Old River), 790 fish would need to be tagged with low survival and 410 for medium survival (SJRG 2013). To estimate a relative effect between the two routes of 50%, 3,510 would need to be released in years with low survival and 1,800 would need to be released in years with medium survival (SJRG 2013). We did not have the resources to purchase enough tags to provide the power to estimate the relative effects between routes at either of these levels for the two groups released in 2012.

Study Fish

Study fish were obtained from the Merced River Hatchery (MRH) and transported to the Tracy Fish Collection Facility (TFCF) of the CVP on April 20 and May 7 for tagging. Fish were kept in chilled, ozonized, Delta water (14-15 ° C) until 3-4 days before tagging to minimize the progression of

proliferative kidney disease (PKD). Low water temperatures inhibit the development of PKD (Ferguson 1981): PKD is progressive at temperatures greater than 15° C (Ferguson 1981). Thus 3-4 days before tagging, tanks holding the fish were slowly switched to ambient Delta water so that they could acclimate to Delta water temperatures prior to tagging and transport to the release site. Fish were sorted such that they were greater than 13 grams (~105 mm forklength [FL]) prior to tagging. Tagged study fish averaged 18.0 grams (SD = 3.7), and 112.8 mm FL (SD = 7.2). Fish were taken off feed 24 hours prior to moving them from MRH to the TFCF and 24 hours prior to surgery.

Tags

Juvenile salmon were tagged with VEMCO V5 180 kHz transmitters that weighed 0.66 grams (g) in air on average (SD = 0.012). Tags were 12.7 millimeters (mm) long, 4.3 mm in height, and 5.6 mm wide (<http://vemco.com/products/v4-v5-180khz/>; accessed 6/15/15). The percentage of tag weight to body weight averaged 3.8% (SD = 0.7%) for the 960 fish tagged, well below the recommended 5%. Only 3% (34 of the 960 fish) had a tag weight to body weight ratio slightly greater than 5%, with all less than 5.4%.

Tags were custom programmed with two separate codes; a traditional Pulse Position Modulation (PPM) style coding along with a new hybrid PPM/High Residence (HR) coding. The HR component of the coding allows for detection at high residence receivers. High residence receivers were placed where tag signal collisions (i.e. many tags emitting signals at the same time to the same receiver) were anticipated (CVP, CCF). The transmission of the PPM identification code was followed by a 25-35 second delay, followed by the PPM/HR code, followed by a 25-35 second delay, and then back to the PPM code, etc. The PPM code consisted of 8 pings approximately every 1.2 to 1.5 seconds. The PPM/HR code consisted of 1 PPM code and 8 HR codes (all the same for each individual fish) with 8 pings approximately every 1.2-1.5 seconds.

Tags were soaked in saline water for at least 24 hours prior to tag activation. Tags were activated using a VEMCO tag activator approximately 24 hours prior to tag implantation. For the first week of releases, time of activation was estimated to the nearest hour, whereas tag activation was identified to the nearest minute for the second group of releases.

Tagging training

Training those who conducted the tagging occurred between April 9 and April 13 at the TFCF using Chinook Salmon from MRH. Three hundred fish were used for training, and were brought to the TFCF on April 4. The training was conducted by staff from the U.S. Geological Survey (USGS)'s Columbia River Research Laboratory (CRRL). During training, the CRRL refined standard operating procedures, (SOP), and trained personnel to surgically implant acoustic tags (Liedtke 2012). Returning taggers received a refresher course on training during which they were required to tag a minimum of 35 fish. New taggers received a more thorough training on surgical techniques and were required to tag a minimum of 75 fish during training. Training included sessions on knot tying, tagging bananas, tagging dead fish and finally tagging live fish, holding them overnight and necropsying them to evaluate techniques and provide feed-back. Lastly, a mock tagging session was held on April 13 to practice logistic procedures and to identify potential problems and discuss solutions.

Tagging

In 2012, two groups of 480 Chinook Salmon were tagged with VEMCO V5 tags over two weekly periods: May 1-5 and May 16-20. Each group of salmon was tagged in 3 days, over a 6 day period; Chinook Salmon were tagged every other day, to facilitate survival comparisons between Chinook Salmon and steelhead (the comparison between salmon and steelhead will not be discussed in this report). Two sessions of tagging were conducted for salmon: one in the morning and one in the afternoon. Morning and afternoon tagging sessions were further divided into shifts with each shift incorporating groups of salmon tagged with either VEMCO or HTI tags. The salmon tagged as part of this study were tagged on May 1, May 3, May 5 and May 16, May 18 and May 20 (Table 1). Tagging was conducted at the TFCF as was done since 2009. Four surgeons were used to tag the fish and each surgeon had an assistant. Three additional individuals (runners) helped to move fish into and out of the tagging operation.

Tags were inserted into the fish body cavity after the fish had been anesthetized with between 6.0 and 6.5 milliliters (ml) of tricaine methanesulfonate (MS-222) buffered with sodium bicarbonate,

until they lost equilibrium. Fish were weighed (to the nearest 0.1 g) and measured to the nearest mm (FL). Surgeries took between 1 minute 20 seconds and 6 minutes 57 seconds, but most were within 2 to 3 minutes. Tagging was done using standard operating procedures (SOP) developed by the CRRL and refined during the training week. The SOP (Appendix 2) directed all aspects of the tagging operation and was based on Adams et al. (1998) and Martinelli et al (1998) and modified as needed.

Transmitter Validation

After the surgical implantation of tags, one or two fish were placed into 19 liter (L) (5 gal) perforated buckets with high dissolved oxygen concentrations (110-130%) and allowed to recover from anesthesia for 10 minutes. During this time, tag codes were verified using a 180 khz hydrophone connected to a VR100. Tags that would not verify using the VR100 were replaced with a new tag in a new fish. After validation, a pair of buckets containing either one or two fish was combined to create a bucket of 3 fish. The bucket was then moved into a holding flume of circulating water to await loading to the transport truck once the tagging session was completed.

Transport to Release Site

After tagging, the 19L perforated buckets, which usually contained three tagged Chinook Salmon each, were held in a flume at the TFCF until they were loaded into transport tanks at the end of each tagging session (morning or afternoon). Immediately prior to loading, all fish were visually inspected for mortality or signs of poor recovery from tagging (e.g. erratic swimming behavior). Fish that died or were not recovering from surgery were replaced with a new tagged fish.

In order to minimize the stress associated with moving fish and for tracking smaller groups of individually tagged fish, two specially designed transport tanks were used to move Chinook Salmon from the TFCF, where the tagging occurred, to the release site at Durham Ferry. The transport tanks for Chinook Salmon were designed to securely hold a series of 19 L perforated buckets filled with fish. Tanks had an internal frame that held 21 or 30 buckets in individual compartments to minimize contact between containers and to prevent tipping. Buckets were covered in the transport tanks with stretched cargo nets to assure buckets did not tip over and lids did not come off. Both transport tanks were mounted on the bed of a 26 foot flatbed truck that was equipped with an oxygen tank and hosing to deliver oxygen to each of the tanks during transport. Two trips to the release site were made each tagging day, with the morning and afternoon sessions of tagged fish being transported separately (Table 1).

After loading buckets into the transport tank, de-chlorinated ice was usually added to the transport tanks to either 1) reduce water temperatures during transport such that they would be closer to the river temperature at the release site, or 2) to prevent water temperatures from increasing during transport. Water temperature and dissolved oxygen (DO) in the transport tanks were recorded after loading buckets and ice (if added) into transport tanks; before leaving the TFCF and at the release site after transport, prior to unloading buckets. The temperature and DO were also measured in the river at the holding/release site.

Transfer to Holding Containers

Once at the release site, the perforated buckets, which typically contained three Chinook Salmon each, were removed from the transport tanks and moved to the river. For all releases, perforated buckets were placed into “sleeves” in a pick-up truck and driven a short distance to the river’s edge. A “sleeve” is a similar-sized, non-perforated bucket that allows more water to stay in the perforated bucket than would be the case without placing it in a “sleeve”. Perforated buckets in sleeves were unloaded from the pick-up truck and carried to the river. Perforated buckets were then separated from the sleeves at the shoreline and submerged in-river to be transported to the holding containers which were anchored one to two meters from shore. Water temperature and dissolved oxygen levels were measured in the river prior to placing the salmon into the holding containers in the river.

Once at the river’s edge, the tagged Chinook Salmon were transferred from the perforated buckets to the holding containers; 120 L (32 gal) perforated plastic garbage cans held in the river. These holding containers were perforated with hole sizes of 0.64 cm in diameter. Five buckets containing fish were emptied into each perforated garbage can. Only four of the five buckets emptied into the garbage cans contained VEMCO tagged fish while the fifth bucket of each group held 3 to 4 HTI fish. Each bucket and garbage can was labeled to track the specific tag codes and assure fish were transferred to the correct holding can for later release at the correct time. Tagged salmon were held in the perforated garbage cans for approximately 24 hours prior to release. Steelhead for the 6 Year Study were held at the same location and released either the day before or the day after the releases of Chinook Salmon; steelhead were released May 1-2, May 3-4, and May 5-6, and May 18-19, May 20-21, and May 22-23.

Fish Releases

The Chinook Salmon, held in perforated garbage cans, were transported downstream by boat to the release location which was in the middle of the channel downstream of the holding location. The fish were released downstream of the holding site to potentially reduce initial predation of tagged fish immediately after release, under the assumption that predators may congregate near the holding location. Releases were made every 4 hours after the 24 hour holding period, at approximately 1500, 1900, 2300 hours (the day after tagging), and 0300, 0700, and 1100 hours (2 days after tagging)(Table 1). Fish releases were made at these four-hour increments through-out the 24-hour period to spread the fish out and to better represent naturally spawned fish that may migrate downstream through-out the 24 hour period. The Chinook Salmon releases were made on May 2-3, May 4-5, May 6-7 and May 17-18, May 19-20, May 21-22 (Table 1).

Immediately prior to release, each holding container was checked for any dead or impaired fish. At the release time, the lid was removed and the holding container was rotated to look for mortalities. The container was then inverted to allow the fish to be released into the river. After the holding container was inverted, the time was recorded. As the holding containers were flipped back over, they were inspected to make sure that none of the released fish swam back into the container. Some exceptions to this procedure occurred as one group was released from shore due to high winds and waves, and three groups were released from shore due to a dead battery in the boat (Table 1).

Once the release was completed, the information on any dead fish was recorded and the tags removed. The tags were bagged and labeled and returned to the tagging location or office for tag code identification.

Dummy-tagged fish

In order to evaluate the effects of tagging and transport on the survival of the tagged fish, several groups of Chinook Salmon were implanted with inactive (“dummy”) transmitters. Dummy tags in 2012 were systematically interspersed into the tagging order for each release group. For each day of tagging and transport, 15 fish were implanted with dummy transmitters and included in the tagging process (Table 1). Procedures for tagging these fish, transporting them to the release site, and holding them at the release site were the same as for fish with active transmitters. Dummy-tagged fish were evaluated for condition and mortality after being held at the release site for approximately 48 hours. After being held, dummy tagged fish were assessed qualitatively for percent scale loss, body color, fin hemorrhaging, eye quality, and gill coloration (Table 2). In addition, two additional groups of 15 dummy-tagged fish (tagged on the same day) were held for approximately 48 hours and assessed for pathogens and other diseases (discussed below).

Fish Health Assessment

As a part of the 2012 South Delta Chinook Salmon Survival Study, the U.S. Fish and Wildlife Service’s CA-NV Fish Health Center (CNFHC) conducted a general pathogen screening and smolt physiological assessment on dummy-tagged fish held at the release site for 48 hours. The health and physiological condition of the study fish can help explain their performance and survival during the studies. Pathogen screenings during past VAMP studies using MRH Chinook Salmon have regularly found infection with the myxozoan parasite *Tetracapsuloides bryosalmonae*, the causative agent of Proliferative Kidney Disease (PKD). This parasite has been shown to cause mortality in Chinook Salmon with increased mortality and faster disease progression in fish at higher water temperatures (Ferguson 1981; Foott et al. 2007). The objectives of this element of the project were to evaluate the juvenile Chinook Salmon used for the studies for specific fish pathogens including *Tetracapsuloides bryosalmonae* and assess smolt development from gill $\text{Na}^+ - \text{K}^+$ -ATPase activity to determine potential differences in health between groups. For a complete description of methods see Appendix 4.

Tag life tests

Two tag life tests were conducted in conjunction with this study. The first tag-life study began on May 16, with 43 tags. The second tag-life study began on May 24, with 40 tags. Tags were activated and then put into mesh bags and held in holding tanks at the TFCF containing ambient Delta water. A VEMCO VR2W was installed in each tank for recording detections of each individual tag. Files of detections were reviewed to identify the tag failure of each individual tag used in the tag life study. These results were then compared to observed tag travel times of the tags used in the study to estimate their tag life and make any necessary corrections to fish survival estimates.

Tag retention test

On May 25, 2012, each of the 4 surgeons tagged 9 to 10 fish with dummy tags to assess tag retention and longer-term mortality of tagged fish. Thirteen of these fish were held in each of 3 separate tanks for 30 days to determine if there was any longer-term mortality of the tagged fish and whether any tags were expelled. Fish were held in tanks at the TFCF for the duration of the 30 days.

Receiver deployment, retrieval, and receiver database

The 2012 Chinook Salmon Survival Study, in conjunction with the 6-Year Steelhead Study used receivers at 26 locations in the lower San Joaquin River and South Delta to Chipps Island (i.e. Mallard Slough) for detecting juvenile salmon and steelhead as they migrated through the Delta (Figure 2). These receivers were placed at key locations throughout the south Delta and similar to those used in VAMP in 2010 and 2011 (Figure 2). Although locations of receivers are similar, the VAMP study used an HTI receiver array, whereas the 2012 study used a VEMCO receiver array. The USBR funded the USGS to deploy, maintain and remove all of the receivers in the array, including receivers at both Jersey Point and Chipps Island in 2012. The detections of tagged salmon on these receivers allowed survival of juvenile salmon to be estimated from Durham Ferry to Chipps Island.

Data processing and survival model

This study used the tag detection data recorded on the receiver array to populate a release-recapture model similar to that used in the 2010 and 2011 VAMP studies (SJGRA 2011, 2013). The release-recapture model used the pattern of detections among all tags to estimate the probabilities of route selection, survival, and transition in various reaches and detection probability at receivers. Parameter estimates were then combined to calculate estimates of reach-specific survival, route-specific survival, and total survival through the Delta to Chipps Island. The release-recapture model (described in more detail below) is a multi-state model based on the models of Cormack (1964), Jolly (1965), and Seber (1965), in combination with the route-specific survival model of Skalski et al. (2002). Tags that appeared to be in predators were identified, and the model was fit first to the complete data set that included all detections, including those from predators, and then to the reduced data set that omitted detections that appeared to come from predators. This allowed comparison of estimates of survival and route selection probabilities with and without tags that appeared to come from predators in order to assess the potential bias associated with predator detections; this approach was similar to that used in the 2010 and 2011 VAMP studies (SJGRA 2011, 2013). More details on all statistical methods follow.

Statistical Methods

Data Processing for Survival Analysis

The University of Washington (UW) received the database of tagging and release data from the US Fish and Wildlife Service (USFWS). The tagging database included the date and time of tagging surgery for each tagged Chinook Salmon released in 2012, as well as the name of the surgeon (i.e., tagger), and the date and time of release of the tagged fish to the river. Fish size (length and weight), tag size, and any notes about fish condition were included, as well as the survival status of the fish at the time of release. Tag serial number and three unique tagging codes were provided for each tag, representing codes for various types of signal coding. Tagging data were summarized according to release group and tagger, and were cross-checked with Pat Brandes (USFWS) for quality control.

Acoustic tag detection data collected at individual monitoring sites (Table 3) were transferred to the USGS in Sacramento, California. A multiple-step process was used to identify and verify detections of fish in the data files, and produce summaries of detection data suitable for converting to tag detection histories. Detections were classified as valid if two or more pings were recorded within a 30 minute time frame on the hydrophones comprising a detection site from any of the three tag codes associated with the tag. The UW received the primary database of autoprocessed detection data from the USGS. These data included the date, time, location, and tag codes and serial number of each valid detection of the acoustic Chinook Salmon tags on the fixed site receivers. The tag serial number was linked to the acoustic tag ID, and was used to identify tag activation time, tag release time, and release group from the tagging database.

The autoprocessed database was cleaned to remove obviously invalid detections. The UW identified potentially invalid detections based on unreasonable travel times or unlikely transitions between detections, and queried the USGS processor about any discrepancies. All corrections were noted and made to the database. All subsequent analysis was based on this cleaned database.

The information for each tag in the database included the date and time of the beginning and end of each detection event when a tag was detected. Unique detection events were distinguished by detection on a separate hydrophone or by a time delay of 30 minutes between repeated hits on the same receiver. Separate events were also distinguished by unique tag encoding schemes (e.g., PPM vs. hybrid PPM/HR). The cleaned detection event data were converted to detections denoting the beginning and end of receiver “visits,” with consecutive visits to a receiver separated either by a gap of 12 hours or more between detections on the receiver, or by detection on a different receiver. Detections from receivers in dual or redundant arrays were pooled for this purpose, as were detections using different tag coding schemes.

Distinguishing between Detections of Salmon and Predators

The possibility of predatory fish eating tagged study fish and then moving past one or more fixed site receivers complicated analysis of the detection data. The Chinook Salmon survival model depended on the assumption that all detections of the acoustic tags represented live juvenile Chinook Salmon, rather than a mix of live salmon and predators that temporarily had a salmon tag in their gut. Without removing the detections that came from predators, the survival model would produce potentially biased

survival estimates of actively migrating juvenile Chinook Salmon through the Delta. The size and type (positive or negative) of the bias would depend on the amount of predation by predatory fish and the spatial distribution of the predatory fish after eating the tagged salmon. In order to minimize bias, the detection data were filtered for predator detections, and detections assumed to come from predators were identified.

The predator filter used for analysis of the 2012 data was based on the predator filter designed and used in the analysis of the 2011 data (SJRG 2013). That predator filter in turn was based on predator analyses presented by Vogel (2010, 2011), as well as conversations with fisheries biologists familiar with the San Joaquin River and Delta regions and the predator decision processes used in previous years (SJRG 2010, 2011). The filter was applied to all detections of all tags. Two data sets were then constructed: the full data set including all detections, including those classified as coming from predators (i.e., “predator-type”), and the reduced data set, restricted to those detections classified as coming from live Chinook Salmon smolts (i.e., “smolt-type”). The survival model was fit to both data sets separately. The results from the analysis of the reduced “smolt-type” data set are presented as the final results of the 2012 Chinook Salmon tagging study. Results from analysis of the full data set including “predator-type” detections were used to indicate the degree of uncertainty in survival estimates arising from the predator decision process.

The predator filter was based on assumed behavioral differences between salmon smolts and predators such as striped bass and white catfish. All detections were considered when implementing the filter, including detections from acoustic receivers that were not otherwise used in the survival model. As part of the decision process, environmental data including river flow, river stage, and water velocity were examined from several points throughout the Delta (Table 4), as available. Hydrologic data were downloaded from the California Data Exchange Center website (<http://cdec.water.ca.gov/selectQuery.html>) and the California Water Data Library (www.water.ca.gov/waterdatalibrary/) on 27 September 2013. Environmental data were reviewed for quality, and obvious errors were omitted.

For each tag detection, several steps were performed to determine if it should be classified as predator or salmon. Initially, all detections were assumed to be of live smolts. A tag was classified as a predator upon the first exhibition of predator-type behavior, with the acknowledged uncertainty that the salmon smolt may actually have been eaten sometime before the first obvious predator-type detection. Once a detection was classified as coming from a predator, all subsequent detections of that tag were likewise classified as predator detections. The assignment of predator status to a detection was made conservatively, with doubtful detections classified as coming from live salmon. In general, the decision process was based on the assumptions that (1) salmon smolts were unlikely to move against the flow, and (2) salmon smolts were actively migrating and thus wanted to move downriver, although they may have temporarily moved upstream with reverse flow.

A tag could be given a predator classification at a detection site on either arrival or departure from the site. A tag classified as being in a predator because of long travel time or movement against the flow was typically given a predator classification upon arrival at the detection site. On the other hand, a tag classified as being in a predator because of long residence time was given a predator classification upon departure from the detection site. Because the survival analysis estimated survival

within reaches between sites, rather than survival during detection at a site, the predator classifications on departure from a site did not result in removal of the detection at that site from the reduced data set. However, all subsequent detections were removed from the reduced data set.

The predator filter used various criteria on several spatial and temporal scales, as described in detail in previous reports (e.g., SJRGA 2013). Criteria fit under various categories, described in more detail in SJRGA (2013): fish speed, residence time, upstream transitions, other unexpected transitions, travel time since release, and movements against flow. The criteria used in the 2011 study were updated to reflect river conditions and observed tag detection patterns in 2012 (Table 5a and 5b). Differences between the 2011 filter and the filter used for the 2012 study (in addition to those identified in Table 5a and 5b) were:

1. Minimum migration rates on upstream-directed transitions were set to 0.1-0.2 km/hr for most upstream transitions. Upstream transitions in Old River from the Highway 4 area to the CVP trashracks and in the Sacramento or San Joaquin River from Threemile Slough to Chipps Island were limited to migration rates no less than 0.5 km/hr.
2. Maximum regional residence times allowed for smolts were set at 60 hours for the San Joaquin River upstream of the head of Old River, and 360 hours in all other regions. In most cases, the maximum regional residence time allowed for smolts making a downstream-directed transition was set at 3 – 5 times the maximum allowable near-field residence time.
3. A maximum of 3 upstream forays and 15 upstream river kilometers was imposed.
4. Maximum allowable travel time since release at Durham Ferry was set at 15 days (360 hours).

The predator scoring and classification method used for the 2011 study was used again for the 2012 study, resulting in tags being classified as in either a predator or a smolt upon arrival at and departure from a given receiver site and visit; for more details, see SJRGA (2013). All detections of a tag subsequent to its first predator designation were classified as coming from a predator, as well.

The criteria used in the predator filter were spatially explicit, with different limits defined for different receivers and transitions (Table 5a and 5b). General components of the approach to various regions are described below. Only regions with observed detections are described; regions that follow the general guidelines described in SJRGA (2013) are not highlighted here.

DFU, DFD = Durham Ferry Upstream (A0) and Durham Ferry Downstream (A2): ignore flow and velocity measures, allow long travel time to accommodate initial disorientation after release, and allow few if any repeat visits.

SJL = San Joaquin River near Lathrop (A5): upstream transitions from Stockton sites are not allowed.

ORE = Old River East (B1): repeat visits are not allowed.

SJG = San Joaquin River at Garwood Bridge (A6): transitions from upstream require arrival on flood tide

SJNB = San Joaquin River at Navy Bridge Drive (A7): allow longer residence time if arrive at slack tide; repeated visits require arriving with opposite flow and velocity conditions to departure conditions.

MAC, MFE/MFW = MacDonald Island (A8), Medford Island (A9): repeated visits require arriving with opposite flow and velocity conditions to departure conditions.

TCE/TCW = Turner Cut (F1): should not move against flow; repeated visits require arriving with opposite flow and velocity conditions to departure conditions.

ORS = Old River South (B2): repeated visits require arriving with opposite flow and velocity conditions to departure conditions.

CVP = Central Valley Project (E1): allow multiple visits; transitions from downstream Old River should not have departed Old River site against flow; no repeat visits or arrivals from downstream if not pumping.

JPE/JPW, FRE/FRW = Jersey Point (G1), False River (H1): no flow/velocity restrictions; allowed for transition from Threemile Slough (TMS/TMN)

Constructing Detection Histories

For each tag, the detection data summarized on the “visit” scale was converted to a detection history (i.e., capture history) that indicated the chronological sequence of detections on the fixed site receivers throughout the study area. In cases in which a tag was observed passing a particular receiver or river junction multiple times, the detection history represented the final route of the tagged fish past the receiver or river junction. Detections from the receivers comprising certain dual arrays were pooled, thereby converting the dual arrays to redundant arrays: the San Joaquin River near Mossdale Bridge (MOS, site A4), Lathrop (SJL, A5), and Garwood Bridge (SJG, A6); and Old River East near the head of Old River (ORE, B1). For some release groups, the receivers comprising the dual array just downstream of the initial release site (DFD, A2) were also pooled in order to achieve a better model fit; in other cases, very low detection probabilities at this site required omitting this site from analysis. Likewise, in some cases the dual arrays at either MacDonald Island (MAC, A8) or Old River South (B2) were pooled in order to improve model fit.

Survival Model

A two-part multi-state statistical release-recapture model was developed to estimate salmon smolt survival and migration route parameters throughout the study area. The full two-part model incorporates all receivers, with the exception of the San Joaquin River receiver just upstream of the head of Old River (HOR = B0), the northern-most receivers in Old and Middle rivers (OLD = B4 and MRE = C3) and the Threemile Slough receivers (TMS/TMN = T1) (Table 3, Figure 2). Because many acoustic receivers in the interior delta had no or few detections, a reduced model was developed by simplifying

the full model and limiting it to receivers with sufficient detections for analysis. The full model is described in detail first, and then the reduced model is presented.

Full Model

The full release-recapture model is a slightly simplified version of the model used to analyze 2011 steelhead data (Buchanan 2013), and similar to the model developed by Perry et al. (2010) and the model developed for the 2009 – 2011 VAMP studies (SJRG 2010, 2011, 2013). Figure 2 shows the layout of the receivers using both descriptive labels for site names and the code names used in the survival model (Table 3). The survival model represents movement and perceived survival throughout the study area to the primary exit point at Chipps Island (i.e., Mallard Island) (Figure 3, Figure 4). Individual receivers comprising dual arrays were identified separately, using “a” and “b” to represent the upstream and downstream receivers, respectively. Not all sites were used in the survival model, although all were used in the predator filter.

Fish moving through the Delta toward Chipps Island may have used any of several routes. The two primary routes modeled were the San Joaquin River route (Route A) and the Old River route (Route B). Route A followed the San Joaquin River past the distributary point with Old River near the town of Lathrop and past the city of Stockton. Downstream of Stockton, fish in the San Joaquin River route (Route A) may have remained in the San Joaquin River past its confluence with the Sacramento River and on to Chipps Island. Alternatively, fish in Route A may have exited the San Joaquin River for the interior Delta at any of several places downstream of Stockton, including Turner Cut, Columbia Cut (just upstream of Medford Island), and the confluence of the San Joaquin River with either Old River or Middle River, at Mandeville Island. Of these four exit points from the San Joaquin River between Stockton and Jersey Point, only Turner Cut was monitored and assigned a route name (F, a subroute of route A). Fish that entered the interior Delta from any of these exit points may have either moved north through the interior Delta and reached Chipps Island by returning to the San Joaquin River and passing Jersey Point and the junction with False River, or they may have moved south through the interior Delta to the state or federal water export facilities, where they may have been salvaged and trucked to release points on the San Joaquin or Sacramento rivers just upstream of Chipps Island. All of these possibilities were included in both subroute F and route A.

For fish that entered Old River at its distributary point on the San Joaquin River just upstream of Lathrop (route B), there were several pathways available to Chipps Island. These fish may have migrated to Chipps Island either by moving northward in either the Old or Middle rivers through the interior Delta, or they may have moved to the state or federal water export facilities to be salvaged and trucked. The Middle River route (subroute C) was monitored and contained within Route B. Passage through the State Water Project via Clifton Court Forebay was monitored at the entrance to the forebay and assigned a route (subroute D). Likewise, passage through the federal Central Valley Project was monitored at the entrance trashracks and in the facility holding tank and assigned a route (subroute E). Subroutes D and E were both contained in subroutes C (Middle River) and F (Turner Cut), as well as in primary routes A (San Joaquin River) and B (Old River). All routes and subroutes included multiple unmonitored pathways for passing through the Delta to Chipps Island.

Several exit points from the San Joaquin River were monitored and given route names for convenience, although they did not determine unique routes to Chipps Island. The first exit point encountered was False River, located off the San Joaquin River just upstream of Jersey Point. Fish entering False River from the San Joaquin River entered the interior Delta at that point, and would not be expected to reach Chipps Island without subsequent detection in another route. Thus, False River was considered an exit point of the study area, rather than a waypoint on the route to Chipps Island. It was given a route name (H) for convenience. Likewise, Jersey Point and Chipps Island were not included in unique routes. Jersey Point was included in many of the previously named routes (in particular, routes A and B, and subroutes C and F), whereas Chipps Island (the final exit point) was included in all previously named routes and subroutes except route H. Thus, Jersey Point and Chipps Island were given their own route name (G). Three additional sets of receivers located in Old River (Route B) and Middle River (Subroute C) north of Highway 4 and in Threemile Slough (Route T) were not used in the survival model. The routes, subroutes, and study area exit points are summarized as follows:

- A = San Joaquin River: survival
- B = Old River: survival
- C = Middle River: survival
- D = State Water Project: survival
- E = Central Valley Project: survival
- F = Turner Cut: survival
- G = Jersey Point, Chipps Island: survival, exit point
- H = False River: exit point
- T = Threemile Slough: not used in survival model

The release-recapture model used parameters that denote the probability of detection (P_{hi}), route entrainment (ψ_{hi}), Chinook Salmon survival (S_{hi}), and transition probabilities equivalent to the joint probability of movement and survival ($\phi_{kj,hi}$) (Figure 3, Figure 4, Table A5-1). Unique detection probabilities were estimated for the individual receivers in a dual array: P_{hia} represented the detection probability of the upstream array at station i in route h , and P_{hib} represented the detection probability of the downstream array.

The model parameters are:

P_{hi} = detection probability: probability of detection at telemetry station i within route h , conditional on surviving to station i , where $i = ia, ib$ for the upstream, downstream receivers in a dual array, respectively.

S_{hi} = perceived survival probability: joint probability of migration and survival from telemetry station i to station $i+1$ within route h , conditional on surviving to station i .

ψ_{hl} = route entrainment probability: probability of a fish entering route h at junction l ($l=1, 2$), conditional on fish surviving to junction l .

$\phi_{kj,hi}$ = transition probability: joint probability of route entrainment, and survival; the probability of migrating, surviving, and moving from station j in route k to station i in route h , conditional on survival to station j in route k .

A variation on the parameter naming convention was used for parameters representing the transition probability to the junction of False River with the San Joaquin River, just upstream of Jersey Point (Figure 2). This river junction marks the distinction between routes G and H, so transition probabilities to this junction are named $\phi_{kj,GH}$ for the joint probability of surviving and moving from station j in route k to the False River junction. Fish may arrive at the junction either from the San Joaquin River or from the interior Delta. The complex tidal forces present in this region prevent distinguishing between smolts using False River as an exit from the San Joaquin and smolts using False River as an entrance to the San Joaquin from Frank's Tract. Regardless of which approach the fish used to reach this junction, the $\phi_{kj,GH}$ parameter (e.g. $\phi_{A9,GH}$) is the transition probability from station j in route k to the junction of False River with the San Joaquin River via any route; ψ_{G1} is the probability of moving downstream toward Jersey Point from the junction; and $\psi_{H1} = 1 - \psi_{G1}$ is the probability of exiting (or re-exiting) the San Joaquin River to False River from the junction (Figure 3).

Because of the complexity of routing in the vicinity of MacDonald Island (referred to as "Channel Markers" in reports from previous years, e.g., SJRGA 2013) on the San Joaquin River, Turner Cut, and Medford Island, and the possibility of reaching the interior Delta via either route A or route B, the full survival model that represented all routes was decomposed into two submodels for analysis. Submodel I modeled the overall migration from release at Durham Ferry to arrival at Chipps Island without modeling the specific routing from the lower San Joaquin River (i.e., from the Turner Cut Junction) through the interior Delta to Chipps Island, although it included detailed subroutes in route B for fish that entered Old River at its upstream junction with the San Joaquin River (Figure 3). In Submodel I, transitions from MacDonald Island (A8) and Turner Cut (F1) to Chipps Island were interpreted as survival probabilities ($S_{A8,G2}$ and $S_{F1,G2}$) because they represented all possible pathways from these sites to Chipps Island. Submodel II, on the other hand, focused entirely on Route A, and used a virtual release of tagged fish detected at the San Joaquin River receiver array near Lathrop, (SJL) to model the detailed routing from the lower San Joaquin River near MacDonald Island and Turner Cut through or around the interior Delta to Jersey Point and Chipps Island (Figure 4). Submodel II included the Medford Island detection site (A9), which was omitted from Submodel I because of complex routing in that region.

Reduced Model

Detection data of tagged Chinook Salmon in the interior Delta in 2012 were very sparse. There were very few detections at the downstream Old and Middle river sites (OR4 [model code B3] and MR4

[C2]) and Central Valley Project (model codes E1 and E2) receivers, and no detections in Middle River at its head (C1) or radial gates (D1 and D2) receivers. There were also no detections at False River (H1) used in the survival analysis because all False River detections were followed by detections either at Jersey Point (G1) or Chipps Island (G2). With so few detections in the Old River route and the interior Delta portions of the San Joaquin River route, it was not possible to fit the full release-recapture model to the 2012 Chinook Salmon data set. Instead, it was necessary to omit all detection sites in the Old River route other than the first two sites in that route: ORE (B1) and ORS (B2). The simplified submodel I (Figure 5) includes the overall probability of surviving from the Old River receivers near the head of Middle River (ORS) to Chipps Island, $S_{B2,G2}$. This parameter includes all ways of getting from ORS (site B2) to Chipps Island (site G2), and is interpreted as the sum of products of the $\phi_{k_i,hi}$ parameters from the full Submodel I:

$$S_{B2,G2} = \phi_{B2,D1}\phi_{D1,D2}\phi_{D2,G2} + \phi_{B2,E1}\phi_{E1,E2}\phi_{E2,G2} + (\phi_{B2,B3}\phi_{B3,GH} + \phi_{B2,C2}\phi_{C2,GH})\psi_{G1}\phi_{G1,G2}.$$

The reduced Submodel I does not decompose $S_{B2,G2}$ into its route-specific components because of sparse data.

The reduced Submodel II focuses on transitions in and from the lower portions of the San Joaquin River, and omits transitions from this region to the interior Delta or water export facilities (Figure 6). While the full Submodel II included transitions from MacDonal Island, Medford Island, and Turner Cut to the interior Delta and water export facilities, insufficient observations of tags making these transitions made it necessary to omit these pathways from the reduced model. Thus, the reduced Submodel II models transitions only to the Jersey Point/False River junction from the MacDonal Island/Medford Island/Turner Cut region. In fact, because no tags were observed exiting the system at False River, it was not possible to separate the probability of getting to the Jersey Point/False River junction ($\phi_{hi,GH}$) from the probability of turning toward Jersey Point (ψ_{G1}); instead, only the product was estimable: $\phi_{hi,G1} = \phi_{hi,GH}\psi_{G1}$, for transitions from site i in route h . Thus, the reduced Submodel II used parameters $\phi_{A8,G1}$, $\phi_{A9,G1}$, and $\phi_{F1,G1}$, which jointly include all routes from the lower San Joaquin River receivers to Jersey Point, including those past the interior Delta receivers in northern Old and Middle rivers (B3 and C2). Likewise, without detections at the head of Middle River receiver (MRH, code C1), it was not possible to separately estimate the probability of surviving from the head of Old River to the head of Middle River (S_{B1}) from the probability of remaining in Old River at the head of Middle River (ψ_{B2}). Only the product was estimate: $\phi_{B1,B2} = S_{B1}\psi_{B2}$. Finally, there were insufficient detections at the receivers upstream of the Durham Ferry release site (DFU, code A0), so the A0 site was removed from the simplified submodel I (Figure 5).

The two simplified submodels I and II were fit concurrently using unique detection and transitions probabilities at shared receivers: SJG (A6), SJNB (A7), MAC (A8), TCE/TCW (F1), and MAE/MAW (G2). Parameters at these sites were estimated separately for the two submodels to avoid “double-counting” tags used in both submodels.

In addition to the model parameters, derived performance metrics measuring migration route probabilities and survival were estimated as functions of the model parameters. Both route entrainment and route-specific survival were estimated for the two primary routes determined by routing at the head of Old River (routes A and B). Route entrainment and route-specific survival were also estimated for the major subroutes of route A; subroutes were not distinguishable for route B. These subroutes were identified by a two-letter code, where the first letter indicates routing used at the head of Old River (i.e., A), and the second letter indicates routing used at the Turner Cut junction: A or F. Thus, the route entrainment probabilities for the route A subroutes were:

$\psi_{AA} = \psi_{A1}\psi_{A2}$: probability of remaining in the San Joaquin River past both the head of Old River and the Turner Cut Junction, and

$\psi_{AF} = \psi_{A1}\psi_{F2}$: probability of remaining in the San Joaquin River past the head of Old River, and exiting to the interior Delta at Turner Cut, where $\psi_{F2} = 1 - \psi_{A2}$.

Route entrainment probabilities were estimated on the large routing scale, as well, focusing on routing only at the head of Old River. The route entrainment parameters were defined as:

$\psi_A = \psi_{A1}$: probability of remaining in the San Joaquin River at the head of Old River

$\psi_B = \psi_{B1}$: probability of entering Old River at the head of Old River.

The probability of surviving from the entrance of the Delta near Mossdale Bridge (site A4, MOS) through an entire migration pathway to Chipps Island was estimated as the product of survival probabilities that trace that pathway:

$S_{AA} = S_{A4}S_{A5}S_{A6}S_{A7}S_{A8,G2}$: Delta survival for fish that remained in the San Joaquin River past the head of Old River and Turner Cut,

$S_{AF} = S_{A4}S_{A5}S_{A6}S_{A7}S_{F1,G2}$: Delta survival for fish that entered Turner Cut from the San Joaquin River, and

$S_B = S_{A4}\phi_{B1,B2}S_{B2,G2}$: Delta survival for fish that entered Old River at its head.

The overall probability of surviving through the Delta in the San Joaquin River route was defined using the subroute-specific survival probabilities and the probabilities of taking each subroute:

$S_A = \psi_{A2}S_{AA} + \psi_{F2}S_{AF}$: Delta survival (from Mossdale to Chipps Island) for fish that remained in the San Joaquin River at the head of Old River.

The parameters $S_{A8,G2}$ and $S_{F1,G2}$ used in S_{AA} and S_{AF} represent the probability of getting to Chipps Island (i.e., Mallard Island, site MAE/MAW) from A8 and F1, respectively. Both parameters represent multiple pathways around or through the Delta to Chipps Island (Figure 2). Fish that were detected at the A8 receivers (MacDonald Island) may have remained in the San Joaquin River all the way to Chipps Island, or they may have entered the interior Delta downstream of Turner Cut. Fish that entered the interior Delta either at Turner Cut or farther downstream may have migrated through the interior Delta to Chipps Island via Frank's Tract or Fisherman's Cut, False River, and Jersey Point; returned to the San Joaquin River via its downstream confluence with either Old or Middle River at Mandeville Island; or gone through salvage and trucking from the water export facilities. All such routes are represented in the $S_{A8,G2}$ and $S_{F1,G2}$ parameters, which were estimated directly using Submodel I.

The route-specific survival probability for the Old River route, S_B , includes a transition probability, $\phi_{B1,B2}$, as a factor. As indicated above, $\phi_{B1,B2}$ is the product of a survival probability and a route entrainment probability: $\phi_{B1,B2} = S_{B1}\psi_{B2}$. No tags were detected on the Middle River receivers near the head of Middle River (site C1). However, if some tags actually had entered Middle River at its head without detection, then $\psi_{B2} < 1$ and $\phi_{B1,B2} < S_{B1}$, resulting in S_B being a minimum estimate of true Delta survival in the Old River route.

Using the estimated migration route probabilities and route-specific survival for these two primary routes (A and B), survival of the population from A4 (Mosssdale) to Chipps Island was estimated as:

$$S_{Total} = \psi_A S_A + \psi_B S_B.$$

Survival was also estimated from Mosssdale to Jersey Point, although this was estimable only for fish in the San Joaquin River route. Survival through this region ("Mid-Delta" or MD) was defined as follows:

$S_{A(MD)} = \psi_{A2} S_{AA(MD)} + \psi_{F2} S_{AF(MD)}$: Mid-Delta survival for fish that remained in the San Joaquin River past the head of Old River,

where

$$S_{AA(MD)} = S_{A4} S_{A5} S_{A6} S_{A7} (\phi_{A8,G1} + \phi_{A8,A9} \phi_{A9,G1}), \text{ and}$$

$$S_{AF(MD)} = S_{A4} S_{A5} S_{A6} S_{A7} \phi_{F1,G1}.$$

Survival was also estimated through the southern portions of the Delta ("Southern Delta" or SD), although once again this was estimable only for fish in the San Joaquin River route:

$$S_{A(SD)} = S_{A4} S_{A5} S_{A6} S_{A7}.$$

The probability of reaching Mossdale from the release point at Durham Ferry, ϕ_{A1A4} , was defined as the product of the intervening reach survival probabilities:

$$\phi_{A1,A4} = \phi_{A1,A2} S_{A2} S_{A3}.$$

This measure reflects a combination of mortality and possible residualization upstream of Old River, although the Chinook Salmon in this study were assumed to be migrating (i.e., no residualization). In cases where the first detection site A2 (DFD) had to be removed from analysis, the alternative model parameter $\phi_{A1,A3} = \phi_{A1,A2} S_{A2}$ was used:

$$\phi_{A1,A4} = \phi_{A1,A3} S_{A3}.$$

Individual detection histories (i.e., capture histories) were constructed for each tag as described above. Each detection history consisted of one or more fields representing initial release (field 1) and the sites where the tag was detected, in chronological order. Detection on both receivers in a dual array was denoted by the code “ab”, detection on only the upstream receiver was denoted “a0”, and detection on only the downstream receiver was denoted “b0”. For example, the detection history DF A2a0 A5 A7 A8ab A9b0 G1a0 G2ab represented a tag that was released at Durham Ferry and detected at the first (but not the second) receiver just downstream of the release site (A2a0), at one or both of the receivers near Lathrop (A5), at the single receiver in the San Joaquin River near the Navy Drive Bridge (A7), both receivers at MacDonald Island (A8ab), the downstream receiver at Medford Island (A9b0), the upstream receiver at Jersey Point (G1a0), and both receivers at Chipps Island (G2ab). A tag with this detection history can be assumed to have passed by certain receivers without detection: A2b, A3, A4, A6, A9a, and G1b. In Submodel I, the detections at A9 and G1 were not modeled, yielding Submodel I parameterization:

$$\phi_{A1,A2} P_{A2a} (1 - P_{A2b}) S_{A2} (1 - P_{A3}) S_{A3} (1 - P_{A4}) S_{A4} \psi_{A1} P_{A5} S_{A5} (1 - P_{A6}) S_{A6} P_{A7} S_{A7} \psi_{A2} P_{A8a} P_{A8b} S_{A8,G2} P_{G2a} P_{G2b}.$$

In Submodel II, this detection history was parameterized starting at the virtual release at site A5 and included detections at A8, A9, and G1:

$$S_{A5} (1 - P_{A6}) S_{A6} P_{A7} S_{A7} \psi_{A2} P_{A8a} P_{A8b} \phi_{A8,A9} (1 - P_{A9a}) P_{A9b} \phi_{A9,G1} P_{G1a} (1 - P_{G1b}) \phi_{G1,G2} P_{G2a} P_{G2b}.$$

Another example is the detection history DF A2ab A4 A5 A6 A7 G2b0. A fish with this detection history was released at Durham Ferry, migrated downstream in the San Joaquin River past the head of Old River with detections at the receivers just downstream of the release site (A2ab), as well as at the Mossdale Bridge (A4), Lathrop (A5), Garwood Bridge (A6), and Navy Drive Bridge (A7) before being detected on the second Chipps Island receiver (G2b0). This fish passed the Turner Cut junction but we have no information on which route it took there, so both routes must be parameterized in both submodels. This fish presumably passed Jersey Point without being detected on either receiver there.

This detection history is modeled partially in Submodel I and partially in Submodel II. In Submodel I, the probability of this detection history is

$$\phi_{A1,A2} P_{A2a} P_{A2b} S_{A2} (1 - P_{A3}) S_{A3} P_{A4} S_{A4} \psi_{A1} P_{A5} S_{A5} P_{A6} S_{A6} P_{A7} S_{A7} \theta P_{G2a} P_{G2b},$$

where $\theta = \psi_{A2} (1 - P_{A8}) S_{A8,G2} + \psi_{F2} (1 - P_{F1}) S_{F1,G2}$, $1 - P_{A8} = (1 - P_{A8a})(1 - P_{A8b})$, and $1 - P_{F1} = (1 - P_{F1a})(1 - P_{F1b})$.

In Submodel II, this detection history is parameterized

$$S_{A5} P_{A6} S_{A6} P_{A7} S_{A7} \left[\psi_{A2} (1 - P_{A8}) (\phi_{A8,G1} + \phi_{A8,A9} \phi_{A9,G1}) + \psi_{F2} (1 - P_{F1}) \phi_{F1,G1} \right] (1 - P_{G1}) \phi_{G1,G2} (1 - P_{G2a}) P_{G2b},$$

where $1 - P_{G1} = (1 - P_{G1a})(1 - P_{G1b})$.

A final example is the detection history DF A3 A4 B1 B2a0. A fish with this detection history was released at Durham Ferry, passed the first receivers without detection, passed the receivers at Banta Carbona (A3) and Mossdale Bridge (A4) with detection, entered Old River through the barrier and was detected on at least one receiver at the first Old River site (B1) and on the upstream receiver at the Old River South site (B2a0). The fish was not detected again after passing the Old River South site. It may have died between that site and Chipps Island (the next site modeled), or it may have reached Chipps Island but evaded detection there. Both possibilities must be included in the model parameterization. This detection history is parameterized only in Submodel I:

$$\phi_{A1,A2} (1 - P_{A2}) S_{A2} P_{A3} S_{A3} P_{A4} S_{A4} (1 - \psi_{A1}) P_{B1} \phi_{B1,B2} P_{B2a} (1 - P_{B2b}) \left[1 - S_{B2,G2} P_{G2} \right],$$

where $1 - P_{A2} = (1 - P_{A2a})(1 - P_{A2b})$ and $P_{G2} = 1 - (1 - P_{G2a})(1 - P_{G2b})$.

Under the assumptions of common survival, route entrainment, and detection probabilities and independent detections among the tagged fish in each release group, the likelihood function for the survival model for each release group is a multinomial likelihood with individual cells denoting each possible capture history.

Parameter Estimation

The multinomial likelihood model described above was fit numerically to the observed set of detection histories according to the principle of maximum likelihood using Program USER software, developed at the UW (Lady et al. 2009). Point estimates and standard errors were computed for each parameter. Standard errors of derived performance measures were estimated using the delta method (Seber 2002: 7-9). Sparse data prevented some parameters from being freely estimated for some release groups. Transition, survival, and detection probabilities were fixed to 1.0 or 0.0 in the USER model as appropriate, based on the observed detections. The model was fit separately for each release.

For each release, the complete data set that included possible detections from predatory fish was analyzed separately from the reduced data set restricted to detections classified as Chinook Salmon smolt detections. Population-level estimates of parameters and performance measures, representing both release groups, were estimated by fitting the model to the pooled detection data from both release groups. For each model fit, goodness-of-fit was assessed visually using Anscombe residuals (McCullagh and Nelder 1989). The sensitivity of parameter and performance metric estimates to inclusion of detection histories with large absolute values of Anscombe residuals was examined for each release group individually.

For each release group and for the pooled data set, the effect of primary route (San Joaquin River or Old River) on estimates of survival to Chipps Island was tested with a two-sided Z-test on the log scale:

$$Z = \frac{\ln(\hat{S}_A) - \ln(\hat{S}_B)}{\sqrt{\hat{V}}},$$

where

$$V = \frac{\text{Var}(\hat{S}_A)}{\hat{S}_A} + \frac{\text{Var}(\hat{S}_B)}{\hat{S}_B} - \frac{2\text{Cov}(\hat{S}_A, \hat{S}_B)}{\hat{S}_A \hat{S}_B}.$$

The parameter V was estimated using Program USER. Also tested was whether tagged Chinook Salmon smolts showed a preference for the San Joaquin River route using a one-sided Z-test with the test statistic:

$$Z = \frac{\hat{\psi}_A - 0.5}{SE(\hat{\psi}_A)}.$$

Statistical significance was tested at the 5% level ($\alpha=0.05$).

Analysis of Tag Failure

The first of two tag-life studies began on May 16 with 43 tags; the last tag failure was recorded on July 6. The second tag-life study began on May 24 with 40 tags, and the last tag failure was recorded on July 12. Observed tag survival was modeled using the 4-parameter vitality curve (Li and Anderson 2009). Stratifying by tag-life study (mid-May or late May) versus pooling across studies was assessed using the Akaike Information Criterion (AIC; Burnham and Anderson 2002).

The fitted tag survival model was used to adjust estimated fish survival and transition probabilities for premature tag failure using methods adapted from Townsend et al. (2006). In Townsend et al. (2006), the probability of tag survival through a reach is estimated based on the average observed travel time of tagged fish through that reach. For this study, travel time and the probability of tag survival to Chipps Island were estimated separately for the different routes (e.g., San Joaquin route

vs. Old River route). Standard errors of the tag-adjusted fish survival and transition probabilities were estimated using the inverse Hessian matrix of the fitted joint fish-tag survival model. The additional uncertainty introduced by variability in tag survival parameters was not estimated, with the result that standard errors may have been slightly low. In previous studies, however, variability in tag-survival parameters has been observed to contribute little to the uncertainty in the fish survival estimates when compared with other, modeled sources of variability (Townsend et al. 2006); thus, the resulting bias in the standard errors was expected to be small.

Analysis of Tagger Effects

Tagger effects were analyzed in several ways. The simplest method used contingency tests of independence on the number of tag detections at key detection sites throughout the study area. Specifically, a lack of independence (i.e., heterogeneity) between the detections distribution and tagger was tested using a chi-squared test ($\alpha=0.05$; Sokal and Rohlf 1995). Detections from downstream sites were pooled for this test in order to achieve adequate cell counts, and the chi-squared test was performed via Monte Carlo simulations to accommodate remaining low cell counts.

Lack of independence may be caused by differences in survival, route entrainment, or detection probabilities. A second method visually compared estimates of cumulative survival throughout the study area among taggers. Sparse detection data in the Old River route for individual taggers prevented estimating reach survival within the Old River route by tagger, so only the overall survival to Chipps Island was estimated for route B for this analysis. A third method used Analysis of Variance to test for a tagger effect on individual reach survival estimates, and an F-test to test for a tagger effect on cumulative survival throughout each major route (routes A and B). Tagger effects on estimates of individual parameters were also assessed using an F-test. Finally, the nonparametric Kruskal-Wallis rank sum test (Sokal and Rohlf 1995, ch. 13) was used to test for whether one or more taggers performed consistently poorer than others, based on individual reach survival or transition probabilities through key reaches. In the event that survival was different for a particular tagger, the model was refit to the pooled release groups without tags from the tagger in question, and the difference in survival estimates due to the tagger was tested using a two-sided Z-test on the lognormal scale. The reduced data set (without predator-type detections), pooled over release groups, was used for these analyses.

Testing Effect of Release Group on Parameter Estimates

The effect of release group on the values of the model survival and transition probability parameters was examined by testing for a statistically significant decrease in parameter estimates for the second release group. For each model survival and transition probability parameter θ , where $\theta = \phi_{kj,hi}$ or $\theta = S_{hi}$, the difference in parameter values between the first and second release groups was defined as

$$\Delta_{\theta} = \theta_1 - \theta_2 ,$$

for model parameter θ_R for release group R ($R = 1, 2$). The difference was estimated by $\hat{\Delta}_\theta = \theta_1 - \theta_2$. The null hypothesis of no difference was tested against the alternative of a positive difference (i.e., higher parameter value for the first release group):

$$H_{0\theta} : \Delta_\theta = 0$$

vs

$$H_{A\theta} : \Delta_\theta > 0.$$

A family-wise significance level of $\alpha=0.10$ was selected, and the Bonferroni multiple comparison correction was used, resulting in a test-wise significance level of 0.0071 for 14 tests (Sokal and Rohlf 1995).

Analysis of Travel Time

Travel time was measured from release at Durham Ferry to each detection site. Travel time was also measured through each reach for tags detected at the beginning and end of the reach, and summarized across all tags with observations. Travel time between two sites was defined as the time delay between the last detection at the first site and the first detection at the second site. In cases where the tagged fish was observed to make multiple visits to a site, the final visit was used for travel time calculations. When possible, travel times were measured separately for different routes through the study area. The harmonic mean was used to summarize travel times.

To evaluate our hypotheses that reduced travel times increased survival, we compared average travel time and survival for the different reaches to see if they were different ($p < 0.05$) for the two release groups. Given that the lengths of the reaches were different we also standardized the length of each reach and survival in the reach by the distance of each reach (in km) prior to comparing average travel time per km to survival per km ($S^{(1/\text{km})}$) across reaches.

Route Entrainment Analysis

A physical barrier was installed at the head of Old River in 2012. The barrier was designed to keep fish from entering Old River, but included culverts that allowed limited fish passage. Only 11 of the 959 (1%) tags released in juvenile Chinook Salmon in 2012 were detected entering the Old River route in 2012, while 449 (47% of 959) were detected in the San Joaquin River route. Because of the barrier and the low number of tags detected in the Old River route, no effort was made to relate route entrainment at the head of Old River to hydrologic conditions in 2012. A route entrainment analysis was performed for the Turner Cut junction instead.

The effects of variability in hydrologic conditions on route entrainment at the junction of Turner Cut with the San Joaquin River were explored using statistical generalized linear models (GLMs) with a binomial error structure and logit link (McCullagh and Nelder 1989). The acoustic tags used in this analysis were restricted to those detected at either of the acoustic receiver dual arrays located just downstream of the Turner Cut junction: site MAC (model code A8) or site TCE/TCW (code F1). Tags

were further restricted to those whose final pass of the Turner Cut junction came from either upstream sites or from the opposite leg of the junction; tags whose final pass of the junction came either from downstream sites (e.g., MFE/MFW) or from a previous visit to the same receivers (e.g., multiple visits to the MAC receivers) were excluded from this analysis. Tags were restricted in this way in order to limit the delay between initial arrival at the junction, when hydrologic covariates were measured, and the tagged fish's final route selection at the junction. No Chinook Salmon tags were observed moving from one junction leg to the other, so in fact only tags that came from upstream were used in this analysis. Predator-type detections were also excluded. Detections from a total of 89 tags were used in this analysis: 79 from release group 1, and 10 from release group 2.

Hydrologic conditions were represented in several ways, primarily total river flow (discharge), water velocity, and river stage. These measures were available at 15-minute intervals from the TRN gaging station in Turner Cut, maintained by the USGS (Table 4). The Turner Cut acoustic receivers (TCE and TCW) were located 0.15 – 0.30 km past the TRN station in Turner Cut. No gaging station was available in the San Joaquin River close to the MAC receivers. The closest stations were PRI (13 km downstream from the junction), and SJG (18 km upstream from the junction) (Table 4). These stations were considered too far distant from the MAC receivers to provide measures of flow, velocity, and river stage sufficiently accurate for describing localized conditions at the Turner Cut junction for the route entrainment analysis. Thus, while measures of hydrologic conditions were available in Turner Cut, measures of flow proportion into Turner Cut were not available.

Additionally, there was no measure of river conditions available just upstream of the junction that might inform about the environment as the fish approached the junction. Instead, gaging data from the SJG gaging station (18 km upstream of the junction) were used as a surrogate for conditions upstream of the junction. Because of the distance between the SJG station and the Turner Cut junction, and the fact that the San Joaquin River becomes considerably wider between the SJG station and the junction, conditions at SJG were used only as an index of average conditions during the time when the fish was in this reach. In particular, no measure of tidal stage or flow direction was used at SJG. Instead, the analysis used the average magnitude (measured as the root mean square, RMS) of flow and velocity at SJG during the tag transition from the time of tag departure from the SJG acoustic receiver (model code A6) to the time of estimated arrival at the Turner Cut junction.

Conditions at the TRN gaging station were measured at the estimated time of arrival at the Turner Cut junction. The location (named TCJ for Turner Cut Junction) used to indicate arrival at the junction was located in the San Joaquin River 1.23 km from the TCE receiver and 2.89 km upstream of the MACU receiver. Time of arrival at TCJ (t_i) was estimated for tag i by a linear interpolation from the observed travel time from the SJNB or SJG acoustic receivers upstream to detection on either the MAC or TCE/TCW receivers just downstream of the junction. Linear interpolation is based on the first-order assumption of constant movement during the transition from the previous site. In a tidal area, it is likely that movement was not actually constant during the transition, but in the absence of more precise spatiotemporal tag detection data, the linear interpolation may nevertheless provide the best estimate of arrival time.

The TRN gaging station typically recorded flow, velocity, and river stage measurements every 15 minutes. Linear interpolation was used to estimate the flow, velocity, and river stage conditions at the estimated time of tag arrival at TCJ:

$$x_i = w_i x_{t_{1(i)}} + (1 - w_i) x_{t_{2(i)}}$$

where $x_{t_{1(i)}}$ and $x_{t_{2(i)}}$ are the two observations of metric x ($x = Q$ [flow], V [velocity], or C [stage]) at the TRN gaging station nearest in time to the time t_i of tag i arrival such that $t_{1(i)} \leq t_i \leq t_{2(i)}$. The weights w_i were defined as

$$w_i = \frac{t_{2(i)} - t_i}{t_{2(i)} - t_{1(i)}},$$

and resulted in weighting x_i toward the closest flow, velocity, or stage observation.

In cases with a short time delay between consecutive flow and velocity observations (i.e., $t_{2(i)} - t_{1(i)} \leq 60$ minutes), the change in conditions between the two time points was used to represent the tidal stage (Perry 2010):

$$\Delta x_i = x_{t_{2(i)}} - x_{t_{1(i)}}$$

for $x = Q, V$, or C , and tag i .

Negative flow measured at the TRN gaging station was interpreted as river flow being directed into the interior Delta, away from the San Joaquin River (Cavallo et al. 2013). Flow reversal (i.e., negative flow at TRN) was represented by the indicator variable U (Perry 2010):

$$U_i = \begin{cases} 1, & \text{for } Q_i < 0 \\ 0, & \text{for } Q_i \geq 0 \end{cases}$$

Prevailing flow and velocity conditions in the reach from the SJG acoustic receiver to arrival at the Turner Cut junction were represented by the root mean square (RMS) of the time series of observed conditions measured at the SJG gaging station during the estimated duration of the transition:

$$x_{RMS(i)} = \sqrt{\frac{1}{n_i} \sum_{j=T_{1(i)}}^{T_{2(i)}} x_j^2}$$

where x_j = observed covariate x at time j at the SJG gaging station ($x = Q$ or V), $T_{1(i)}$ = closest observation time of covariate x to the final detection of tag i on the SJG acoustic receivers, and $T_{2(i)} =$

closest observation time of covariate x to the estimated time of arrival of tag i at TCJ. If the time delay between either $T_{1(i)}$ and final detection of tag i on the SJG acoustic receivers, or $T_{2(i)}$ and estimated time of arrival of tag i at TCJ, was greater than 1 hour, then no measure of covariate x from the SJG gaging station was used for tag i .

Daily export rate for day of arrival of tag i at TCJ was measured at the Central Valley Project (E_{iCVP}) and State Water Project (E_{iSWP}) (data downloaded from DayFlow on November 5, 2013). Fork length at tagging L_i and release group RG_i were also considered. Finally, arrival time (day vs. night) at the Turner Cut Junction site (TCJ) was measured based on whether the tagged Chinook Salmon first arrived at TCJ between sunrise and sunset (day_i).

All continuous covariates were standardized, i.e.,

$$\tilde{x}_{ij} = \frac{x_{ij} - \bar{x}_j}{s(x_j)}$$

for the observation x of covariate j from tag i . The indicator variables U , RG , and day were not standardized.

The form of the generalized linear model was

$$\ln\left(\frac{\psi_{iA}}{\psi_{iF}}\right) = \beta_0 + \beta_1(\tilde{x}_{i1}) + \beta_2(\tilde{x}_{i2}) + \dots + \beta_p(\tilde{x}_{ip})$$

where $\tilde{x}_{i1}, \tilde{x}_{i2}, \dots, \tilde{x}_{ip}$ are the observed values of standardized covariates for tag i (covariates 1, 2, ..., p , see below), ψ_{iA} is the predicted probability that the fish with tag i selected route A (San Joaquin River route), and $\psi_{iF} = 1 - \psi_{iA}$ (F = Turner Cut route). Route choice for tag i was determined based on detection of tag i at either site A8 (route A) or site F1 (route F). Estimated detection probabilities for the two release groups were 0.97 – 1.00 for site A8 and 1.00 for site F1 (Appendix 5, Table 5A-2), so no groups were omitted because of low detection probability.

Single-variate regression was performed first, and covariates were ranked by P-values from the appropriate F-test (if the model was overdispersed) or χ^2 test (McCullagh and Nelder 1989). Covariates found to be significant alone ($\alpha=0.05$) were then analyzed together in a series of multivariate regression models. Because of high correlation between flow and velocity measured from the same site, and to a lesser extent, correlation between flow or velocity and river stage, the covariates flow, velocity, and river stage were analyzed in separate models. The exception was that the flow index in the reach from SJG to TCJ (Q_{SJG}) was included in the river stage model. Exports at CVP and SWP had low correlation over the time period in question, so CVP and SWP exports were considered in the same models. The general forms of the three multivariate models were:

$$\text{Flow model: } Q_{TRN} + Q_{SJG} + \Delta Q_{TRN} + U + day + E_{CVP} + E_{SWP} + L + RG$$

$$\text{Velocity model: } V_{TRN} + V_{SJG} + \Delta V_{TRN} + U + day + E_{CVP} + E_{SWP} + L + RG$$

$$\text{Stage model: } C_{TRN} + Q_{SJG} + \Delta C_{TRN} + U + day + E_{CVP} + E_{SWP} + L + RG.$$

In general, only terms that were significant in the single-variate models were included as candidates in the flow, velocity, and stage models. However, the flow, velocity, and stage metrics from the TRN gaging station were included as candidates in their respective models, regardless of their significance in the single-variate models. Backwards selection with F-tests was used to find the most parsimonious model in each category (flow, velocity, and stage) that explained the most variation in the data (McCullagh and Nelder 1989). Main effects and two-way interaction effects were considered. The model that resulted from the backwards selection process in each category (flow, velocity, or stage) was compared using an F-test to the full model from that category to ensure that all significant main effects were included. AIC was used to select among the flow, velocity, and stage models. Model fit was assessed by grouping data into discrete classes according to the independent covariate, and comparing predicted and observed frequencies of route entrainment into the San Joaquin using the Pearson chi-squared test (Sokal and Rohlf 1995).

Comparison of survival between Mossdale and Jersey Point in 2012 compared to past years.

A multiple regression was run on the combined data set of survival estimates from Mossdale to Jersey Point with the HORB using CWT's in 1994, 1997, 2000-2004 (SJRGA 2013) and using acoustic tags for the two releases in 2012 to determine if tag type (acoustic tag or coded wire tag) was a significant factor in addition to flow for predicting survival. We also compared the results observed in 2012 to those predicted from the CWT relationship with flow at the same flow levels as those experienced by tagged fish in the two 2012 releases. The data were also plotted and the two regression lines were compared; CWT data only and the CWT data combined with the 2012 acoustic tag data.

Results

Transport to Release Site

No mortalities were observed after transport to the release site. Water temperatures ranged from 16.8°C to 20.3° C after loading, prior to transport. Water temperatures ranged from 16.5°C to 20.5°C after transport and before unloading at the release site. Water temperature in the river at the release site ranged from 17.5°C to 20.7°C, with the average during the first week being lower (18.3°C) than for the second week (19.7°C) (Table 6). By adding ice, water temperatures did not change substantially during transport (Table 6 and Appendix 3) and water temperatures in the transport tanks when arriving at the release site were usually within a degree C of the water temperature in the river (Table 6). During transport water temperatures did not rise or lower more than 0.5°C, and transport

tank temperatures were similar between tanks within about 0.5 °C (Appendix 3). Dissolved oxygen levels ranged between 8.73 and 11.89 mg/l for all measurements in the transport tanks or in the river (Table 6).

Fish Releases

No mortalities occurred after holding and prior to release in the 2012 Chinook Salmon study (Table 6).

Dummy Tagged fish

None of the 60 dummy-tagged Chinook Salmon were found dead when evaluated after being held for 48 hours (Table 7). Three fish from the May 20 group had abnormal gill coloration. All remaining fish were found swimming vigorously, had normal gill coloration, normal eye quality, normal body coloration and no fin hemorrhaging. Mean scale loss for all fish assessed ranged from 2.3 to 5.5%. Eight of the 60 examined fish were found to have stitched organs. Mean FL of the four groups of dummy tagged fish ranged from 108.2 to 112.0 mm. These data indicate that the fish used for the Chinook Salmon study in 2012 appeared to be in generally good condition (Table 7).

Fish Health

Pathogen testing conducted on dummy-tag cohorts of acoustic tagged MRH juvenile Chinook Salmon used in studies corresponding to May 7 and May 23 releases showed no virus or *Renibacterium salmoninarum* infection detected in the fish. The May 23 group had 37% prevalence of both suture abnormalities and *Aeromonas – Pseudomonas* sp. infection however there was little correlation between the two findings. As in the past, *Tetracapsuloides bryosalmonae* infection was highly prevalent ($\geq 97\%$) and the associated Proliferative Kidney Disease became more pronounced in the May 23 sample. No mortality occurred to these fish prior to assessment after they had been held for 48 hours for either sample date. Gill Na-K-ATPase data was not reported due to a problem with a key assay reagent. The combination of kidney impairment and poor suture condition of the May 23 salmon indicates that health of the two release groups was not equivalent. See Appendix 4 for more detail on the results of the fish health evaluations.

Tag retention test

Of the 39 dummy tagged fish held for 30 days, 3 died within the first 5 days after tagging. No other mortality was observed during the 30 day period. This suggests that the tagging process alone may have caused some (less than 10%) of the mortality observed during the study. None expelled their tag.

Detections of Acoustic-Tagged Fish

There were 960 acoustic tags released in juvenile Chinook Salmon at Durham Ferry in 2012, but one was removed from the analyses due to the tag “looking odd” resulting in data from only 959 being analyzed. Of these, 713 (74%) were detected on one or more receivers either upstream or downstream of the release site (Table 8), including any predator detections. A total of 707 tags (74%) were detected at least once downstream of the release site, and 482 (50%) were detected in the study area from

Mossdale to Chipps Island (Table 8). Although more tags from the second release group were detected between the release site and the upstream boundary of the study area (Mossdale), considerably more tags from the first release group were detected in the study area than from the second release group (301 vs. 181) (Table 8).

The large majority of the tags detected in the study area were detected in the San Joaquin River route (449 of 482), while only 11 tags were detected in the Old River route (Table 8). Additionally, some tags were detected in the study area near Mossdale Bridge but not downstream of the head of Old River. In general, tag detection counts in the San Joaquin River route decreased as distance from the release point increased. Of the 449 tags observed in the San Joaquin River route, 449 were detected on the receivers near Lathrop; 310 were detected on one or both of the receivers near Stockton (SJG or SJNB); 111 were detected on the receivers in the San Joaquin River near MacDonald Island or in Turner Cut; and 47 were detected at Medford Island (Table 9).

Some of the 449 tags detected in the San Joaquin River downstream of the head of Old River were not assigned to that route for survival analysis because they were subsequently observed upstream of Old River and had no later downstream detections (Table 8). Overall, 446 of the 449 tags observed in the San Joaquin River downstream of Old River were assigned to that route for survival analysis. Of these, 13 tags were observed exiting the San Joaquin River at Turner Cut, three were observed at the Old or Middle River receivers near of Empire Cut, one was observed at the Old and Middle River receivers near Highway 4, one was observed at the CVP trashrack, and none were observed at the radial gates at the entrance to the Clifton Court Forebay (Table 9). A total of 28 San Joaquin River route tags were detected at the Jersey Point/False River receivers, including seven detections on the False River receivers (Table 9). However, all of the tags detected at False River were later detected either at Jersey Point or at Chipps Island, and so no San Joaquin River route tags were used in the survival model at False River (Table 10). A total of 14 San Joaquin River route tags were eventually detected at Chipps Island, including predator-type detections (Table 9).

Only 11 tags were detected in the Old River route, and all but one, were assigned to that route for survival analysis (Table 8). Nine (9) tags were detected both at the Old River East receivers near the head of Old River (ORE) and the Old River receivers near the head of Middle River (ORS). Four tags were detected at the CVP trashracks, and none at the radial gates at the entrance to the Clifton Court Forebay (Table 9). One tag from the Old River route was detected at both the Old River sites near Highway 4 and near Empire Cut; it was last detected at Empire Cut. No tags from the Old River route were detected at any of the Middle River sites (Table 9). One of the 11 tags in the Old River route was observed at Chipps Island, and it passed through the holding tank at the Central Valley Project (Tables 9 and 10).

In addition to the Old and Middle receivers located near Empire Cut, the Threemile Slough receivers recorded detections of tags but were purposely omitted from the full survival model. Six tags were detected on the Threemile Slough receivers: four came directly from the San Joaquin River receivers at Medford Island and MacDonald Island, and two were last detected at Jersey Point before being detected at Threemile Slough (Table 9). Those that had come from Medford Island and MacDonald Island continued on to either Jersey Point or Chipps Island, while those that came upriver to Threemile Slough from Jersey Point had no subsequent detections.

The predator filter used to distinguish between detections of juvenile Chinook Salmon and detections of predatory fish that had eaten tagged smolts classified 130 of the 959 tags released (14%) as being detected in a predator at some point during the study (Table 11). Of the 482 tags detected in the study area (i.e., at Mossdale or points downstream), 95 tags (20% of 482) were classified as being in a predator, and the majority (94 of 95) were first classified as being in a predator within the study area. The remaining tag was classified as a predator at Banta Carbona (upstream of the study area) but was later detected in the San Joaquin River at the Lathrop receiver (SJL). Approximately 7% (36 of 535) of the tags detected upstream of Mossdale were classified as being in a predator in that region (Table 11). Two of the tags that were first classified as predators in the study area were subsequently detected upstream of Mossdale. Two of the nine tags detected at upstream Old River sites (ORE and ORS) were classified as in a predator (Table 11).

Within the study area, the detection sites with the largest number of first-time predator-type detections were Lathrop (14 of 449, 3%), Garwood Bridge (18 of 310, 6%), Navy Drive Bridge (23 of 241, 10%), and MacDonald Island (18 of 100, 18%) (Tables 9 and 11). The majority of predator classifications at these four sites were assigned on tag departure from the detection site in question because of long residence times and movements against the flow. Because those detections that are assigned the predator classification only on departure are not removed from analysis in the survival model, only a few detections were actually removed from these sites.

When the predator-type detections were removed, slightly fewer detections were available for the survival analysis (Tables 12-14). With the predator-type detections removed, 697 of the 959 (73%) tags released were detected downstream of the release site, and 480 (50% of those released) were detected in the study area from Mossdale to Chipps Island (Table 12). A similar percentage of the tags from each release group were detected anywhere as a smolt (73% and 72% for the two release groups). Considerably more tags from the first release group were detected in the study area than from the second release group (63% vs. 37%) (Table 12).

Removing predator-type detections did not appreciably change the spatial patterns in the detection counts. The large majority of the tags detected in the study area were detected in the San Joaquin River route (444 of 480, 93%) and assigned to that route for the survival analysis. Only 11 tags were observed in the Old River route (Table 12). Another 25 tags were detected at the Mossdale receivers, but not downstream of the head of Old River (Table 12). Most of the changes to detection counts introduced by removing predator-type detections occurred at receivers in the San Joaquin River, both upstream and downstream of the head of Old River (Tables 9 and 13). There was no change in tag counts at Jersey Point, False River, and Chipps Island. There were very few detections at receivers throughout the western and northern regions of the interior Delta (Table 13), and somewhat fewer once detections were formatted for survival analysis (Table 14). Whether predator-type detections were included or not, detections from those sites had to be omitted from the survival model (Tables 10 and 14) (See *Statistical Methods: Survival Model – Reduced Model*).

Tag-Survival Model and Tag-Life Adjustments

The Akaike Information Criterion (AIC) indicated that pooling data from both tag-life studies (AIC = 18.1) was preferable to stratifying by study month (AIC = 33.4). Thus, a single tag survival model was

fitted and used to adjust fish survival estimates for premature tag failure. The estimated mean time to failure from the pooled data was 41.7 days ($SE = 7.5$ days) (Figure 7).

The complete set of detection data, including predator-type detections, contained some detections that occurred after the tags began dying (Figures 8 and 9). The sites with the latest detections were Banta Carbona and the San Joaquin River receivers near the Lathrop, Garwood Bridge, Navy Bridge and MacDonald Island. Some of these late-arriving detections may have come from predators. Tag-life corrections were made to survival estimates to account for the premature tag failure observed in the tag-life studies. All estimates of reach survival for the acoustic tags were greater than 0.99 (out of a possible range of 0 – 1). Thus, there was very little effect of either premature tag failure or corrections for tag failure on the estimates of salmon reach survival in 2012.

Tagger Effects

Fish in the release groups were evenly distributed across tagger (Table 15). For each tagger, the number tagged was distributed evenly across the two release groups. A chi-squared test found no evidence of lack of independence of tagger across the release groups ($\chi^2 = 0.0279$, $df=3$, $P=0.9988$). The distribution of tags detected at various key detection sites or regions of the study area was well-distributed across taggers, showing no evidence of a tagger effect on survival, route entrainment, or detection probabilities at these sites ($\chi^2 = 16.8759$, simulated P-value = 0.5372; Table 16).

Estimates of cumulative survival throughout the San Joaquin River route to Chipps Island showed generally small, non-significant effects of tagger through the system (Figure 10). Tagger C had consistently higher point estimates of cumulative survival through the receiver at Navy Drive Bridge, after which cumulative survival from this tagger were no greater than from the other taggers. Despite the higher point estimates of survival observed for Tagger C, the differences were not statistically significant (ANOVA, $P = 0.1944$). Furthermore, rank tests found no evidence of consistent differences in reach survival across fish from different taggers either upstream of the head of Old River ($P=0.9217$) or in the San Joaquin River route ($P=0.9704$). Fish tagged by Tagger B had significantly lower survival estimates through the San Joaquin River reach from the Navy Bridge to the Turner Cut junction (i.e., MacDonald Island and Turner Cut) (F-test: $P = 0.0078$); however, fish from Tagger B showed no difference in survival estimates in other reaches or to Chipps Island overall compared to the other taggers (Figure 10).

In particular, there was no difference in overall survival to Chipps Island among taggers through the San Joaquin River route ($P=0.4655$). Only one fish was observed to arrive at Chipps Island via the Old River route, so no tagger effects could be explored for that route. The survival model was fit to the data pooled from all taggers without Tagger B, and estimates of four key performance measures were compared to results found with Tagger B: S_{Total} , S_A , S_B , and $\phi_{A1,A4}$. Statistical Z-tests on the log-scale found no significant difference between estimates of these parameters with and without data from fish tagged by Tagger B ($P \geq 0.5835$).

Survival and Route Entrainment Probabilities

As described above, detections from the receivers at the entrances to the water export facilities and in the holding tank at the Central Valley Project were removed from the survival model because of sparse data, as were detections from the Old and Middle River receivers near Highway 4. In some cases, there were too few detections at the dual array just downstream of Durham Ferry (DFD, site A2) to include this site in the model. In these cases, the model used the composite parameter

$\phi_{A1,A3} = \phi_{A1,A2} S_{A2}$ in place of $\phi_{A1,A2}$ and S_{A2} . Also, in several cases analysis of model residuals showed that incorporating the full dual receiver array at some detection sites reduced the quality of the model fit to the data. In such cases when it was possible to simplify the data structure and still attain useful and valid parameter estimates, detections from the dual array in question were pooled to create a redundant array for better model fit. This occurred at the downstream Durham Ferry site (A2), MacDonald Island (A8), Old River South (near the head of Middle River, B2), and Jersey Point (G1).

No tags from the second release group (released in mid-May) were detected at Chipps Island in 2012, yielding a total Delta survival estimate of 0 ($SE = 0$) for that group whether or not predator-type detections were included. The first release group (released in early May) had positive survival ($S_{total} = 0.05$; $SE = 0.01$), yielding a population estimate for all fish in the tagging study of 0.03 ($SE = 0.01$) (Table 17). Using only those detections classified as coming from juvenile Chinook Salmon and excluding the predator-type detections, the estimated probability of remaining in the San Joaquin River at the junction with Old River ($\psi_A = \psi_{A1}$) was 0.98 ($SE = 0.01$) for both release groups (Table 17), and both release groups demonstrated a significant preference for the San Joaquin River route ($P < 0.0001$ for each group). The estimated survival from Mossdale to Chipps Island via the San Joaquin River route (S_A) was 0.05 ($SE = 0.01$) for the first release group, and 0 ($SE = 0$) for the second group; the overall population estimate was 0.03 ($SE = 0.01$) (Table 17). Very few fish took the Old River route (11 overall). Although the point estimate of survival to Chipps Island via this route ($S_B = 0.16$) was relatively high compared to the estimated survival via the San Joaquin River route ($S_A = 0.05$), the small number of fish observed taking the Old River route resulted in very high uncertainty in the Old River route survival estimate ($SE = 0.15$ for S_B); thus no significant difference in route-specific survival was detected for the first release group ($P = 0.1977$). The estimated route-specific survival to Chipps Island via the Old River route was 0 for the second release group, yielding a population estimate of $S_B = 0.11$ ($SE = 0.10$); again, there was no significant difference in population survival estimates between the two routes ($P = 0.1999$) (Table 17).

Survival in the Old River route used the parameter $\phi_{B1,B2}$ in place of S_{B1} because there were no detections at site C1 (MRH) (see *Statistical Methods*). The transition parameter $\phi_{B1,B2} = S_{B1} \psi_{B2}$, so if $\psi_{B2} < 1$, then S_B is underestimated using this formulation. For the first release group, $\phi_{B1,B2} = 1$ ($SE =$

0), so both $S_{B1} = 1$ and $\psi_{B2} = 1$, and S_B is not underestimated (Table A5-2). For the second release group, $\phi_{B1,B2} = 0.67$ ($SE = 0.27$), implying that either $S_{B1} < 1$ or $\psi_{B2} < 1$, or both (Table A5-2). However, there was only a single tag detected at site B1 (ORE) that was not later detected as a smolt at site B2 (ORS), and this tag was actually detected at B2 with a predator classification at that site. Thus, there is no evidence that $\psi_{B2} < 1$ for either release group, and so it is reasonable to interpret estimates of S_B as unbiased rather than as minima. Furthermore, the lack of detections of tags from the second release group at Chipps Island would yield $S_B = 0$ for that release group in any event. Thus, there is no reason to assume that survival to Chipps Island via the Old River route is underestimated.

Survival was estimated to Jersey Point for fish that used the San Joaquin River route. This survival measure ($S_{A(MD)}$) was estimated at 0.09 ($SE = 0.02$) for the first release group, 0.01 ($SE = 0.01$) for the second release group, and 0.06 ($SE = 0.01$) overall (Table 17). No estimates were available for the Old River route. Survival ($S_{A(SD)}$) to the receivers just downstream of the Turner Cut junction on the San Joaquin River (i.e., MacDonald Island and Turner Cut receivers) was estimated at 0.33 ($SE = 0.03$) for the first release group, 0.07 ($SE = 0.02$) for the second release group, and 0.23 ($SE = 0.02$) overall (Table 17). Thus it is apparent that survival was low both to the Turner Cut junction and from that junction to Jersey Point, especially for fish from the second release group.

Survival was lower for the second release group than for the first group throughout the San Joaquin River. Estimated survival from the release site to Mossdale ($\phi_{A1,A4}$) was considerably lower ($p < 0.0001$) for the second release group (0.37 for the second group vs. 0.63 for the first group), as was survival through the Southern Delta (0.07 vs. 0.33; $p < 0.0001$), Middle Delta to Jersey Point (0.01 vs. 0.09; $p < 0.0001$), and the entire Delta to Chipps Island (0 vs. 0.05; $p < 0.0001$) (Table 17). Estimated survival was also lower through the modeled portions of the Old River route, i.e., from the head of Old River to the head of Middle River for the second release group. For the first release group, estimated survival through this reach was 1.0; for the second release group, it was 0.67 ($SE = 0.27$); however, the difference was not statistically significant ($p = 0.1106$) (Table A5-2). Although the estimate for this reach for the second release group had high uncertainty, the point estimate fits the pattern observed in the San Joaquin River of lower survival for the second release group relative to the first release group.

Including predator-type detections in the analysis produced very similar results on all spatial scales, including survival to Chipps Island, Jersey Point, and the Turner Cut junction (Table 18). The largest difference was in estimates of San Joaquin River survival through the Southern Delta to the Turner Cut junction ($S_{A(SD)}$), which increased by 0.01 for both release groups and overall (overall estimate = 0.24, $SE = 0.02$) (Table 18). Including predator detections did not alter the comparisons between release groups; estimated survival was lower for the second release group throughout the various San Joaquin River regions (Table 18; $P < 0.0001$).

Parameter estimates were significantly (family-wise $\alpha=0.10$) higher for the first release group compared to the second release group for parameters S_{A2} , S_{A3} , S_{A4} , S_{A5} , S_{A7} , $\phi_{A8,G1}$, and $\phi_{G1,G2}$ (Table 19).

Travel Time

Average travel time through the system from release at Durham Ferry to Chipps Island was 5.75 days based on 11 detections ($SE = 0.41$ days) (Table 20a). Travel time to Chipps Island ranged from 4.1 days to 10.4 days, all from the first release group. The large majority of tags that reached Chipps Island came via the San Joaquin River route; the single tag that arrived at Chipps Island via the Old River route had a total travel time of 4.12 days, which was faster than any of the 14 tags that arrived via the San Joaquin River route. All tags observed at Jersey Point arrived via the San Joaquin River route in 3 – 9 days, with an average of approximately 6 days (Table 20a).

Travel time from release to the Mossdale Bridge receivers ranged from 0.3 to 3.9 days, and averaged 0.53 days (harmonic mean; $SE = 0.01$ days) (Table 20a). Fish with the longer travel times to Mossdale tended to come from the second release group, although both release groups included fish that arrived in under 8 hours. Travel time from release to the Turner Cut junction receivers (i.e., to Turner Cut or MacDonald Island) ranged from 1.5 days to 8.2 days, and averaged between 2 and 4 days (Table 20a). Fish with the longer travel times to Mossdale tended to come from the second release group, although both release groups included fish that arrived in under 8 hours. Travel time from release to the Turner Cut junction receivers (i.e., to Turner Cut or MacDonald Island) ranged from 1.5 days to 8.2 days, and averaged between 2 and 4 days (Table 20a).

Only 2 tags were detected at the Old River receivers near Highway 4 (OR4). One of these tags came via the Old River route and arrived 4.3 days after release, while the other tag arrived via Turner Cut from the San Joaquin River route 5.1 days after release. For the few tags that were detected at the entrance to the Central Valley Project, tags that came via the Old River route tended to have shorter travel times than tags that arrived via the San Joaquin River route (Table 20a). Sample sizes were too small to draw definitive conclusions, but these observations may have been expected because of the longer route to the interior and western receivers via the San Joaquin River route.

Including predator-type detections had only a small effect on average travel times through the system (Table 20b). Travel times to the San Joaquin River receivers at MacDonald Island and Turner Cut were generally slightly longer when predator-type detections were included. This was because travel times were measured to the beginning of the tag's final visit to each site, and many tags classified as being in predators at those sites were observed making multiple visits to those sites. The longer travel times observed for the data set that includes the predator-type detections reflect the assumption used in the predator filter that predators are more likely than smolts to exhibit long travel times.

Average travel time through reaches for tags classified as being in smolts ranged from 0.01 days (approximately 20 minutes) for the single tag observed moving from the Central Valley Project trashracks to the holding tank, to over 2 days for tags moving from MacDonald Island to Jersey Point, and over 3 days for tags moving from MacDonald Island and Medford Island to Chipps Island (Table 21a). While there were several tags that moved from MacDonald Island to Jersey Point in under 2 days, there

were also several tags that took over 5 days to make the journey. Similar travel times were observed from the Medford Island receivers to the Jersey Point receivers, although the average travel time was somewhat lower from Medford Island (approximately 1.54 days over both release groups) (Table 21a). The reach from MacDonald Island to Jersey Point was one of the longer reaches in the study area (approximately 26 rkm), so it not surprising that it had some of the longer observed travel times. However, the reach from Jersey Point to Chipps Island was also approximately 26 rkm in length, and travel time through this reached tended to be shorter, ranging from 16 hours to 2.1 days and averaging 1.21 days ($SE = 0.14$ days) (Table 21a). The region between Jersey Point and Chipps Island is strongly affected by tides, which may delay migrating fish, but it is nevertheless channelized. The region between MacDonald Island and Jersey Point, on the other hand, includes Frank's Tract, and it is possible that migrating Chinook Salmon smolts are delayed there for a considerable time. In general, there were too few detections in the interior Delta to make comparisons of travel time through reaches in that region with travel time through reaches contained within the San Joaquin River route. Including predator-type detections did not greatly affect the pattern of observed travel times through the various reaches (Table 21b).

There was a significant negative relationship ($p < 0.05$) between travel time per km and survival per km in river reaches upstream of the Lathrop/Old River junction for the second release group, suggesting as travel time per km increased, survival per km decreased (Figure 11, Table 22). Survival also decreased as travel time increased in reaches between Durham Ferry and Lathrop/Old River junction for the first release group, but the regression line was not significant at the $p < 0.05$ level. Survival was higher for the first release group, than for the second release group in these three reaches of the river (Figure 11, Table 19). Also there appeared to be a slight increase in travel time (slower migration rate) between Mossdale and Lathrop/Old River junction and between Banta Carbona and Mossdale for the second release group relative to the first release group (Figure 11, Table 22).

In contrast, there did not appear to be a relationship between travel time per km and survival per km for reaches between the Lathrop/Old River junction and Jersey Point (tidal reaches) for either of the release groups in 2012 (Figure 12). While survival through the reach (or joint probability of moving to and surviving to the downstream location) was significantly higher (Table 19) for the first release group for three of these reaches in the San Joaquin River downstream of Lathrop (Lathrop to Garwood Bridge, S_{A5} ; Navy Drive Bridge to MacDonald Island or Turner Cut, S_{A7} ; and the reach between MacDonald Island to Jersey Point, $\phi_{A8,G1}$ [not shown on Figure 12]), others were not significantly higher (e.g. Garwood Bridge to Navy Bridge Drive [S_{A6}], MacDonald Island to Medford Island [$\phi_{A8,A9}$], and Medford Island to Jersey Point [$\phi_{A9,G1}$]) (Table 19). Travel times in these reaches were similar for the two release groups (Figure 12).

Route Entrainment Analysis

River flow (discharge) at the TRN gaging station in Turner Cut ranged from -4,402 cfs to 3,361 cfs (average = -1070 cfs) during the estimated arrival time of the tagged Chinook Salmon at the Turner Cut junction location (TCJ) in 2012. Water velocity in Turner Cut was highly correlated with river flow ($r = 0.999$), and velocity values ranged from -0.8 ft/s to 0.6 ft/s (average = -0.1 ft/s). The flow in Turner

Cut was negative (i.e., directed to the interior Delta) upon arrival at TCJ of approximately 61% (54 of 89) tags in this analysis. River stage measured in Turner Cut was moderately correlated with both river flow and velocity ($r=-0.70$), and ranged from 6.7 ft to 10.9 ft (average = 9.1 ft). Changes in river stage in the 15-minute observation period containing the arrival of the tagged Chinook Salmon to the TCJ ranged from -0.2 ft to 0.2 ft (average = 0 ft). Changes in river stage were not correlated with stage ($r=-0.13$). The index of river flow in the reach from Stockton to Turner Cut was uncorrelated with flow and velocity in Turner Cut upon arrival at TCJ ($r= 0.01$), and only moderately correlated with river stage at Turner Cut ($r= -0.29$). The flow index in the Stockton-Turner Cut reach ranged from 2,324 cfs to 3,400 cfs (average = 2,785 cfs).

The daily export rate at CVP ranged from 821 cfs to 1,016 cfs (average = 960 cfs); exports at CVP were generally low in both early and late May, and was greatest in mid-May. The daily export rate at the State Water Project (SWP) ranged from 507 cfs to 3,698 cfs (average = 1,908 cfs). SWP exports were more variable than CVP exports but also peaked in the third week of May. Exports from CVP and SWP were uncorrelated ($r= -0.01$). Neither CVP nor SWP exports was correlated with either flow ($r=0.09$ for CVP, $r=-0.03$ for SWP) or river stage ($r=0.00$ for CVP, $r=-0.14$ for SWP) in Turner Cut. The majority of tags (66 of 89, 74%) arrived at the Turner Cut junction during daylight hours.

The single-variate analyses found no significant effects ($\alpha=0.05$) of any of the covariates considered ($P>0.40$ for all covariates; Table 23). This negative result may reflect the true lack of a relationship between environmental variables and route selection at Turner Cut, or it may be an artifact of the low degrees of freedom available and the resulting low statistical power; because only 11 fish were observed entering Turner Cut (out of 89), there were only 11 degrees of freedom total. A study with a larger sample size and more fish observed using Turner Cut may provide evidence of a relationship between one or more of the covariates and route selection at this junction in future.

Comparison of Delta Survival to Past Years

In a multiple regression, tag type (acoustic or CWT) did not come out as an important variable affecting survival, whereas flow did (Table 24). Using the relationship developed from the CWT data (Figure 13), we calculated what survival from Mossdale to Jersey Point was expected to be at the two flow levels in 2012: predicted survival was 0.12 at flows of 3543 cfs and 0 at flows of 2327cfs, very close to what we observed (0.09, $SE = 0.02$, at the higher flow and 0.01, $SE = 0.01$, at the lower flow). The relationships between flow at Vernalis and survival from Mossdale to Jersey Point with the HORB, developed from the historical CWT data and from all of the data (historic CWT data and acoustic tag data added from 2012), were similar (Figure 13). The slopes of the two linear regression lines were the same (0.0001), and the intercepts were similar (-0.2345 for the CWT data only and -0.2295 for the combined data (Figure 13)) . Both relationships were statistically significant ($p < 0.01$).

Discussion

The similarity between parameter estimates with and without predator-type detections raises questions about the predator filter. One possible explanation for the similar estimates is that the

majority of the mortality was not directly caused by the predatory fish used to build the predator filter, or that many of the predatory fish feeding on the tagged salmon merely evaded detection. Chinook Salmon smolts may have been eaten by sedentary predators, birds, or mammals (e.g., otters), or by predatory fish that moved about the Delta but evaded the acoustic receivers. Alternatively, Chinook Salmon smolts may have died due to disease or habitat quality. In either case, the tags of the deceased salmon smolts may have settled on the river bottom away from the acoustic receivers; in these cases, the predator filter would correctly identify existing detections of these tags as in smolts rather than predators, and the survival model estimates would be unbiased.

Another possibility is that the filter missed detections of predators, and thus the resulting filtered data set (which supposedly has no detections from predators) is only artificially similar to the unfiltered data set (which includes detections from predators). If this is the case, then survival estimates for the (presumed) smolt-only data set would be biased because they would be based partially on predator detections. The type of bias depends on where the predator filter failed. For example, none of the tags detected at Chipps Island were classified as being in predators by the existing filter. A filter that recategorizes some of those detections as predator detections may yield survival estimates to Chipps Island that are lower than that estimated in this study (0.03). This would happen as long as the revised filter agreed with the original filter in upstream regions. On the other hand, if the predator filter was inefficient (i.e., wrong) upriver of Mossdale such that detections passed by the filter as smolts were actually detections of predators, then it is possible that true survival to Chipps Island was actually higher than estimated (0.03); this may happen if there were fewer actual smolts starting at Mossdale than appeared from the original filter. Of the 959 tags released at Durham Ferry, only 480 (50%) were detected at Mossdale, and 478 of them were classified as in smolts upon arrival at Mossdale (Tables 9 and 13). Only 15 of these tags were detected at Chipps Island. Adjusting the predator filter cannot add more detections at Chipps Island, but it may remove detections at Mossdale. A revised filter that used more stringent criteria upstream of Mossdale was constructed and implemented on the detection data. The revisions to the filter were:

- no upstream-directed transitions allowed upstream of Mossdale
- no repeat visits to sites upstream of Mossdale
- maximum residence time of 2 hours at any site upstream of Mossdale
- maximum regional residence time of 15 hours upstream of Mossdale
- minimum migration rate of 0.2 km/hr for all transitions upstream of Mossdale

This stricter filter resulted in 477 of the 480 detections at Mossdale being classified as in smolts, compared to 478 classified as in smolts using the original predator filter. The Delta survival estimate from the stricter predator filter was 0.03 for the population (i.e., both release groups pooled), unchanged from the estimate using the original filter. Thus, it is unlikely that errors in the predator filter resulted in the similar results with and without the predator-type detections.

Our first objective of the 2012 study was to determine survival of emigrating salmon smolts from Mossdale to Chipps Island during two time periods (prior to May 15 and after May 15) in the presence of the HORB to determine if there was a benefit from the flow augmentation from the Merced

River in 2012. Average river flow measured at the Vernalis gaging station when fish from the first release group were traveling through the Delta to Chipps Island (from release through approximately 10 days after the end of release period) was 3,543 cfs, while for the period of comparable length for the second release group was 2,327 cfs (Figure 14). Survival was higher ($p < 0.0001$) through the Delta (S_{Total}) for the first release group (0.05) relative to the second release group (0.00) (Table 17). Thus these findings appear to support our hypothesis that the increased flow from the Merced River flow augmentation increased survival through the Delta.

Our second objective was to assess whether the higher flows from the Merced River flow augmentation resulted in a reduction in travel time and higher survival, specifically in the riverine reaches of the Delta, and resulted in higher through-Delta survival. Shorter travel times would reduce the time tagged fish were exposed to mortality factors such as predation, high water temperatures, and toxics. Travel times in reaches of the Delta between Durham Ferry and a series of downstream locations (Mosssdale, Lathrop, Garwood Bridge, Navy Drive Bridge, and MacDonald Island) were all significantly less (i.e. faster migration) for the first release group than the second release group (Table 20a; $p < 0.05$). The travel times in these reaches appeared to be strongly influenced by the travel time for the reach between Lathrop (SJL) and Garwood Bridge (SJG). Travel time between SJL and SJG was significantly less ($p < 0.05$) for the first release group (0.60; $SE = 0.02$) which experienced the higher flows, than for the second release group (0.86; $SE = 0.05$) which experienced the lower flows (Table 21a). Survival through this reach was also higher for the first release group (0.81; $SE = 0.02$) relative to the second release group (0.48; $SE = 0.04$) ($p < 0.0001$) (S_{A5} ; Table A5-2). Thus, the data in this specific, partly riverine, reach of the Delta are consistent with our hypothesis that an increase in flow would reduce travel time and be associated with higher survival.

To further evaluate the possible relationship between travel time and survival in the remaining reaches, travel time and survival were standardized to a per-km basis. With this standardization, we found that as travel time per km increased, survival decreased for both release groups in the three riverine reaches between Durham Ferry and the Lathrop/Old River junction (Figure 11). Travel time per km was greater for the second group relative to the first group for two of the three reaches; (Banta Carbona to Mosssdale and Mosssdale to Lathrop/Old River, but not Durham Ferry to Banta Carbona) whereas survival was always lower for the second release group (lower flows) relative to the first group (higher flows) for these three reaches (Figure 11, Table 22). Thus the difference in travel time per km for the first group relative to the second did not always support our hypotheses that the higher survival per km resulted from a decrease in travel time per km from the higher flows in these riverine reaches.

Travel time per km was somewhat less and survival greater for the first release group relative to the second release group in two reaches: 1) between Lathrop and Garwood Bridge (discussed above) and 2) between Garwood Bridge and Navy Bridge Drive (Figure 12, Table 22); the shorter travel time from the increased flow may partially explain the higher point estimate of survival for release 1 compared to release 2 between Garwood Bridge and Navy Bridge, although the increase in survival is not statistically significant at the 5% level (Table 19); however, it is not possible to determine causation from this study.

Once fish enter the interior Delta or into the strongly tidally influenced San Joaquin River, travel times were expected to increase and survival was expected to decrease. While we did generally see longer travel times per km in the tidal reaches (reaches downstream of Navy Bridge Drive), it was not always greater (Table 22; e.g. travel time per km was shorter from MacDonald Island to Medford Island than it was from Lathrop to Garwood Bridge). Travel time per km was also less for the second release group than for the first, even though survival was generally higher for the first group relative to the second in all reaches downstream of Navy Bridge Drive, except between MacDonald Island and Medford Island, when survival per km was higher for the second group (Table 22). Since the increased flow probably was not enough to change velocities significantly in the downstream tidal reaches, the increased survival of the first group relative to the second in most of these tidal reaches suggests there are other mechanisms either associated with flow or other factors that resulted in the increases in survival in these tidal reaches of the Delta.

Once fish move into the interior Delta, they are exposed to flows moving toward the export facilities, which may increase their travel time and reduce their survival to Jersey Point or Chipps Island. While many of the tagged fish may have been diverted from the San Joaquin River into the interior Delta downstream of Turner Cut, we were only able to identify those entering the interior Delta through Turner Cut. We had hypothesized that tagged fish moving into the interior Delta (e.g. Turner Cut) would have increased travel times over those not being diverted into Turner Cut. Since none of the tagged fish that entered Turner Cut survived to Chipps Island for either the first or second release group, we could not compare travel times between release groups or for the Turner Cut route relative to the other routes. One fish that entered Turner Cut from the first release group was observed in the CVP holding tank, but did not survive to reach Chipps Island. We were also not able to assess the impact on survival of tagged fish being routed to the SWP and CVP as detections from the receivers at the entrances to the water export facilities and in the holding tank at the Central Valley Project were removed from the survival model because of sparse data due to the presence of the HORB.

The results of comparing travel time to survival suggests that the increased flow during the first release did not always result in decreased travel times, although it did coincide with an increase in survival in more of the riverine reaches. It was the higher survival in the majority of the reaches (both riverine and tidal) during the first release that resulted in a higher overall survival through the Delta for the first release group relative to the second release group.

However, there are other possible hypotheses for the lower survival in the second release group compared to the first release group, including differences in fish condition, tagging and release procedures, and other environmental conditions. The same tagging and release procedures were used for both release groups, including the same taggers, presumably with the same skill set, so that does not appear to be responsible for the differences in survival we observed. Fish from the second release group were slightly larger on average than fish from the first release group (mean FL = 109.9 mm and 115.7 mm for the first and second release groups, respectively), so it was reasonable to expect higher survival for the second release group rather than lower survival, but we did not observe this. Although the two release groups were released only two weeks apart, they experienced different environmental conditions other than flow. During the same two time periods, combined exports at CVP and SWP varied from 1,513 cfs to 5,054 (mean = 3,200 cfs), with similar means in the two periods. However,

exports tended to be high toward the end of the first period, when relatively few fish from the first release were still migrating, and also high near the beginning of the second period, when the majority of fish from the second release group were migrating (Figure 15).

It is also possible that the difference in flow conditions may have resulted in the different survival rates via a mechanism other than travel time, such as temperature, increased predation or toxicity. We had hypothesized that the higher inflow from the Merced flow augmentation would potentially reduce the effects of these mortality factors by reducing temperature stress, diluting toxics or reducing predator metabolic demands from the lower water temperatures. Water temperature measured at the San Joaquin River gage near Lathrop was almost 2 degrees higher on average for the second release group (67.5 °F [19.7°C]) than for the first group (65.6 °F [18.7°C]), which may have negatively affected the survival of the second release group, and been a consequence of the lower flows experienced by the second release group (Figure 16). We were unable to assess the hypothesis that increased metabolic demands from predators due to the warmer water temperatures was the cause for the increased mortality for the second release group relative to the first release group.

To assess the hypothesis that the increased flow from the Merced River flow augmentation may have diluted toxicity in the Delta, we observed that survival was significantly higher for the first group relative to the second group in the reach between SJL and SJG (Table 19). This reach from SJL to the SJG is one of the longer reaches of the Delta at 18 km (Table 22), and it includes a variety of habitats. It is not entirely riverine, but includes the transition to tidal habitat, depending on inflow. The reach is more riverine at higher inflows, and more tidal at lower inflows. The Stockton Wastewater treatment plant releases its effluent in the lower part of this reach which may have an effect on survival, especially during periods of low flow. During periods of low flow the movement of the tidal prism upstream may result in concentration of the effluent in this reach and dilution from flow would be less. There is also the possibility that increased temperatures exacerbate the toxicity effects of the effluent on juvenile salmon survival. Further evaluation of water quality in this reach may be warranted, building on studies conducted near there in 2008 (SJRG 2009) after a significant die-off of acoustic tags near this location in 2007 – a low flow year (SJRG 2008).

In addition, it is possible that the higher incidence of PKD infection for the second release group reduced their survival to Chipps Island relative to the first release group. Infection does not necessarily lead to death but would reduce fitness from anemia, kidney dysfunction, and immune suppression even if the fish survived the disease (Angelidis et al 1987, Hedrick and Aronstien 1987 as cited in Nichols et al 2012). The increase in water temperature may have contributed to the higher incidence of PKD infection for the second release group relative to the first as PKD is a progressive disease at water temperatures greater than 15°C (Okamura and Wood 2002 as cited in SJRG 2013).

Unfortunately, PKD infection is not just a problem for the experimental fish we used in 2012, but was noted as a problem in monitoring on the Merced River. Smolts caught in the Hopeton rotary screw trap on the Merced River (presumably wild stock) also had high levels of PKD infection in 2012 (Nichols et al. 2012). This is also not new, as 90-100% of naturally produced fish in a 2001 survey of Merced outmigrant salmonid health were observed to be infected with PKD (Nichols and Foott 2002 as cited in Nichols et al. 2012). Even some of salmon transferred from MRH to the lab at the Fish Health Center soon after ponding in February of 2012, developed light infections of PKD (Nichols et al 2012).

However, the worst infections identified in the 2012 study were later in the season, with gross clinical signs of PKD (anemia and swollen kidney) observed for naturally produced fish on May 9 (2 out of 24), and high numbers of parasites observed for both naturally produced (May 9 and May 15) and hatchery fish (May 15) (Nichols et al. 2012).

PKD is caused by infection by the endoparasitic myxozoan, *Tetracapsuloides bryosalmonae*. Reducing byrzoan habitat directly upstream of the hatchery and in the Merced River could be a viable disease management strategy (Foott et al. 2007). Increasing flows, if they result in decreasing water temperatures, would serve to reduce the severity of PKD for both experimental and wild fish emigrating from the San Joaquin basin. Higher water temperatures in the river and at the hatchery may have increased the severity of the PKD infection for the second group of tagged fish in 2012, relative to the first group; this may account for some of the increased mortality observed in the second group. Higher water temperatures are affected by both flow and air temperature upstream of the Delta. Cold water releases from the upstream reservoir on the Merced River may have reduced the water temperatures for the first release group over what they would have been without the water release.

Our third objective of the 2012 study was to identify route selection at HOR and at Turner Cut under the two different periods with varying flows and exports. Since the physical HORB was in place in 2012, route selection into the San Joaquin River was high for both groups (0.98; $SE = 0.02$) and did not vary between release groups (Table 17) or when predator type detections were included (Table 18). Route selection at Turner Cut was 0.11 ($SE = 0.03$) for the first release group, and 0.16 ($SE = 0.11$) for the second release group (Table 17) when predator-type detections were removed and similar when predator-type detections were included (0.12; $SE = 0.03$ for the first release group and 0.14; $SE = 0.04$ for the second release group) (Table 18). Differences in the proportion diverted into Turner Cut at the TCJ between release groups were not statistically different: with 11 to 16% of the tagged fish diverted into Turner Cut, none of which survived to Chipps Island ($S_{F1,G2}$; Tables A5-2 and A5-3). Zero probability of survival to Chipps Island for the tagged fish that entered Turner Cut negatively affected total through-Delta survival for both release groups. A study with a larger sample size and more fish observed using Turner Cut may provide evidence of a relationship between one or more covariates (e.g. flow, and tides) and route selection at this junction in future.

It is possible that the lower flows, higher water temperatures, higher toxicity, higher incident of disease (PKD) and possibly higher export rates during the time of peak migration may have combined to negatively affect salmon survival from the second release. Diversion into Turner Cut decreased survival of both groups. With only two release groups and observational data, however, it is not possible to conclude more. Combining these results with those from additional years may shed light on possible causes of mortality in the Delta. The Interagency Ecological Program has funded a multi-year analysis of the data from 2010, 2011, 2012 and 2013 and results will be forthcoming.

Based on the results of this study in 2012, naturally spawned or hatchery juvenile salmonids from the San Joaquin tributaries likely experienced variable survival within the migration period through the Delta, with greater survival during the Merced River flow augmentation period and lower survival during the later remainder period of migration. Higher flows appeared to benefit survival through

multiple intertwined mechanisms including shorter travel times, lower water temperatures, and reduced disease impacts.

The comparison of estimates of survival from Mossdale to Jersey Point for the two release groups in 2012, to estimates generated using CWT's with the HORB, suggests that survival observed in 2012 was within that expected based on the past CWT relationship, and that differences in flow between the two releases in 2012 likely increased survival over what it would have been without the flow pulse. However, without direct manipulation and further replication, cause and effect cannot be determined. While this comparison supports our hypothesis that the increased flow from the flow augmentation in the Merced River during the first release group increased survival, it also shows that survival for both groups in 2012 was relatively low, compared to that measured in other years with the HORB (Figure 13). These data suggest a higher flows of approximately 6,000 cfs with the HORB, are needed to achieve survival through the Delta of approximately 0.40. Additional studies, especially during higher flow periods, with the HORB in place, are needed to confirm these results.

Acknowledgements:

Funding for the project came from the restoration funds of the Central Valley Project Improvement Act, the U.S. Bureau of Reclamation, and the Department of Water Resources. Several individuals from a variety of agencies made this project possible. Those agencies and individuals who participated in the tagging and release components of the project were; USFWS: Amber Aguilera, Denise Barnard, Crystal Castle, Dustin Dinh, David Dominguez, Kyle Fronte, Garrett Giannetta, Jack Ingram, Carlie Jackson, Joseph Kirsch, David LaPlante, Jerrica Lewis, Mike Marshall, Louanne McMartin, Greg Nelson, Jacob Osborne, Lori Smith, Brent Trim, and Rob Wilson; California Department of Water Resources: Roxanne Kesler, Bryce Kozak, and Matt Silva; AECOM: Curtis Yip; and USBR: Raymond Bark and Josh Israel. USGS provided training for the surgeons (Theresa [Marty] Liedtke) and was responsible for the deployment, maintenance and retrieval of the receiver array (Jon Burau, Chris Vallee, Jim George and Norbert VandenBranden). Mike Simpson, retired from USGS, processed the data prior to giving it to Rebecca Buchanan of University of Washington for analyses.

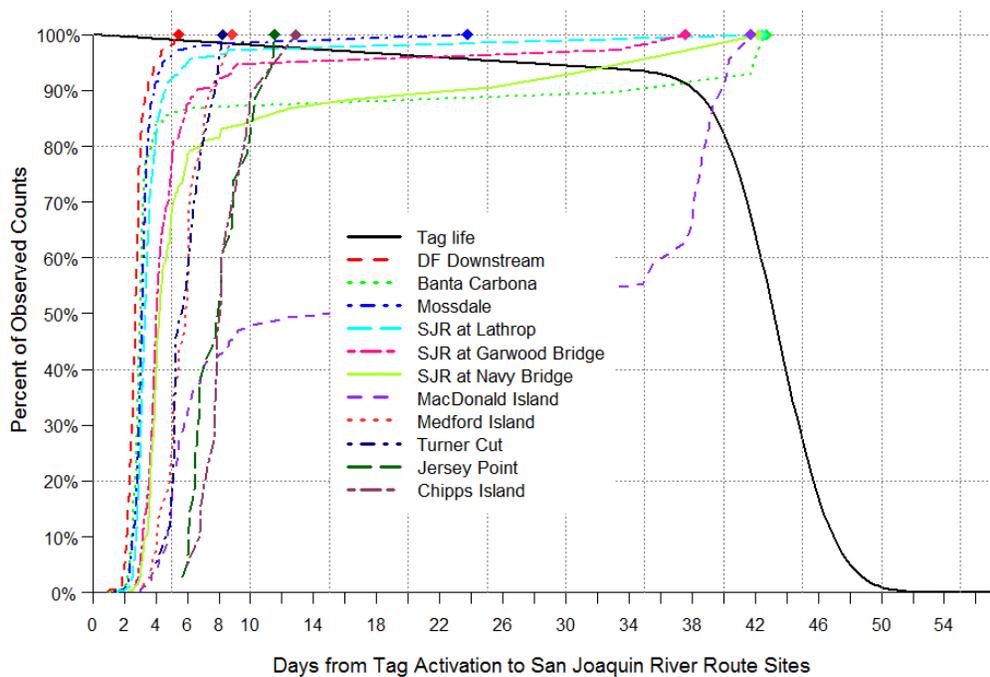

Figure 8. Four-parameter vitality survival curve for tag life, and the cumulative arrival timing of acoustic-tagged juvenile Chinook Salmon at receivers in the San Joaquin River route to Chipps Island in 2012, including detections that may have come from predators.

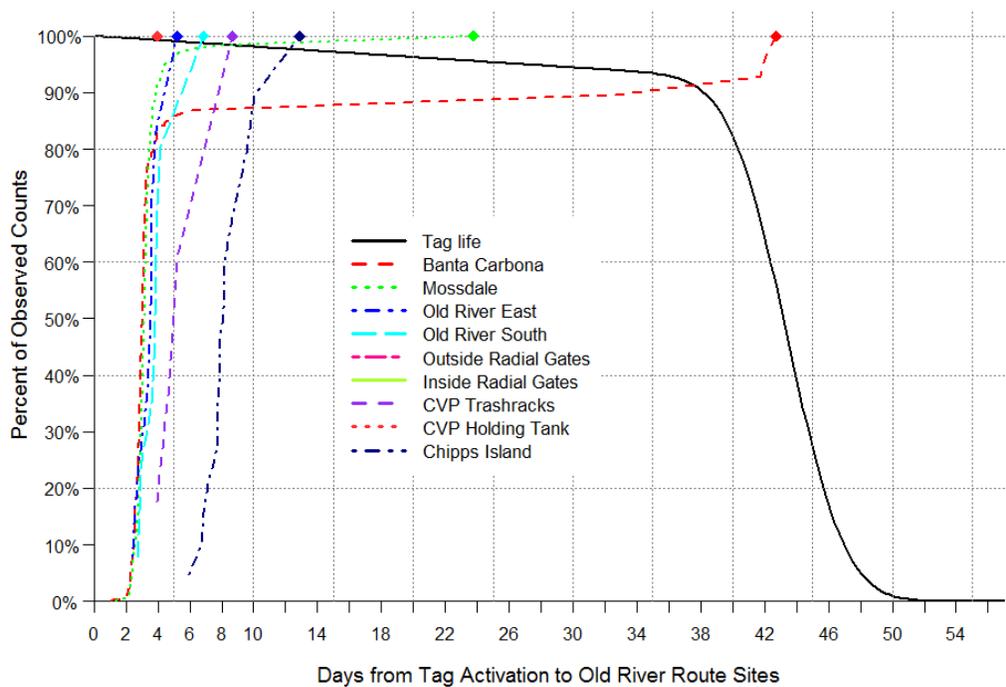

Figure 9. Four-parameter vitality survival curve for tag life, and the cumulative arrival timing of acoustic-tagged juvenile Chinook Salmon at receivers in the Old River route to Chipps Island in 2012, including detections that may have come from predators.

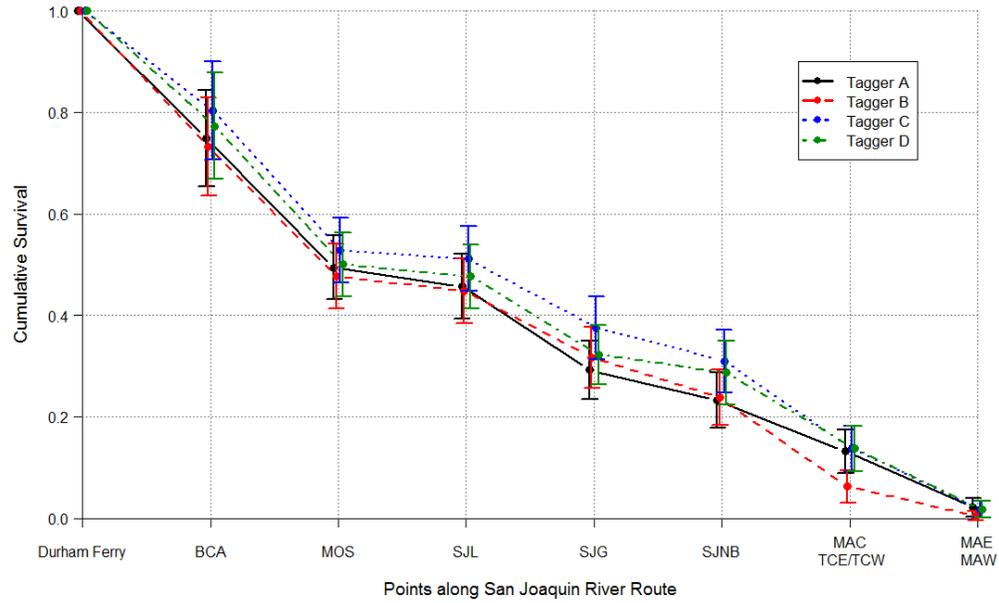

Figure 10. Cumulative survival from release at Durham Ferry to various points along the San Joaquin River route to Chipps Island, by tagger. Error bars are 95% confidence intervals.

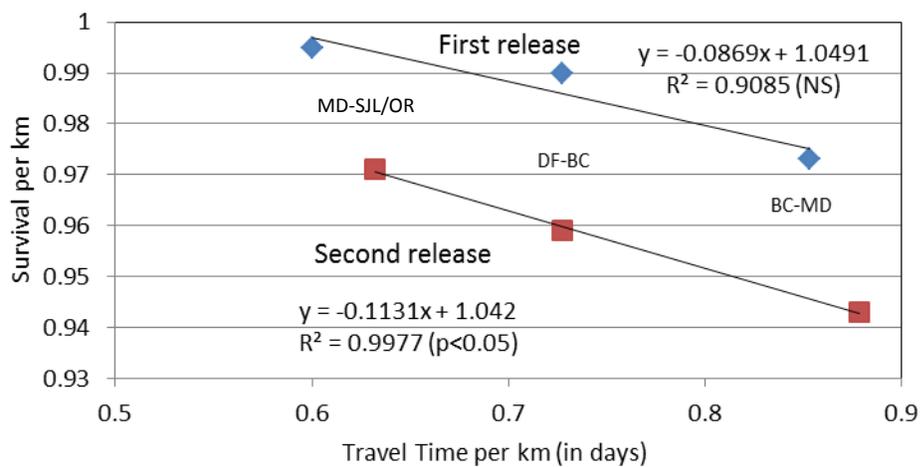

Figure 11: Travel time per km (in days) versus survival per km for river reaches, upstream of Mossdale in release group 1 and release group 2. Survival and travel time were without predator-type detections. Refer to Table 22 for data used.

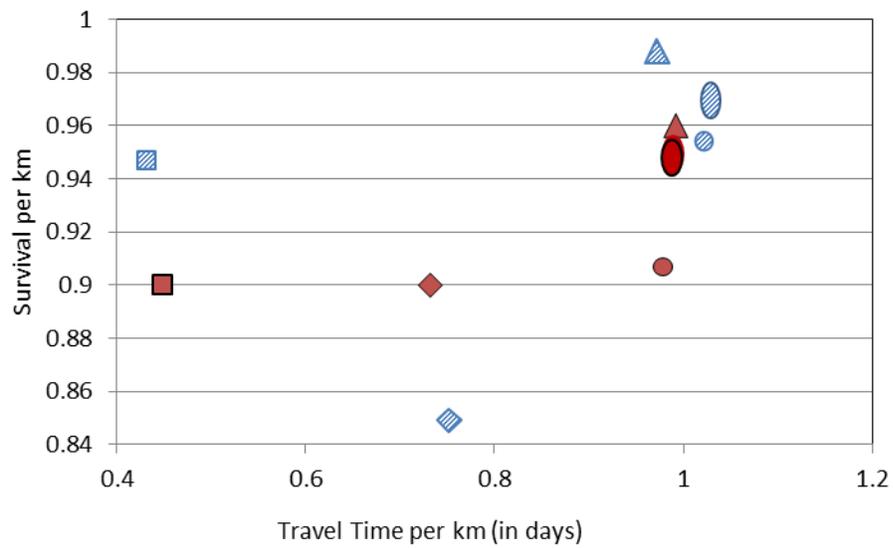

Figure 12: Travel time per km (in days) versus survival per km for reaches in the San Joaquin Delta for release group 1 (blue diagonal) and release group 2 (red solid). From Upstream to Downstream, reaches in order are: Lathrop to Garwood Bridge (triangles), Garwood Bridge to Navy Bridge Drive (squares), Navy Bridge to Turner Cut Junction (circles), MacDonald Island to Medford Island (diamonds) and Medford Island to Jersey Point (ovals). No recoveries were made at Chipps Island for the second release group to estimate travel time from Jersey Point to Chipps Island.

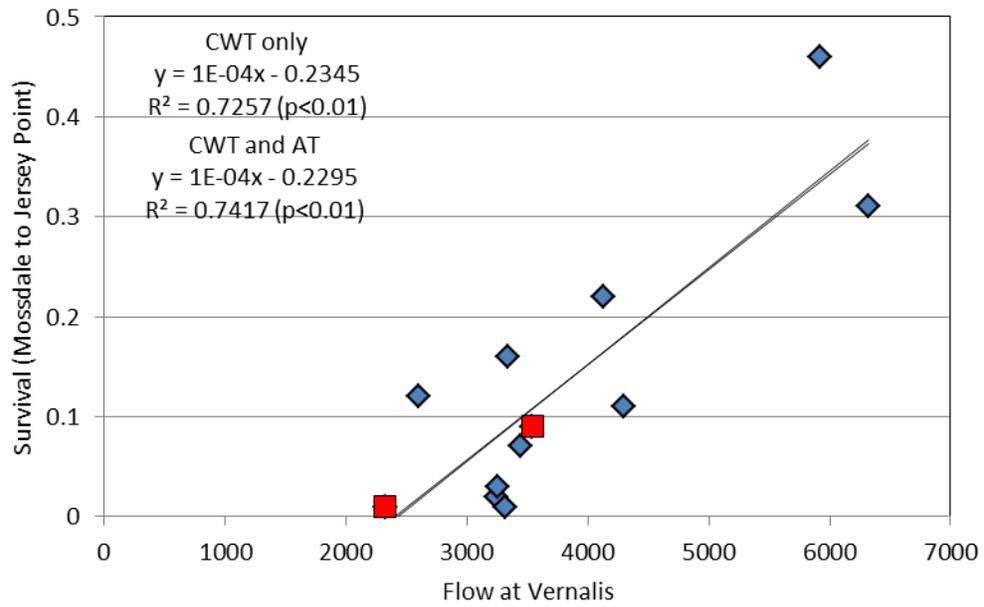

Figure 13: Estimates of survival between Mossdale and Jersey Point for CWT salmon (blue diamonds) and acoustic tag fish in 2012 (red squares) with the physical head of Old River barrier installed. Linear regression lines are plotted for both sets of data but overlap.

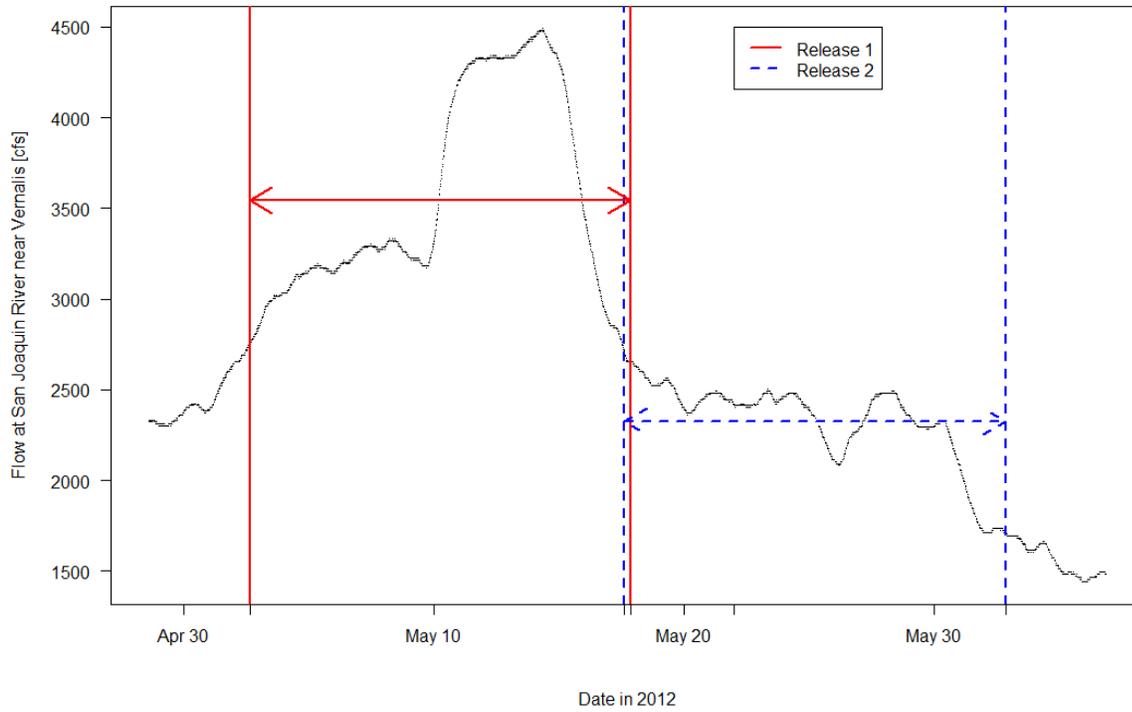

Figure 14. River discharge (flow) at Vernalis during 2012 study. Vertical lines represent expected period of travel from initial release at Durham Ferry to Chipps Island, based on release dates and maximum observed travel time over both releases. Arrow heights indicates mean flow during travel period.

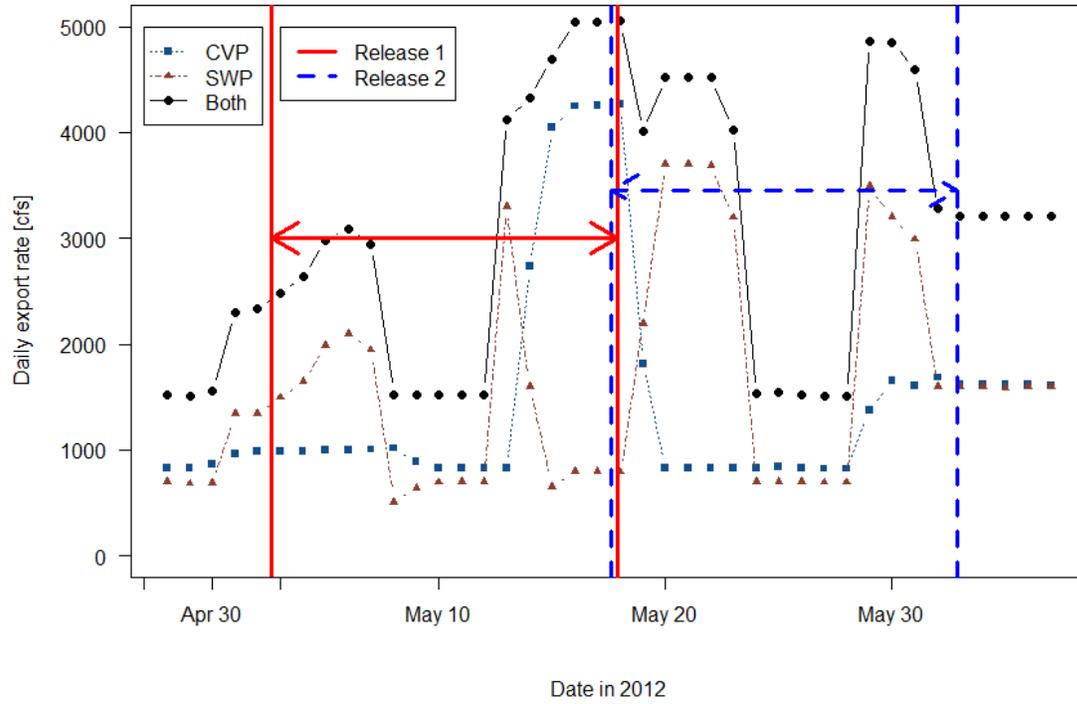

Figure 15. Daily export rate (cfs) at CVP and SWP during 2012 study. Vertical lines represent expected period of travel from initial release at Durham Ferry to Chipps Island, based on release dates and maximum observed travel time over both releases. Arrow height indicates mean combined export rate during travel period.

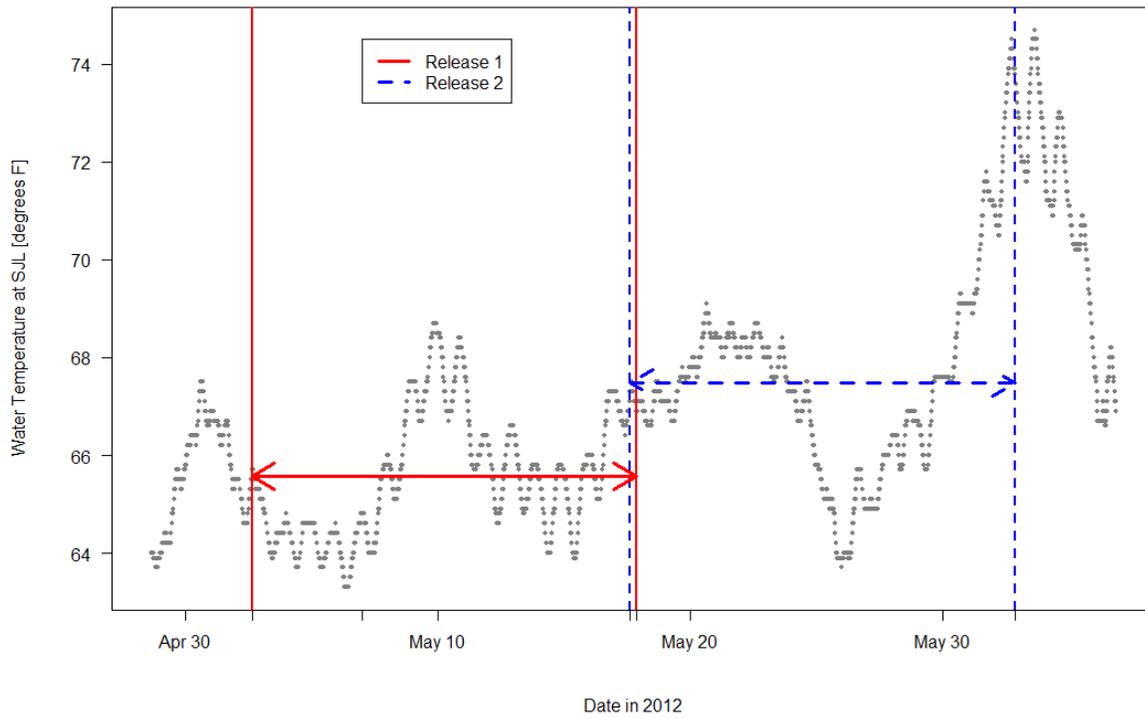

Figure 16. Temperature (°F) at the San Joaquin River gaging station near Lathrop during 2012 study. Vertical lines represent expected period of travel from initial release at Durham Ferry to Chipps Island, based on release dates and maximum observed travel time over both releases. Arrow height indicates mean temperature during travel period.

¹ one tag not used in analyses; tag looked odd, ² released from shore due to high winds or dead battery in boat.

Table 2. Characteristics assessed for Chinook Salmon smolt condition and short-term survival

Characteristic	Normal	Abnormal
Percent Scale Loss	Lower relative numbers based on 0-100%	Higher relative numbers based on 0-100%
Body Color	High contrast dark dorsal surfaces and light sides	Low contrast dorsal surfaces and coppery colored sides
Fin Hemorrhaging	No bleeding at base of fins	Blood present at base of fins
Eyes	Normally shaped	Bulging or with hemorrhaging
Gill Color	Dark beet red to cherry red colored gill filaments	Grey to light red colored gill filaments
Vigor	Active swimming (prior to anesthesia)	Lethargic or motionless (prior to anesthesia)

Table 3. Names and descriptions of receivers and hydrophones used in the 2012 Chinook Salmon tagging study, with receiver codes used in Figure 2, the survival model (Figures 2 – 5), and in data processing by the United States Geological Survey (USGS). The release site was located at Durham Ferry.

Individual Receiver Name and Description	Hydrophone Location		Receiver Code	Survival Model Code	Data Processing Code
	Latitude (°N)	Longitude (°W)			
San Joaquin River near Durham Ferry upstream of the release site, upstream node	37.685806	121.256500	DFU1	A0a	300856
San Joaquin River near Durham Ferry upstream of the release site, downstream node	37.686444	121.256806	DFU2	A0b	300857

d = Release group 1 had significantly higher survival than release group 2 ($P < 0.0001$).

Table 19. Estimates (standard errors in parentheses) of model survival and transition parameters by release group, and of the difference (Δ) between release group estimates: Δ = Release group 1 - Release group 2. P = P-value from one-sided z-test of $\Delta > 1$. Estimates were based on data that excluded predator-type detections. * = significant (positive) difference between release groups for family-wise $\alpha=0.10$.

^aThese reaches are in the Old River route

Table 20a. Average travel time in days (harmonic mean) of acoustic-tagged juvenile Chinook Salmon from release at Durham Ferry during the 2012 tagging study, without predator-type detections (see Table 20b for travel time from release with predator-type detections). Standard errors are in parentheses. There were no detections at the MRH, RGU, or RGD sites; all tags detected at FRE/FRW or MR4 were later detected at competing receivers, so those sites are omitted here.

Appendices 1-5:

Appendix 1. Analyses of CWT salmon released in the south Delta by Ken Newman as part of the VAMP peer review in 2010.

Analyses of Salmon CWT Releases into the San Joaquin System
 Ken B. Newman, USFWS
 2 March 2010

1. Overview

- Objectives: to understand how different factors (flows, exports, barrier at head of Old River, HORE) affect survival of juvenile salmon outmigrating from San Joaquin system
- Data Generation: CWT Release-Recovery "sets", 4-5 release locations and 2-3 recovery locations
- Data Analysis: (Bayesian) Hierarchical Models
- Key Results: Usually higher survival if stay in San Joaquin River than if go down Old River BUT lots of Environmental Variation, i.e., low Signal:Noise Ratio!

2. Data Generation

- (a) Between 1985 and 2006, 35 Release-Recovery sets.
- (b) Within a set, at most 3 release locations (e.g., Mossdale, Dos Reis, and Jersey Point).
- (c) At most 3 recovery locations: Chipps Island, Ocean fisheries, and since 2000, Antioch
- (d) \Rightarrow 212 observations

3. Data Analysis

- (a) BHMs (Bayesian Hierarchical Models)
- (b) Key idea: 2 or more levels of modeling

5. Caveats and Comments

- Priors *do* matter, especially with Hierarchical Models
- More to wring out of CWTs? Using time of capture? Add arrival time/travel time model?
- Acoustic tags far preferable?
- Value in probing extreme values for flows and exports

Appendix 2: Standard Operating Procedure

Acoustic Tagging for Salmon 2012 South Delta Studies 4/10/12 (file dated 4/23/12)

Equipment Set Up:

- Fill surgical instrument disinfection trays with chlorhexidine (brand name Nolvasan)
 - Autoclave instruments such that each tagging event begins with sterile instruments
- Activate transmitters and confirm operational status
 - Position the transmitter in an isolated compartment to enable tracking of the transmitter ID through the implantation process
- Disinfect transmitters in chlorhexidine
 - Ensure at least 20 minutes of contact time with chlorhexidine
 - Following disinfection, thoroughly rinse transmitters in distilled or de-ionized water prior to implantation
 - Following disinfection, transmitters should only be handled by gloved hands or clean surgical instruments such as forceps
- Fill rinse tray with de-ionized or distilled water
- Set up scale, measuring board, and surgical platform or foam
 - Apply stress coat to weigh boat, measuring board, and platform to reduce damage to fish skin or mucus layer
- Fill gravity feed carboys. Add 2 ml of the MS-222 stock solution and 2 ml of the sodium bicarbonate stock solution to the 10 L of water in the MS-222 carboy. Concentration may be increased upon group consensus and in consultation with coordinator.
- Fill anesthesia container to indicated volume line. Set the initial concentration in collaboration with the tagging coordinator. Suggested starting concentration is 70 mg/ L. Concentration may be adjusted upon group consensus and in consultation with coordinator. Concentration changes should be executed for all taggers simultaneously and recorded on the tagging datasheet.
- Prepare recovery containers by filling with water, adding stress coat, and supersaturating with oxygen
 - Immediately following surgery fish will be held in recovery containers that provide 130% to 150% DO for a minimum of 10 minutes
 - Holding time in recovery containers begins when the last fish is added to the container and will be monitored using a timer
- Prepare a reject container for fish that cannot be tagged by filling with water and equipping with a bubbler . These fish will be returned to a separate holding tank.
- Start tagging data sheets. Note the time the tagging session was started and complete all appropriate data fields. Start a Daily Fish Reject Tally datasheet to account for fish that are handled but not tagged.
- The tagger should wear medical-grade exam gloves during all fish handling and tagging procedures
- Prepare the transport truck to accept containers of tagged fish.
- Prepare transport containers and lids to receive tagged fish

Surgery

- Food should be withheld from fish for ~24 h prior to surgical implantation of the transmitter.
- Anesthetize fish
 - Net one fish from source tank/raceway and place directly into an anesthesia container. Immediately start a timer to monitor anesthesia exposure time and place a lid on the container.
 - Remove the lid after about 1 minute to observe the fish for loss of equilibrium. Keep the fish in the water for an additional 30-60 seconds after it has lost equilibrium. Time to sedation should normally be 2-4 minutes, with an average of about 3 minutes. If loss of equilibrium takes less than 1 minute or if a fish is exposed to anesthesia for more than 5 minutes, reject that fish. If after anesthetizing a few fish they are consistently losing equilibrium in more or less time than typical, the anesthesia concentration may need to

be adjusted. Anesthesia concentration should only be adjusted in coordination with all study taggers and the tagging coordinator.

- Changes to anesthesia concentration should be done at 5 mg/L increments. For example, if the initial dosage was 70 mg/L, an adjusted dose should be 65 mg/L or 75 mg/L.
 - When an anesthesia change is agreed upon, all taggers should drain their anesthesia containers, refill with 10 L of water, and re-mix to the new anesthesia concentration
 - If a fish is unacceptable for tagging due to issues with anesthesia, place the fish in the “Reject” container and log it on the reject tally datasheet.
 - The anesthesia container should be emptied and remixed at regular intervals throughout the tagging operation to ensure the appropriate concentration and to avoid warming
 - The gravity feed containers should be monitored for volume and temperature and changed as needed to avoid inadequate volume to complete a surgery and significant warming
- Recording fish length, weight, and condition
 - Start a timer when a fish is removed from the anesthesia container to record the time the fish is out of water (recorded as “air time”).
 - Transfer the fish to the scale and record the weight to the nearest 0.1g
 - Scales should be calibrated regularly to ensure accuracy
 - Fish must weigh at least 13 g to be selected for tagging so that tag burden does not exceed 5% of the weight of the fish. Transmitters used for this study are Vemco brand V5 models, weighing 0.65 g in air.
 - Transfer the fish to the measuring board and determine forklength to the nearest mm.
 - Check for any abnormalities and descaling. If the fish is abnormal or grossly descaled, note this on the datasheet and place the fish in the reject container.
 - Scale condition is noted as Normal (N), Partial (P), or Descaled (D) and is assessed on the most compromised side of each fish. The normal scale condition is defined as loss of less than 5% of scales on one side of the fish. Partial descaling is defined as loss of 6-19% of scales on one side of the fish. Fish are classified as descaled if they have lost 20% or more of the scales on one side of the fish, and should not be tagged due to compromised osmoregulatory ability.
 - Data must be vocally relayed to the recorder, and the recorder should repeat the information back to the tagger to avoid miscommunication.
 - Any fish dropped on the floor should be rejected.
- Transmitter Implantation
 - Anesthesia should be administered through the gravity feed irrigation system as soon as the fish is on the surgical platform. Use the flow control valves to adjust the flow rate as needed so that the opercular rate of the fish is steady.
 - Note that low-flow or inconsistent irrigation can mimic shallow anesthesia
 - Using a scalpel, make an incision approximately 3-5 mm in length beginning a few mm in front of the pelvic girdle. The incision should be about 3 mm away from and parallel to the mid-ventral line, and just deep enough to penetrate the peritoneum, avoiding the internal organs. The spleen is generally near the incision point so the depth and placement of the incision are critical.
 - There is no exact specification for the selection of a micro scalpel for steelhead. A general recommendation is to use a 5 mm blade for fish larger than about 50 g.
 - The incision should only be long enough to allow entry of the tag.
 - Forceps may be used to open the incision to check for potential organ damage. If you observe damage or note excessive bleeding, reject the fish.
 - Scalpel blades can be used on several fish, but if the scalpel is pulling roughly or making jagged incisions, it should be changed prior to tagging the next fish.

- Gently insert the tag into the body cavity and position it so that it lies directly beneath the incision and the ceramic head is facing forward. This positioning will provide a barrier between the suture needle and internal organs.
- Close the incision with two simple interrupted stitches.
 - Vicryl Plus sutures are recommended
 - 5-0 suture size is appropriate for juvenile Chinook Salmon or similar fish with weights less than~ 50 g
 - If the incision cannot effectively be closed with two stitches, a third stitch may be added. The presence of a third suture should be noted on the datasheet.
- Ideally the gravity feed irrigation system should be switched to fresh water or a combination of sedation and freshwater during the final stages of surgery to begin recovery from anesthesia. Typically a good time to switch to freshwater is when the second suture is initiated.
- Transfer the fish from the surgical platform to a recovery container and stop the timer recording air time
 - Avoid excessive handling of fish during transfer. Ideally the fish will be moved to the recovery container on the surgical platform to reduce handling.
- Once a recovery container has been fully stocked, start a timer to monitor the 10 min of exposure to high DO concentrations for recovery.
- Between surgeries the tagger should place surgical instruments and any partially consumed suture material into the chlorhexidine bath. Multiple sets of surgical instruments should be rotated to ensure 10 min of contact time with chlorhexidine. Once disinfected, instruments should be rinsed in distilled or de-ionized water. Organic debris in the disinfectant bath reduces effectiveness, so be sure to change the bath regularly.

Tag Validation

- Filled recovery containers will be moved to the tag validation station.
 - Recovery containers may be moved from the tagging location to the tag validation station during the 10 min recovery time, but they must not be established on flow-through water exchange. The flow-through exchange will immediately reduce the DO saturation.
- Use the appropriate receiving system to confirm the identity and function of the transmitters in the recovery container. Record validation on the datasheet.
- Following tag validation, recovery containers are held in a flow-through tank until the tagging session is complete, at which time they are loaded onto a truck for transport to the holding and release location.

Cleanup

- Both the tagger and assistant must review the full complement of tagging datasheets and initial each sheet to confirm that the set of transmitters they were assigned to implant have been implanted. Use the list of transmitters provided by the tag coordinator to ensure that all transmitters supplied to you were implanted and recorded. Both the tagger and the assistant must initial the header of each of the datasheets. This review step is completed for each tagging session (that is, for each transport truck that is loaded).
- Return tag tray and datasheets to coordinator at end of each tagging session.
- Complete the reject fish tally datasheet and return to the tag coordinator.
- Use a spray disinfectant to disinfect tagging surfaces and supplies, and position them to dry.
- Return any rejected fish to the appropriate raceway where they cannot be selected for future tagging efforts.
- At the completion of the tagging effort each day, package surgical instruments for the autoclave so they can be sterilized prior to the next tagging session.

Important things to remember:

- Water containers used for tagging should be filled just prior to tagging to avoid temperature changes and should be changed frequently.
- Fish cannot be transferred between water sources until the difference between the water temperatures of the two sources is less than two degrees Celsius.
- No water sources used in the tagging operation should be more than two degrees different in water temperature from the source water temperature.
- All containers holding fish should have lids in place.
- If a tag is dropped bring it to the tagging coordinator to confirm that it is still functioning before it is implanted. The transmitter may also require disinfection if it fell onto a dirty surface.
- Carefully handle all fish containers to minimize disturbances to fish.
- Containers used to transport fish to the release site cannot be used for tagging operations until they have been held in the freezer for 24 h.

Appendix 4:

U.S. Fish & Wildlife Service

FY2012 Technical Report:
Pathogen screening and gill Na-K-ATPase assessment of juvenile Chinook salmon used in south delta acoustic tag studies.

J. Scott Foott

September 2012

US Fish and Wildlife Service
California-Nevada Fish Health Center
24411 Coleman Fish Hatchery Rd
Anderson, CA 96007

SUMMARY:

Pathogen testing was conducted on dummy-tag cohorts of acoustic tagged Merced River Hatchery juvenile Chinook salmon used in studies corresponding to 7 May and 23 May releases. No virus or *Renibacterium salmoninarum* infection was detected in the fish. The 23 May group had 37% prevalence of both suture abnormalities and *Aeromonas* – *Pseudomonas* sp. infection however there was little correlation between the 2 findings. As in the past, *Tetracapsuloides bryosalmonae* infection was highly prevalent ($\geq 97\%$) and the associated Proliferative Kidney Disease became more pronounced in the 23 May sample. No mortality occurred in the live cage populations at either sample date. Gill Na-K-ATPase data is not reported due to a problem with a key assay reagent. The combination of kidney impairment and poor suture condition of the 23 May salmon indicates that health of the two release groups was not equivalent.

INTRODUCTION

As a component of the 2012 Chinook salmon survival studies on reach-specific survival and distribution of migrating Chinook salmon in the San Joaquin River and delta, the CA-NV Fish Health Center conducted a general pathogen screening and smolt physiological assessment. The health and physiological condition of the study fish can help explain their performance and survival during the studies. Pathogen screenings during past VAMP studies using Merced River Hatchery (MRH) Chinook have regularly found infection with the myxozoan parasite *Tetracapsuloides bryosalmonae*, the causative agent of Proliferative Kidney Disease (PKD). This parasite has been shown to cause mortality in Chinook salmon with increased mortality and faster disease progression in fish at higher water temperatures (Ferguson 1981; Foott et al. 2007). The objectives of this project were to survey the juvenile Chinook salmon used for the studies for specific fish pathogens including *Tetracapsuloides bryosalmonae* and assess smolt development from gill $\text{Na}^+ - \text{K}^+$ -ATPase activity.

METHODS

Prior to the 7 May and 23 May sample, 30 juvenile salmon were held within live cages for approximately 48h in the San Joaquin River at Durham Ferry. These fish were surgically-implanted with a dummy tag similar in size to the acoustic tag of release cohorts. Fish were evaluated for gill and skin condition (including suture) and tissues collected for assays. A grading scale ranging 0-3 was used to score inflammation or ulceration of tissue at the suture location and openness of the surgical incision (based on training session by Cramer Fish Sciences attended by J. Day).

- 0: Clean, completely closed and healed incision with taut suture. No external indication of pulling of tissue or inflammation.
- 1: Mostly closed, but not healed incision. Minor petechial hemorrhage.
- 2: Incision more than half open, and not healed. Inflammation present over more than half the suture area.
- 3: Incision completely open. Severely inflamed tissue surrounding and/or pushing out from incision site. Severe hemorrhaging extending equal to or greater than the length of the incision site. Suture may be lost entirely or embedded within inflamed tissue. Necrotic tissue visible.

Gill lamellae were collected first into SEI buffer and frozen on dry ice. Gill Na^+/K^+ -Adenosine Triphosphatase (ATPase) activity was assayed by the method of McCormick (1993). Kidney was collected aseptically and inoculated onto brain-heart infusion agar. Bacterial isolates were screened by standard microscopic and biochemical tests (USFWS and AFS-FHS 2010). *Renibacterium salmoninarum* (bacteria that causes bacterial kidney disease) was screened by fluorescent antibody test (FAT) of kidney imprints. Three fish pooled samples of kidney and spleen were inoculated onto EPC and CHSE-214 cell lines held at 15°C for 21 d (USFWS and AFS-FHS 2010). The gill, liver, intestine and posterior kidney were rapidly removed from the fish and immediately fixed in Davidson's fixative, processed for 5 μm paraffin sections and stained with

hematoxylin and eosin (Humason 1979). Infections of the myxozoan parasite, *T. bryosalmonae*, were rated for intensity of parasite infection and associated tissue inflammation (Proliferative Kidney Disease). Intensity of infection was rated as none (zero), low (<10), moderate (11-30) or high (>30) based on number of *T. bryosalmonae* trophozoites observed in the kidney section. Severity of kidney inflammation (PKD) was rated as normal, focal, multifocal or diffuse.

RESULTS AND DISCUSSION

All salmon were alive at the time of sample collection for both dates. Suture condition of 23 May fish was judged to be poor (11 of 30 fish with #2 or 3 ratings). Several sutures were observed on the pelvic girdle. All sutures in the 7 May group were intact and showed no hemorrhage.

The prevalence of systemic bacterial infection (*Aeromonas* – *Pseudomonas* sp. (aquatic bacteria clade) was also 37% in the 23 May group however there was little association with suture hemorrhage (only 4 of 11 fish with hemorrhaged sutures had bacterial infections). No virus or *Renibacterium salmoninarum* infection was detected in the fish (Table 1). *Tetracapsuloides bryosalmonae* was seen in $\geq 97\%$ of the kidney sections from both sample groups (Table 1).

Table A4-1. Prevalence of infection (number positive / total sample) for systemic bacteria (AP= *Aeromonas* or *Pseudomonas* sp.), *R. salmoninarum* by direct fluorescent antibody test (Rsal-DFAT), virus, and *T. bryosalmonae* observed in kidney sections.

<u>Sample date</u>	<u>Bacteria</u>	<u>Rsal - DFAT</u>	<u>Virus</u>	<u><i>T.bryosalmonae</i></u>
7 May	1 / 30 (3) AP	0 / 29	0 / 10 (3p)	29 / 30 (97)
23 May	11 / 30 (37) AP	0 / 30	0 / 10 (3p)	30 / 30 (100)

The *T. bryosalmonae* infection was judged to be at an early state in the 7 May sample fish. High numbers of the parasites were seen in both groups however kidney inflammation was markedly worse in the 23 May fish (Fig. 1 and 2). Swollen kidneys and spleens were also observed in the 23 May group. Overt anemia (pale gills) was not seen in any salmon on either collection date. The systemic nature of the infection was reflected in the occurrence of the parasite in multiple tissues (spleen, visceral adipose capillaries, liver sinuses, and kidney) including blood vessels within the gill (Fig. 3). One 7 May gill section contained two *Ichthyophthirius multifilii* trophozoites however there was little tissue response. Liver hepatocytes showed little glycogen or fat content in both sample groups possibly reflective of low feed rate. No gill Na-K-ATPase data is reported due to abnormal kinetic profiles. The ADP standard curve was normal which indicates that the majority of enzymes and co-factors were functional. The pH and magnesium conditions were also normal for the assay. We suspect that the recently purchased Sigma Chemical Adenosine TriPhosphate was faulty as this nucleotide is the substrate for the ouabain-sensitive gill Na-K-ATPase enzyme.

The advanced proliferative kidney disease, increased prevalence of systemic bacteria, and hemorrhaged sutures observed in the 23 May salmon suggests that the two release groups were not equivalent in health condition. The impact on immediate (1-3 days) post-release survival of these impairments on 23 May salmon is likely to be limited however longer term survival and swimming performance could be reduced. Past work on PKD effects on smolt performance have shown that severe kidney inflammation and anemia are associated with impaired swimming and saltwater adaptation (Foott et al. 2007 and 2008).

Figure A4-1. Prevalence of *T. byrosalmonae* intensity ratings for Chinook salmon sampled on 7 and 23 May. Intensity of *T. byrosalmonae* infection observed in kidney section rated as none (0), low (<10), moderate (11-30), and high (>30). Numbers over ratings are prevalence data. Majority of parasites observed in the 7 May kidneys were found in the sinuses indicating an early stage of infection.

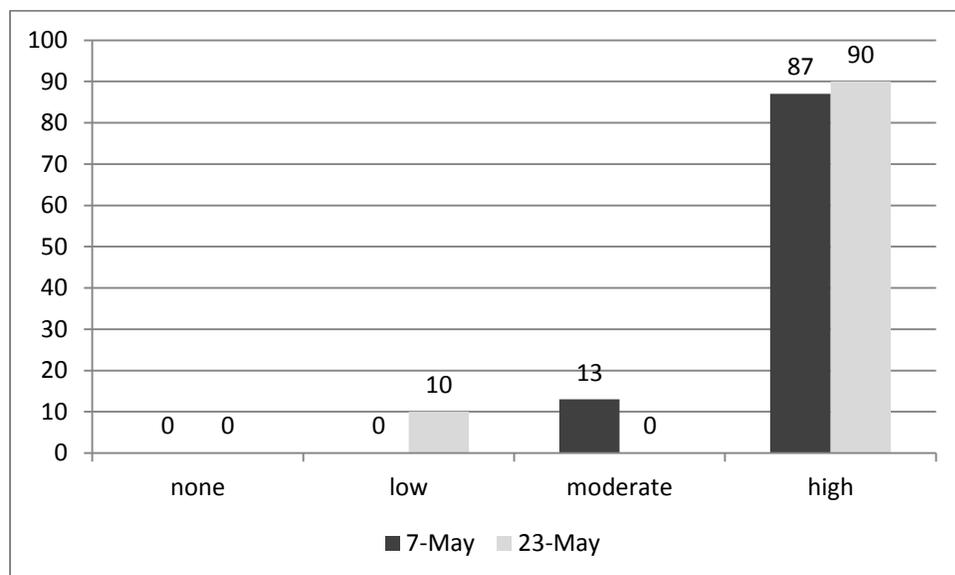

Figure A4-2. Prevalence of proliferative kidney disease ratings for Chinook salmon sampled on 7 and 23 May. Severity of kidney inflammation rated as normal, focal, multifocal, or diffuse. Numbers over ratings are prevalence data.

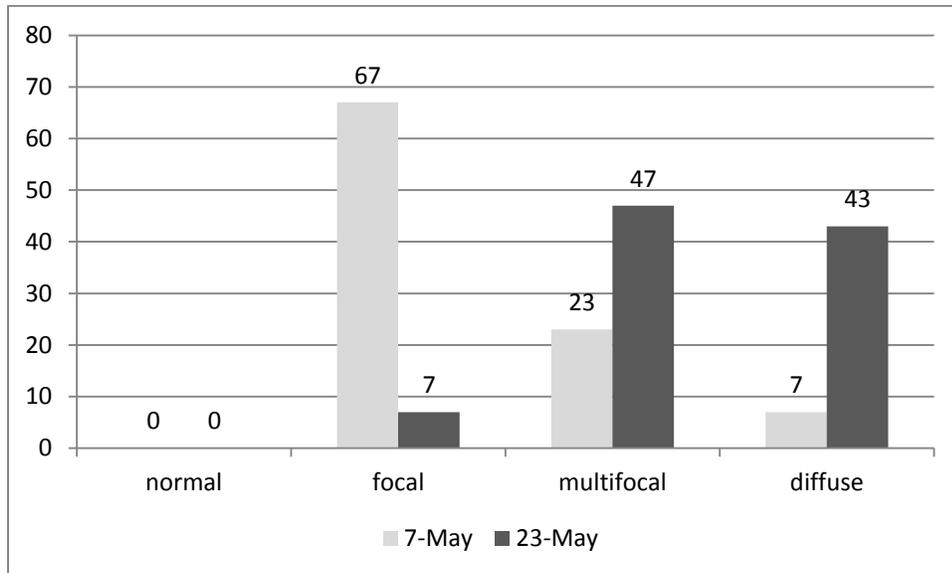

Figure A4-3. Micrograph of *T. byosalmonae* (arrow) within gill blood vessel.

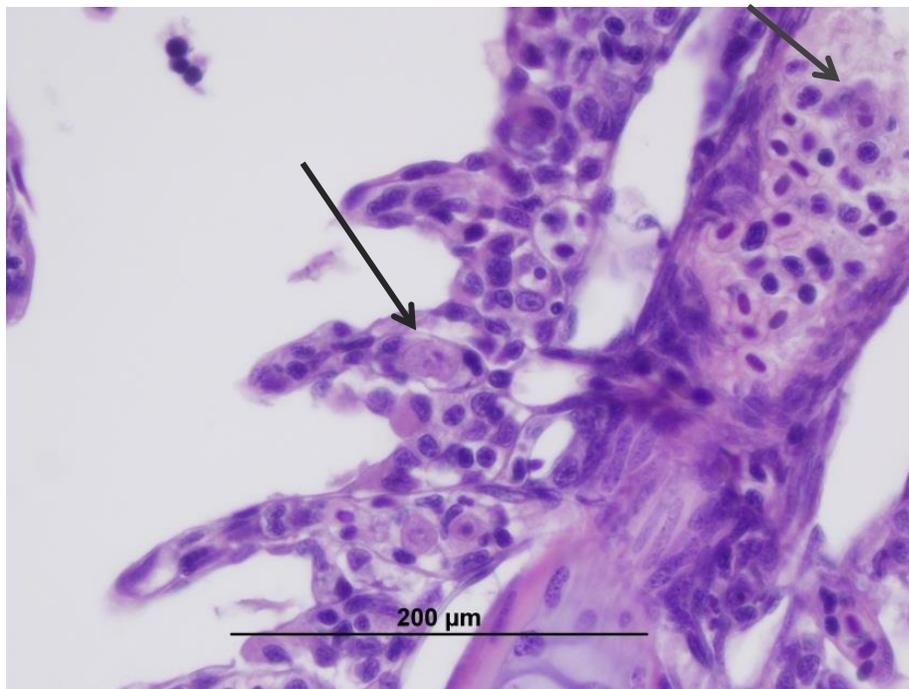

Figure A4-4. Suture condition rating 2 (exposed edge with hemorrhage) in 23 May salmon.

ACKNOWLEDGEMENTS

Ken Nichols, Anne Bolick, Kim True, and Julie Day with the FHC performed both field and laboratory work on this project and biologists with the USFWS Stockton FWO provided access to the live cages at Durham Ferry.

Appendix 5. Survival Model Parameters

Table A5-1. Definitions of parameters used in the release-recapture survival model; full or reduced model, or both, is specified. Parameters used only in particular submodels are noted.

Parameter	Model	Definition
S_{A2}	Both	Probability of survival from Durham Ferry Downstream (DFD) to Banta Carbona (BCA)
S_{A3}	Both	Probability of survival from Banta Carbona (BCA) to Mossdale (MOS)
S_{A4}	Both	Probability of survival from Mossdale (MOS) to Lathrop (SJL) or Old River East (ORE)
S_{A5}	Both	Probability of survival from Lathrop (SJL) to Garwood Bridge (SJG)
S_{A6}	Both	Probability of survival from Garwood Bridge (SJG) to Navy Drive Bridge (SJNB)
S_{A7}	Both	Probability of survival from Navy Drive Bridge (SJNB) to MacDonald Island (MAC) or Turner Cut (TCE/TCW)
$S_{A7,G2}$	Both	Overall survival from Navy Drive Bridge (SJNB) to Chipps Island (MAE/MAW) (derived from Submodel I)
$S_{A8,G2}$	Both	Overall survival from MacDonald Island (MAC) to Chipps Island (MAE/MAW) (Submodel I)
S_{B1}	Full	Probability of survival from Old River East (ORE) to Old River South (ORS)
$S_{B2,G2}$	Reduced	Overall survival from Old River South (ORS) to Chipps Island (MAE/MAW) (derived from Submodel I)
$S_{F1,G2}$	Both	Overall survival from Turner Cut (TCE/TCW) to Chipps Island (MAE/MAW) (Submodel I)
$\phi_{A1,A0}$	Full	Joint probability of moving from Durham Ferry release site upstream toward DFU, and surviving to DFU
$\phi_{A1,A2}$	Both	Joint probability of moving from Durham Ferry release site downstream toward DFD, and surviving to DFD
$\phi_{A1,A3}$	Both	Joint probability of moving from Durham Ferry release site downstream toward BCA, and surviving to BCA; = $\phi_{A1,A2} S_{A2}$
$\phi_{A8,A9}$	Both	Joint probability of moving from MAC toward MFE/MFW, and surviving from MAC to MFE/MFW (Submodel II)
$\phi_{A8,B3}$	Full	Joint probability of moving from MAC toward OR4, and surviving from MAC to OR4 (Submodel II)
$\phi_{A8,C2}$	Full	Joint probability of moving from MAC toward MR4, and surviving from MAC to MR4 (Submodel II)
$\phi_{A8,GH}$	Full	Joint probability of moving from MAC directly toward Jersey Point (JPE/JPW) or False River (FRE/FRW) without passing Highway 4 sites, and surviving JPE/JPW or FRE/FRW (Submodel II)
$\phi_{A8,G1}$	Reduced	Joint probability of moving from MAC toward Jersey Point (JPE/JPW) and surviving to JPE/JPW (Submodel II); = $\phi_{A8,GH} \psi_{G1(A)}$
$\phi_{A9,B3}$	Full	Joint probability of moving from MFE/MFW toward OR4, and surviving from MFE/MFW to OR4 (Submodel II)
$\phi_{A9,C2}$	Full	Joint probability of moving from MFE/MFW toward MR4, and surviving from MFE/MFW to MR4 (Submodel II)
$\phi_{A9,GH}$	Full	Joint probability of moving from MFE/MFW directly toward Jersey Point (JPE/JPW) or False River (FRE/FRW) without passing Highway 4 sites, and surviving to JPE/JPW or FRE/FRW (Submodel II)
$\phi_{A9,G1}$	Reduced	Joint probability of moving from MFE/MFW toward Jersey Point (JPE/JPW) and surviving to JPE/JPW (Submodel II); = $\phi_{A9,GH} \psi_{G1(A)}$

Abstract

The survival of juvenile Chinook Salmon through the lower San Joaquin River and Sacramento–San Joaquin River Delta in California was estimated using acoustic tags in the spring of 2009 and 2010. The focus was on route use and survival within two major routes through the Delta: the San Joaquin River, which skirts most of the interior Delta to the east, and the Old River, a tributary of the San Joaquin River leading to federal and state water export facilities that pump water out of the Delta. The estimated probability of using the Old River route was 0.47 in both 2009 and 2010. Survival through the southern (i.e., upstream) portion of the Delta was very low in 2009, estimated at 0.06, and there was no significant difference between the Old River and San Joaquin River routes. Estimated survival through the Southern Delta was considerably higher in 2010 (0.56), being higher in the Old River route than in the San Joaquin route. Total estimated survival through the entire Delta (estimated only in 2010) was low (0.05); again, survival was higher through the Old River. Most fish in the Old River that survived to the end of the Delta had been salvaged from the federal water export facility on the Old River and trucked around the remainder of the Delta. The very low survival estimates reported here are considerably lower than observed salmon survival through comparable reaches of other large West Coast river systems and are unlikely to be sustainable for this salmon population. More research into mortality factors in the Delta and new management actions will be necessary to recover this population.

The Central Valley of California marks the southern limit of Chinook Salmon *Oncorhynchus tshawytscha* in North America (Healey 1991). Chinook Salmon population abundances in this region have been much reduced from the 19th century in response to a number of factors, including habitat loss, hatcheries, and water development (e.g., pumping water out of the basin; Healey 1991; Fisher 1994). Today, the Sacramento–San Joaquin River Delta is a highly modified environment with levees and drained fields replacing tidal wetlands, and riprap replacing natural shoreline. Demand for Delta waters is high. State and federal water export facilities

extract water from the southern portion of the Delta (Figure 1) for agricultural, industrial, and municipal use throughout California. The Delta provides drinking water for approximately 27 million Californians and irrigation water for more than 1,800 agricultural users, and 4.6–6.3 million acre-feet of water are exported from the Delta annually (DSC 2011). This intense exporting combined with tidal fluctuations can sometimes cause net flows in the Delta to be directed upstream rather than downstream (Brandes and McLain 2001). Pollution from industry, agricultural and urban runoff, and erosion are also concerns (DSC 2011). Both native and nonnative species of

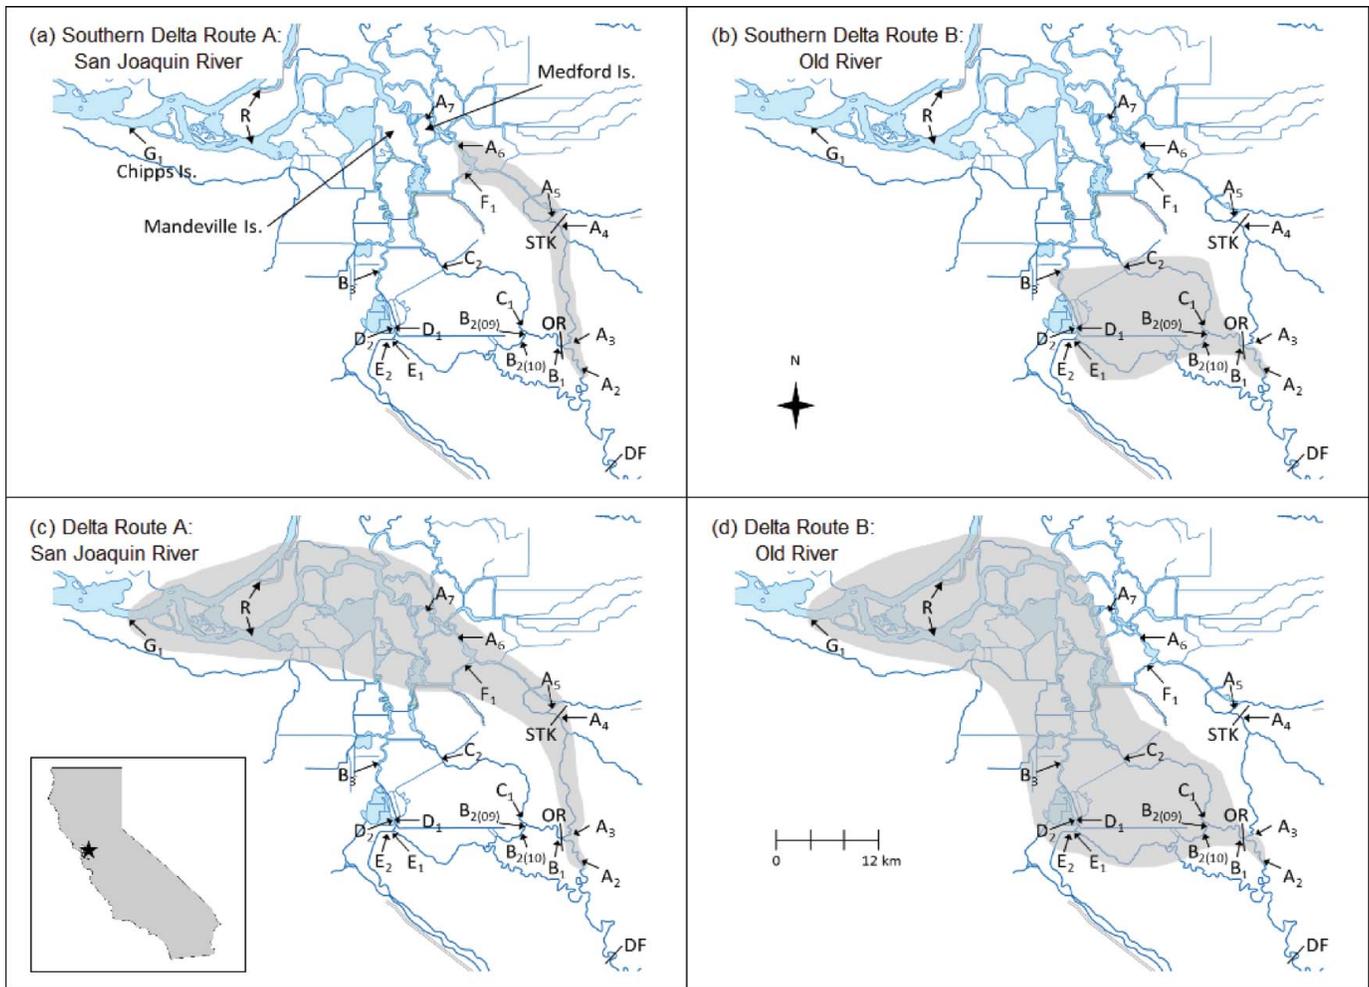

FIGURE 1. Acoustic telemetry receiver sites throughout the San Joaquin River Delta for the juvenile Chinook Salmon tagging studies in 2009 and 2010. The region included in each major route through the study area is shaded for the Southern Delta for the (a) San Joaquin River and (b) Old River routes and through the entire Delta for the (c) San Joaquin River and (d) Old River routes. Sites in the San Joaquin, Old, and Middle rivers are labeled A, B, and C, respectively. The label for site B2 includes the study years 2009 (09) and 2010 (10). Sites A7, C1, and G1 were used only in 2010. Mossdale is denoted by A2, Chipps Island at river kilometer 0 by G1, the federal water export facilities by E1 and E2, and state water export facilities by D1 and D2. The city of Stockton is near sites A5 and A6. Sites B3 and C2 are located near California Highway 4. Release sites are designated as follows: DF = Durham Ferry (2009, 2010), OR = Old River (2010), STK = Stockton (2010), and R = release after salvage and trucking. Route-specific survival and route entrainment probability were estimated for the Southern Delta in 2009 and 2010 and for the entire Delta in 2010. [Figure available in color online.]

predatory fish (e.g., Striped Bass *Morone saxatilis*, Largemouth Bass *Micropterus salmoides*, White Catfish *Ameiurus catus*) inhabit these areas and feed on migrating smolts, as do avian predators including double-crested cormorants *Phalacrocorax auritus* and white pelicans *Pelecanus erythrorhynchos*. All of these factors lower survival of migrating salmon smolts relative to historical conditions.

The Vernalis Adaptive Management Plan (VAMP) is a large-scale, long-term (12-year) experimental management program begun in 2000 that was designed to protect juvenile Chinook Salmon as they migrate from the San Joaquin River through the Sacramento–San Joaquin River Delta (Figure 1; SJRGA 2005, 2007, 2010, 2011). Part of the VAMP is a multiyear tagging study to monitor juvenile salmon survival through the Delta; the

long-term goal is to relate Delta survival to changes in river flow (discharge) and water export levels in the presence of a temporary barrier at the head of the Old River, which was designed to prevent salmon from entering the Old River (Figure 1). Prior to 2006, VAMP tagging studies relied on coded wire tags (CWTs), which provided information on salmon survival on a large spatial scale using 100,000–300,000 study fish each year (Newman 2008). Starting in 2006, the tagging studies began using micro-acoustic tags, which provide more precise survival information on a smaller spatial scale with much smaller releases groups (e.g., about 1,000 fish). Coded wire tags were discontinued in 2007. Study years 2006 and 2007 were pilot studies providing feedback on design and implementation of the acoustic tag studies. The 2008 study deployed an extensive array of acoustic

hydrophones throughout the Delta but suffered from a high degree of premature tag failure (Holbrook et al. 2013). Thus, 2009 and 2010 were the first years that provided sufficient information to estimate salmon survival through portions of the Delta on a relatively detailed spatial scale, yielding the first estimates of how fish distribute across various migration routes. Further, these 2 years represent different hydrologic conditions—very low flows in 2009 and above normal flows in 2010—thus providing preliminary information needed to identify a relationship between survival and flow. Survival through the southern portion of the Delta was estimated in both 2009 and 2010, and survival through the entire Delta was estimated in 2010 (described below; Figure 1). In both years, survival estimates were compared through two major migration routes: the San Joaquin River route and the Old River route. We present here the first spatially detailed estimates of survival and route use by juvenile Chinook Salmon through the lower San Joaquin River into the Delta.

STUDY AREA

Historically, focus has been on the survival of fish through the Delta to Chipps Island, located in Suisan Bay at the confluence of the San Joaquin and Sacramento rivers near Pittsburg, California, at river kilometer (rkm) 0 (Figure 1). Fish moving through the Delta toward Chipps Island may use any of several routes. The simplest route follows the San Joaquin River until it joins the Sacramento River near Chipps Island (Figure 1a, c; route A). An alternative route uses the Old River from its head on the San Joaquin River to Chipps Island, either via its confluence with the San Joaquin River just west of Mandeville Island, or through Middle River or the state and federal water export facilities (Figure 1b, d; route B). Additional subroutes were monitored for fish use but were contained within either route A or route B. Subroute C consists of the Middle River from the Old River to the San Joaquin downstream of Medford Island. Two other subroutes were the water export facilities off the Old River: fish entering either the State Water Project (subroute D) or the Central Valley Project (subroute E) had the possibility of being trucked from those sites and released upstream of Chipps Island. Subroutes C, D, and E were all contained in route B (Old River). Finally, fish that remained in the San Joaquin River past Stockton may have entered Turner Cut and maneuvered to Chipps Island through the interior of the Delta (subroute F). Fish in routes B, C, and F all had multiple unmonitored pathways available for passing through the Delta toward Chipps Island.

Survival through the study area was estimated on two spatial scales: (1) the southern portion of the Delta, which is bounded downstream by the federal and state water export facilities, California Highway 4, and the Turner Cut junction with the San Joaquin River (the “Southern Delta”; Figure 1a, b) and (2) the entire Delta, which is bounded downstream by Chipps Island (the “Delta”; Figure 1c, d). Both the Southern Delta and Delta regions were bounded upstream by the acoustic receiver (site A2) located near Mossdale Bridge, upstream of the Old River

junction with the San Joaquin River. The Southern Delta region was entirely contained within the Delta region (Figure 1). In 2009, no acoustic receivers were deployed at Chipps Island, so the study area was limited to the Southern Delta. In 2010, a more extensive detection field was installed, including dual receivers at Chipps Island (G1) (Figure 1). Thus, in 2010, the study area included the entire migration path through the Delta region. Two migration routes were monitored through both the Southern Delta and Delta regions: the San Joaquin Route (route A in Figure 1a, c) and the Old River route (route B in Figure 1b, d).

Since the 1990s, a temporary physical or nonphysical barrier (sound, strobe lights, and a bubble curtain) has often been installed at the head of the Old River with the aim of preventing migrating smolts from entering that river. In 2009 and 2010, a nonphysical barrier was installed there, and its smolt-guidance effectiveness was evaluated in studies concurrent with the VAMP studies (Bowen et al. 2009; Bowen and Bark 2012). The nonphysical barrier was operated during passage of approximately half of each VAMP release group in 2009 or 2010. No physical barrier was installed.

METHODS

Tagging and release methods.—Both study years used the Hydroacoustic Technology, Inc. (HTI) Model 795 microacoustic tag (diameter = 6.7 mm, length = 16.3–16.4 mm, average weight in air = 0.65 g). In 2009 a total of 933 juvenile Chinook Salmon (fall–spring-run hybrids) originating from the Feather River Fish Hatchery were tagged and released between 22 April and 13 May (fork length = 85.0–110.0 mm, mean = 94.8 mm; Table 1). Difficulties in rearing fish to size resulted in an average tag burden (i.e., the ratio of tag weight to body weight) of 7.1% (range = 4.4–10.2%), which was higher than desired ($\leq 5.5\%$; Brown et al. 2006). Six fish died in 2009 between tagging and release. In 2010, a total of 993 juvenile fall-run Chinook Salmon originating from the Merced River Fish Hatchery were tagged and released between 27 April and 20 May (fork length = 99.0–121.0 mm, mean = 110.5 mm). Tag burden in 2010 was 2.8–5.8% (mean = 4.2%; Table 1). Four fish died in 2010 between tagging and release.

In both years, tagging was performed at the Tracy Fish Facility located in the Delta approximately 30–45 km from the release site(s). Tagging procedures followed those outlined in Adams et al. (1998) and Martinelli et al. (1998). Fish were anesthetized in a 70-mg/L tricaine methanesulfonate solution, buffered with an equal concentration of sodium bicarbonate, and surgically implanted with programmed acoustic transmitters. Typical surgery times were less than 3 min. Nonfunctioning tags were removed from the study. After surgery, fish were placed in 19-L containers with high dissolved oxygen (DO) concentrations (110–130%) for recovery. Each holding container was perforated to allow partial water transfer and held no more than three tagged fish. After initial recovery from surgery, tagged fish were transported in buckets to the release site in transport

TABLE 1. Release data for groups of Chinook salmon smolts used in the 2009 and 2010 Vernalis Adaptive Management Plan studies, where DF = Durham Ferry, STK = Stockton, and OR = Old River. In 2009, releases were pooled into strata for analysis; in 2010, releases from separate locations were jointly analyzed for a single release occasion.

tanks designed to guard against fluctuations in water temperature and DO. Transport to the release site took approximately 45–60 min. At the release site, tagged fish were held in either 1-m³ net pens (3-mm mesh; first release in 2009) or in perforated 121.1-L plastic garbage cans (2010) for a minimum of 24 h before release.

In 2009, all fish were released on the San Joaquin River at Durham Ferry, located at approximately rkm 110 (measured from the river mouth at Chipps Island) approximately 20 km upstream of the boundary of the study area (Mossdale Bridge; Figure 1). The release site was located upstream of the study area to allow fish to recover from handling and distribute naturally in the river channel before entering the study area. In 2010, each of seven release occasions consisted of an initial release at Durham Ferry and two supplemental releases, one located in the Old River near the junction with the San Joaquin River

and the other located in the San Joaquin River near the city of Stockton (Figure 1). The supplemental releases were designed to provide enough tagged fish in the lower reaches of the study area to estimate survival all the way to Chipps Island, even if survival was low from Durham Ferry.

For each study year, an in-tank tag life study was performed to measure the rate of tag failure under the tag operating parameters (i.e., encoding, range, and pulse width) used in the study. Stratified random sampling of tags across manufacturing lots and tag codes was used to ensure that tags in the tag-life study represented the population of tags released in study fish.

In both study years, tag effects on short-term (48-h) survival were assessed using dummy (i.e., inactive)-tagged and untagged fish that were handled using the same procedures as fish with active transmitters. No significant difference in survival was observed between dummy-tagged and untagged fish over the

48-h period (SRJGA 2010, 2011). Tag effects on longer-term (≤ 21 d) survival and predator avoidance were expected to be small based on existing studies on effects of acoustic tags on juvenile Chinook Salmon with comparable tag burden (e.g., Anglea et al. 2004).

Water temperatures at the release locations were $< 20^{\circ}\text{C}$ during most releases, ranging from 16.1°C to 21.1°C in 2009 and from 14.2°C to 18.8°C in 2010. Temperature increased as a function of distance downstream from Durham Ferry in both the San Joaquin River main stem and the Delta and increased throughout the season. Temperatures in the study area exceeded 20°C starting in mid-May in 2009 and in early June in 2010.

Hydrophone placement.—An extensive array of acoustic hydrophones and receivers was deployed throughout the Delta in each study year, with 19 receivers and hydrophones being deployed in 2009 and 32 receivers (35 hydrophones) in 2010 (Figure 1). Acoustic receivers were named according to migration route (A–G). Chippis Island, the final destination of all routes in 2010, was assigned its own route name (G). At each location, one to four hydrophones were deployed to achieve full cross-sectional coverage of the channel.

Acoustic receivers were located at the Delta entrance (Mosssdale, site A2) in both 2009 and 2010, at the Delta exit (Chippis Island, G1) in 2010, and at key points in between in both years (Figure 1). The Mosssdale site was moved 1.4 km downstream in 2010 to an acoustically quieter site. All available migration routes were monitored at the Old River (sites A3 and B1) and Turner Cut (A6 and F1) diversions from the San Joaquin River (Figure 1). Receivers were located on the San Joaquin River in Stockton near the Stockton Waste Water Treatment Facility (A4) and near the Navy Drive Bridge just upstream of the Stockton Deep Water Ship Channel (A5) because of concern about salmon survival past the water treatment plant. Receivers were also located at the entrance to the state and federal water export facilities on the Old River (Figure 1). At the federal facility (Central Valley Project, CVP), receivers were placed just upstream and downstream of the trash racks (E1) and in the holding tank (E2), where salvaged fish were held before transportation by truck to release sites in the lower Delta on the San Joaquin and Sacramento rivers (R). At the state facility, receivers were placed both outside (D1) and inside (D2) the radial entrance gates to the Clifton Court Forebay (CCF), the reservoir from which the State Water Project draws water. Both the CVP trash racks and the CCF radial gates are known feeding areas for piscine predators (Vogel 2010, 2011). Receivers were also located downstream in the Old (B3) and Middle (C2) rivers near the Highway 4 bridge. Dual receiver arrays were placed at some sites to provide data to estimate detection probabilities, typically at the downstream boundary of the study area and at sites just downstream of river junctions. Both acoustic lines within each dual array (average 0.3 km apart) were designed for full coverage of the channel. The nonphysical barrier located at the head of the Old River was evaluated via a separate network of hydrophones that were not used in the VAMP study (Bowen et al. 2009; Bowen and Bark 2012).

The locations of the hydrophones were dictated by the possible migration routes (San Joaquin [A], and Old River [B]) and subroutes, and by the two spatial scales on which inference was to be made (Southern Delta and Delta). The acoustic receivers located in Turner Cut (F1) and at the channel markers in the San Joaquin River near the Turner Cut junction (A6) monitored the exit of the San Joaquin route through the Southern Delta region in both 2009 and 2010 (Figure 1a). Likewise, the exit of the Old River route through the Southern Delta region was monitored by receivers at the state and federal water facilities and near Highway 4 in both 2009 and 2010 (Figure 1b). In 2010, the exit of both the San Joaquin route (Figure 1c) and the Old River route (Figure 1d) through the entire Delta region was monitored by dual receivers at Chippis Island.

Signal processing.—The raw tag detection data generated by the acoustic telemetry receivers were processed by identifying the date and time of each tag detection. Unique tags were identified by the period ($1/\text{frequency}$) of the acoustic signal. The 2009 data were processed manually using the HTI proprietary software *MarkTags*. The 2010 data were processed using a combination of automatic and manual processing, manual processing being limited to key detection sites (SJRGGA 2011).

The San Joaquin River Delta is home to several populations of predatory fish that are large enough to feed on juvenile salmonids, including Striped Bass, Largemouth Bass, and White Catfish. A predatory fish that has eaten an acoustic-tagged juvenile salmon and then moves past a hydrophone may introduce misleading tag detections into the data. Thus, it was necessary to identify and remove those detections that came from predators. Likely predator detections were identified in a decision process that used up to three levels of spatial–temporal analysis, based on the methods of Vogel (2010, 2011): near-field, mid-field, and far-field. Near-field analysis required manual processing of the raw acoustic telemetry data, and interpreted the pattern of the acoustic signal during detection as an indicator of fish movement near the receiver. Mid-field analysis focused on residence time within the detection field of each receiver, and transitions between neighboring receivers. Far-field analysis examined transitions on the scale of the study area. All available detection data were considered in identifying likely predator detections, as well as environmental data such as river flow and tidal stage, measured at several gaging stations throughout the Delta (downloaded from the California Data Exchange Center Web site: <http://cdec.water.ca.gov>). The predator decision process was based on the assumptions that Chinook Salmon smolts were emigrating and so were directed downstream, and that they were unlikely to move between acoustic receivers (≥ 2 km) against river flow. Movements directed upstream against the flow were considered evidence of predation, although short-term upstream movements under reverse flow or slack tide conditions were deemed consistent with a salmon smolt. Unusually fast or slow transitions between detection sites or particularly long residence time at a detection site were also considered evidence of predation. In 2009, the near-field analysis comprised the majority of the predation decision process. In 2010, more emphasis

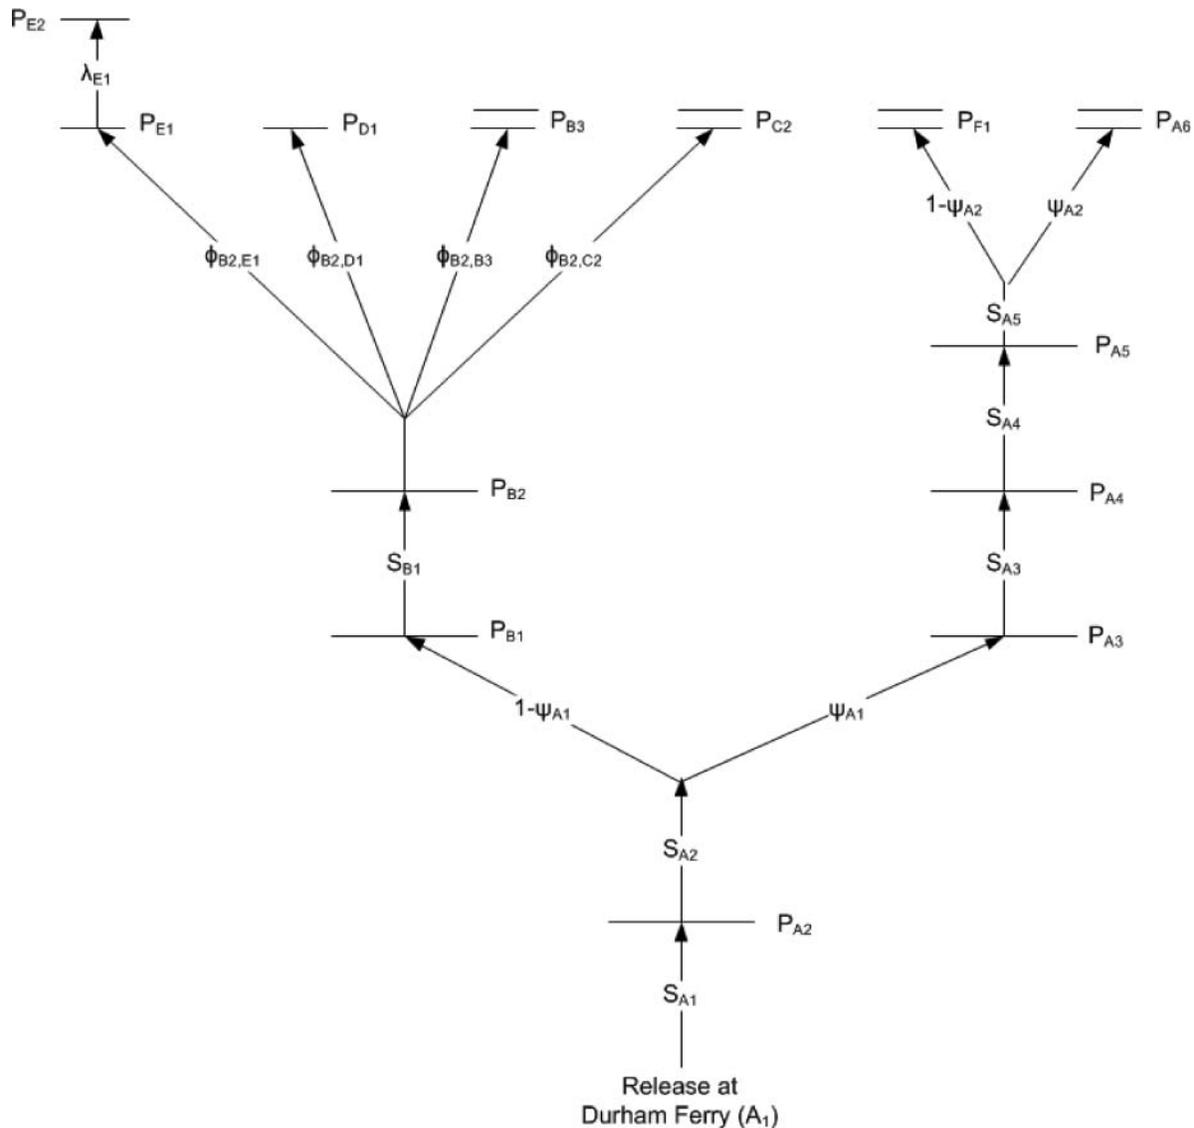

FIGURE 2. Model schematic for the 2009 Chinook Salmon smolt tagging study. Horizontal lines indicate acoustic receivers; parallel lines indicate dual receiver arrays. Model parameters are salmon reach survival (S), detection probabilities (P), route entrainment probabilities (ψ), transition probabilities ($\phi = \psi S$), and "last reach" parameters ($\lambda = \phi P$).

was placed on travel time, residence time, and movements in relation to river flow (mid-field and far-field analysis).

After removing the suspected predator detections, the processed data were converted to individual detection histories for each tagged fish. The detection history identified the chronological sequence of sites where the tag was detected. In the event that a tag was detected at a site or river junction multiple times, the last path past the site or river junction was used in the detection history as the best depiction of the final fate of the fish in the region.

Statistical survival and migration model.—A multistate statistical release–recapture model (Buchanan and Skalski 2010) was developed and used to estimate salmon smolt survival, de-

tection probabilities, and route-use ("entrainment") probabilities (Figures 2, 3). The release–recapture model was similar to the model developed by Perry et al. (2010), with states representing the various routes through the Delta. Detection sites (acoustic receivers) were named according to route.

The release–recapture models used for both study years used parameters that denoted the probability of detection (P_{hi}), route entrainment probability (ψ_{hl}), salmon reach survival (S_{hi}), and transition probabilities ($\phi_{kj,hi}$) equivalent to the joint probability of movement and survival, where h and k represent route, i and j represent detection sites within a route, and l represents junctions within a route (Figures 2, 3). The transition probability $\phi_{kj,hi}$ from site j in route k to site i in route h included all

possible routes between the two sites and was used when it was not possible to separately estimate the route entrainment and survival probabilities. Unique transition parameters were estimated at receiver D1 located outside the radial gates of the Clifton Court Forebay depending on gate status at the time of fish arrival (open or closed) in the 2010 study. Gate status data were unavailable for the 2009 study.

In some cases, it was not possible to separately estimate the transition probability to a site and the detection probability at the site. This occurred primarily at the entrances to the water export facilities (E1 = CVP trash racks, and D1 = first CCF receiver) due to sparse data. In these cases, the joint probability of survival from the previous receiver to receiver i in route h was estimated as $\lambda_{hi} = \phi_{kj,hi} P_{hi}$. We assumed that the detection probability was 100% at the radial gate receivers inside Clifton Court Forebay and in the holding tank at the Central Valley Project. These assumptions, necessary in the absence of receivers located downstream of those detection sites and unique to those routes, were reasonable as long as the receivers were operating.

A multinomial likelihood model was constructed based on possible capture histories under the assumptions of common survival, route entrainment, and detection probabilities and independent detections among the tagged fish in each release group. The likelihood model was fit using maximum likelihood in the software Program USER (Lady and Skalski 2008), providing point estimates and standard errors of model parameters and derived performance measures.

In addition to the model parameters, performance at the migration route level was estimated as functions of the model parameters. The probability of a smolt taking the San Joaquin River route (route A) was ψ_{A1} , while the probability of using the Old River route (route B) was $1 - \psi_{A1}$. Regional passage survival (S_R for region R) was estimated on two spatial scales: the southern Delta ($R = SD$; 2009 and 2010) and the entire San Joaquin River delta ($R = D$) from Mossdale Bridge to Chipps Island (2010) (Figure 1). Regional passage survival for region R ($R = SD$ or D) was defined in terms of both the route entrainment probability (ψ_{A1}) and the route-specific survival probabilities:

$$S_R = \psi_{A1} S_{A(R)} + (1 - \psi_{A1}) S_{B(R)}.$$

The route-specific survival probabilities through region R (i.e., $S_{A(R)}$ and $S_{B(R)}$ for $R = SD$ or D) were defined as

$$S_{A(R)} = S_{A2} S_{A3} S_{A4} S_{A5(R)}$$

and

$$S_{B(R)} = S_{A2} S_{B1} S_{B2(R)}.$$

The survival probabilities through the final reaches of each route (i.e., $S_{A5(R)}$ and $S_{B2(R)}$) were defined as

$$S_{A5(R)} = \begin{cases} S_{A5}, & \text{for } R = SD \\ S_{A5}(\psi_{A2}\phi_{A6,A7}\phi_{A7,G1} + [1 - \psi_{A2}]\phi_{F1,G1}), & \text{for } R = D \end{cases}$$

and

$$S_{B2(R)} = \begin{cases} \phi_{B2,B3} + \phi_{B2,C2} + \phi_{B2,D1} + \phi_{B2,E1}, & \text{for } R = SD \\ \phi_{B2,B3}\phi_{B3,G1} + \phi_{B2,C2}\phi_{C2,G1} \\ \quad + \phi_{B2,D1}\phi_{D1,D2}\phi_{D2,G1} \\ \quad + \phi_{B2,E1}\phi_{E1,E2}\phi_{E2,G1}, & \text{for } R = D. \end{cases}$$

For fish that reached the interior receivers at the Clifton Court Forebay or CVP in 2010, the parameters $\phi_{D2,G1}$ and $\phi_{E2,G1}$ included survival during and after collection and transport. Although a subroute of the Old River route to Chipps Island, through Middle River from the junction with the Old River (subroute C) was monitored in 2010, no salmon were observed leaving the Old River at that junction (site C1). Thus, the probability of a smolt taking the Middle River route to Chipps Island was estimated to be zero.

In 2009, release groups were pooled into three strata based on release timing, common environmental conditions, and monitoring equipment status: stratum 1 = releases 1–2, stratum 2 = releases 3–6, and stratum 3 = release 7 (Table 1). Malfunctioning acoustic receivers meant that some parameters could not be estimated for some strata. Model selection was used to assess the effect of stratum on model parameters common to multiple strata. In 2010, data from each of the seven release occasions (initial release at Durham Ferry combined with supplemental releases) were analyzed separately. For each release occasion, several alternative survival models were fit, differing in whether the initial (Durham Ferry) and supplemental release groups shared common detection, route entrainment, and survival parameters over common reaches. Model selection was used to find the most parsimonious model that fit all the data, following the general approach described in Burnham et al. (1987) for comparing treatment groups. Detection probabilities were parameterized first, with survival, transition, and route entrainment probabilities parameterized next. Backwards selection was used to identify the farthest reach upstream for which parameters from the initial and supplemental releases could be equated without reducing model fit. The most general models were considered first, with unique parameters for each release group for all reaches, and tested against simpler models with common parameters across the initial and supplemental release groups for the downstream reaches. All models used unique survival and transition probabilities in the first reach downstream of the supplemental release sites. Model selection was performed using the Akaike Information Criterion (AIC) as described in Burnham and Anderson (2002). Final parameter estimates were weighted averages of the release-specific estimates from the selected model, with weights equal to the

number of fish from the release group present at the supplemental release site (estimated for the initial release group). Goodness of fit was assessed using Anscombe residuals (McCullagh and Nelder 1989: p. 38).

RESULTS

2009 Results

None of the 50 tags in the 2009 tag-life study failed before day 21. Because all detections of tagged salmon smolts occurred well before day 21 after tag activation, no adjustment for tag failure was made to the survival estimates from the release-recapture model.

Initial survival after release was low in 2009, with estimates of survival from Durham Ferry to the Mossdale Bridge (site A2, approximately 20 rkm) averaging 0.47 ($SE = 0.02$). The majority of the acoustic-tag detections downstream of Durham Ferry were at the upstream sites in the San Joaquin (A2, A3) and in the Old River (B1). Very few tagged salmon smolts were detected at the exit points of the Southern Delta region in either the San Joaquin River route or the Old River route. No tagged salmon were detected at the Turner Cut receivers (F1), the Middle River receivers at Highway 4 (C2), or the interior receivers at Clifton Court Forebay (D2).

Total salmon survival through the Southern Delta region (S_{SD}) was estimable only for stratum 2 (releases 3–6) because the failure of certain acoustic receivers resulted in missing data from the three other release groups. Estimated route-specific survival through the Southern Delta was $\hat{S}_{A(SD)} = 0.05$ ($SE = 0.02$) in the San Joaquin route and $\hat{S}_{B(SD)} = 0.08$ ($SE = 0.02$) in the Old River route (Table 2). Survival estimates through the Southern

Delta in the two routes were not significantly different (Z -test, $P = 0.4788$). The route entrainment probabilities at the junction of the Old River with the San Joaquin River were estimated at $\hat{\psi}_{A1} = 0.47$ ($SE = 0.03$) for the San Joaquin River, and $1 - \hat{\psi}_{A1} = 0.53$ ($SE = 0.03$) for the Old River. Consequently, overall survival through the Southern Delta in 2009 was estimated as $\hat{S}_{SD} = 0.06$ ($SE = 0.01$; Table 2).

The first two release groups in 2009 (stratum 1) showed a higher probability of entering the Old River ($1 - \hat{\psi}_{A1} = 0.64$; $SE = 0.04$) than remaining in the San Joaquin ($P = 0.0002$). Release groups 3–6 (stratum 2) showed no preference for either route ($P > 0.05$), with $1 - \hat{\psi}_{A1} = 0.48$ ($SE = 0.04$) for the Old River route entrainment probability. No estimates of the route entrainment probabilities were available for group 7 (stratum 3) because of equipment malfunction.

Median travel time through the Southern Delta reaches ranged from 0.2 d ($SE = 0.2$) from the Stockton USGS gauge (A4) to the Navy Drive Bridge in Stockton (A5; approximately 3 km), to 2.1 d ($SE = 0.3$) from Lathrop (A3) to the Stockton USGS gauge (A4; approximately 15 km).

2010 Results

Failure times of the 48 tags in the tag-life study ranged from 10 to 36 d. The early failure of several tags in the tag-life study made it necessary to incorporate tag-life adjustments into survival estimates (Townsend et al. 2006). The estimated probability of tag survival to the time of arrival at each detection site ranged from 0.987 to Chippis Island (G1) to 0.995 to Mossdale (A2). Tag survival estimates for the supplemental releases at the Old River and Stockton were generally higher than for the initial releases at Durham Ferry.

TABLE 2. Estimates of route-specific survival (S ; standard errors in parentheses) of Chinook Salmon smolts through the Southern Delta (SD) and the entire Delta to Chippis Island (D) in the San Joaquin River (A) and Old River (B) and route entrainment probability into the San Joaquin River (A) at the head of the Old River for study years 2009 and 2010. Estimates of survival through the entire Delta are not available for 2009.

All releases in the 2010 study had high initial survival, with estimates of survival from Durham Ferry to the Mossdale Bridge receiver (site A2; approximately 21 km) averaging 0.94 (range = 0.86–1.00). The Old River supplemental release groups had an average estimated survival to the head of Middle River (sites B2, C1) of 0.89 (range = 0.84–0.97). The Stockton supplemental release groups had an average estimated survival to the Navy Bridge in Stockton (site A5) of 0.82–1.07 (average = 0.95). Only a single tag released at either Durham Ferry or the Old River was detected in Middle River, so Middle River was omitted from the survival model. None of the 14 tags detected at Turner Cut were subsequently detected at Chipps Island.

Estimates of the probability of fish remaining in the San Joaquin River at the head of the Old River in 2010 ranged from 0.39 to 0.59 across the seven release groups (average = 0.47; $SE = 0.02$; Table 2). Only for release 3 did fish show a statistically significant ($\alpha = 0.05$) preference for the Old River over the San Joaquin River ($P = 0.0443$; one-sided Z-test).

Route-specific survival through the Southern Delta region in 2010 had an average estimate of $\hat{S}_{A(SD)} = 0.32$ ($SE = 0.02$) in the San Joaquin route and $\hat{S}_{B(SD)} = 0.77$ ($SE = 0.05$) in the Old River route. For each release occasion, survival through the Southern Delta was significantly higher in the Old River route ($P \leq 0.003$; one-sided Z-test on the lognormal scale), which ended at the water export facilities and Highway 4. Combined salmon survival through the Southern Delta region in 2010 was estimated at $\hat{S}_{SD} = 0.56$ ($SE = 0.03$), averaged over all seven release groups (Table 2).

Survival through the entire San Joaquin River Delta region (from Mossdale to Chipps Island, approximately 89 km) was considerably lower than through only the Southern Delta region in 2010, the average overall estimate being $\hat{S}_D = 0.05$ ($SE = 0.01$; Table 2). Estimated survival from Mossdale to Chipps Island averaged $\hat{S}_{A(D)} = 0.04$ ($SE = 0.01$) in the San Joaquin route, and $\hat{S}_{B(D)} = 0.07$ ($SE = 0.01$) in the Old River route. Only the first release group showed a significant difference in survival to Chipps Island between the two routes, survival through the San Joaquin route ($\hat{S}_{A(D)} = 0.07$, $SE = 0.31$) being higher than through the Old River route ($\hat{S}_{B(D)} = 0.00$, $SE = 0$; $P = 0.0100$; Table 2). Lack of significance for other release groups may have been a result of low statistical power. Pooled over release groups, however, estimated survival to Chipps Island was significantly higher through the Old River route than through the San Joaquin River route ($P = 0.0133$).

For tags released at Durham Ferry, the median travel time through the reaches ranged from 0.1 d ($SE = 0.01$) between the two Stockton receivers (A4 to A5; approximately 3 km) to 3.2 d ($SE = 0.5$) from Medford Island (A7) to Chipps Island (G1); of the multiple paths between A7 and G1, the path that used only the San Joaquin River was approximately 46 km long. No tags were observed to move from Turner Cut to Chipps Island, and the median transition from Old River South (B2) to the CVP trash racks (E1) was 0.9 d ($SE = 0.1$).

Among the 29 salmon released at Durham Ferry in 2010 that were subsequently detected at Chipps Island, 31% (9 fish) used the San Joaquin route and 69% used the Old River route. The median travel time from the head of the Old River to Chipps Island was 5.7 d (migration rate = 14.0 km/d) through the San Joaquin route, compared with 7.2 d (7 km/d) for the single fish in the Old River route that migrated in-river past Highway 4, and 2.6 d for the 19 fish in the Old River route that passed through the Central Valley Project. Travel time for the CVP fish included time spent in holding tanks and truck transport to release sites just upstream of Chipps Island, as part of the salvage operation at the facility. It appears that the fastest route through the San Joaquin River Delta to Chipps Island in 2010 was through the Old River and the CVP.

DISCUSSION

The results of 2 years of acoustic-tagging studies reported here shed light on the survival of juvenile fall Chinook Salmon in the San Joaquin River Delta. Although estimated survival was considerably higher in 2010 than in 2009, overall survival was low in both years, and survival and migration rates tended to be higher upstream and lower downstream. This pattern was observed throughout the Southern Delta in both 2009 and 2010 and throughout the entire Delta in 2010. Some reduction in migration rate is expected as fish move downstream because the cyclic tidal environment may reverse the direction of river flow and temporarily push smolts upstream. Slower migration rates, in turn, may lead to lower survival in downstream reaches, with slower-moving smolts being less able to evade predators (Anderson et al. 2005).

When survival estimates were adjusted for reach length (i.e., survival rate = $\hat{S}(km^{-1})$), two regions displayed consistently low survival rates. The San Joaquin River reach from the receiver near the Navy Drive Bridge in Stockton to the Turner Cut junction had an estimated survival rate of 0.85 in 2009 and 0.94 in 2010. The reaches in the southwestern portion of the Old River route (i.e., from the head of Middle River to the entrances of the CVP and Clifton Court Forebay and to the Old River at Highway 4) had comparable survival rate estimates in both years, ranging from 0.83 to 0.90 in 2009 and 0.94–0.95 in 2010. All other Southern Delta reaches had higher estimated survival rates, while the only reach in the full Delta study area with lower survival rate was the San Joaquin River reach from the Turner Cut junction to Medford Island (0.86 in 2010). The San Joaquin River reaches from Stockton to the Turner Cut junction and Medford Island and the western portions of the Old River route warrant further investigation into mortality factors.

The estimated probability of survival throughout the Southern Delta region was generally higher in 2010 than in 2009 in both the San Joaquin River route and the Old River route. In particular, survival in the Old River from the junction with Middle River to the entrance of the water export facilities and Highway 4 appeared considerably higher in 2010 (average estimate = 0.92)

than in 2009 (average = 0.16). Overall, the survival estimates through the Southern Delta region in 2009 (average = 0.06) were comparable to the survival estimates through the entire Delta region in 2010 (average = 0.05). Although no direct estimates of survival through the entire Delta were available in 2009, we can conclude that total survival was <0.06 . The drop in survival in 2010 from the Southern Delta (0.56) to the entire Delta (0.05) suggests that total survival through the entire Delta in 2009 may have been as low as 0.005. Even considering the uncertainty inherent in the predator decision process, we can conclude that survival through the Delta was very low in 2009. If the survival probability estimated in 2009 was similar to survival in other low-flow years, current recovery efforts for San Joaquin River Chinook Salmon may be inadequate during dry years.

Despite interannual survival differences, the average estimated probability of fish entering the Old River from the San Joaquin (0.53) did not differ between 2009 and 2010. This route's entrainment probability was estimated in the presence of the nonphysical barrier operated at the head of the Old River. The barrier was found to be effective at deterring smolts from entering the Old River in 2010, but not in 2009 (Bowen et al. 2009; Bowen and Bark 2012, "protection efficiency"). Nevertheless, the effect of the barrier on the overall VAMP study results was limited because the barrier was operated only for approximately half of each release group, and estimates of the Old River route entrainment probability probably decreased by <0.1 because of the barrier study.

The 2009 and 2010 survival estimates reported here depend partly on the decision process used to identify and remove possible predator detections. Without removing any suspect detections, overall survival through the Southern Delta region would be estimated at 0.34 in 2009 and 0.79 in 2010 and at 0.11 through the entire Delta region in 2010. Thus, estimated survival would be higher in both years, but the comparisons between 2009 and 2010 and between the Southern Delta and the entire Delta would remain. However, many of the detections producing these higher survival estimates came from tags with considerably longer residence times (e.g., up to 810 h) or longer travel times than expected for emigrating juvenile salmonids (e.g., average residence time of approximately 0.5 h at most detection sites). Additionally, the fit of the statistical survival model declined when the presumed predator detections were included, suggesting that they were unlikely to have come from emigrating salmonids. The results presented here are based on our current understanding of behavior differences between juvenile salmon and predators such as striped bass. Nevertheless, more work needs to be done to develop methods for distinguishing between detections of salmon and detections of predators, especially for acoustic tagging studies in highly complex environments such as the Delta.

There are several possible explanations for the differences in Southern Delta survival observed between 2009 and 2010. River flows in 2009 were very low, whereas 2010 had considerably higher flows (Figure 4). Water exports from the federal and state

export facilities occurred at a slightly higher and more variable rate in 2009, the combined average export level being $56.4 \text{ m}^3/\text{s}$ (range = $38.2\text{--}73.3 \text{ m}^3/\text{s}$; SJRGA 2010). In 2010, the combined average export level was $43.0 \text{ m}^3/\text{s}$ (range = $37.4\text{--}44.2 \text{ m}^3/\text{s}$) (SJRGA 2011). Both lower flows and higher exports may have contributed to the lower survival observed in 2009, although the difference in average export level between 2009 and 2010 is small compared with possible daily variation in export levels ($42.5\text{--}322.8 \text{ m}^3/\text{s}$). Differences in the source and condition of the study fish may also have contributed to performance differences between the 2 years. The 2009 study fish were hybrids of spring and fall-run Chinook Salmon from the Feather River Fish Hatchery (FRH), located in the Sacramento River basin. These hybrid fish tended to be smaller than the 2010 study fish, which were fall-run Chinook Salmon from the Merced River Fish Hatchery (MRH; located in the San Joaquin River basin). Historically, experiments in the San Joaquin Delta have used MRH fish. In 2009, however, low numbers of MRH fish prompted the switch to the FRH for that year's tagging study, despite concern that FRH fish (genetically from the Sacramento River) may not adequately represent survival of San Joaquin fall-run Chinook Salmon (Brandes and McLain 2001). In 2010, rebounding numbers at the MRH allowed us to return to MRH fish for that year's tagging study.

The smaller size of the 2009 fish resulted in an average tag burden that was higher than in 2010, and also higher than desired ($\leq 5.5\%$; Brown et al. 2006). The higher tag burden in 2009 may have contributed to the high mortality in the first reach after release (Durham Ferry to Mossdale Bridge), where an estimated 53% of study fish died in 2009. However, differences in river conditions and predator distribution may also have contributed to differences in estimated mortality in this reach between the 2 years. Dry conditions and low flows in 2009 may have concentrated predators and prey (smolts) in a smaller volume of water. Higher water temperatures in 2009 may have kept the predators more active (e.g., Niimi and Beamish 1974), and also more likely to reside in the San Joaquin River between Durham Ferry and Mossdale Bridge, where water temperatures tend to be cooler than in the Delta.

Despite the differences in survival between the 2009 and 2010 study years, both studies found that juvenile fall run Chinook Salmon have very low survival through the San Joaquin River Delta, well under 0.10. Our 2010 estimates were similar to the lower range of previous survival estimates of San Joaquin smolts based on CWT data (Brandes and McLain 2001). However, the extremely low survival potentially experienced through the Delta in 2009 would have been lower than the lowest CWT estimates. Even the higher survival observed in 2010 was considerably lower than survival estimates of juvenile late fall-run Chinook Salmon from the Sacramento River through the Delta, which ranged from 0.35 to 0.54 in the winter of 2007 (Perry et al. 2010). The Perry study used comparable methods, with similar study design, tagging, and analysis. However, the late fall run Chinook Salmon used in

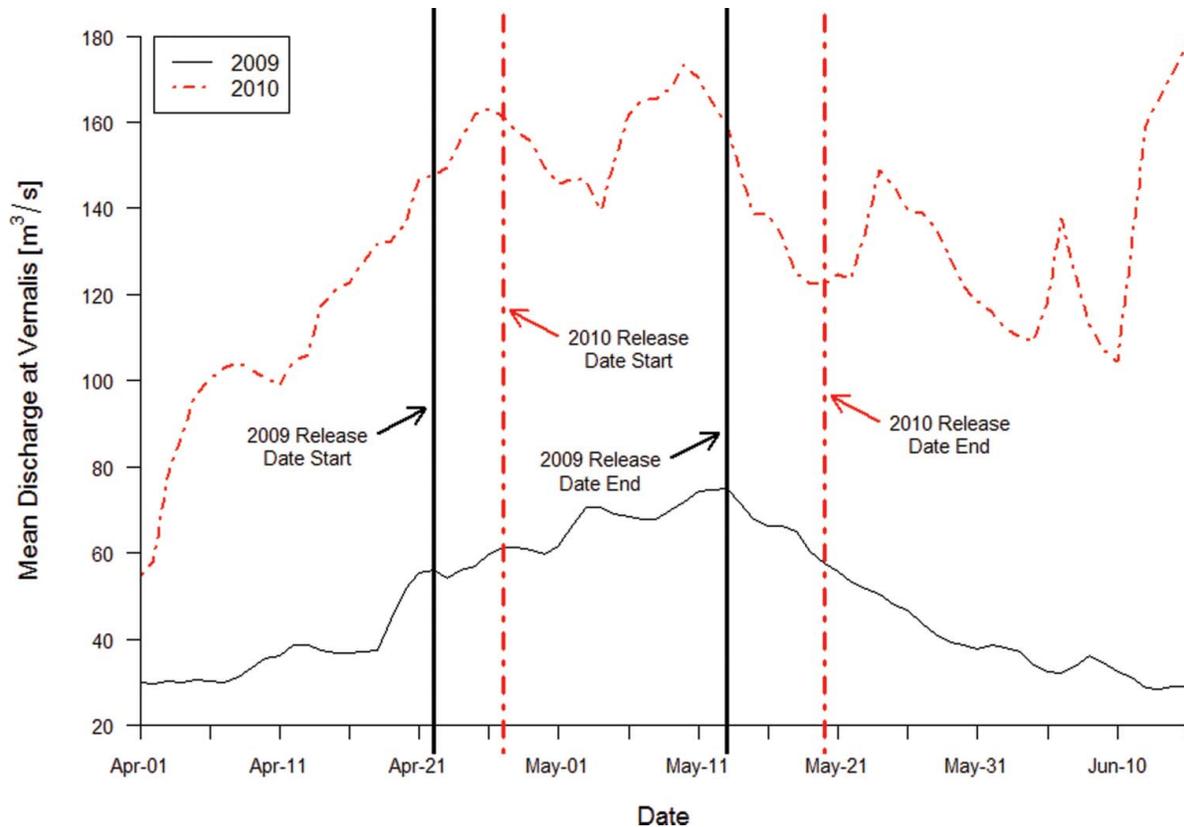

FIGURE 4. Mean daily discharge of the San Joaquin River at the U.S. Geological Survey gauge near Vernalis, California (rkm 113 from Chipps Island), during Chinook Salmon tagging studies in 2009 and 2010. [Figure available in color online.]

the Perry study migrate in winter, whereas the fall-run Chinook Salmon used in the VAMP study migrate months earlier in spring. Thus, not only were the VAMP fish smaller than the Perry study fish, they also migrated when higher predator activity is expected because of warmer temperatures and the striped bass spring spawning migration (Radtke 1966). Thus, there are several possible explanations why the VAMP study may be expected to estimate lower survival than the Perry study.

Estimates of juvenile Chinook Salmon survival through comparable environments in other basins tend to be higher than those observed in the 2009 and 2010 VAMP studies. McMichael et al. (2010) used acoustic tags to estimate survival of Chinook salmon smolts through the lower 192 rkm of the Columbia River to the river mouth; scaled by distance, the survival rate estimates ($\hat{S}^{(km^{-1})}$) were 0.999 for yearlings and 0.998 for subyearlings. Acoustic-tagged spring Chinook Salmon from the Thompson–Fraser river system had estimated survival rates of 0.989–0.997 (average = 0.995) through more than 330 rkm to the Fraser River mouth in 2004–2006 (Welch et al. 2008). These survival rates are considerably higher than both the VAMP-estimated Southern Delta survival rate of 0.92 in 2009 and the estimated entire Delta survival rate of 0.97 in 2010. Even the lowest survival rate estimate reported by Welch et al. (2008) for the Fraser River (0.989 in 2004) corresponds to much higher total survival

over a distance comparable to the VAMP study area (approximately 89 rkm). Over this distance, a population with a survival rate of 0.989/km would have an overall survival probability of 0.37, as opposed to the 2010 estimate of 0.05. Although direct comparison with other basins is difficult, it appears that the salmon smolts used in the 2009 and 2010 VAMP studies are not surviving as well on their seaward migration as other salmon population on the western coast of North America.

Part of the VAMP is a management plan based on the assumption that salmon survival to Chipps Island is higher through the San Joaquin River route than through the Old River route. This assumption is based on CWT studies between 1985 and 1990 that consistently found higher (but not statistically significant) point estimates of survival for smolts released in the San Joaquin River downstream of the Old River than for those released in the Old River (Brandes and McLain, 2001). Modeling of these data and other CWT data indicated that keeping salmon out of the Old River improved their survival (Newman 2008). The 2008 VAMP acoustic tag study results, although hampered by a high degree of premature tag failure, suggest that survival to Chipps Island was also higher through the San Joaquin River than through the Old River route in 2008 (Holbrook et al. 2009). Furthermore, there is evidence that salmon from the Sacramento River have a higher probability of reaching Chipps Island if they

remain in the Sacramento River rather than entering the central Delta (Newman and Brandes 2010, Perry et al. 2010). Since the 1990s, management has experimented with efforts to keep fish in the San Joaquin River and out of the Old River by installing a barrier (physical or nonphysical) at the head of the Old River. Our results suggest that prevailing ideas about relative survival in the two routes may be too simple, given that we found no conclusive evidence that survival was higher in the San Joaquin River route than in the Old River route. One difference between the 2009 and 2010 study years and previous years was the switch from a physical barrier to testing a nonphysical barrier at the head of the Old River in 2009 and 2010. Historically, the physical barrier at the Old River routed both fish and river flow into the San Joaquin River (SJRG 2005). In contrast, the nonphysical barrier used in 2009 and 2010 routed fish but not flow into the San Joaquin (Bowen et al. 2009; Bowen and Bark 2012). With salmon smolt survival in the San Joaquin River thought to increase with flow (SJRG 2007), it is possible that the nonphysical barrier deprived smolts routed to the San Joaquin River of the increased flows necessary for improved survival (Perry et al. 2013). There is also a concern that the larger in-water structure associated with the nonphysical barrier may create habitat for increased predation at the site. More study is needed.

The San Joaquin River Delta represents just a small portion of the entire juvenile out-migration of San Joaquin Chinook Salmon and in recent years has typically been traversed in <2 weeks (SJRG 2011; Holbrook et al. 2013). With survival through only a portion of the juvenile migration estimated at <0.10, management efforts in the lower San Joaquin River and Delta must be more protective if salmon populations are to persist in this region. However, effective management must be based on a better understanding of the factors influencing mortality than is currently available. More research into salmon use of and survival in the Delta is needed, especially in dry years that may represent future conditions under climate change. In light of increasing human demands for Central Valley water, it is unlikely that salmon survival will improve on its own. If the survival estimates observed in these two studies are representative of the future, only extreme measures have a chance of saving San Joaquin River Chinook Salmon.

ACKNOWLEDGMENTS

Many people and groups were involved in designing and implementing the VAMP study. We thank Natural Resource Scientists, Inc., California Department of Fish and Game, California Department of Water Resources, the U.S. Fish and Wildlife Service (Stockton office), the U.S. Bureau of Reclamation, Normandeau and Associates (Stevenson, Washington), and the U.S. Geological Survey (Columbia River Research Lab and Sacramento office) for their contributions to the study. We also thank Mark Bowen from the U.S. Bureau of Reclamation for access to detection data from the nonphysical barrier study at the head of the Old River, and three anonymous reviewers

for their helpful suggestions. Funding for the VAMP study was provided by the signatories to the San Joaquin River Agreement, and funding for analysis and manuscript preparation was provided by the San Joaquin River Group Authority.

Edited by George N. Somero, Stanford University, Pacific Grove, CA, and approved October 3, 2007 (received for review June 29, 2007)

Ecological observations sustained over decades often reveal abrupt changes in biological communities that signal altered ecosystem states. We report a large shift in the biological communities of San Francisco Bay, first detected as increasing phytoplankton biomass and occurrences of new seasonal blooms that began in 1999. This phytoplankton increase is paradoxical because it occurred in an era of decreasing wastewater nutrient inputs and reduced nitrogen and phosphorus concentrations, contrary to the guiding paradigm that algal biomass in estuaries increases in proportion to nutrient inputs from their watersheds. Coincidental changes included sharp declines in the abundance of bivalve mollusks, the key phytoplankton consumers in this estuary, and record high abundances of several bivalve predators: Bay shrimp, English sole, and Dungeness crab. The phytoplankton increase is consistent with a trophic cascade resulting from heightened predation on bivalves and suppression of their filtration control on phytoplankton growth. These community changes in San Francisco Bay across three trophic levels followed a state change in the California Current System characterized by increased upwelling intensity, amplified primary production, and strengthened southerly flows. These diagnostic features of the East Pacific “cold phase” lead to strong recruitment and immigration of juvenile flatfish and crustaceans into estuaries where they feed and develop. This study, built from three decades of observation, reveals a previously unrecognized mechanism of ocean–estuary connectivity. Interdecadal oceanic regime changes can propagate into estuaries, altering their community structure and efficiency of transforming land-derived nutrients into algal biomass.

climate variability | coastal eutrophication | ocean–estuary connectivity | regime shift | trophic cascade

Ecosystem observations sustained over decades often produce surprises, revealing novel processes that regulate abundance, composition, and productivity of biological communities. In 1999, we were surprised by an October phytoplankton bloom in San Francisco Bay (SFB), a departure from the seasonal pattern observed over two preceding decades. This event signaled a large biological change manifesting over subsequent years as increasing phytoplankton biomass and new seasonal blooms. This change is puzzling because it occurred in an era of decreasing nutrient inputs. Phytoplankton increase is a well documented response to nutrient enrichment from fertilizer runoff and wastewater discharge to coastal ecosystems (1). Nutrient enrichment has promoted excessive algal production and severely degraded habitat quality in the Chesapeake Bay, northern Gulf of Mexico, and Baltic and Adriatic seas. The SFB “paradox” presented here is contrary to these experiences elsewhere and provides strong evidence that additional processes, beyond nutrient supply, can cause sustained increases in algal biomass. We use data from the United States Geological Survey (USGS) long-term study of SFB to describe the patterns of phytoplankton increase and then present evidence from other studies that the underlying process is a trophic cascade having origins in the Pacific Ocean.

Long-term research has been sustained in SFB, which exemplifies a large ecosystem at the land–sea interface influenced by natural processes of variability and multiple modes of human disturbance (2). SFB receives large inputs of nitrogen and phosphorus from its 153,000-km² agricultural watershed and its densely populated urban watershed. Nutrient inputs are comparable to those delivered to Chesapeake Bay, but SFB is a low-productivity estuary with no recurrent problems of hypoxia or harmful algal blooms (1). This eutrophication resistance has manifested over 20 years of observation as persistent low phytoplankton biomass and high nutrient concentrations. Median summer–autumn concentrations of dissolved inorganic nitrogen and phosphorus were 32.3 and 2.3 μM , respectively, in South SFB over the period 1977–1998. These values are 10 times higher than nutrient concentrations that limit phytoplankton growth, and they represent large stocks of unutilized nitrogen and phosphorus. Resistance mechanisms include tidal- and wind-driven mixing that prevent stratification, large sediment inputs and high turbidity that limits light penetration and phytoplankton photosynthesis, and fast filtration removal of phytoplankton cells by bivalve mollusks (3). Here, we report recent phytoplankton increases that signal a weakened resistance to nutrient pollution, and propose a top-down mechanism induced by a state change in the northeast Pacific Ocean. This study reveals how the expression of eutrophication from land runoff to estuaries can fluctuate with ocean-derived changes in biological community structure, a previously unrecognized mechanism of ocean–estuary connectivity with implications for how we study and manage nearshore coastal ecosystems.

Results

We have measured phytoplankton biomass as chlorophyll *a* (Chl-*a*) concentration at least monthly in SFB since 1978. Observations from 1978–1998 showed a recurrent annual pattern of low phytoplankton biomass punctuated by short-lived spring blooms. This pattern changed abruptly in 1999 with the first record of an autumn bloom, detected as elevated Chl-*a* at concentrations never observed during autumn sampling the previous 22 years (Fig. 1*A*). Autumn–winter blooms in subsequent years included unprecedented occurrences of dinoflagellate red tides (4). New seasonal blooms, coupled with increasing baseline Chl-*a*, have led to increased overall phytoplankton biomass (Fig. 1*B*). Trends over time (Theil–Sen slopes of decadal Chl-*a* series) revealed statistically significant ($P < 0.05$) phytoplankton increases beginning after 1999 (Fig. 1*C*). These changes

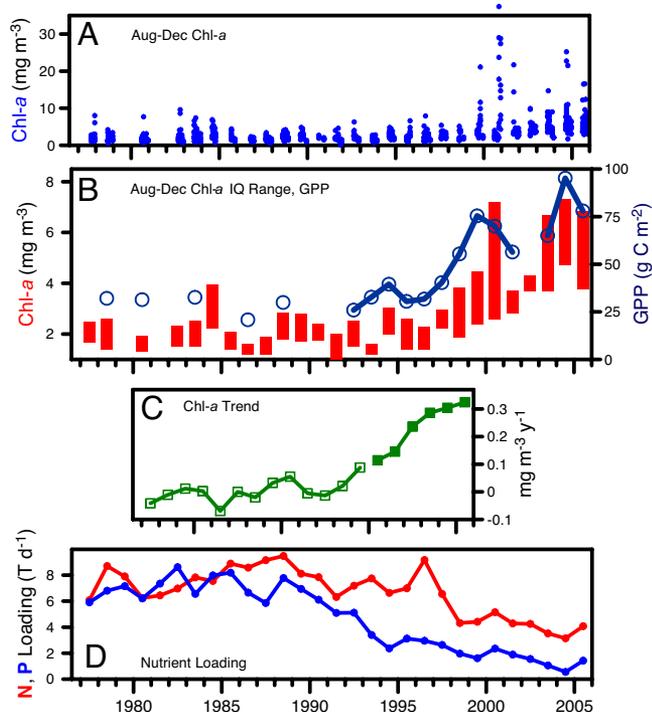

Fig. 1. Indicators of phytoplankton change in South SFB. (A) Occurrences of autumn blooms (August through December Chl-a >10) since 1999. (B) Increases in August through December Chl-a (interquartile ranges are shown as bars) and gross primary production (GPP) (open circles). (C) Ten-year windowed trends showing statistically significant ($P < 0.05$; filled squares) Chl-a increases after 1999. (D) Annual inputs of dissolved inorganic nitrogen and phosphorus from the San Jose–Santa Clara Wastewater Treatment Plant [N. Van Keuren (City of San Jose), personal communication], the largest municipal discharger to South SFB.

are also ecologically significant: estimated August through December primary production [supporting information (SI) Text] more than doubled (Fig. 1B), from 32 g C m^{-2} (pre-1998 mean) to 73 g C m^{-2} (post-1998 mean). Seasonal analysis of the 1978–2005 series detected positive Chl-a trends every month, of

which eight were statistically significant (Fig. 2E). These observations are compelling evidence of phytoplankton increase at a magnitude observed in other estuaries as a response to increasing nutrient input.

Water quality and biological communities of estuaries are strongly influenced by freshwater inputs that deliver sediments, nutrients, and contaminants from land runoff and wastewater discharge. South SFB is situated in a densely populated urban watershed, and 98% of its nitrogen input (see table 8 of ref. 5) is from municipal wastewater treatment plants (North SFB is more strongly influenced by agricultural inputs from the Sacramento and San Joaquin rivers). We explored water-quality data for indicators that the phytoplankton increase in SFB was caused by changing inputs from the surrounding landscape that could increase algal growth rate. Phytoplankton biomass grows as algal cells divide at rates regulated by macronutrient (nitrogen, phosphorus) concentrations, water temperature, and light energy. But monthly trends of dissolved inorganic nitrogen (DIN) and dissolved reactive phosphorus (DRP) concentrations in SFB were negative for each month, approaching maximum trends of $-10\% \text{ y}^{-1}$ (Fig. 2A and B). These large nutrient declines are consistent with progressive improvements in municipal wastewater treatment leading to decreasing N and P input from the urban watershed (Fig. 1D) and expectations of a corresponding reduction in algal biomass.

Monthly trends of water temperature in SFB over the period 1978–2005 were small and not statistically significant (Fig. 2D). SFB has high concentrations of suspended sediments that limit light penetration and photosynthesis, a primary factor in this estuary’s low productivity and low nutrient assimilation efficiency (1). But monthly trends of suspended particulate matter (SPM) were positive for each month (Fig. 2F), so turbidity and light limitation have not diminished over time. Algal blooms can be triggered by salinity stratification that creates a shallow high-light surface layer of fast phytoplankton growth (3). Salinity stratification of estuaries is strongest during years of high river flow and low surface salinity. Trends of surface salinity in SFB varied across months, but none were statistically significant (Fig. 2C), and there were no significant trends of stratification intensity (difference between bottom and surface salinity). We conclude that the phytoplankton increase in SFB was not caused by secular increases in the phytoplankton growth rate because nutrients have declined, turbidity has (weakly) increased, stratification has not strengthened, and water temperature has not changed inside the estuary.

We next explored biological monitoring data to consider an alternative, top-down explanation for the phytoplankton increase in SFB as a result of reduced consumption by herbivores. A large fraction of phytoplankton primary production in SFB is consumed by bivalve mollusks, and high bivalve biomass and filtration rates are keys to the low phytoplankton–high nutrient state. Summer–autumn rates of phytoplankton growth and bivalve consumption have historically been balanced (3), and simulations with a numerical model demonstrate a high sensitivity of phytoplankton biomass to changes in bivalve grazing intensity (6). The mean biomass of suspension-feeding bivalves (e.g., *Corbula amurensis*, *Venerupis japonica*, *Musculista senhousia*, and *Mya arenaria*) was 7.9 g m^{-2} (ash-free dry weight) in samples collected across shallow habitats in South SFB from 1987 through 1998. However, six surveys conducted after 1998 revealed surprisingly small populations (Fig. 3A and SI Table 1) and complete absence of these bivalves at many sampling sites, with a mean biomass of only 0.4 g m^{-2} . The ≈ 20 -fold bivalve decline after 1998 and its coincidence with a positive Chl-a trend suggests that the phytoplankton increase in SFB was a response to decreased bivalve abundance and phytoplankton consumption.

Surveys by the California Department of Fish and Game provide evidence that the bivalve population collapse was, at

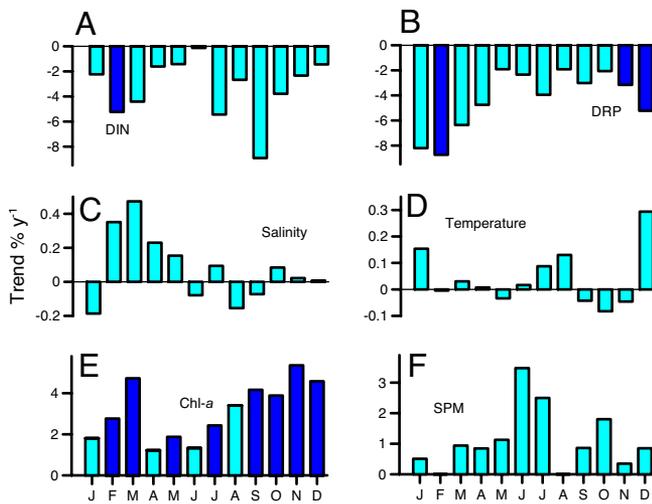

Fig. 2. Monthly trends of water quality in South SFB based on USGS measurements of DIN and DRP for the years 1990–2005, and surface salinity, water temperature, Chl-a, and SPM for the years 1978–2005. Units are percent change y^{-1} . Darker bars indicate statistically significant trends ($P < 0.05$).

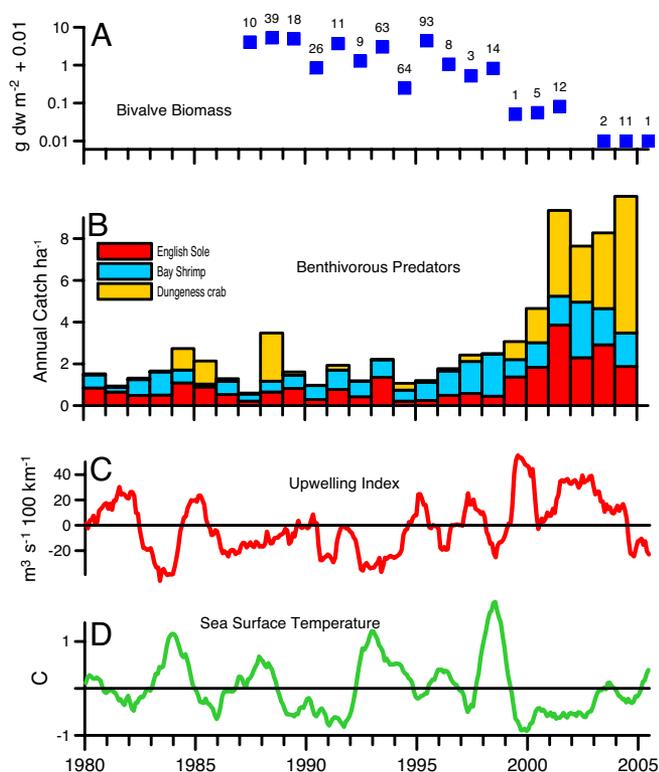

Fig. 3. Indices of biological community change within SFB and physical changes in the adjacent California Current. (A) Annual median biomass of filter-feeding bivalves across shallow habitats in South SFB; numbers above filter-squares indicate sample number per year. (B) Mean annual catch ha^{-1} , normalized to 1980–2005 averages, of English sole, Bay shrimp, and Dungeness crab, from monthly sampling across the marine domains of SFB. (C) Anomalies in upwelling intensity computed by the National Oceanic and Atmospheric Administration from atmospheric pressure fields. (D) Sea surface temperature measured at the Farallon Islands. The bottom series (C and D) are 12-mo running averages of deviations from 1977–2005 monthly means.

least partly, a result of increased predation. Cumulative abundance of *Crangon* shrimp and juvenile Dungeness crab (*Cancer magister*) and English sole (*Parophrys vetulus*) increased to record levels in SFB after 1999 and persisted at high stock densities (Fig. 3B). These species are widespread predators in SFB that feed on benthic invertebrates including bivalve mollusks. The sum of their mean abundances (normalized to 1980–2005 means) was 7.1 from 2000 through 2004 compared with 1.8 over the preceding 20 years. Fluctuations of bivalve biomass are strongly associated with interannual and decadal changes in the abundances of their predators: bivalve recruitment has failed in other estuaries during years of high predator (*Crangon* spp.) abundance (7), and collapse of bay scallop stocks in the coastal Atlantic coincided with increased abundances of bottom-feeding skates and rays (8).

Discussion

The unexpected phytoplankton increase in SFB was one component of a broad suite of biological community changes that began after 1998 and appear to be linked through a trophic cascade (9). Abundance records suggest that heightened predation by fish and crustaceans reduced bivalve abundance and phytoplankton consumption, allowing algal biomass to grow and episodic blooms to develop after spring. Such trophic cascades have been induced through experimental additions of predatory fish in lakes (10), and large-scale community changes cascade across trophic levels in marine ecosystems when apex predators

are removed by fishing (8, 11). Trophic cascades induced by human activities can exacerbate the harmful consequences of nutrient enrichment: harvest of oysters and removal of their filtration function has contributed to the large buildup of phytoplankton biomass and associated water-quality degradation of Chesapeake Bay (12). Our observations highlight again the powerful top-down control of phytoplankton biomass by bivalve suspension feeders in shallow marine ecosystems, manifested elsewhere as abrupt phytoplankton decreases after bivalve invasions from introductions of alien species (13) or hydrologic manipulations (14).

The trophic cascade described here was not associated with changes in fishing intensity, species introductions, or other human interventions. However, it coincided with pronounced physical changes in the California Current System (CCS), suggesting that it might be linked to coupled physical and biological changes in the northeast Pacific Ocean. The 1997–1998 El Niño was the strongest on record (15), and it was followed by an equally strong La Niña in 1999. This abrupt El Niño–La Niña transition across the Pacific basin initiated a multiyear period of strong upwelling and enhanced southerly flow in the California Current that transported subarctic waters along the coast (16). At the latitude of SFB, these changes were seen as sustained positive upwelling anomalies and low surface temperature at the Farallon Islands from 1999 through 2004 (Fig. 3C and D). Current measurements and drifter studies also documented unusually strong southward advection off Oregon, producing an equatorward displacement anomaly of 2,000 km during 2001–2002 and a source of cold water from northern latitudes (17). This “cold phase” of the East Pacific induced a suite of ecological changes along the North American coast, including southerly displacement of pelagic species and increased primary production, zooplankton biomass, and populations of cold-water pelagic fish (18).

The coincidental timing of phytoplankton increase in SFB with altered coastal currents suggests a coupling between SFB and the CCS through high annual variability in the recruitment of marine species whose juvenile stages immigrate into estuaries. This variability may occur through multiple mechanisms. Distributions of adult Dungeness crab and English sole are normally centered above the latitude of SFB, so cooling of the CCS may lead to southerly displacement of adult stocks whose distributions shift with changes in coastal temperature (19). Annual recruitment of Dungeness crab is strongest during cool years in the CCS as a result of reduced egg mortality, enhanced transport of pelagic larvae to settlement areas, or high primary production and food supply rates characteristic of La Niña-type conditions (20). The specific mechanisms of recruitment variability are unknown and likely vary among species. However, the coherent physical changes in the CCS and increased immigration of juvenile flatfish and crustaceans inside SFB are strong evidence that atmospherically driven changes in ocean boundary currents can induce large biological changes within estuaries (21). These changes can include trophic cascades leading to increased primary production and more efficient transformation of land-derived nutrients into algal biomass.

We suspect that there are subtle but important secondary manifestations of the trophic cascade outlined above. For example, the coastal Pacific is a source of phytoplankton biomass to SFB when blooms develop offshore and cells are transported into the Bay by tidal pumping (22). The new seasonal blooms after 1998 were dominated by large diatom species (e.g., *Thalassiosira punctigera*) characteristic of CCS communities during upwelling events, or dinoflagellates (e.g., *Akashiwo sanguinea*) after upwelling relaxation (4). Amplified cycles of upwelling and relaxation during cold phases of the East Pacific can provide either a significant amount of coastal-produced phytoplankton biomass (21, 23) or resting stages or vegetative cells to seed subsequent blooms within estuaries

(24). Much of the imported biomass to SFB was presumably consumed by bivalves when they were abundant (pre-1999), just as imported phytoplankton are rapidly consumed by oysters in the upwelling-influenced Willapa Bay (23). Conversely, ocean-derived phytoplankton biomass can persist or grow in SFB when bivalve abundance is low. Thus, although the steady increase in phytoplankton biomass after 1998 (Fig. 1B) seems to reflect growth within SFB, the new seasonal blooms (Fig. 1A) may be supplied at least in part by coastal phytoplankton species. Nonetheless, the appearance of these new seasonal blooms is ultimately conditional on the trophic cascade that enhances algal population growth within the SFB.

The guiding paradigm of estuarine ecology is that runoff from land is the essential driver of biological and water-quality variability. We illustrate how the coastal ocean can be an equally powerful driver of estuarine change. Oceanographers and atmospheric scientists have learned how redistributions of major atmospheric pressure systems over ocean basins can alter winds, coastal currents, water temperature, and productivity, leading to regime changes in the abundance and distribution of fish, birds, and mammals (25). Our observations in SFB began in 1977, coincidentally the last regime change of the Pacific Decadal Oscillation (PDO) (26) when the East Pacific entered a “warm phase” of weak coastal upwelling and reduced southerly transport by the California Current. Unprecedented biological changes across three trophic levels occurred in SFB after the East Pacific returned to a state approximating the cold phase of the PDO. More than two decades of observation were required to discover how an oceanic regime change can induce an altered ecological state of a large estuary.

Long-term observations of SFB reveal a previously unrecognized mode of ecosystem variability that has implications for the way we study and manage estuaries. Estuaries are the most degraded marine ecosystems (12), and recent assessments highlight the growing environmental and societal costs of this degradation (27), motivating a sense of urgency to implement strategies of ecosystem-based rehabilitation and sustainability (28). Our study suggests that programs to rehabilitate damaged estuaries should build from a broadened geographic reference that includes the interplay between processes occurring over ocean basins and within watersheds, and an expanded temporal reference that includes natural cycles and trends of ocean-atmosphere variability operating over multiple decades.

Data and Methods

Hydrography and Water Quality. We analyzed results of near-surface measurements at eight stations in South SFB where the 1978–2005 data record contains few gaps and trend tests can be applied (USGS stations 21, 22, 24, 25, 27, 29, 30, and 32; see SI Fig. 4). Chl-*a* was measured from *in vivo* fluorescence with calibration of fluorometers (Turner Designs Model 10 before 1987, and Sea Tech or Turner Designs SCUFA since 1987) using 10–20 discrete measures of extracted Chl-*a* from filtered samples each cruise (29). Daily calibrations were necessary because of significant fluctuations in the fluorescence:Chl-*a* ratio. Water samples were preserved in acid Lugol's solution and examined by light microscopy to identify, measure, and count phytoplankton cells (30).

From 1978 to 1987, salinity, temperature, and SPM concentration were measured by pumping bay water to a shipboard salinometer, thermistor, and nephelometer. Since 1987, these constituents have been measured by using a Seabird SBE 9/11 CTD and optical backscatter sensor (OBS). The nephelometer and OBS were calibrated each cruise with discrete measures of SPM determined as dry mass retained on 0.4- μm polycarbonate filters. Nutrient samples were filtered through 0.4- μm polycarbonate filters and frozen until analyzed for DIN ($\text{DIN} = \text{NH}_4^+ + \text{NO}_3^- + \text{NO}_2^-$) and DRP by using modifications of standard colorimetric methods (31). The light attenuation coefficient k

(m^{-1}) was computed from vertical irradiance profiles measured with a LI-COR 192S quantum sensor. We used a linear model to estimate k from SPM ($k = 0.567 + 0.0586 \times \text{SPM}$; adjusted $R^2 = 0.863$) when light profiles were not measured. All data are available online (<http://sfbay.wr.usgs.gov/access/wqdata>).

Primary Production. Direct measurements of gross primary production were used to build an empirical model (SI Fig. 5) for calculating primary production over the full record of Chl-*a* and turbidity measurements. For each day and station, we first calculated the median SPM and Chl-*a* concentrations for depths ≤ 3 m. Under the assumptions that vertical attenuation of photosynthetically available radiation (PAR) does not change with depth, Chl-*a* is vertically homogeneous, and primary production is proportional to light absorbed by photosynthetic pigments, gross primary production (GPP) for a given location and day can be estimated from

$$\text{GPP} = \frac{4.6\Psi BI_0}{k}, \quad [1]$$

where Ψ ($\text{mg C} [\text{mg Chl-}a]^{-1} [\text{mol m}^{-2}]^{-1}$) is the water column light utilization efficiency, B (mg m^{-3}) is the median Chl-*a* in the upper 3 m, and I_0 [$\text{E} (\text{einstein} = 1 \text{ mol of photons}) \text{m}^{-2} \text{d}^{-1}$] is the photosynthetically active radiation. This approach has been verified in many estuarine systems when Ψ is calibrated for local conditions. The value used here ($\Psi = 0.82$) is based on 60 ^{14}C -uptake assays conducted in SFB between 1993 and 1998 (SI Fig. 5).

The longest period of relevant solar irradiance data were provided by an annually calibrated LI-COR 192 quantum sensor mounted on the USGS R/V *Polaris* during 1980–1994. The nearest sensor covering the entire period of interest is located at Davis, California, but irradiance at the latter location averages $\approx 10\%$ higher due to a lower incidence of fog. The Davis time series did allow us to verify that there was no secular trend in irradiance during the entire period. We computed GPP from an average annual cycle (SI Fig. 6) calculated from the 1980–1994 quantum sensor data and then smoothed using a spline with 30 d.f. (<http://finzi.psych.upenn.edu/R/library/stats/html/smooth.spline.html>).

Daily GPP estimates were linearly interpolated to provide a continuous record at each station. UTM coordinates were used to determine the straight-line distances between adjacent stations: L_1, \dots, L_7 . The transect-average GPP for any time period was calculated as

$$\text{GPP}_{\text{bay}} = \frac{\sum_{i=1}^7 L_i \frac{(\text{GPP}_i + \text{GPP}_{i+1})}{2}}{\sum_{i=1}^7 L_i}, \quad [2]$$

where GPP_{bay} is the transect average and GPP_i is the value for station i . Estimates were made only for those years in which data were available for at least 75% of the month \times station data matrix.

Estimation of Monthly Water Quality Trends. Long-term trends for Chl-*a*, salinity, temperature, and SPM (Fig. 2) were calculated by using USGS data collected at stations 21, 22, 24, 25, 27, 29, 30, and 32 from January 1978 through December 2005. All samples from the upper 3 m were aggregated by their median for each sampling time and location. The spatially weighted average of each water quality variable for each transect was then calculated as

$$C_{\text{bay}} = \frac{\sum_{i=1}^7 L_i \frac{(C_i + C_{i+1})}{2}}{\sum_{i=1}^7 L_i}, \quad [3]$$

where C_{bay} is the transect average and C_i is the value for station i . The long-term trend for each water quality variable by month was then calculated as the Theil–Sen slope, which is the median slope of the lines joining all pairs of points in the same month but in different years. The statistical significance of the slope for each month was determined by the Mann–Kendall test (32).

Long-term trends for DIN and DRP (Fig. 2 A and B) were calculated by using data collected from January 1990 through December 2005 (earlier records are too sparse to include in trend tests). All samples within 0–3 m from the surface were aggregated by their median for each sampling time and location. Transects for each sampling day were summarized by the median value of all available data, rather than weighted averages, because of missing data. The long-term trends and their statistical significance were then calculated as above.

Estimation of Windowed Chlorophyll Trends. Windowed (decadal) trends for Chl-*a* used the same data as for the long-term monthly trends. Trends were determined for each successive decade ending in the years 1987–2005. Trends were calculated by the overall Theil–Sen slope; i.e., using lines joining all pairs of data points in the same month but in different years. The statistical significance of each trend was determined by the seasonal Kendall test, corrected for serial correlation (32). All calculations and tests, unless otherwise specified, were carried out in the R software environment (33). The *USGS Library for S-Plus* was used for the seasonal Kendall tests (34).

Bivalve Filter Feeders. Several independent research or monitoring surveys sampled benthic macrofauna across shallow habitats in the southernmost regions of South SFB from 1987 through 2005. From results of these surveys, we estimated the biomass (ash-free dry tissue weight) of filter-feeding bivalves using abundances, size distributions, and length–weight relationships determined for individual species. Sampling protocols varied

among studies, and general length–weight relationships were applied when these were not measured (SI Table 1).

Demersal Fish, Crabs, and Bay Shrimp. The California Department of Fish and Game has sampled fish, crabs, and shrimp in open-water habitats of SFB since 1980 (www.delta.dfg.ca.gov/baydelta/monitoring/baystudy.asp). Demersal species were sampled with an otter trawl having a 2.5-cm stretch mesh body and a 1.3-cm stretch mesh cod end. We present the annual mean catch per unit effort (CPUE, number ha^{-1}) from monthly (February through October) sampling at 24 stations in the marine domains of SFB (South SFB, Central SFB, and San Pablo Bay). CPUE was calculated for each species as total catch divided by area swept during a 5-min trawl at each station ($n = 5,486$). We present the mean annual CPUE, normalized to 1980–2005 means, for three benthivorous predators: juvenile English sole (*Parophrys vetulus*), juvenile Dungeness crab (*Cancer magister*), and Bay shrimp (*Crangon franciscorum*, *Crangon nigricauda*, and *Crangon nigromaculata*).

Oceanographic Data. We used the monthly Upwelling Index computed by the National Oceanic and Atmospheric Administration Pacific Fisheries Environmental Laboratory from surface atmospheric pressure fields (www.pfeg.noaa.gov/products/PFEL/modeled/indices/upwelling/NA/upwell_menu_NA.html). We report the mean of upwelling indices computed at 36°N and 39°N, stations that bound the entrance to SFB. Sea surface temperature (SST) was measured at the Farallon Islands by the Point Reyes Bird Observatory (http://shorestation.ucsd.edu/active/index_active.html). The series presented here (Fig. 3 C and D) are 12-mo running averages of monthly deviations from 1977–2005 monthly means to remove seasonal effects and highlight departures from normal patterns of upwelling and SST in the California Current.

We thank our colleague Jim Kuwabara for sharing bivalve data, PRBO Conservation Science for providing sea surface temperature data, and N. Van Keuren (City of San Jose) for annual nutrient loadings from the San Jose–Santa Clara Wastewater treatment plant. Long-term observations and research in San Francisco Bay are supported by the United States Geological Survey (USGS) Office of Hydrologic Research, the USGS Toxic Substances Hydrology Program, the USGS Priority Ecosystems Science Program, the San Francisco Bay Regional Monitoring Program through the San Francisco Estuary Institute, and the Interagency Ecological Program for the San Francisco Estuary through the California Department of Fish and Game San Francisco Bay Study.

Turbidity as a control on phytoplankton biomass and productivity in estuaries

JAMES E. CLOERN*

(Received 5 September 1986; in revised form 21 May 1987; accepted 22 May 1987)

Abstract—In many coastal plain estuaries light attenuation by suspended sediments confines the photic zone to a small fraction of the water column, such that light limitation is a major control on phytoplankton production and turnover rate. For a variety of estuarine systems (e.g. San Francisco Bay, Puget Sound, Delaware Bay, Hudson River plume), photic-zone productivity can be estimated as a function of phytoplankton biomass times mean irradiance of the photic zone. Net water column productivity also varies with light availability, and in San Francisco Bay net productivity is zero (estimated respiratory loss of phytoplankton balances photosynthesis) when the ratio of photic depth (Z_p) to mixed depth (Z_m) is less than about 0.2. Thus whenever $Z_p:Z_m < 0.2$, the water column is a sink for phytoplankton production.

Much of the spatial and temporal variability of phytoplankton biomass or productivity in estuaries is explained by variations in the ratio of photic depth to mixed depth. For example, phytoplankton blooms often coincide with stratification events that reduce the depth of the surface mixed layer (increase $Z_p:Z_m$). Shallow estuarine embayments (high $Z_p:Z_m$) are often characterized by high phytoplankton biomass relative to adjacent channels (low $Z_p:Z_m$). Many estuaries have longitudinal gradients in productivity that mirror the distribution of suspended sediments: productivity is low near the riverine source of sediments (low $Z_p:Z_m$) and increases toward the estuary mouth where turbidity decreases. Some of these generalizations are qualitative in nature, and detailed understanding of the interaction between turbidity and estuarine phytoplankton dynamics requires improved understanding of vertical mixing rates and phytoplankton respiration.

INTRODUCTION

Estuaries are perceived as highly productive ecosystems because they are often nutrient-rich and have multiple sources of organic carbon to sustain populations of heterotrophs, including riverine and waste inputs and autochthonous primary production by vascular plants, macroalgae, phytoplankton, and benthic microalgae. However, the perception of high productivity should not necessarily extend to the open water column of estuaries where annual phytoplankton production can be less than that of other marine environments. In their review, BOYNTON *et al.* (1982) calculated a mean annual phytoplankton productivity of 190 g C m^{-2} for 45 estuaries. Although this mean value is higher than productivity of the open ocean, it may not exceed phytoplankton productivity in the nearshore coastal ocean. In those few geographic areas where annual phytoplankton production has been measured in an estuary and in the adjacent coastal zone, productivity generally appears to be highest in the coastal ocean (e.g. Table 1).

Phytoplankton production can be very low in coastal plain and river-dominated estuaries, environments with high turbidity caused by river inputs of suspended particu-

late matter (SPM) and/or resuspension of bottom sediments. SPM concentrations in these estuaries often exceed 50 mg l^{-1} , such that light is attenuated rapidly in the water column and phytoplankton photosynthesis is confined to a shallow photic zone. As a consequence, phytoplankton dynamics (including productivity and spatial/temporal changes in biomass) are largely controlled by light availability. This conclusion is consistent with results from both theoretical studies and field investigations. For example, WOFSY'S (1983) model indicates that phytoplankton biomass is an inverse function of SPM concentration, and that light limitation prevents phytoplankton blooms when SPM concentration exceeds 50 mg l^{-1} . PETERSON and FESTA (1984) have used numerical simulation experiments to explore the relations between SPM concentration and phytoplankton biomass and productivity. They conclude that estuarine productivity becomes strongly depressed as SPM concentration increases from 10 to 100 mg l^{-1} . In the past two decades there have been numerous studies of individual estuaries supporting the conclusion that light limitation is the major environmental control on primary production. Examples include the Bristol Channel (JOINT and POMROY, 1981), Ems-Dollard (COLIJN, 1983), Wadden Sea (CADÉE and HEGEMAN, 1979), Delaware Bay (PENNOCK and SHARP, 1986), upper Chesapeake Bay (HARDING *et al.*, 1986), and the Hudson (MALONE, 1976) and Columbia River (SMALL and FREY, 1984) estuaries.

The purpose of this paper is to review some concepts of how turbidity (SPM) influences estuarine phytoplankton, using results from an ongoing study of San Francisco Bay. Although there are direct interactions between phytoplankton and suspended mineral particles (e.g. adhesion and aggregation; AVNIMELECH *et al.*, 1982), I consider here only the indirect effects of SPM through light attenuation. Most concepts that apply to San Francisco Bay also apply to other turbid estuaries, and results from other studies are used to demonstrate how light availability can regulate estuarine phytoplankton dynamics.

SAN FRANCISCO BAY

San Francisco Bay as a representative estuary

San Francisco Bay has been the site of multidisciplinary research in the past decade, much of which is summarized or referenced in CONOMOS (1979), CLOERN and NICHOLS (1985), and NICHOLS *et al.* (1986). This large estuary of the Sacramento and San Joaquin rivers has a number of features that typify shallow and coastal plain estuaries, including: (1) morphology characterized by a central channel of 10–20 m depth flanked by subtidal

shoals <3 m deep; (2) suspended and consolidated sediments composed primarily of lithogenous materials, mostly silt and clay (CONOMOS and PETERSON, 1977); (3) large seasonal variations in the riverine input of suspended sediments, with maxima during winter storms; and (4) a large spatial gradient in turbidity with highest SPM concentrations in the upper estuary, and lowest SPM concentration at the estuary mouth. Further, San Francisco Bay comprises two distinct estuaries. The northern reach (including San Pablo and Suisun Bays, Fig. 1) is representative of partially mixed estuaries with well-developed gravitational circulation (PETERSON *et al.*, 1975) and a turbidity maximum during summer (CONOMOS and PETERSON, 1977). In contrast, the South Bay (Fig. 1) is a lagoon-type estuary with no large, direct source of freshwater. The South Bay is typically well mixed and has substantially lower SPM concentrations than the upper estuary. Results presented here are from several related studies begun in 1980 and utilizing a network of sample sites (Fig. 1) representing (1) the river-ocean gradients of SPM concentration and phytoplankton biomass, and (2) the transverse gradients between the channel and shallows.

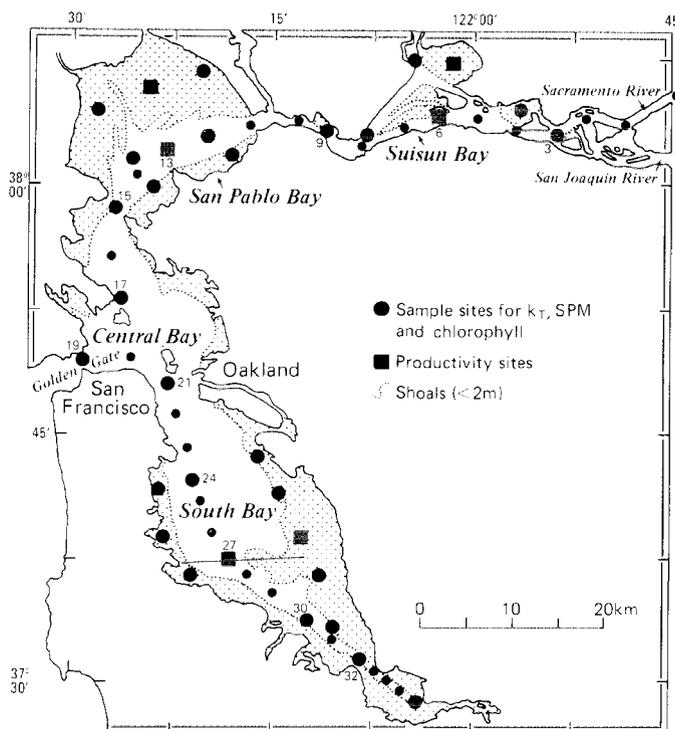

Fig. 1. Map of San Francisco Bay showing sampling sites (large symbols) for biweekly measurement of SPM, k_T , and chlorophyll *a* during 1980. Small circles represent sites where k_T and chlorophyll *a* were estimated from turbidity (nephelometry) and *in vivo* fluorescence. Squares represent sites where primary productivity was measured during 1980 and 1982 (all methods are detailed in CLOERN *et al.*, 1985). Solid line across the South Bay represents the surface transect for continuous measurement of chlorophyll *a* shown in Fig. 7.

TURBIDITY OF ESTUARIES

Turbidity of San Francisco Bay was mapped over an annual cycle by measuring the downwelling light extinction coefficient k_T and SPM concentration, at about 30 fixed sites (Fig. 1) twice monthly during 1980. Regression analysis showed a linear relation between k_T and SPM concentration (Fig. 2). The intercept of this regression (0.77 m^{-1}) represents a mean value for the "background" extinction coefficient due to light attenuation by water, dissolved constituents and the seston uncorrelated with SPM (e.g. phytoplankton). The slope of this regression is a measure of the specific attenuation coefficient (k'_s) of suspended sediments in San Francisco Bay. Although the magnitude of k'_s varies among water bodies depending on the nature of their suspensoids (KIRK, 1985), the mean value for San Francisco Bay ($0.06 \text{ m}^2 \text{ g}^{-1}$) is identical to that measured in the New York Bight with comparable methods (MALONE, 1976), and is similar to k'_s measured in the Ems-Dollard Estuary ($0.03 \text{ m}^2 \text{ g}^{-1}$; COLIJN, 1982) and in Delaware Bay ($0.075 \text{ m}^2 \text{ g}^{-1}$; PENNOCK, 1985).

Strong correlations between k_T and SPM (e.g. Fig. 2) imply that light attenuation in estuaries is primarily a function of suspended sediment concentration. This is an important distinction between estuaries and the open ocean where SPM concentration is low and k_T is more strongly correlated with phytoplankton biomass (SMJIH and BAKER, 1978). Data in Fig. 2 demonstrate the turbidity range commonly observed in estuaries. In San Francisco Bay, k_T ranges between about 1 m^{-1} in the outer estuary to $>10 \text{ m}^{-1}$ in the shallows of the inner estuary. Assuming that the photic depth (Z_p) for algal photosynthesis is the depth of 1% surface irradiance (i.e. $Z_p = 4.61/k_T$), this range of k_T is equivalent to photic depths between about 5 and $<0.5 \text{ m}$. The photic depth of large rivers and river-dominated estuaries is typically $<5 \text{ m}$, and often $<1 \text{ m}$ during peaks in river discharge, or in the estuarine turbidity maximum, or in shallow embayments where resuspension increases the SPM concentration.

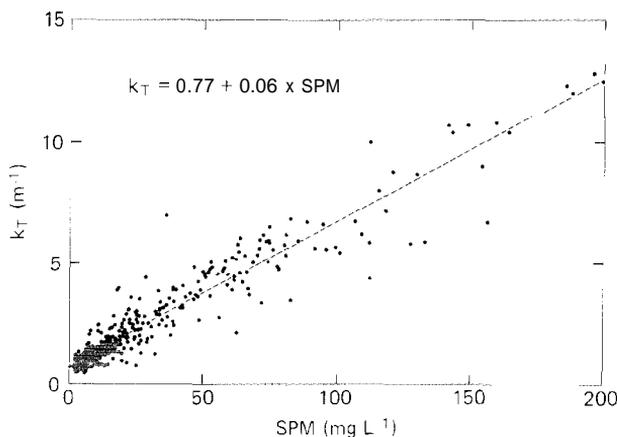

Fig. 2. Linear regression of extinction coefficient k_T against SPM concentration, for measurements made throughout San Francisco Bay during 1980 ($n = 417$; $r^2 = 0.91$). SPM concentration was measured gravimetrically and k_T was calculated from depth profiles of irradiance measured with a LiCor 192S quantum sensor [see HAGER and HARMON (1984) and CLOERN *et al.* (1985) for detailed methods].

Figure 3 summarizes the range of photic depths measured in a variety of estuaries, and compares these with Z_p for some fjords, neritic waters, and the open ocean. The contrast in light penetration between estuaries and other marine systems is obvious, and the extreme shallowness of the photic zone is another fundamental distinction that separates estuaries from coastal and oceanic waters. As a consequence, phytoplankton populations in shallow, turbid estuaries reside in a very different environment than those in deeper, clearer waters of the coastal and open ocean. This distinction has important implications for primary productivity.

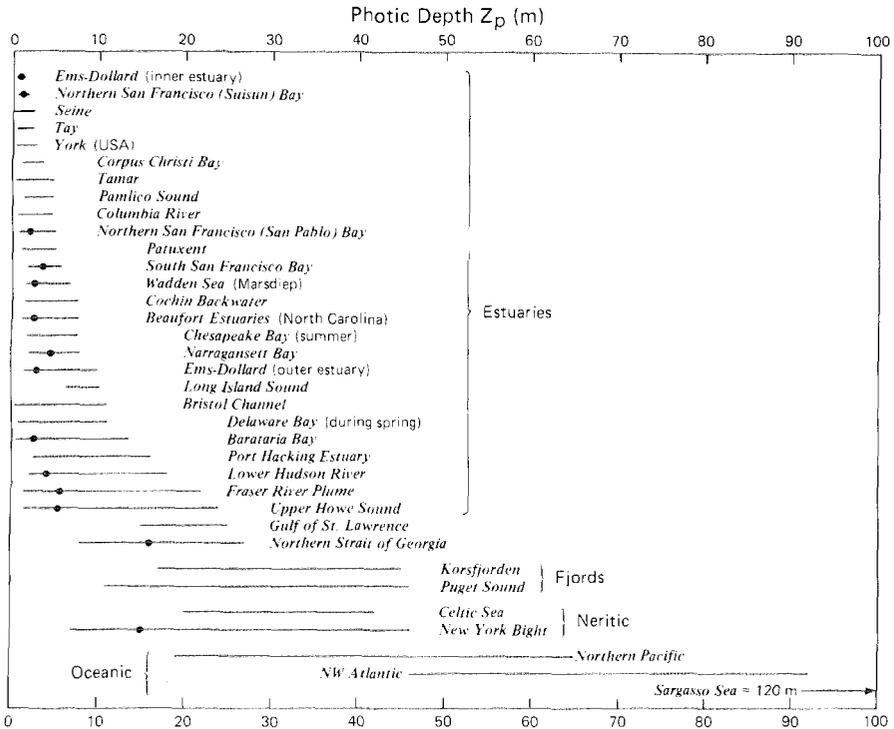

Fig. 3. Photic depths (means shown as circles and ranges shown as horizontal lines) in a variety of estuaries, compared to other marine waters. Photic depths were calculated as $4.61/k_T$ where k_T was either (1) measured directly, (2) estimated as $1.7/\text{Secchi depth}$, or (3) estimated as $0.06 \times \text{SPM}$ where SPM was measured. Data are from the following: Ems-Dollard (COLLIN, 1982), San Francisco Bay (CLOERN *et al.*, 1985), Seine (ROMANA, 1979), Tay (SHOLKOVITZ, 1979), York (MEADE, 1972), Corpus Christi Bay (FLINT, 1984), Tamar (OWENS, 1985), Pamlico (KUENZLER *et al.*, 1979), Columbia River (SMALL and FREY, 1984), Patuxent (STROSS and STOTILEMEYER, 1965), Wadden Sea (CADÉE and HEGEMAN, 1979), Cochin Backwater (QASIM, 1979), Beaufort estuaries (THAYER, 1971), Chesapeake Bay (CHAMP *et al.*, 1980), Narragansett Bay (OVIATT *et al.*, 1981), Long Island Sound and northwest Atlantic (reported by RYHER and YENTSCH, 1957), Bristol Channel (JOINT and POMROY, 1981), Delaware Bay (PENNOCK, 1985), Barataria Bay (SKLAR and TURNER, 1981), Port Hacking Estuary (SCOTT, 1978), Hudson River and New York Bight (MALONE, 1980), Fraser River and Strait of Georgia (STOCKNER *et al.*, 1979), Howe Sound (STOCKNER *et al.*, 1977), Gulf of St. Lawrence (SEVIGNY *et al.*, 1979), Korsfjorden (ERGA and HEIMDAL, 1984), Puget Sound (WINTER *et al.*, 1975), Celtic Sea (PINGREE *et al.*, 1976), North Pacific (OTOBE *et al.*, 1977), Sargasso Sea (STEEMANN NIELSEN, 1975).

ESTUARINE PRIMARY PRODUCTIVITY

Most of the spatial and temporal variability of phytoplankton productivity within San Francisco Bay is correlated with variations in biomass B (mg m^{-3} of chlorophyll a) and an index of light availability $Z_p I_0$ (I_0 = surface irradiance in units of $\text{Ein m}^{-2} \text{d}^{-1}$, where $1 \text{ Ein} = 1 \text{ mole of photons}$). For South Bay and northern San Francisco Bay, daily primary productivity in the photic zone ($\text{mg C m}^{-2} \text{d}^{-1}$) can be estimated with linear functions of $BZ_p I_0$ (COLE and CLOERN, 1984):

$$\text{South Bay: } P_p = 94 + 0.88[BZ_p I_0], n = 29, r^2 = 0.88 \quad (1)$$

$$\text{North Bay: } P_p = 63 + 0.67[BZ_p I_0], n = 53, r^2 = 0.72. \quad (2)$$

Similar analysis of productivity measurements for other estuaries suggests that such relations may apply universally (COLE and CLOERN, 1987). For example, in four estuarine/coastal environments where methods were comparable (Puget Sound, New York Bight, South and North San Francisco Bay), measures of daily productivity fit one linear function:

$$P_p = 146 + 0.73[BZ_p I_0], n = 210, r^2 = 0.82. \quad (3)$$

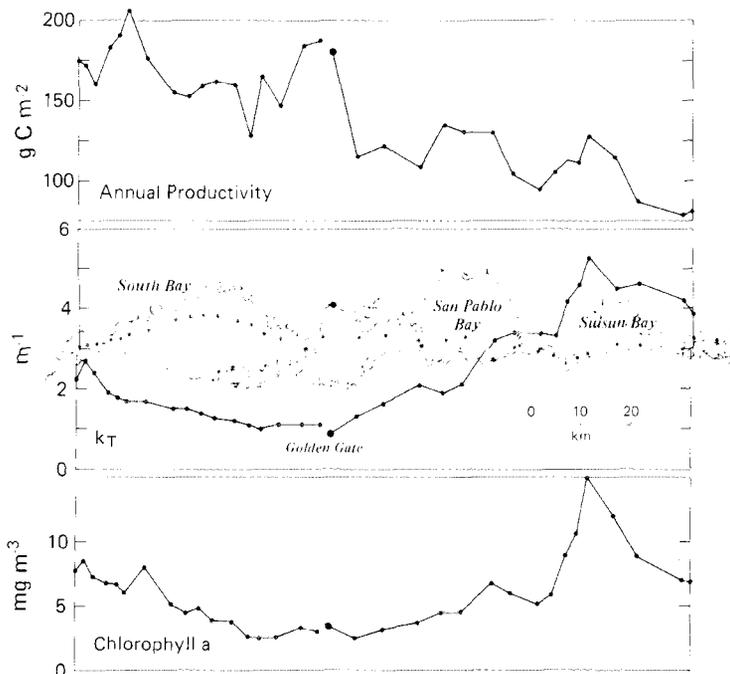

Fig. 4. Longitudinal profiles of estimated annual primary productivity, mean extinction coefficient k_T , and mean chlorophyll a concentration in San Francisco Bay during 1980. Overlay map shows the location of sampling stations. Daily productivity (P_p) was estimated at each sampling site in the channel using equations (1)–(2), surface B determined from *in vivo* fluorescence, Z_p from estimates of k_T by nephelometry, and I_0 measured with LiCor 190S quantum sensors placed in mid-South Bay and in San Pablo Bay throughout 1980. Interpolated values of B and Z_p were used between the biweekly sampling dates. For each site, daily P_p estimates were then summed to yield annual photic zone productivity.

This relation implies that biomass-specific productivity in estuaries is controlled primarily by light availability. Although it is premature to suggest that one empirical model describes P_p for all estuaries, we do know that biomass-specific productivity (P_p/B) is a linear function of light availability in a wide range of estuarine environments including the Ems-Dollard (COLIJN, 1983), western Wadden Sea (CADÉE and HEGEMAN, 1979), Delaware Bay (PENNOCK and SHARP, 1986), Peconic Bay (BRUNO *et al.*, 1983), Great South Bay (LIVELY *et al.*, 1983), and the lower Hudson River Estuary (MALONE, 1977).

Empirical functions such as equations (1)–(3) can be used to estimate primary productivity whenever B , Z_p , and I_0 are known. This approach was used to map predicted annual production along the main axis of San Francisco Bay from the Sacramento River to the estuary mouth at Golden Gate and into the South Bay (Fig. 4). Estimated annual production ranged from about 80 g C m^{-2} in Suisun Bay near the

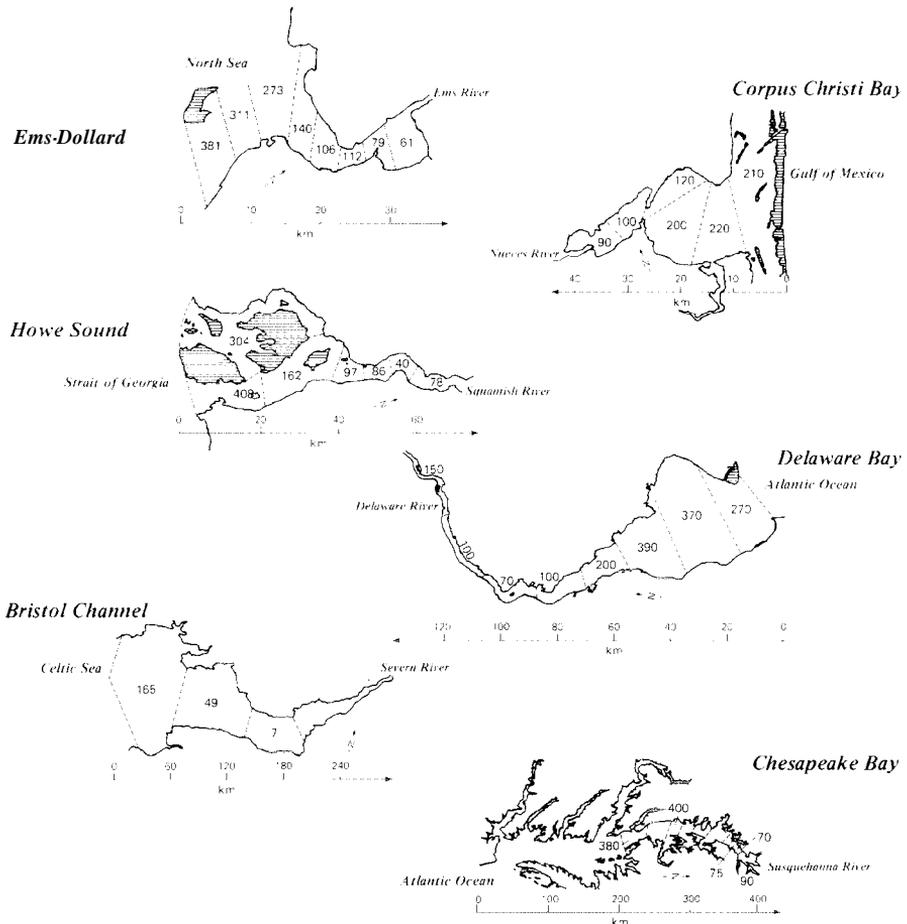

Fig. 5. Horizontal distributions of annual primary productivity in six estuaries, showing spatial gradients between the river and coastal ocean. Data are from COLIJN (1983), FLINI (1984), STOCKNER *et al.* (1977), PENNOCK and SHARP (1986), JOINT and POMROY (1981), and FLEMER (1970).

Sacramento River, to about 210 g C m^{-2} in the lower South Bay (Fig. 4). Hence the large-scale spatial variability in San Francisco Bay is characterized by increasing productivity away from the riverine source of suspended sediments. This distribution of annual production differs from that of phytoplankton biomass, which is highest in the upper estuary (Fig. 4). However, the spatial variability of annual production is related to photic depth, and generally mirrors the distribution of turbidity measured as k_T . Mean values of k_T decrease from the turbidity maximum in Suisun Bay toward the estuary mouth, and are lower in South Bay than in the upper estuary (Fig. 4).

Distributions shown in Fig. 4 indicate that San Francisco Bay is characterized by a longitudinal gradient in primary productivity, that productivity (unlike biomass) increases seaward, and that the overriding control on the distribution of annual production is the longitudinal gradient of photic depth (i.e. k_T) which reflects the distribution of river-derived suspended sediments. These features were observed over 20 years ago in the Patuxent River Estuary (STROSS and STOTFLEMEYER, 1965), and recent investigations have demonstrated similar spatial patterns in other estuaries. Figure 5 shows the large-scale horizontal distribution of annual phytoplankton production in six estuaries. In all cases, production is highest near the estuary mouth, lowest in the upper estuary (or in the turbidity maximum), and mirrors the distribution of k_T . This spatial pattern apparently continues into the coastal zone, where productivity can increase further. For example, annual production in the adjacent coastal ocean exceeds that of the Ems-Dollard, Wassaw Sound, and Hudson, Fraser, and Columbia River estuaries (Table 1). Hence our perception of estuaries as highly productive ecosystems should be qualified with the observation that phytoplankton productivity can be higher in nearby coastal waters where the photic zone is deeper and nutrient concentrations are still sufficient to sustain algal growth.

SIGNIFICANCE OF THE PHOTIC DEPTH: MIXED DEPTH

Net water column productivity

Because the photic depth (Z_p) can be a small fraction of the water column (or surface mixed layer depth, Z_m) in estuaries, measures of photic zone productivity (P_p) do not necessarily reflect the importance of phytoplankton production as a food resource for herbivores. Net production in the water column or mixed layer ($P_{,,}$) is a more useful measure for understanding carbon or energy flow to grazers, and $P_{,,}$ is less than P_p whenever $Z_p < Z_m$. The difference between P_p and $P_{,,}$ is the respiratory loss of assimilated carbon by phytoplankton in the aphotic zone, which can be substantial. The measurement of phytoplankton respiration persists as a difficult problem, but from laboratory studies of algal cultures we can infer bounds on this loss to illustrate the distinction between net production in the photic zone (P_p) and water column ($P_{,,}$).

Photosynthetic rate p ($\text{mg C m}^{-3} \text{ d}^{-1}$) is described by several empirical functions of irradiance I , including the formulation of PLATI and JASSBY (1976):

$$p = p_{\max}[\tanh(al) - rp_{\max}], \quad (4)$$

where p_{\max} is maximum gross photosynthetic rate, a defines photosynthetic efficiency at low irradiance, and r is the respiratory loss rate as a fraction of p_{\max} . Equation (4) can be used to calculate relative productivity (p/p_{\max}) at any depth z in the water column:

$$p' = p/p_{\max} = \tanh(al_z) - r \quad (5)$$

$$p' = \tanh[aI_0 \exp(-k_T z)] - r. \quad (6)$$

Integration of equation (6) over the mixed depth Z_m yields a relative productivity in the water column:

$$P'_m = \int_0^{Z_m} [\tanh(aI_0 \exp\{-k_T z\}) - r] dz. \quad (7)$$

To illustrate the significance of respiratory losses when $Z_p < Z_m$, equation (7) was solved numerically using different values for k_T (i.e. Z_p) and fixed values for a ($= 0.1 \text{ m}^2 \text{ d Ein}^{-1}$), I_0 ($= 40 \text{ Ein m}^{-2} \text{ d}^{-1}$), and Z_m ($= 10 \text{ m}$) representing the San Francisco Bay channel during summer. Relative productivity was then plotted against the ratio of photic depth to mixed depth in Fig. 6, comparing solutions for three values of the specific phytoplankton respiration rate r . This figure shows that net water column production decreases rapidly when $Z_p:Z_m < 1$, and it approaches zero as $Z_p:Z_m$ approaches a critical ratio of between 0.1 and 0.5 (depending on r). Physiological studies suggest that r can range between about 0.05 and 0.25 (e.g. VERITY, 1982), and that a representative value may be around 0.1.

The functions shown in Fig. 6 demonstrate a fundamental property of estuaries and other turbid environments. Regardless of phytoplankton biomass, net water column production is negative whenever the photic depth is less than about 20% of the mixed depth (as in the ocean; SVERDRUP, 1953). This situation occurs, for example, in upper San Francisco Bay during summer. The mean value of $Z_p:Z_m$ in the channel of Suisun Bay is about 0.1 (CLOEKN *et al.*, 1985), indicating that this part of the estuary is a net respiratory sink for phytoplankton production. Hence the biomass maximum in San Francisco Bay (Fig. 4) occurs in a region where net production may be less than zero. The distinction between water column (or mixed layer) production and photic-zone production is therefore critical in turbid estuaries, and measures confined to the photic zone (e.g. Fig. 4) can grossly misrepresent the net production of organic matter that is available to support populations of heterotrophs.

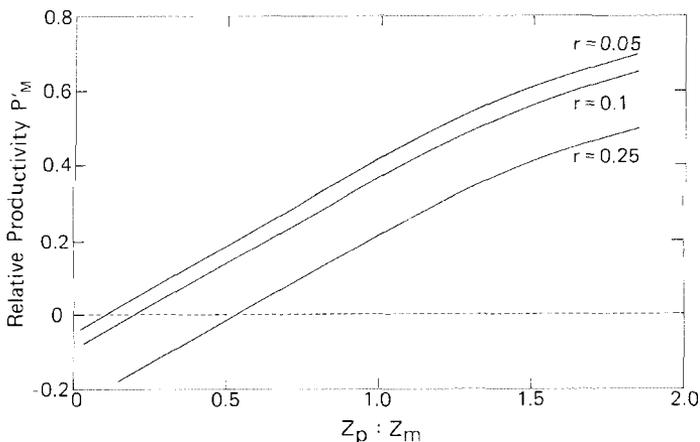

Fig. 6. Relative primary productivity P'_m (equation 7) vs the ratio of photic depth:mixed depth, for three values of the specific respiration rate r .

Spatial distribution of phytoplankton biomass

Because light availability controls productivity it must also play a major role in determining the population growth rate of estuarine phytoplankton, and we expect that biomass should vary across spatial gradients in the ratio of photic depth to mixed depth. For example, in well-mixed estuaries the ratio $Z_p:Z_m$ follows contours of bathymetry and highest phytoplankton biomass is expected to occur over subtidal shoals where Z_m is small and light availability is maximal. To demonstrate this, phytoplankton biomass (calculated chlorophyll *a* from *in-vivo* fluorescence) was measured continuously along transects between the deep channel and subtidal shoals of South San Francisco Bay during March 1985, when the water column was well mixed. A representative profile is given in Fig. 7 showing that biomass increased almost exponentially between the channel and eastern shoals. Biomass was low in the channel where calculated $Z_p:Z_m$ was less than 0.5, and it increased five-fold across the shoals where $Z_p:Z_m$ approached 1.

This horizontal distribution of biomass is consistent with spatial patterns inferred from point samples collected previously. During 1980, mean annual biomass in the shallow embayments of San Francisco Bay was 2–3 times higher than in the nearby channel (CLOERN *et al.*, 1985). During the 1980 summer bloom in Suisun Bay, high resolution mapping by remote sensing showed that chlorophyll *a* concentration consistently exceeded 60 mg m^{-3} in the shoals, and was $<30 \text{ mg m}^{-3}$ in the adjacent channel (CAIS *et al.*, 1985). Hence, in San Francisco Bay, the large-scale spatial variability of phytoplankton biomass is characterized by large transverse gradients, and this variability is caused at least partly by horizontal gradients in light availability and phytoplankton growth rate. Similar spatial patterns have been observed in other estuaries such as Delaware Bay (PENNOCK, 1985), Chesapeake Bay (MALONE *et al.*, 1986), and the Hudson Estuary (SIROIS and FREDERICK, 1978), and are predicted from WOFSY'S (1083) model of phytoplankton growth as a function of k_T and Z_m .

Temporal variability of phytoplankton biomass

Much of the temporal variability of estuarine phytoplankton biomass is also related to variations in light availability. For example, HITCHCOCK and SMAYDA (1977) attribute

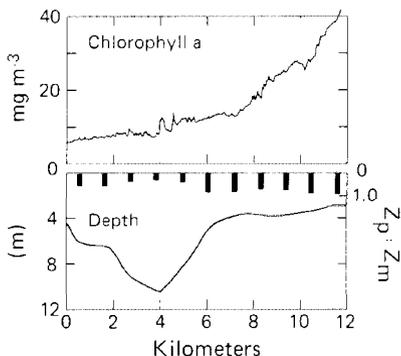

Fig. 7. Profile of near-surface chlorophyll *a*, calculated $Z_p:Z_m$ (vertical bars), and bathymetry along a transverse transect in mid-South San Francisco Bay (see Fig. 1), 21 March 1985. Chlorophyll *a* was estimated from *in vivo* fluorescence [see POWELL *et al.* (1986) for methods]. Water depth (Z_m) was recorded at 11 positions along the transect with a fathometer, and photic depth (Z_p) was estimated at these sites from values of k_T derived from nephelometry.

annual variations in the timing of the Narragansett Bay winter bloom to annual variations in mean water column irradiance \bar{I} ; the winter bloom commences only when \bar{I} exceeds about 40 langley's d^{-1} (19 W m^{-2}). Seasonal variations in SPM concentration can also influence light penetration and phytoplankton dynamics. In San Francisco Bay, bottom resuspension intensifies during mid-summer when wind speed and mean tidal current speed are both rapid. As a consequence, SPM concentration increases, Z_p decreases, growth rates (P_m/B) are near zero, and phytoplankton biomass is low in the upper estuary during mid-summer (CLOERN *et al.*, 1985).

Another important mechanism of temporal variability in $Z_p:Z_m$ is the establishment of density stratification which reduces the mixed layer depth (Z_m) and increases light availability to phytoplankton retained above the pycnocline. Density stratification in estuaries is maintained primarily by buoyancy input from freshwater inflow and is eroded by tidal stirring. Hence stratification events can follow pulsed inputs of freshwater and can respond to changes in tidal current speed (HAAS, 1977; CLOERN, 1984). In South San Francisco Bay, the spring phytoplankton bloom is usually associated with salinity stratification. Two mechanisms may support the spring bloom during stratification events: (1) reduced grazing losses to benthic suspension feeders (CLOERN, 1982), and (2) increased growth rates of phytoplankton in the surface layer as Z_m decreases. For example, an extreme stratification event occurred in early April 1983 when phytoplankton biomass increased rapidly in the surface layer (big. 8). On 29 March 1983 (during a spring tide), the water column of lower South Bay was well mixed and phytoplankton biomass was low. By 8 April 1983 (during a neap tide), a sharp pycnocline had formed at about 6 m and phytoplankton biomass increased four-fold in the surface layer. Similar phytoplankton blooms accompany stratification events in other estuarine systems, including the York River (HAAS *et al.*, 1981), St. Lawrence River (SINCLAIR, 1978), Delaware Bay (PENNOCK, 1985), the Strait of Georgia (STOCKNER *et al.*, 1979), the Korsfjorden (ERGA and HEIMDAL, 1984), and Puget Sound (WINTER *et al.*, 1975). Because estuarine phytoplankton are light-limited, temporal variability in vertical mixing (i.e. Z_m) is a primary mechanism of temporal variability in biomass.

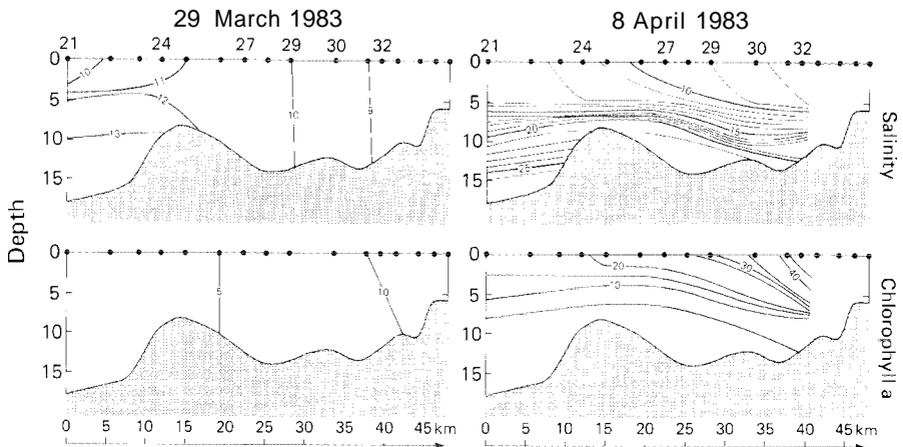

Fig. 8. Salinity and chlorophyll a contours along the South San Francisco Bay channel on 29 March and 8 April 1983. Sample sites correspond to those shown in Fig. 1.

CONCLUSIONS

Results from San Francisco Bay and other estuaries support the generalization that light availability is the critical environmental control on estuarine phytoplankton dynamics. Photic-zone productivity is strongly correlated with light availability, and in many estuaries the spatial distribution of phytoplankton production mirrors the distribution of suspended sediments, i.e. production is highest at the estuary mouth. The growth rate of phytoplankton populations is presumably also a function of light availability, and much of the spatial and temporal variability in biomass can be explained by variations in light exposure. Large-scale horizontal variability of phytoplankton biomass follows distributions of the photic depth: mixed depth ratio ($Z_p:Z_m$), and phytoplankton blooms occur when $Z_p:Z_m$ increases (e.g. through reduction of Z_m by salinity stratification).

Studies of estuarine productivity also suggest, but cannot yet confirm, two important hypotheses. First, depth profiles of algal photosynthesis indicate that the water column of turbid estuaries can be a respiratory sink ($P < 0$), even when phytoplankton biomass is high. This conclusion is based upon assumptions concerning the rates of two processes: vertical mixing (to define Z_m), and phytoplankton dark respiration. Neither process has been studied rigorously in estuaries, and our estimates of net water column production will remain tenuous until simultaneous measures of vertical mixing and respiratory loss are done across a spectrum of estuary types. Second, horizontal profiles suggest that phytoplankton productivity in estuaries may be less than in the adjacent coastal ocean. Our perception of estuaries as highly productive ecosystems should be placed in a broader geographic context, and this requires measurement of production along the continuum from rivers into the coastal ocean. Both hypotheses form a basis for the future research that is needed to better define the role of estuaries as sources of organic matter for consumer organisms.

Acknowledgements—I thank my colleagues Jan Thompson, Brian Cole, Dave Peterson, and Fred Nichols for their thoughtful comments and suggestions that contributed to the production of this paper.

Significance of biomass and light availability to phytoplankton productivity in San Francisco Bay

Brian E. Cole and James E. Cloern

US Geological Survey, 345 Middlefield Road, MS 96, Menlo Park, California 94025, USA

ABSTRACT: Primary productivity was measured monthly at 6 sites within San Francisco Bay, USA, throughout 1980. The 6 sites were chosen to represent a range of estuarine environments with respect to salinity, phytoplankton community composition, turbidity, and water depth. Annual net production over the photic zone ranged from 95 to 150 g C m⁻², and was highest in regions of lowest turbidity. Daily photic zone net productivity PN_{pd} ranged from 0.05 to 2.2 g C m⁻² d⁻¹, and was significantly correlated with the composite parameter B I₀/ε (where B = phytoplankton biomass; I₀ = daily surface insolation; ε = attenuation coefficient). Linear regression of PN_{pd} against B I₀/ε indicated that most (82 %) of the spatio-temporal variability in primary productivity within this estuary is explained by variations in light availability and phytoplankton biomass. We also calculated annual water-column net productivity PN_{wy} as a fraction of annual gross productivity PG_y. The ratio PN_{wy} : PG_y was inversely related to the ratio of water depth H to annual mean photic depth \bar{Z}_p . This linear relation indicates that the water column of San Francisco Bay is a net photosynthetic source of organic carbon only when the ratio H : \bar{Z}_p < 6. In deep turbid habitats, where H : \bar{Z}_p > 6, respiratory loss exceeds productivity. Thus, 2 empirical formulations allow us to estimate productivity over the photic zone and water column from simple properties that are easily measured.

INTRODUCTION

Estimates of annual phytoplankton productivity in estuaries range between 6.8 g C m⁻² (Joint and Pomroy, 1981) in very turbid water to 530 g C m⁻² (Stockner and Cliff, 1979) in a clearer system. However, the study of production by estuarine phytoplankton is in its infancy, and although annual rates of phytoplankton production have been reported for a number of estuaries (Boynton et al., 1982), the processes that control primary and secondary productivity in estuaries are poorly understood. In a review of factors controlling phytoplankton production in 63 estuarine systems, Boynton et al. (1982) note that environmental data are poor predictors of primary productivity. They conclude that in a broad spectrum of estuaries algal production is high in warm periods and that the ratio of nitrogen to phosphorus is low during algal blooms. Otherwise, they find that generalities regarding primary productivity cannot be made when all estuarine systems are considered together.

Spatial and seasonal changes in phytoplankton productivity are described for numerous estuaries (e.g. Williams, 1966; Williams and Murdoch, 1966; Flemer,

1970; Cadée and Hegeman, 1974; Malone, 1977; Cadée, 1978; Colijn, 1978; Stockner and Cliff, 1979; Stockner et al., 1979; Joint and Pomroy, 1981). From such studies we know that productivity in a nutrient replete estuary can vary with phytoplankton biomass, turbidity, daylength, or temperature, but the findings from specific locations cannot be easily related to other estuarine systems. Except for Boynton et al. (1982), there has been little effort in developing a unified theory of what factors control primary productivity in diverse estuarine systems. In simplest terms, primary productivity in nutrient-rich waters is a function of 3 basic variables: phytoplankton biomass, biomass-specific carbon assimilation rate, and light availability. Although these may vary due to changes in phytoplankton community composition, light adaptation, grazing, settling, transport processes, temperature, daylength, or turbulence, if appropriately expressed, productivity should be predictable in terms of the 3 basic variables.

In this paper we present the results of an annual study of phytoplankton production in San Francisco Bay, USA. We show that seasonal variations in productivity differ among geographic regions within the estu-

ary, but that daily net productivity in the photic zone is highly correlated with a simple composite parameter composed of phytoplankton biomass and light availability. We also show that the concept of critical depth : mixed depth ratio, which has become a paradigm of phytoplankton ecology in oceans and lakes (Parsons and Takahashi, 1973; Harris, 1978), has relevance to turbid estuaries such as San Francisco Bay. Using the water depth : photic depth ratio we predict the fraction of gross primary production that is lost to respiration and the fraction that remains for potential consumption by herbivores.

San Francisco Bay (Fig. 1) offers a variety of subenvironments for studying the regulation of primary pro-

(1979). Each major embayment (South Bay, San Pablo Bay, Suisun Bay) is composed of a central, relatively deep (≈ 10 to 15 m) channel where the photic zone is about 10 % of the water depth, bounded by broad expanses of shoals (≈ 2 m depth) where the photic zone is 50 to 100 % of water depth. Typically, nutrient levels throughout the Bay exceed $10 \mu\text{M}$ dissolved inorganic nitrogen, $2 \mu\text{M}$ phosphate, and $50 \mu\text{M}$ silicate (Conomos et al., 1979). Phytoplankton community composition differs in the three major embayments. The South Bay population is usually dominated by microflagellates ($< 15 \mu\text{m}$ length) and small ($< 10 \mu\text{m}$ diameter) centric diatoms, although *Skeletonema costatum* and larger ($> 70 \mu\text{m}$ diameter) diatoms *Thalassiosira* spp. and *Coscinodiscus* spp. are occasionally abundant. In San Pablo Bay the population comprises marine-brackish diatoms and microflagellates, whereas in Suisun Bay freshwater diatoms usually predominate in winter and *S. costatum* and *T. eccentrica* are dominant during the summer bloom (Wong and Cloern, 1982).

METHODS

Between January 1980 and February 1981 light attenuation, chlorophyll *a*, and phytoplankton production were measured monthly at a deep-water and shallow-water site in each of the 3 major embayments in San Francisco Bay (Fig. 1). Light attenuation coefficient ϵ (all symbols and units are given in Table 1) was measured using a LiCor model 185 quantum meter coupled to a 192S sensor. Total ambient insolation I_0 (photosynthetically active radiation) during the course of an incubation experiment was measured using a LiCor 190 quantum sensor and a recording integrator. Photic depth Z_p (depth of 1 % ambient light energy) was estimated as $\ln(100)/\epsilon$.

Triplicate chlorophyll *a* samples from each site were prescreened through $59 \mu\text{m}$ Nitex screen (see below), then filtered onto Gelman type A/E glass-fiber filters. Chlorophyll *a* concentration B , corrected for phaeopigments, was determined by fluorometry (Strickland and Parsons, 1972). Although prescreening with a $59 \mu\text{m}$ mesh may remove large algal cells or chains, there was never a measurable difference in *in vivo* fluorescence between whole and screened samples, except at Station 318 on May 8 and at Stations 13 and 318 on June 5.

Productivity samples were collected from a single depth, 2 m in the channel and 1 m in the shoals, and also prescreened through a $59 \mu\text{m}$ Nitex screen. The small mesh was used to eliminate grazing by copepod nauplii and tintinnid ciliates which at times constituted a substantial fraction of zooplankton biomass (Hutchinson, 1981; 1982a, b). Following inoculation with carbon 14 ($5 \mu\text{Ci}$ in a 150 ml bottle), 24 h simu-

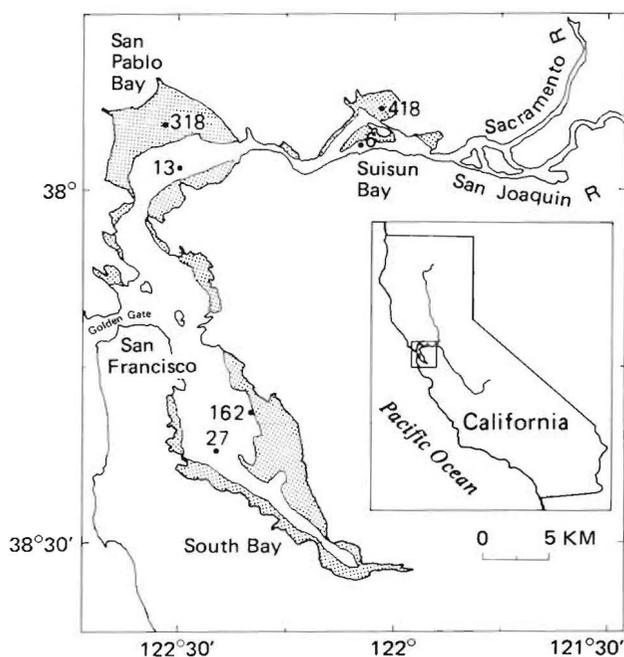

Fig. 1. Map of San Francisco Bay showing locations of incubation sampling sites. Shaded portions: areas where water depths (MLLW) are less than 2 m

duction in nutrient-rich, turbid waters. The northern reach, which includes San Pablo Bay and Suisun Bay, is a river-dominated estuary. It is partially or well mixed (depending on discharge from the Sacramento and San Joaquin Rivers), turbid, and characterized by a large horizontal salinity gradient. In contrast, the southern reach (South Bay) is a brackish embayment that has no large direct riverine source of freshwater, is usually vertically mixed (although salinity stratification occurs in winter–spring; Cloern, 1984), is less turbid than the northern reach, and usually has a small horizontal salinity gradient. Detailed descriptions of the hydrographic, nutrient, and biological character of the San Francisco Bay system are given in Conomos

Table 1. Definitions of variables (and their units)

Variable	Definition	Units
ϵ	Light attenuation coefficient	m^{-1}
I_o	Ambient photosynthetically active radiation	Einsteins $(m^2 d)^{-1}$
Z_p	Photic-zone depth	m
B	Chlorophyll <i>a</i> concentration	mg chl <i>a</i> m^{-3}
P_m^B	Maximum carbon assimilation rate	mg C (mg chl <i>a</i> d) $^{-1}$
PN_{pd}	Daily photic zone net productivity	g C $(m^2 d)^{-1}$
PN_{py}	Annual photic zone net productivity	g C $(m^2 yr)^{-1}$
R^B	Biomass-specific respiration rate	mg C (mg chl <i>a</i> d) $^{-1}$
PG_y	Annual gross productivity	g C $(m^2 yr)^{-1}$
\bar{Z}_p	Annual mean photic depth	m
H	Water-column depth	m
PN_{wy}	Annual water column net productivity	g C $(m^2 yr)^{-1}$
R_{wy}	Annual water-column respiration	g C $(m^2 yr)^{-1}$
R_{py}	Annual photic-zone respiration	g C $(m^2 yr)^{-1}$

lated *in situ* incubations were done in a deck incubator. Samples were exposed to natural sunlight of 8 intensities: 100, 55, 30, 15, 8, 3, 1, and 0 % of ambient irradiance. On clear days, light entering the deck incubator was attenuated by an additional 25 to 40 % with a neutral density Plexiglas filter positioned over the samples. Hence, photoinhibition, which is unlikely to occur in turbid well-mixed environments (Marra, 1978; Joint and Pomroy, 1981), was never observed. Irradiance within the incubator was continuously recorded with a submersible quantum sensor.

Following incubation, subsamples from each bottle were filtered by gravity or low pressure (< 110 mm Hg) through Gelman type A/E glass-fiber filters. A 3 ml aliquot of each filtrate and duplicate unfiltered 3 ml aliquots from each bottle were placed in scintillation vials. After adding 0.1 ml of 0.2 N HCl, each aliquot was bubbled under vacuum for 15 min while $^{14}CO_2$ was stripped from the sample (Schindler et al., 1972). The residual activity of the sample was measured using a liquid scintillation spectrometer. All carbon uptake rates were corrected for activity of the filtrate (excretion) and dark-bottle uptake.

Maximum daily carbon assimilation rates P_m^B were derived from chlorophyll *a* normalized photosynthesis-irradiance (P-I) curves. The Gauss-Newton nonlinear least squares technique was used to obtain the best fit of the data to the hyperbolic tangent function (Platt and Jassby, 1976):

$$P^B = P_m^B \tanh(\alpha I / P_m^B) - R^B \quad (1)$$

Simulated incubation depths were calculated as $-\ln(I_i/I_o)/\epsilon$, where I_i/I_o is the fraction of daily surface insolation received by bottle *i*. Daily photic zone net productivity PN_{pd} was calculated by integrating (trapezoidal quadrature) measured rates of carbon uptake [mg C $(m^3 d)^{-1}$] over the photic depth. Annual

photic zone net productivity PN_{py} was estimated for each site by integrating PN_{pd} over the year. Baywide the specific respiration rate R^B , as the intercept of the P-I curves (Steemann Nielsen and Hansen, 1959), averaged 4.5 % of P_m^B over the year. Since even after a 24 h incubation it is unlikely that samples held at low-light had reached a net productivity rate (Hobson et al., 1976), the intercepts were probably underestimates of the true specific respiration rate (Peterson, 1980). In previous studies in San Francisco Bay (Peterson et al., in press) a typical respiration rate was found to be about 10 % of P_m^B using oxygen light-dark bottle techniques in 24 h incubations. In the analysis presented below, we assumed that R^B was constant and equal to 0.1 P_m^B , and calculated annual gross productivity PG_y as the sum of annual net productivity and integral respiration over the photic zone.

RESULTS

Ambient insolation during the course of the experiments (Fig. 2a, 3a, 4a) was similar for all sites and ranged from 8 to 55 Einsteins $(m^2 d)^{-1}$. Attenuation coefficients varied substantially between embayments and at times between channel and shoal sites within embayments (Fig. 2b, 3b, 4b). Photic depths in South Bay were fairly constant throughout the year and averaged about 3.2 m. In San Pablo Bay large variations in attenuation coefficient resulted in fluctuations of photic depth that ranged from about 0.3 to 6.6 m. Photic depths at both sites in Suisun Bay remained < 1 m throughout most of the year. The annual range of attenuation coefficients was large at most sites, but based on annual mean attenuation coefficients (Table 2) turbidity in South Bay was less than in San Pablo Bay which was less than in Suisun Bay. In

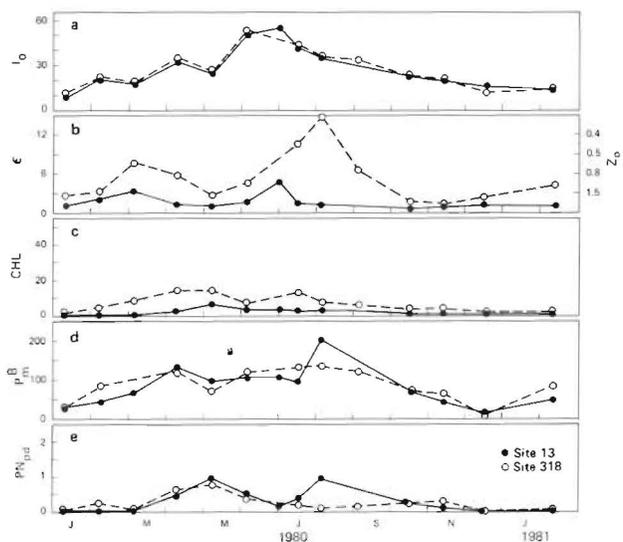

Fig. 3. San Pablo Bay. Seasonal variation of (a) ambient irradiance I_0 ($E m^{-2} d^{-1}$); (b) attenuation coefficient ϵ (m^{-1}) and photic depth Z_p (m); (c) chlorophyll a CHL ($mg m^{-3}$); (d) maximum carbon assimilation rate P_m^B [$mg C (mg chl a d)^{-1}$]; (e) daily net productivity PN_{pd} [$mg C (m^2 d)^{-1}$] for Incubation Sites 13 (●) and 318 (○)

addition, attenuation coefficients were consistently greater in the shoals than the channel of San Pablo Bay and Suisun Bay.

Although the absolute chlorophyll *a* level for a given date was typically higher at the shallow water incubation site than at the adjacent channel site, the seasonality of chlorophyll *a* was similar for the 2 incubation

sites within each embayment and distinct from the seasonality in the other two embayments (Fig. 2c, 3c, 4c). In South Bay (Fig. 2c) there was a late winter-early spring chlorophyll *a* maximum of approximately $24 mg m^{-3}$ after which chlorophyll *a* levels remained less than about $2 mg m^{-3}$. Maximum chlorophyll *a* levels in San Pablo Bay (Fig. 3c) were observed in spring. The increase and decline in biomass occurred over a longer period at the shoal site than at the deep-water location. Chlorophyll *a* concentrations at San Pablo Bay sites ranged from 0.7 to $6.4 mg m^{-3}$ at Station 13 and from 1.5 to $14.4 mg m^{-3}$ at Station 318. Maximum concentrations of chlorophyll *a* at the Suisun Bay incubation sites (Fig. 4c) exceeded those from the other 2 embayments. Winter lows of $< 1 mg chl a m^{-3}$ were followed by a gradual increase to summer maxima of 35 and $50 mg chl a m^{-3}$ at the deep-water and shallow-water sites respectively.

Daily carbon assimilation rates were usually similar at both incubation sites within each embayment (Fig. 2d, 3d, 4d). Although seasonality in P_m^B was similar at Sites 27, 162, and 13, it differed among the other sampling sites. In South Bay and San Pablo Bay, P_m^B generally increased from winter lows (P_m^B rates in South Bay were not attained in January or February) to maximum rates in midsummer. Low winter P_m^B rates in Suisun Bay were followed by annual maximum values in March after which there was a gradual decline in P_m^B over the year. Baywide, winter minimum P_m^B rates were 25 to $30 mg C (mg chl a d)^{-1}$, whereas maximum rates ranged from $230 mg C (mg chl a d)^{-1}$ in South Bay to

Table 2. Annual mean and range of attenuation coefficient (ϵ), photic depth (\bar{Z}_p), water depth (H) [MLLW water depth + 1 m], and H/\bar{Z}_p ratio for the 6 incubation sites

Station		ϵ (m^{-1})	Range	\bar{Z}_p (m)	H (m)	H/\bar{Z}_p
South Bay	27	1.3	0.7– 2.5	3.5	12	3.4
	162	1.7	0.8– 5.1	2.7	3.0	1.1

approximately 170 in San Pablo Bay and 83 mg C ($mg\ chl\ a\ d$) $^{-1}$ in Suisun Bay.

Although seasonality in daily net productivity (Fig. 2e, 3e, 4e) was generally similar to the pattern observed for chlorophyll *a* at each of the 6 incubation sites, baywide the levels of productivity had little relation to chlorophyll *a* concentration. At both sites in South Bay (Fig. 2e) the annual pattern in PN_{pd} was dominated by 2 peaks in early spring of 1.2 to 2.2 g C ($m^2\ d$) $^{-1}$. At all other times during the year productivity was low, not exceeding 0.5 g C ($m^2\ d$) $^{-1}$. In San Pablo Bay low [$< 0.05\ g\ C\ (m^2\ d)^{-1}$] levels of productivity in winter (Fig. 3e) were followed by a peak in spring at both the channel and shoal sites coincident with peaks in chlorophyll *a*. At the channel site a second peak in productivity, of similar magnitude to the spring peak, occurred simultaneously with a marked increase in P_m^B (Fig. 3d) and decreased turbidity (Fig. 3b). In Suisun Bay extremely low productivity during winter (Fig. 4e) preceded increased PN_{pd} that was coincident with the summer increase of chlorophyll *a*. Even though biomass in Suisun Bay was the highest observed throughout the San Francisco Bay system, maximum levels of phytoplankton productivity at Stations 6 and 418 did not exceed 0.55 g C ($m^2\ d$) $^{-1}$. Annual net productivity PN_{py} over the photic zone was 150, 110 to 130, and 95 g C m^{-2} for the South Bay, San Pablo Bay, and Suisun Bay sites respectively.

DISCUSSION

Predicting daily productivity

Although the seasonality of parameters that potentially control phytoplankton productivity in San Francisco Bay was diverse, PN_{pd} was primarily a function of phytoplankton biomass and light availability. Falkowski (1981) has also derived an empirical function that relates integral productivity to B and I_o in the New York Bight. Gieskes and Kraay (1977) similarly conclude that the productivity of surface-water samples in

the Southern North Sea can be estimated well from chlorophyll *a* concentration and incident light. When all measured values of PN_{pd} were regressed against the simple composite parameter $B I_o/\epsilon$ (Table 3; Fig. 5), we found that, both within individual embayments and baywide, about 80 % of the seasonal variability in PN_{pd} was correlated with this simple parameter. Therefore, nutrient availability, temperature, and physiological state of the phytoplankton play only minor roles in regulating productivity. All linear regressions were highly significant ($r = 0.88$ to 0.97 , $P < 0.001$) and indicated that this relation held over a wide range of I_o , ϵ , B , P_m^B , and phytoplankton communities.

PN_{pd} was consistently predicted well using this composite parameter, whereas correlations between PN_{pd} and either I_o/ϵ , I_o , ϵ , or P_m^B were weak (Table 3). Because carbon uptake is dependent on phytoplankton biomass, it is common practice to normalize productivity by the chlorophyll *a* content of the sample. Within a localized area, even normalizing integral productivity to photic zone chlorophyll *a* at times during the year (Malone, 1977; Bruno et al., 1983) aids in determining the factors regulating phytoplankton production. In San Francisco Bay there was a significant correlation ($P < 0.05$) between PN_{pd} and phytoplankton biomass (B) at 5 of the 6 incubation sites (Table 3). In each embayment the seasonal pattern in productivity was generally reflective of the seasonality in biomass (Fig. 2c, e; 3c, e; 4c, e). Except at Site 418, variations solely in chlorophyll *a* accounted for more than 50 % of the variation in observed PN_{pd} (Table 3). Within a restricted environmental setting (i.e. separate embayments), changes in chlorophyll *a* concentration accounted for most of the variation in productivity. However, only 12 % of the baywide annual variation in productivity was correlated with changes in biomass. Because there was a wide range in slopes (6.5 to 156; data not shown) for regressions between productivity and chlorophyll *a* at the 6 sites, the single regression of PN_{pd} and B data from all sites accounted for only a small fraction (12 %) of the variation in PN_{pd} baywide (Table 3). Thus, although at a given location phyto-

plankton biomass was indicative of photic-zone productivity, our results suggest that the use of chlorophyll *a* alone is of little value in predicting PN_{pd} among diverse areas. This is consistent with the conclusions of Cadée and Hegeman (1974) and Boynton et al. (1982) that over a wide range of environmental conditions or aquatic environments productivity cannot be estimated from measures of chlorophyll *a* alone.

late well with changes in P_m^B (Table 3). The poor correlation between primary productivity and P_m^B probably results from the fact that productivity is largely determined by biomass, and that spatio-temporal variations in biomass within San Francisco Bay are not controlled by the same processes that regulate growth rate (i.e. P_m^B). For example, the summer biomass maximum in Suisun Bay results from the physical accumulation of

In addition to phytoplankton biomass, productivity in estuaries is commonly believed to be a function of photic-zone irradiance because there is decreased productivity in turbid regions relative to clearer waters (Flemer, 1970; Cadée and Hegeman, 1974; Malone, 1977; Cadée, 1978; Colijn, 1978; Stockner et al., 1979; Joint and Pomroy, 1981). However, the most appropriate means of quantifying the light available to phytoplankton in a photic zone is not obvious. Photosynthetically available light must be related to both ambient light (I_0) and the depth of the photic zone, a measure derived from the attenuation coefficient (ϵ). We assumed that ϵ , I_0 , and I_0/ϵ , as indices of light availability, might be useful predictors of daily productivity. At some sites the use of I_0 and I_0/ϵ increased the predictability of PN_{pd} (Table 3). But neither ϵ , I_0 , or I_0/ϵ individually accounted for more than 43 % of the variation in daily productivity. The poor relationship between PN_{pd} and ϵ was surprising because there was a significant relationship between PN_{py} and annual mean photic depth \bar{Z}_p , which was calculated from ϵ (Fig. 6).

Positive correlations are reported between photic zone productivity and P_m^B in some estuaries (Williams and Murdoch, 1966; Malone, 1977), but in San Francisco Bay changes in PN_{pd} were poorly correlated with P_m^B (Table 3). In South Bay and San Pablo Bay, P_m^B generally increased until midsummer, whereas PN_{pd} was maximum in spring. In contrast, maximum PN_{pd} in Suisun Bay was observed in summer, whereas maximum P_m^B was seen in late winter. Over the year-long study, only at Station 13 did variations in PN_{pd} corre-

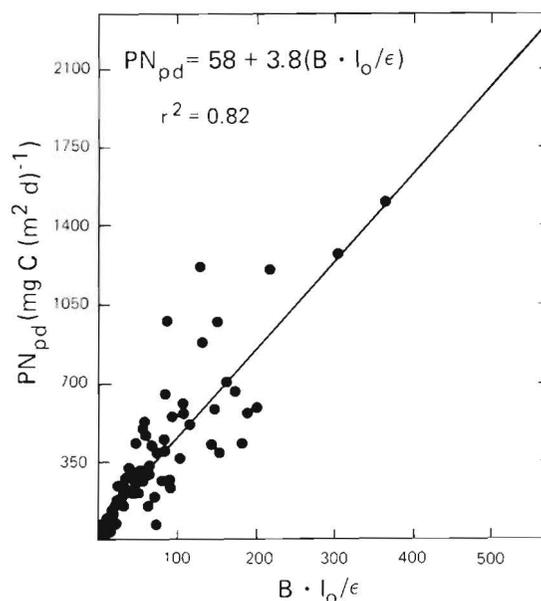

Fig. 5. Regression of daily net productivity PN_{pd} against composite parameter $B I_0/\epsilon$

phytoplankton by estuarine circulation, rather than from rapid growth rates (Cloern et al., 1983), and the spring bloom in South Bay results partly from decreased benthic grazing pressure when the water column is stratified (Cloern, 1982). Only in estuaries where biomass and carbon assimilation rates are controlled by the same processes (e.g. specific growth rate)

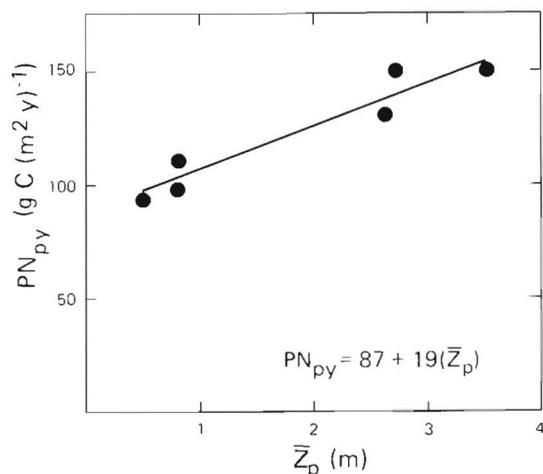

Fig. 6. Annual net productivity PN_{py} as a function of annual mean photic depth \bar{Z}_p at the 6 incubation sites

would a strong correlation between productivity and P_m^B be expected.

Predicting net water-column productivity

The high turbidity of estuaries has a profound impact not only on gross production but also upon the fraction of gross production available to higher trophic levels. Estuaries are generally shallow, but a large portion of the water column is aphotic or exposed to low irradiance. Because photosynthesis is restricted to the photic zone (Z_p), respiratory losses, which occur over the entire water-column depth (H), can greatly reduce net productivity when the ratio H/Z_p becomes large. The importance of the interaction between surface irradiance, mixed depth, photic depth, and production : respiration ratios in regulating productivity was first noted by Gran and Braarud (1935). Their concepts were developed into mathematical models (Sverdrup, 1953; Patten, 1968) to define the 'critical depth' for integral production (i.e. the depth at which respiration in the water column equals carbon production in the photic zone). By examining the mixed depth : photic depth ratio and making assumptions regarding the constancy of the production : respiration ratio (Harris, 1978), one can define conditions which control the seasonality of phytoplankton blooms in marine and freshwater environments (Parsons and Takahashi, 1973; Harris, 1978). Although H/Z_p ratios vary widely in estuaries, the concept of critical depth has not been proposed as an explanation for the differences in productivity observed in different estuaries or the temporal changes in productivity or biomass within an estuarine system. Our data suggest that the concept of critical depth is applicable to estuarine systems and

that the fraction of gross primary production which is potentially available for higher trophic levels can be estimated from the ratio H/Z_p . In these calculations we assume that mixed depth is equal to water depth, a condition which is typical in San Francisco Bay.

Assuming vertical homogeneity and that respiration rate equals $0.1 P_m^B$, annual water column respiration R_{wy} can be calculated as:

$$R_{wy} = \int_1^{365} (0.1 P_m^B B H) dt \quad (2)$$

Similarly, annual respiratory losses in the photic zone R_{py} can be estimated by substituting \bar{Z}_p for H in equation 2. We estimate that annual gross phytoplankton productivity ($PG_y = PN_{py} + R_{py}$) at the 6 sites ranged from 110 to 190 $g\ C\ m^{-2}$ and over the year respiration throughout the water column ranged from 49 to 250 $g\ C\ m^{-2}$ (Table 4).

Because \bar{Z}_p may be small relative to H , respiratory loss can cause some locations to be a net sink rather than a source of phytoplankton carbon (compare PG_y and R_{wy} for Site 6 in Table 4). The fraction of PG_y remaining after R_{wy} is accounted for is:

$$PN_{wy}/PG_y = (PG_y - R_{wy})/PG_y \quad (3)$$

The ratio PN_{wy}/PG_y (net productivity : gross productivity) was small or negative at deep (large H) and turbid (small \bar{Z}_p) sites (Table 4), which suggests that PN_{wy}/PG_y may be a simple function of the ratio H/\bar{Z}_p . Given the constraint that the limit of $PN_{wy}/PG_y = 1$ as R_{wy} (i.e. H) approaches zero (Eq. 3), values of PN_{wy}/PG_y for the 6 sites were, in fact, linearly related to H/\bar{Z}_p (Fig. 7):

$$PN_{wy}/PG_y = 1 - 0.166 (H/\bar{Z}_p) \quad (4)$$

The intercept of this function defines that critical ratio H/\bar{Z}_p above which net production becomes negative. On an annual basis for San Francisco Bay, this critical value was $H/\bar{Z}_p = 6$ (Fig. 7). Sverdrup (1953), in describing the conditions necessary for the onset of a spring bloom in the Norwegian Sea, concludes that when the mixed depth exceeds the production zone depth by 5 times the population decreases. In Lake Windermere values of mixed depth : photic depth between 3 and 4 are typical during low chlorophyll *a* periods, and chlorophyll *a* levels rise when the ratio decreases (Talling, 1971).

The need for reliable estimates of specific respiration rate has been noted by numerous researchers. Estimates of respiration in the literature range from 4 % (Platt and Jassby, 1976) to 50 % (Eppley and Sharp, 1975) of maximum assimilation rate. In San Francisco Bay R^B is generally 8 to 30 % of P_m^B (Peterson et al., in press). The 10 % respiration value used in these calcu-

	418	110	93	54	.51

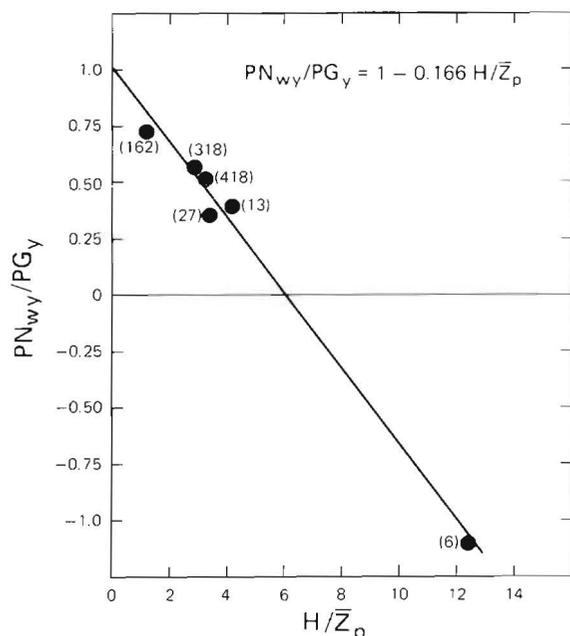

Fig. 7. Ratio of water-column net productivity to gross productivity PN_{wy}/PG_y as a function of H/Z_p

lations is probably reasonable or conservative. If respiration rates are actually higher, say 25% of P_m^B (Falkowski and Owens, 1978), then water column respiration would be 2.5 times greater and an even smaller fraction of phytoplankton production would be available to grazers (see below).

Carbon available to higher trophic levels

Implications of the critical depth concept also lead to the conclusion that not only do variations in H/Z_p ratios have profound consequences for phytoplankton population dynamics, but also that the availability of phytoplankton carbon to higher trophic levels varies with changes in this ratio. From Equation 4 and as shown in Fig. 7, the fraction of gross phytoplankton production available to herbivores can be estimated from the ratio H/Z_p . High standing stocks of phytoplankton (chloro-

phyll a) are often considered to be indicative of abundant food for higher trophic levels. As shown by our results, such a presumption may be misleading. For example, Site 6 in Suisun Bay had the highest concentrations of chlorophyll a, but because the photic zone was only a small fraction of the water-column depth (Table 2), respiratory losses exceeded gross primary production (Table 4). Baywide, there was a greater fraction of production available for herbivores at the shallow-water sites (162, 318, 418), where the ratio H/Z_p was smaller (Fig. 7), than at the deep-water sites (27, 13, 6). The extensive shallow areas of San Francisco Bay in general, and Suisun Bay in particular, must be largely responsible for maintaining the system's capacity to support herbivore populations. An estuary's capability to support higher trophic levels should thus depend in part on the size and relative proportion of areas with low and high ratios of H/Z_p rather than solely depend on phytoplankton biomass.

These findings imply 2 general conclusions. First, in deep turbid channels (e.g. Suisun Bay) the requirements for cell maintenance (respiration) are such that phytoplankton populations cannot be maintained by *in situ* growth. Rather, as postulated by Cloern and Cheng (1981) and Cloern et al. (1983), the populations found in these areas must be advected in from areas with conditions more favorable for growth (i.e. lower H/Z_p ratios). Second, the nutritional mode of herbivores might vary with turbidity. Areal productivity decreases with increasing turbidity (Fig. 6, this paper; Cadée and Hegeman, 1974; Malone, 1977; Cadée, 1978; Colijn, 1978; Joint and Pomroy, 1981), and a large fraction of phytoplankton carbon is lost through respiration in deep, turbid environments. Therefore, either the biomass of herbivores should decline in turbid environments or higher trophic levels in such environments must depend to a large degree on suspended detritus or particulate organic carbon in the sediments. Consumers in a turbid environment may therefore be less dependent upon phytoplankton production as a food source than consumers in clearer waters. Because the nutritional value of detritus is

lower than that of phytoplankton (Kirby-Smith, 1976; Heinle et al., 1977) and there is a negative relation between the percentage of detritus in the diet and growth of copepods (Heinle et al., 1977; Chervin, 1978; Chervin et al., 1981) and scallops (Kirby-Smith, 1976), one might expect to see lower macrofauna biomass in areas where there is a greater dependence on detrital carbon than phytoplankton carbon for food.

The diet for the individual species has not been studied, but distributions of zooplankton and benthic animals in San Francisco Bay support these hypotheses. In the 3 major embayments, biomass of zooplankton and benthic infauna are greater where turbidity is low, the ratio H/\bar{Z}_p is low, and there is a large proportion of phytoplankton carbon available for consumers. The average fraction of gross phytoplankton production available for consumption by herbivores in South Bay, San Pablo Bay, and Suisun Bay was 53, 48, and -29% respectively (mean PN_{wy}/PG_y ratio of channel and shoal sites from Table 4). Mean annual zooplankton biomass during 1980 was 21, 16, and 9.9 mg C m⁻³ in these same embayments (Hutchinson 1982a, b). Similarly, Thompson and Nichols (1981) report that, based on data collected in 1973, wet weight biomass of benthic macrofauna is greatest in South Bay (4800 g m⁻²) and least in Suisun Bay (100 g m⁻²) with levels in San Pablo Bay (520 g m⁻²) being intermediate between the two.

The results of our study show that daily photic zone net primary productivity in San Francisco Bay can be estimated from a simple function: $PN_{pd} = 58 + 3.8 (B I_o/\epsilon)$. Moreover, the fraction of phytoplankton carbon production available for higher trophic levels can be estimated from the ratio H/\bar{Z}_p . Thus, the capability of this complex ecosystem to support secondary production can be predicted from simple, easily measured parameters. However, it should be noted that the accuracy of calculated net water-column productivity is dependent upon accurate measures of phytoplankton respiration, a process which is not easily measured and which may be variable.

Acknowledgements. We thank Andrea Alpine for supplying the chlorophyll *a* data, assisting in collecting the productivity data, and for many helpful discussions and criticisms during field work and manuscript preparation. We also appreciate the assistance of Anne Hutchinson, Peter Alexander, Sally Wienke, and Suzanne Cartegana in collecting and analyzing the data. Valuable ideas and criticisms were provided by Janet Thompson, Steven Hager, and Frank Triska during analysis of the results and writing of the paper.

Delta Chinook Final Report

Curry Cunningham, Noble Hendrix, Eva Dusek-Jennings, Robert Lessard and Ray Hilborn

EXECUTIVE SUMMARY

This project developed a stage-structured life history model of summer, spring and winter run Chinook salmon, fitted this model to available data on salmon stock abundance and environmental conditions, and estimated the impact of the environmental conditions on survival of the different stocks of Chinook salmon. This model was then used to forecast how differences in future climate change, marine conditions or productivity, and water exports would affect the survival of the different stocks of Chinook salmon.

We used several statistical techniques to evaluate the relative importance of environmental variables on the survival including both information theoretic approaches and Bayesian approaches. Due to the large number of potential explanatory covariates (59) and the inability to fit all combinations of these covariates, we used Akaike Information Criterion for small sample size (AICc) and a novel method for exploring the model space. The approach used a forward stepwise model building with AICc as the selection criteria. The steps were: 1) fit a null model without any covariate effects to the available data; 2) construct a proposal model by selecting a covariate at random from amongst the set of 59 possible covariates; 3) fit the proposed model to the data; 4) compare the proposal model to the null model; 5) keep proposal model if reduction in AICc value is greater than 2 units; 6) repeat sampling covariates without replacement, fitting the model to data, and evaluating AICc i.e. until all covariates have been tested.

Using the information theoretic approaches we found support for environmental impacts of 14 variables including flow, temperature, sediment concentration, export inflow ratios, exports, ocean upwelling, curl and PDO. The top three environmental drivers affecting fall run were export to inflow ratio, spring upwelling south of the Farallon Islands, and the delta gross channel depletion. The top three drivers affecting spring run were size at Chipps Island, export levels, and sediment concentration at Freemont. The three main factors affecting winter-run were minimum flow during fry rearing, temperatures during egg incubation, and spring upwelling south of the Farallon Islands. We then conducted a Bayesian analysis using these 14 variables to calculate the posterior distribution of the impact of these variables on survival.

We conducted forward simulations under four different export regimes to understand how management of exports would affect each of the races. Furthermore, we evaluated export management under two different climate scenarios and two ocean productivity scenarios to understand how climate variability and ocean productivity may act in concert with management of exports to affect the three Chinook runs. We developed a harvest model that reflected current management of the Central Valley Chinook stocks in which low levels of winter run escapement can reduce fall run harvest.

39 We found that both climate and exports affected projected survival and the potential
40 recruits per spawner for wild populations. Under current export levels all stocks of spring run
41 would increase across all climate scenarios tested. Winter run would increase except under the
42 most pessimistic of the four climate conditions we evaluated. Mainstem Fall run would have
43 recruits per spawner greater than 1 under the two optimistic climate scenarios and less than 1
44 under the two pessimistic climate scenarios although the future trend in mainstem fall chinook
45 could be heavily influenced by straying from hatcheries and thus hard to predict. A 30%
46 increase in exports decreased spring and fall stock survival to the point where they would all
47 decline regardless of the climate scenario. A 30% decrease in exports improved survival and
48 recruits per spawner for all stocks.

49 We found spring Chinook stocks to be most sensitive to exports and less sensitive to
50 climate conditions, whereas winter Chinook were more sensitive to climate conditions than
51 exports.

52 We did not evaluate alternative ocean harvest scenarios, although reduction or
53 elimination of ocean harvest would increase survival to spawning and thus contribute to
54 rebuilding in the same way as better climate or reduced exports.

55 INTRODUCTION

56 Salmon populations in the Sacramento River are far below historical numbers. Fisheries
57 closures have been implemented to protect spring-run Chinook (SRC), winter-run Chinook
58 (WRC), and even fall-run Chinook (FRC), which until 2005, had been considered a healthy
59 stock. The FRC was the staple of the California salmon fishery, has been closed in several years.
60 The FRC have been the most heavily subsidized with hatchery fish. The impact on commercial
61 and recreational fisheries has been dramatic. A variety of reasons in both freshwater and marine
62 environments have been cited as causes of the decline, but it appears that salmon have been
63 subjected to something of a “perfect storm” of deleterious effects, both natural and
64 anthropogenic in origin.

65 Historically both WRC and SRC used the upstream, higher altitude tributaries of the
66 Sacramento River, but the current extent of accessible freshwater habitat differs greatly and their
67 lower abundances have led to concern and listing by both state and federal agencies (Yoshiyama
68 et al. 1998, 2000, Lindley et al. 2004). WRC and SRC were separated both temporally and
69 geographically in their spawning habitat. Winter-run historically used the headwater springs,
70 spawned in the early summer, emerged from the gravel in late summer, emigrated over the
71 winter, and entered the ocean the following spring (Lindley et al. 2004). Development of eggs
72 was dependent on relatively constant flow and cool temperatures of the spring fed streams.
73 Currently, WRC are confined to spawning in the Sacramento River. SRC used the high spring
74 flows to reach the upper tributaries of the Sacramento in summer and waited out the summer in
75 high elevation pools. Spawning commenced in the fall and juveniles emerged the following
76 spring. Stream residency varied and could last over a year. Out-migration occurred in both
77 spring and fall depending upon time of residency. There are currently several extant
78 subpopulations of SRC. Lindley et al. (2004) suggest that there are four principle groupings that
79 might form the basis of a meta-population structure: 1. Winter-run, 2. Butte Creek spring-run, 3.

80 Deer and Mill Creek spring-run, 4. Fall-run, late fall-run and Feather/Yuba spring-run. Since
81 several of these runs overlap in their usage of stream and mainstem habitat, it is reasonable to
82 consider that they may compete for resources and therefore a modeling approach that accounts
83 for these overlaps could improve the precision of population predictions. Additionally, variation
84 in survival of one population can provide additional statistical ability to the estimation of
85 environmental effects that influence both populations.

86 Over the past several decades, substantial resources have been devoted to the
87 management of water resources, fisheries, and habitat in the San Francisco Bay-Sacramento
88 River Delta (Bay-Delta) ecosystem in general, with particular attention being given to resident
89 Chinook salmon runs. There has been increasing concern for species in decline, with the listing
90 of WRC and SRC in the Central Valley (CV) under both federal (Endangered Species Act, ESA)
91 and state laws. The exceedingly low return of FRC in 2008 led to a complete closure of salmon
92 fisheries. Many studies have been conducted in an attempt to explain sources of mortality in
93 freshwater and in the ocean. Tagging studies have shown extremely low survival in freshwater.
94 Wells et al. (2007) showed strong associations between survival and ocean climate indices,
95 providing evidence for a linkage between survival and primary productivity during the marine
96 portion of the life cycle.

97 Fish interact with natural and anthropogenic aspects of their environment and there can
98 be significant variation in such externalities. Decisions regarding fisheries management, water
99 management and research direction should account for all significant and predictable sources of
100 variation in those externalities where they have a measurable effect on survival. What is lacking
101 is an integrative model that can provide a level of detail in water resource management and
102 fishery management that accounts for interactions between salmon populations, both in the wild
103 as well implicitly captured in the mechanics of fisheries policy.

104 Although mathematical models of salmon species have been developed both at the
105 individual (e.g., Kimmerer 2001, Jager and Rose 2003) and the population (e.g., Botsford and
106 Brittnacher 1998) level, management and research direction have been based primarily on
107 qualitative compilations of what is known about individual salmon runs. Management would
108 benefit from models that more closely link environmental conditions to biological response.
109 Lessard et al. (*submitted manuscript*) built upon the general principle that survival could be
110 broken down into life history stages so that the relevant environmental factors in each stage
111 could be factored into the estimation of the productivity and capacity parameters that predict
112 density dependence in survival rates. A series of competing models were compared using a
113 statistical modeling and population dynamics platform (OBAN), each reconstructing population
114 dynamics and estimating the relative effects of environmental conditions in freshwater and ocean
115 stages. The study found that temperature, flow and exports explained most of the variation in
116 freshwater. Historically, gate positions of bypasses and cross channels have explained some of
117 the variation in survival, however, water management agencies have responded to biological
118 needs and have in recent years adjusted the timing and magnitude of water redirection activities
119 to mitigate negative effects on salmon. Wind stress curl, a primary productivity surrogate (Wells
120 et al. 2008), was the leading factor explaining variation in ocean survival, although indices such
121 as the Pacific Decadal Oscillation (Mantua et al. 1997) and sea surface temperature also
122 explained variation in ocean survival, although not throughout enough of the timeframe of the
123 study to be statistically competitive in model selection.

124 For the population dynamics portion of the project, we developed a multi-stock model of
125 the three Central Valley Chinook salmon species-at-risk (WRC, SRC and FRC) that incorporates
126 mortality in all phases of salmon life history, and includes the effects of uncertainty in assessing
127 population status. The approach involves several categories of models: (1) the population
128 dynamics models, (2) the parameter estimation model, (3) the growth model, and (4) the fisheries
129 management model that calibrates fishing effort to the predicted runs of the individual
130 populations.

131 **PART I FITTING A STATISTICAL MODEL**

132 *METHODS; MODEL DESCRIPTION*

133 The goal of this project was evaluate the environmental drivers of survival for Chinook
134 salmon populations spawning in the Sacramento River, CA watershed, in a statistically rigorous
135 manner. More generally, our purpose was to test a range of hypotheses describing the putative
136 factors facilitating or limiting survival, factors both natural and anthropogenic in origin and
137 describing both biotic and abiotic processes. To achieve this goal we have created a stage-
138 structured population dynamics model, which estimates the direction and magnitude of influence
139 that a range of these factors, or environmental covariates, have on survival through specific
140 portions of the Chinook life cycle, when fit to available juvenile and adult spawning abundance
141 data. The population dynamics model is currently used to explore the environmental drivers of
142 survival for four fall-run populations including: 1) Mainstem Sacramento wild-spawning
143 Chinook, 2) Battle Creek Coleman National Fish Hatchery produced Chinook, 3) Feather River
144 Hatchery produced Chinook, and 4) American River Nimbus Hatchery produced Chinook, as
145 well as three spring-run populations including: 1) Deer Creek, 2) Mill Creek, and 3) Butte Creek,
146 wild-spawning Chinook.

147 The stage-structured population dynamics model described in this document compliments
148 and expands upon previous analyses of interactions between environmental factors and survival
149 of Chinook salmon populations of the Sacramento River watershed in several ways. First, while
150 many previous analyses have modeled the survival or productivity of single components of the
151 Sacramento River Chinook stock complex (i.e. (Newman and Rice 2002, Lindley and Mohr
152 2003, Newman and Brandes 2010, Zeug et al. 2012), fall-run (Newman and Rice 2002), late-fall-
153 run (Newman and Brandes 2010), winter-run (Lindley and Mohr 2003, Zeug et al. 2012)) in
154 isolation, the current population dynamics model is applied to multiple populations of both
155 spring-run and fall-run Chinook and evaluates interactions between these populations at points in
156 the life cycle where co-rearing and co-migration occurs. Second, the current population
157 dynamics model approximates both wild and hatchery type life histories, utilizing historical
158 records of hatchery releases from the Coleman National Fish Hatchery on Battle Creek, the
159 Feather River Hatchery, and the Nimbus Fish Hatchery on the American River compiled by
160 Huber and Carlson (in review). Third, we have utilized estimates of stray rates between
161 hatcheries and wild populations of fall-run Chinook available from the proportional coded wire
162 tagging program (Kormos et al. 2012, Palmer-Zwahlen and Kormos 2013), to reconstruct
163 spawning abundance data in the presence of straying, prior to fitting the estimation model.
164 Fourth, while previous analyses have primarily evaluated survival variation in either the

165 freshwater or marine portions of the Chinook life cycle, we have created a population dynamics
 166 model with both marine and freshwater stages, permitting the testing of competing hypotheses
 167 for putative survival influences in all habitats utilized by Sacramento River Chinook. Fifth, while
 168 previous stage-structured population dynamics models used to evaluate the interaction between
 169 environmental factors and the survival of Sacramento Chinook including Zeug et al. (2012) have
 170 defined these interactions based upon a priori information or findings from other systems or
 171 laboratory experimentation, the population dynamics model we have created is statistical in
 172 nature, estimating the effect of the hypothesized environmental drivers of survival based upon
 173 historical variation observed in adult and juvenile abundance. The result is a flexible multi-stock,
 174 stage-structured, statistical, population dynamics model that estimates the influence of natural
 175 and anthropogenic environmental factors on survival of Chinook salmon throughout their life
 176 cycle, using both Bayesian and Maximum Likelihood methods.

177 *The Data*

178 In order to estimate the effect of various environmental covariates as well as basal
 179 productivity and capacity for the seven populations in specific life stages, the estimation model is
 180 conditioned on different types of data available for the Sacramento River system. The first type
 181 of data that are required by the estimation model are time-series of explanatory environmental
 182 covariates. For each environmental covariate being evaluated for its influence on Chinook
 183 survival, it is necessary to provide, a historical record of its value over time as a model input.
 184 Covariate data are z-standardized (Zar 2010) based upon the mean and standard deviation of the
 185 time-series (Eq. I.1).

$$186 \quad (I.1) \quad X_{t,i} = \frac{x_{t,i} - \sum_{t=1}^{Nt} x_{t,i} / Nt}{\sigma_i}$$

187 In this way, the *i*th covariate at time *t* ($x_{t,i}$) is transformed into units of standard deviations
 188 from the time-series mean, rather than untransformed values that span many orders of magnitude
 189 among covariates. By transforming covariate data into the same units, the magnitude of
 190 subsequently estimated coefficients describing the influence of individual covariates are more
 191 readily comparable and estimable.

192 Potential covariates were chosen for evaluation within the estimation model based upon
 193 first principals and a valid biological rationale for why each might be expected to influence
 194 either survival rate or stage-specific capacity. Covariates were developed came from a wide
 195 range of sources, including a review of the pertinent literature and expert opinion, and were
 196 created using data from the period of time throughout the year over which they were expected to
 197 exhibit the greatest influence (Table I.1).

202

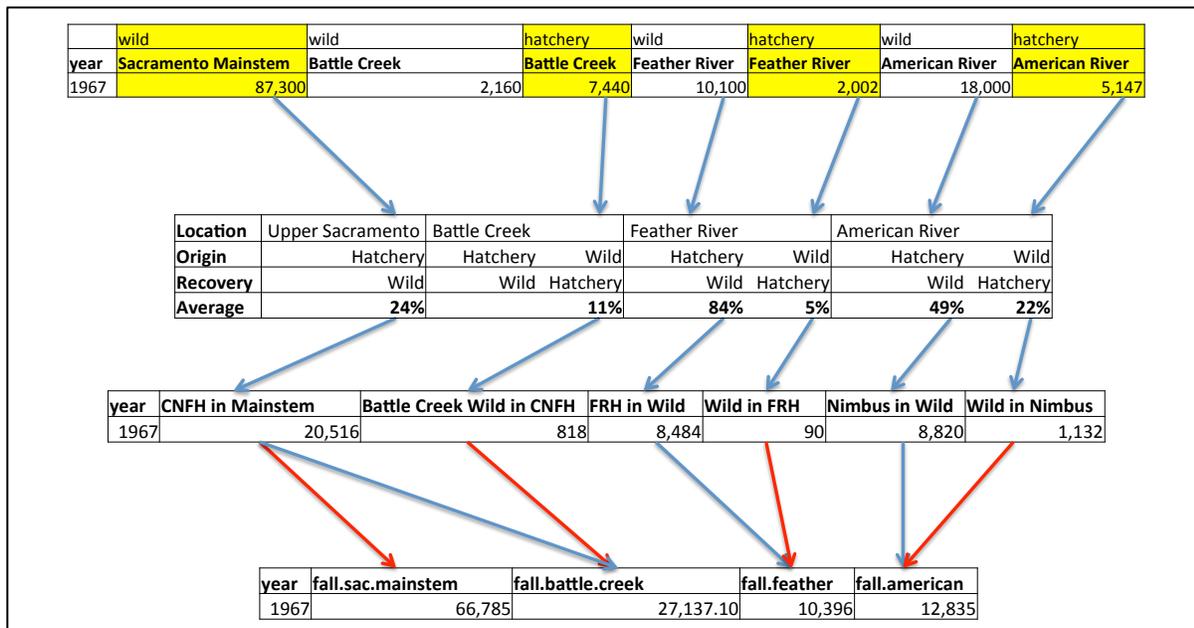

203 The second type of data required are time-series of abundance data for the populations
 204 included in the multi-stock population dynamics model. Estimates of the number of adult
 205 Chinook returning to natural spawning grounds and hatcheries are available from the GrandTab
 206 database (CDF&W 2014) for all seven populations evaluated as part of this study. However,
 207 since the Central Valley Constant Fractional Marking Program (CFM) was initiated in 2007, it
 208 has been possible to estimate the contribution of hatchery-origin Chinook to the spawning
 209 abundance observed on wild spawning grounds and the contribution of wild-origin Chinook

210 production to observed returns to regional hatcheries (Kormos et al. 2012). Historical
 211 abundances for the seven Chinook populations were reconstructed to account for straying
 212 between hatcheries and natural spawning grounds, using the average of the estimated proportion
 213 of observed adult Chinook straying in 2010 (Kormos et al. 2012) and 2011 (Palmer-Zwahlen and
 214 Kormos 2013). Average (2010-2011) proportions of observed adult abundance that were
 215 comprised of hatchery and wild individuals in each population (Table I.2), were used to
 216 reconstruct historical abundances for the fall-run spawning populations.

Location	Origin	Recovery	2010	2011	Average
Upper Sacramento	Hatchery	Wild	20%	27%	24%
Battle Creek	Hatchery	Wild			
	Wild	Hatchery	11%	11%	11%
Feather River	Hatchery	Wild	78%	90%	84%
	Wild	Hatchery	5%	4%	5%
American River	Hatchery	Wild	32%	66%	49%
	Wild	Hatchery	21%	23%	22%

217
 218 **Table I.2. Proportion of observed adult abundance by location estimated from CWT**
 219 **recoveries to be of wild or hatchery origin in 2010 and 2011, and the average used to**
 220 **reconstruct historical abundances.**

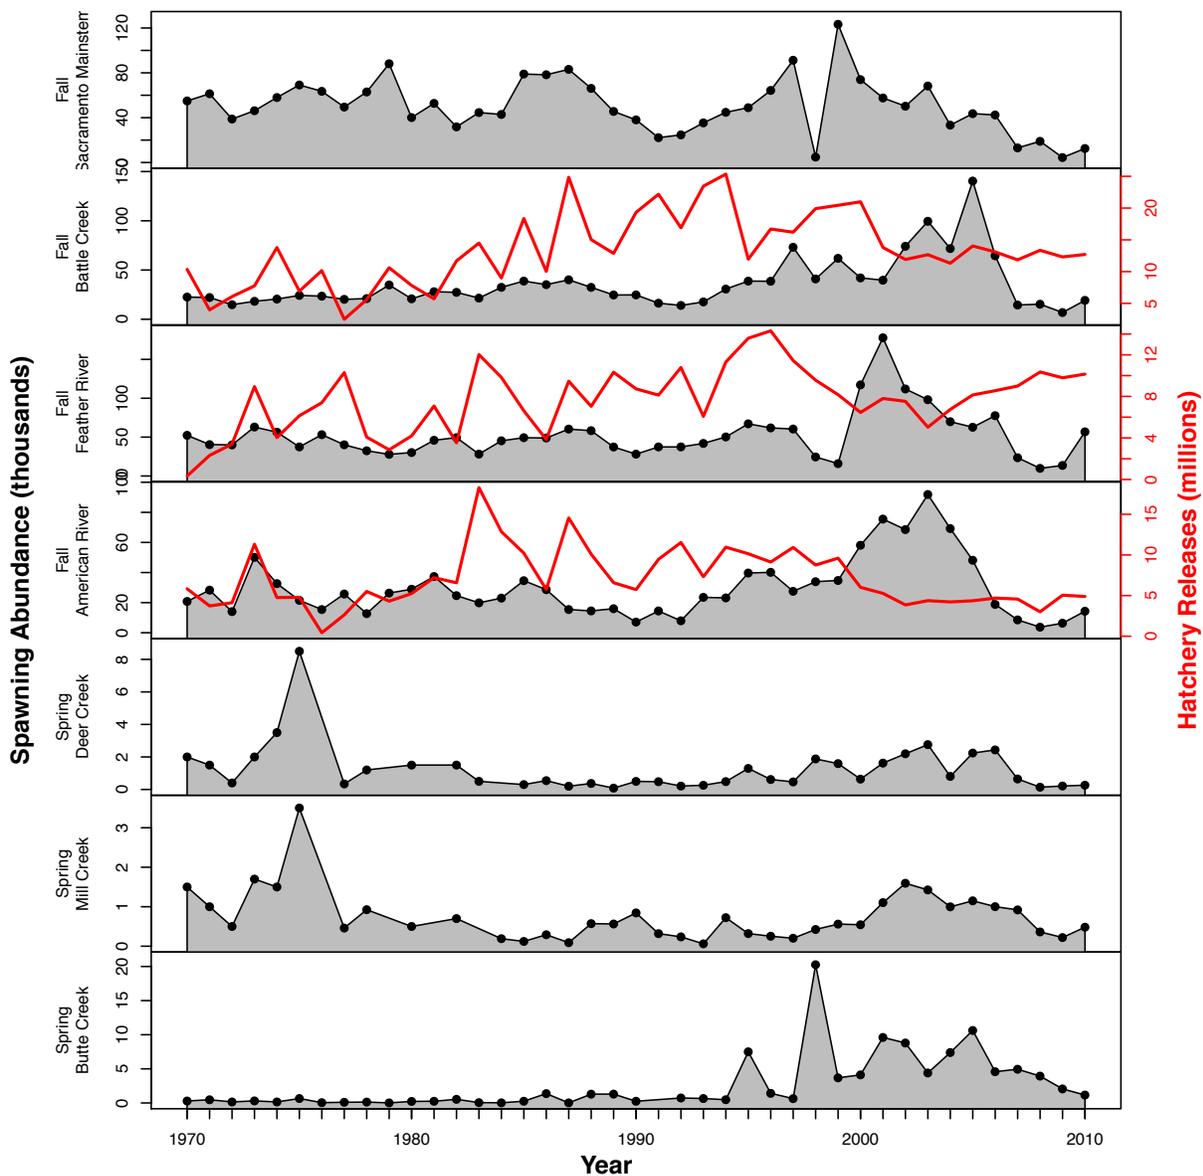

221 For example, in order to reconstruct the fall-run wild Sacramento mainstem spawning
 222 abundance, each year 24% of the observed spawning abundance was remove and reallocated to
 223 the Coleman National Fish Hatchery (Battle Creek) adult abundance, while 11% of the observed
 224 Battle Creek hatchery (CNFH) abundance was removed as wild migrants into the hatchery (Fig.
 225 I.1).

226
 227 **Figure I.1. Empirical schematic showing how the historical abundance of the 1967**
 228 **population for the four fall-run Chinook populations were reconstructed through**
 229 **additional or removal of the abundance of other stocks.**

230 Adult abundances for the four fall-run Chinook populations were reconstructed using the
 231 methods detailed above for years 1967 – 2010 (Fig. I.2). Existing adult abundance estimates
 232 reported by CDF&W (2014) for the spring-run populations included in our analyses (i.e. Deer,
 233 Mill, and Butte Creeks) were assumed to be minimally impacted by hatchery straying and
 234 therefore unaltered (Fig. I.2).

235

236 **Figure I.2. Adult abundance (grey area plot) and hatchery release (red line) data for**
 237 **Sacramento River Chinook. Fall-run abundances are reconstructed based upon hatchery-**
 238 **wild stray rate estimates, while spring-run abundances are as reported in GrandTab 2014.**
 239

240 Estimates of juvenile Chinook abundance in Sacramento River system were also used to
 241 inform estimates of model parameters. The inclusion of additional abundance indices to which

242 the estimation model is fit, confers a greater ability to partition mortality between life stages and
 243 more precise estimation of the strength and magnitude of influence from environmental
 244 covariates. Poytress et al. (2014) have used available trap efficiency information to calculate
 245 absolute abundance indices for juvenile Chinook passing Red Bluff Diversion Dam, partitioned
 246 by race. Fall-run juvenile Chinook abundance estimates from 2002 forward were assumed to be
 247 comprised predominantly of two populations, the wild Sacramento Mainstem population and the
 248 Battle Creek (CNFH) Hatchery population. Therefore, model estimates of the combined
 249 abundance of these two populations were compared to the estimates provided by Poytress et al.
 250 (2014) in likelihood calculations.

251 The third type of data required by the estimation model are historical hatchery releases.
 252 As constructed, the estimation model allows for specification of the wild or hatchery life-history
 253 type for each population. Three of the seven populations currently included in our analysis are
 254 of hatchery origin, therefore annual hatchery release numbers were required for the Battle Creek
 255 (CNFH) Hatchery, Feather River Hatchery, and American River (Nimbus) Hatchery populations.
 256 Huber and Carlson (in review) have expended significant time and effort to digitize and render
 257 historical hatchery reports in an easily accessible and usable format. For the three hatchery
 258 population included in our analysis, we have used these hatchery release data to in place of the
 259 functional relationship between spawning abundance and fecundity assumed for the wild
 260 spawning populations. Figure I.2 shows hatchery release numbers from Huber and Carlson (in
 261 review) for each of the three fall-run hatchery populations.

262 Hatchery release practices have historically differed amongst facilities and over time,
 263 with on-sight releases, releases in the Sacramento-San Joaquin delta, releases in San Francisco
 264 Bay, and many locations in between (Huber and Carlson in review). At this time, hatchery
 265 release location was not specifically considered. However, for populations whose release
 266 strategies allow fish to bypass the mortality incurred in the upriver stage, this should manifest as
 267 a reduction in the estimated influence of covariates linked to the upriver stage. In this way,
 268 although we do not specifically adjust the model stage pathway depending on hatchery release
 269 location in each year, this should not be expected to introduce any significant bias in our
 270 estimates of coefficients describing the influence of environmental covariates.

271 The fourth type of data required for these analyses were annual estimates of harvest rate
 272 by population. Harvest rate estimates are available from the U.S. Fish and Wildlife Chinookprod
 273 database. For each population of interest, this database uses both the abundance estimates from
 274 the Grandtab (CDF&W 2014) database and ocean harvest numbers from the Pacific Fishery
 275 Management Council (PFMC) to calculate harvest rates in the marine and in-river regions. For
 276 our purposes, we have calculated the total harvest rate by stock and year as the sum of ocean (
 277 $C_{t,p}^{ocean}$) and in-river catch ($C_{t,p}^{in-river}$), divided by the total abundance including observed
 278 escapement ($E_{t,p}$) and catches for that population (p) in that year (t) (Eq. I.2).

$$279 \quad (I.2) \quad hr_{t,p} = \frac{C_{t,p}^{ocean} + C_{t,p}^{in-river}}{E_{t,p} + C_{t,p}^{ocean} + C_{t,p}^{in-river}}$$

280 *Estimation model structure*

281 The purpose of our analysis is to test the various hypotheses regarding what natural and
282 anthropogenic factors have influenced Sacramento River Chinook salmon survival historically,
283 during both the freshwater and marine portions of the Chinook life cycle. Furthermore, we wish
284 to use estimates of the drivers of Chinook survival to generate robust predictions for future
285 abundance under a range of alternative climate change, oceanographic, and water management
286 scenarios. In order to achieve this objective we have created a population dynamics model that
287 estimates the influence of environmental covariates as well as population-specific basal
288 productivity (maximum survival) rates and rearing capacities for different stages in the life cycle.

289 The statistical population dynamics model is stage-structured, simulating the entire
290 Chinook life cycle from egg to spawning adult, and partitioning mortality events between those
291 separate spatio-temporal stages. For the freshwater portion of the life cycle, these stages are
292 defined by the migration pathways exhibited by the various Chinook populations and the
293 availability of two data types. First, freshwater life stages are defined in accordance with the
294 availability of environmental covariate data, so as to accurately reflect the point in time and
295 location within Sacramento River network where the Chinook have the most substantial
296 exposure to the environmental covariates. Second, model stages are structured to correspond
297 with juvenile indices of abundance at Red Bluff, CA (Poytress et al. 2014). The estimation model
298 contains six stages, three associated with juvenile rearing in freshwater and nearshore regions,
299 and three associated with the marine component of the life cycle (Fig. I.3). The first stage
300 represents rearing of juveniles in tributaries and upper reaches of the Sacramento River
301 mainstem. The second model stage represents the area within the Sacramento River watershed
302 including the Sacramento-San Joaquin Delta through Chipps Island. The third stage represents
303 juvenile rearing in the nearshore region from San Francisco Bay and the Gulf of Farallones.
304 Stages 4-6 represent the years spent in the marine environment, with associated probability of
305 maturation and potential for ocean harvest.

306
307 **Figure I.3. Map of estimation model stage structure.**

308 The population dynamics model tracks cohorts of Chinook from specific brood years
309 forward in time across sequential model stages. Chinook abundance is represented by $N_{y,s,p}$ or
310 the number of individuals from brood year y , surviving to stage s , of population p . The
311 abundance of Chinook of brood year y and population p , surviving to the end of the current stage
312 (s) is dependent upon the year, stage, and population specific survival rate $SR_{y,s,p}$ in Equation
313 I.3.

314 (I.3)
$$N_{y,s,p} = N_{y,s-1,p} * SR_{y,s,p}$$

315 Survival through the spatio-temporally explicit life stages is described by a Beverton-Holt
316 transition function (Moussalli and Hilborn 1986). The Beverton-Holt equation, while
317 traditionally used in the evaluation of spawner-recruit data (Beverton and Holt 1957), provides a
318 useful approximation for survival of individuals from one model stage to the next, as influenced
319 by two factors: 1) the productivity rate $p_{y,s,p}$, and 2) the rearing capacity $K_{y,s,p}$ of each stage (Eq.
320 I.4).

321 (I.4)
$$SR_{y,s,p} = \frac{p_{y,s,p}}{1 + \frac{p_{y,s,p} * \sum_{i=1}^{Npop} \alpha_{p,i,s} * N_{y,s-1,i}}{K_{y,s,p}}}$$

322 In this formulation (Eq. I.4) the year, stage, and population-specific productivity ($p_{y,s,p}$)
323 represents the maximum survival rate in the absence of density-dependent compensation.

324 Conversely, the year, stage, and population-specific capacity ($K_{y,s,p}$) describes the total number
 325 of individuals that can potential survive through the model stage. However, given that we are
 326 evaluating multiple co-migrating and co-rearing populations, equation I.4 also includes an
 327 interaction effect ($\alpha_{p,i,s}$) which describes how many individuals of the focal population p are
 328 displaced with respect to the stage capacity ($K_{y,s,p}$) for each individual of population i . In this
 329 way no interaction effect for a stage may be specified with a zero value for all elements of $\alpha_{p,i,s}$
 330 except $\alpha_{p,i=p,s}$. Positive, non-zero values indicate that the abundance of other populations (i)
 331 results in a reduction in overall rearing capacity for the focal population (p), and therefore
 332 reduced survival at high abundance levels which approach the stage-specific capacity ($K_{y,s,p}$).
 333 Specifying $\alpha_{p,i,s}$ elements equal to one create a situation where capacity is shared across
 334 populations with symmetric impacts on capacity.

335 In our current analysis we have identified the Sacramento-San Joaquin Delta stage (2nd)
 336 and nearshore stage (3rd) as points of possible competition and therefore capacity interactions
 337 within the model. Fall-run and spring-run juvenile Chinook are assumed to compete with
 338 members of their own race within these two stages of the life cycle and therefore shared
 339 capacities are assumed, with symmetric interactions (i.e. $\alpha_{p,i,s}$ elements equal to 1).

340 The productivity ($p_{y,s,p}$) capacity ($K_{y,s,p}$) parameters in the population dynamics model
 341 are time varying and assumed to change in response to inter-annual variation in the
 342 environmental covariates under evaluation. The productivity parameter for population p , of
 343 brood year y , in stage s is a function of the basal productivity $\beta_{s,p,0}$, or the average survival for
 344 members of that population in the current stage, as well as the sum of environmental covariate c
 345 values at time t ($X_{t,c}$) multiplied by their respective coefficients ($\beta_{s,p,c}$) which describe the
 346 influence of each covariate on stage and population-specific productivity $p_{y,s,p}$ (Eq. I.5).

$$347 \quad (I.5) \quad p_{y,s,p} = \frac{1}{1 + \exp\left(-\beta_{s,p,0} - \sum_{c=1}^{Nc_{s,p}} \beta_{s,p,c} * X_{t,c}\right)}$$

$$t = y + \delta_c$$

348 δ_c is the covariate-specific temporal reference which is the difference between the brood
 349 year y and the year in which the cohort will interact with that covariate, and is used as a pointer
 350 to ensure that the covariate value for the correct year is used when tracking each cohort forward
 351 in time, and $Nc_{s,p}$ is the number of productivity covariates linked to each population in each
 352 stage. The overall productivity parameter value ($p_{y,s,p}$) is a logit transformation of the additive
 353 effects of the basal productivity rate and covariate effects, which ensures that its value is
 354 smoothly scaled between 0 and 1 (Eq. I.5).

355 The capacity parameter for each population's brood year specific cohort in each stage
 356 ($K_{y,s,p}$) is likewise a function of a basal, or average, stage and population specific capacity across
 357 years ($\gamma_{s,p,0}$) and the additive effects of capacity-related covariates ($Y_{t,k}$) and the population-
 358 specific coefficients ($\gamma_{s,p,k}$) describing the magnitude and direction of influence each holds (Eq.
 359 I.6).

360 (I.6)
$$K_{y,s,p} = \exp\left(\gamma_{s,p,0} + \sum_{k=1}^{Nk_{s,p}} \gamma_{s,p,k} * Y_{t,k}\right)$$

361
$$t = y + \delta_k$$

361 The capacity parameter ($K_{y,s,p}$) is described in natural log space for ease of estimation
 362 and to ensure it is bounded within the set of positive values, where k is the covariate reference
 363 number and δ_k is the temporal reference for the offset from the brood year for each covariate,
 364 indicating when the population interacts with each specific covariate in the life cycle.

365 However, for populations of Chinook occupying the same habitats and subject to the
 366 same environmental covariates, it may be reasonable to assume that a common response in
 367 survival to a particular covariate is exhibited. For this reason we have further allowed for a
 368 coefficient describing the effect of a particular covariate to be shared across populations. In this
 369 way several productivity ($\beta_{s,c}$) capacity ($\gamma_{s,k}$) coefficients may be common across a subset of
 370 populations. This reduces model complexity, increases parsimony, and improves the ability to
 371 estimate of coefficient values for which a common survival response is biologically defensible.

372 The basal capacity parameters for a population ($\gamma_{s,p,0}$, see Eq. I.6), or group of interacting
 373 populations for which $\alpha_{p,i,s} > 0$ (see Eq. I.4), represent the maximum rearing capacity for that
 374 population in that stage over time in the absence of influence from environmental covariates. For
 375 populations that are currently well below historical abundance levels, or for populations without
 376 subsequent juvenile abundance estimates, it is often difficult to estimate these basal stage
 377 capacity values. However, auxiliary information may be used to inform these stage-specific
 378 capacities. Recent work by Noble Hendrix, in collaboration with researchers at NOAA, has
 379 resulted in monthly juvenile Chinook salmon capacity estimates for the Sacramento River
 380 mainstem and the Sacramento-San Joaquin Delta (Hendrix et al. 2014). In place of estimating
 381 stage capacities for: 1) Sacramento River mainstem-spawning wild fall-run Chinook in the
 382 upstream stage (1st), 2) mainstem-spawning wild, Battle Creek (CNFH) hatchery, Feather River
 383 Hatchery, and American River (Nimbus) Hatchery, populations in the Sacramento-San Joaquin
 384 Delta stage (2nd), and 3) Deer, Mill, and Butte Creek populations in the Sacramento-San Joaquin
 385 Delta stage (2nd), we have used capacity estimates available from NOAA in-stream Chinook
 386 capacity modelling (see Appendix A - Delta Submodel). The average of estimated monthly
 387 capacities in the Sacramento Mainstem for the period between January and April in each year,
 388 was used for as the input capacity for mainstem-spawning wild fall-run population. The average
 389 of estimated monthly Sacramento – San Joaquin Delta rearing capacities for the March – May
 390 and February – April periods, were used as the input capacities for the fall-run and spring-run
 391 populations in that stage, respectively.

392 Capacity estimates for the Sacramento-San Joaquin Delta from NOAA in-stream
 393 Chinook habitat capacity modelling were only available after 1980 (Hendrix et al. 2014). Given
 394 that our population dynamics model begins in year 1967, it was necessary to assume a fixed
 395 capacity for the period prior to 1980. NOAA Delta capacity estimates correlate most directly
 396 with water year type, therefore the average of estimated capacities for the fall-run and spring-run
 397 populations by water year type were calculated and used in place of actual capacity estimates

398 prior to 1980. These average capacities by water year type and Chinook run type were used in
399 years prior to 1980 based on the reported water year.

400 Survival for cohorts of Chinook is tracked forward in time across spatio-temporal model
401 stages in the same manner (Eq. I.4, I.5, I.6) independent of whether the stage is in the freshwater
402 or marine portion of the life cycle and independent of the ontogenetic status of individuals.
403 However, for the final three model stages representing the 1st, 2nd, and 3rd year in the ocean, it is
404 necessary to account for both the maturation process and marine harvest when tracking the
405 number of individuals entering the next stage. Harvest mortality is assumed to occur after the
406 annual mortality event, but prior to maturation. Catch by year, population, and stage ($C_{t,p,s}$) is
407 the number of surviving individuals multiplied by the population specific harvest rate observed
408 in each year ($hr_{t,p}$), scaled by the stage (i.e. ocean age) specific catchability coefficient (ϵ_s) (Eq.
409 I.7).

$$C_{t,p,s} = N_{y,s,p} * SR_{y,s,p} * (hr_{t,p} / \epsilon_s)$$

410 (I.7) $t = y + \rho_s$
 $\epsilon_s = \{0, 0, 0, 0, 1.54, 1.0\}$

411 In equation I.7, ρ_s is the temporal offset for model stages that indicates the difference
412 between the brood year and the calendar year, so that the proper annual harvest rate may be
413 referenced. Annual harvest rate estimates were obtained from the Pacific Fishery Management
414 Council (PFMC).

415 For the three ocean life-stages, the number of individuals of a cohort moving to the next
416 stage is governed by the survival rate ($SR_{y,s,p}$), annual catch estimate ($C_{t,p,s}$), and the maturation
417 probability (ϕ_s) (Eq. I.8).

$$N_{y,s+1,p} = (N_{y,s,p} * SR_{y,s,p} - C_{t,p,s}) * (1 - \phi_s)$$

418 (I.8) $\phi_s = \{0, 0, 0, 0.1, 0.942, 1\}$
 $t = y + \rho_s$

419 While the cohort specific survival rate varies over time, the maturation probability (ϕ_s) is
420 assumed to be temporally invariant. So then, the number of individuals of a cohort advancing to
421 the next ocean stage is the number in the previous stage ($N_{y,s,p}$) that have survived, less the
422 proportion that matures and begins homeward migration (Eq. I.8). The return abundance ($R_{y,s,p}$)
423 is the number of individuals from a cohort that survived marine and harvest mortality, and have
424 initiated the maturation process and return to freshwater to spawn (Eq. I.9).

425 (I.9) $R_{y,s,p} = (N_{y,s,p} * SR_{y,s,p} - C_{t,p,s}) * \phi_s$

426 The predicted number of spawning adults of each population in each year ($\hat{A}_{t,p}$) is the
427 sum of returning individuals ($R_{y,s,p}$) across stages or equivalently ocean age classes (Eq. I.10).

428 (I.10)
$$\hat{A}_{t,p} = \sum_{s=1}^{Nstage} R_{y,s,p}$$

$$t = y + \rho_s$$

429 Depending on whether a wild-type or hatchery-type life history is assumed for each
 430 population the next cohort ($N_{y,s=1,p}$) will be created either based on the predicted number of
 431 spawning adults and an assumed fecundity value of 2000 eggs/individuals (Eq. I.11) or based
 432 upon recorded releases from hatchery facilities (Eq. I.12).

433 (I.11)
$$N_{y,s=1,p} = \hat{A}_{t=y,p} * fec$$

434 (I.12)
$$N_{y,s=1,p} = RH_{t=y,p}$$

435 In order to estimate the value for model parameters including basal productivities ($\beta_{s,p,0}$)
 436 and capacities ($\gamma_{s,p,0}$) for each population in each stage, and coefficients describing the direction
 437 and magnitude of influence each environmental covariate has on either productivity ($\beta_{s,p,c}$) or
 438 capacity ($\gamma_{s,p,k}$) for individual populations or shared amongst populations ($\beta_{s,c}$ and $\gamma_{s,k}$), the
 439 model must be fit to available abundance data. We employ a maximum likelihood approach to
 440 compare abundance predictions with available data and estimate model parameter values
 441 (Hilborn and Mangel 1997). Predicted adult spawning abundances are calculated (Eq. I.10) as
 442 part of the population dynamics model. Absolute abundance estimates for juveniles are available
 443 for Chinook passing Red Bluff Diversion Dam (Poytress et al. 2014), and we assume that the
 444 mainstem Sacramento wild population and Battle Creek hatchery (CNFH) population comprise
 445 the majority of the juvenile fall-run Chinook sampled at this location, so the juvenile abundance
 446 estimate is calculated as the sum of these two populations (Eq. I.13)

447 (I.13)
$$\hat{J}_t = \sum_{p=1}^2 N_{y,s=1,p}$$

$$t = y + \rho_{s=1}$$

448 Model predicted adult spawning abundances are compared to empirical data, and model
 449 parameters are estimated by minimizing the negative log-likelihood of the model given the
 450 observed data (Eq. I.14).

451 (I.14)
$$L_A(\Theta | A_{t,p}) = \prod_{t=1}^n \frac{1}{\hat{\sigma}_p \sqrt{2\pi}} \exp \left[-\frac{(\ln(A_{t,p}) - \ln(\hat{A}_{t,p}))^2}{2\hat{\sigma}_p^2} \right]$$

452 The likelihood of the model parameters, given the spawning abundance data, assume a
 453 that observation error in log transformed abundances are normally distributed, with the standard
 454 deviation of the observation error distribution ($\hat{\sigma}_p$) equal to the maximum likelihood estimate
 455 (Eq. I.15).

456 (I.15)
$$\hat{\sigma}_p = \sqrt{\sum_{t=1}^n \frac{(\ln(A_{t,p}) - \ln(\hat{A}_{t,p}))^2}{n}}$$

457 Under the same assumptions the observation error likelihood of the model parameters
458 given juvenile abundance data (Eq. I.13) was calculated (Eq. I.16)

459 (I.16)
$$L_J(\Theta | J_t) = \prod_{t=1}^n \frac{1}{\hat{\sigma}_J \sqrt{2\pi}} \exp\left[-\frac{(\ln(J_t) - \ln(\hat{J}_t))^2}{2\hat{\sigma}_J^2}\right]$$

460 using the maximum likelihood estimate for the standard deviation of the normal
461 observation error distribution from the juvenile data (Eq. I.17).

462 (I.17)
$$\hat{\sigma}_J = \sqrt{\sum_{t=1}^n \frac{(\ln(J_t) - \ln(\hat{J}_t))^2}{n}}$$

463 The total data likelihood (Eq. I.18) is the sum of the negative log of the likelihood from
464 the juvenile and adult abundance data.

465 (I.18)
$$LL_T = -\ln(L_A) - \ln(L_J)$$

466 Model parameter values that minimized the total negative log likelihood (LL_T) were
467 found using AD Model Builder (Fournier et al. 2012). AD Model Builder (ADMB) is a software
468 platform allowing complex non-linear minimizations for models containing a large number of
469 parameters while also permitting profile likelihoods or posterior distributions for parameters of
470 interest to be estimated. ADMB was selected as the software design platform for this project
471 because of its flexibility, computational efficiency and ability to reliably sample a complex
472 multivariate likelihood surface. In addition to its benefits as a fast and stable optimization tool
473 for fitting statistical models to data, ADMB also estimates uncertainty in and correlations
474 between model parameters based on their derivative structure.

475 When fit to available abundance data the ADMB stage-structured population dynamics
476 model provides estimates of model parameters, uncertainty in those parameter estimates, and the
477 hessian matrix for model parameters from which the parameter covariance matrix may be
478 derived. However, with 37 separate environmental covariates to be tested as competing
479 hypotheses it was necessary to define metrics for model fit and parsimony. We use the Akaike
480 Information Criterion corrected for small sample sizes (AICc) (Burnham and Anderson 2002) as
481 a metric for model parsimony (Eq. I.19).

482 (I.19)
$$AICc = 2LL_T + 2p + \frac{2p(p+1)}{n-p-1}$$

483 AICc balances the degree to which a model is able to explain the variability in data (LL_T)
 484 against the number of parameters estimated (p) and number of data used in estimation (n), and
 485 provides a basis for model selection. The second statistic used to evaluate model fit is the mean
 486 absolute percent error in model predictions (Eq. I.20).

$$487 \quad (I.20) \quad MAPE_p = \frac{\sum_{t=1}^n \left| \frac{\hat{A}_{t,p} - A_{t,p}}{A_{t,p}} \right|}{n}$$

488 The method we have employed in the Sacramento for modelling the anadromous
 489 salmonid life cycle as a series of sequential, spatially-explicit, stage-specific Beverton-Holt
 490 transition functions that relate density-dependent survival to habitat covariates is similar to those
 491 successfully used to address conservation questions regarding other Chinook salmon populations
 492 along the West Coast. The Shiraz model developed by Scheuerell et al. (2006), employed to
 493 evaluate anthropogenic and habitat effects on production of Chinook in the Snohomish River
 494 basin of Puget Sound, Washington, was one of the first to specify interactions between habitat
 495 variables and the productivity and capacity parameters of the Beverton-Holt functions describing
 496 survival through life stages. Subsequently, Battin et al. (2007) and Honea et al. (2009) employed
 497 stage-structured models governed by linked Beverton-Holt transition functions to evaluate the
 498 influence of climate change, hydrologic variability, and habitat restoration on populations of
 499 Chinook salmon in the Columbia River basin. All three of these analyses used a Shiraz-type
 500 approach by linking habitat and climate covariates to stage-specific survival.

501 However, the model we have designed for evaluating the environmental drivers of
 502 survival for Chinook salmon in the Sacramento River differs from the Shiraz-type models
 503 described above (Scheuerell et al. 2006, Battin et al. 2007, Honea et al. 2009) in several
 504 fundamental ways. First, the model used in these analyses is statistical in nature. Whereas
 505 Scheuerell et al. (2006), Honea et al. (2009), and Battin et al. (2007), all specify the relationships
 506 between environmental covariates and the productivity and capacity parameters of the Beverton-
 507 Holt function for each stage, based upon *in situ* observations, laboratory experiments, or expert
 508 opinion, the estimation framework we have created for the analysis of the drivers of Sacramento
 509 River Chinook survival estimates these relationships directly from the abundance data. Second,
 510 estimation of the relationships between environmental covariates and the Beverton-Holt
 511 productivity and capacity parameters, will not only provide point estimates of the effect of each
 512 covariate, but also estimates of uncertainty. By estimating both the value for coefficients
 513 describing covariate effects, as well as their uncertainty, we are not only be able to discern which
 514 covariates have the largest influence, but also which covariates have had a consistent influence
 515 historically. Finally, by estimating the value of coefficients describing the magnitude and
 516 direction of influence each environmental covariate has on stage-specific productivity or
 517 capacity, our method allows for the propagation of estimation uncertainty in those relationships
 518 forward when those model parameters are used to predict future abundance trends under
 519 alternative climate, marine productivity, or water use scenarios.

520 *METHODS UNCERTAINTY – AICc SELECTIONS AND MCMC METHODS*

521 In order to test a range of hypotheses regarding which environmental covariates influence
 522 the survival of seven populations of Sacramento River Chinook, we constructed a stage-
 523 structured statistical population dynamics model. When fit to available adult and juvenile
 524 abundance data, this model estimates the magnitude and direction of influence that a set of
 525 environmental covariates has on two components of Chinook survival, namely life-stage specific
 526 productivity (maximum survival) rates and capacities. In the process of fitting population
 527 dynamics models to data as part of our analysis, there were two sources of uncertainty that we
 528 considered directly. The first was structural uncertainty, or uncertainty in the subset of
 529 environmental covariates that best represent the processes driving changes in abundance over
 530 time. The second is estimation uncertainty, or uncertainty in our ability to identify the true
 531 direction and magnitude of the effect each environmental covariate imposes on Chinook
 532 survival. To address structural uncertainty in our analysis, we used a process of forward stepwise
 533 model building, based upon an AICc criteria, with replication to ensure complete evaluation of
 534 model space, or the range of potential models that may be used to describe trends in abundance
 535 over time. This process allowed us to define the “best” model or subset of potential
 536 environmental covariates (hypotheses) for describing observed population dynamics. To address
 537 the second type of uncertainty in our analysis, estimation uncertainty, we employed Markov
 538 Chain Monte-Carlo estimation methods to quantify the probability distributions for the
 539 coefficients describing the effect of each environmental covariate on survival.

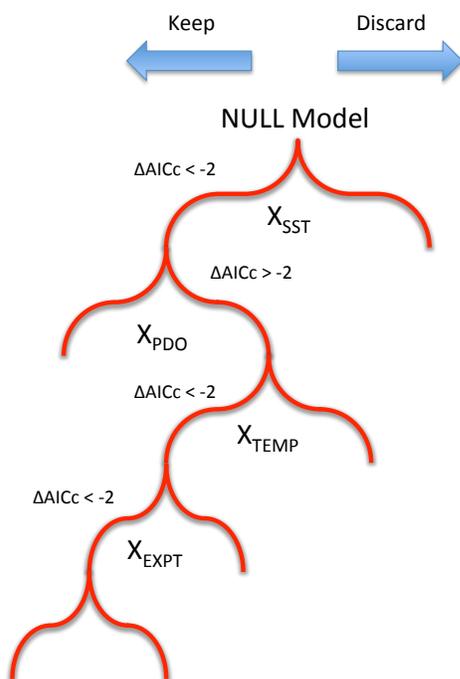

540 *Stepwise AICc Model Selection*

541 In total 37 separate environmental covariates were identified by the study team as
 542 potential drivers of interannual variation in Sacramento Chinook survival. Describing the effects
 543 of these 37 environmental covariates on separate populations in the form of either population-
 544 specific effects or common influences on groups of populations, resulted in a total 59 covariate-
 545 by-population effects, whose influence on survival may be estimated based on their ability to
 546 explain observed Chinook abundance data. Each of these 59 covariate-by-population effects
 547 represents an alternative hypothesis to be tested in our analysis.

548 Hypotheses for covariate-by-population effects on Chinook survival may be compared to
 549 a “null” model that attempts to explain variation in the time-series’ of observed juvenile and
 550 adult abundance data based on only observed ocean harvest rates, hatchery release numbers,
 551 estimated productivities (maximum survival rates) for populations in the first life-stage, and
 552 annual capacities specified by the juvenile capacity modelling (Hendrix et al. 2014). The null
 553 model represents the base case, without any influence from environmental covariates. However,
 554 in order to define the model with the best potential to provide accurate predictions for population
 555 responses to future environmental, climate, and water management scenarios it was necessary to
 556 find the most parsimonious model, or subset of explanatory covariates. Model parsimony is
 557 defined by the balance between the ability to accurately explain variation in observed data, while
 558 estimating the fewest parameters possible. The Akaike information criterion, corrected for small
 559 sample sizes (AICc, Eq. I.19), quantifies model parsimony and provides a metric for selecting
 560 amongst competing models (Burnham and Anderson 2002). Competing models incorporating

561 alternative combinations of covariate effects were compared based on their AICc values in order
 562 to define a “best-fit” model for generating predictions for future abundance trends.

563 With a total of 59 independent covariate-by-population effects to be tested for their
 564 ability to explain variation in historical Sacramento Chinook survival, the number of possible
 565 combinations of these effects, or potential models, is quite large. It becomes unrealistic to fit
 566 every possible model permutation to the available data and compare AICc values. Therefore we
 567 used a method for exploring the model space, or the range of potential models incorporating
 568 different combinations of these effects, which involved a forward stepwise model building with
 569 AICc as the selection criteria. Forward stepwise model building begins first by fitting the null
 570 model, without any covariate effects, to the available data. Second, a covariate is selected at
 571 random from amongst the set of 59 possible covariate-by-population effects and included in the
 572 model, and this model is subsequently fit to the data. Third, the AICc value for this new model is
 573 compared to that of the null model. If a reduction in AICc value for the model including the
 574 additional covariate of greater than 2 units is observed ($\Delta AICc \leq 2$), when the old model is
 575 compared to the model incorporating the new covariate, that covariate is kept, otherwise it is
 576 removed from the model. Moving forward, this process of randomly sampling covariates without
 577 replacement, fitting the model to data, and evaluating $\Delta AICc$, (i.e. steps two and three) are
 578 repeated until all covariates have been tested for their ability to improve model parsimony (see
 579 Fig. I.4).

580
 581 **Figure I.4. Diagram of forward stepwise AICc model building process. Starting from the**
 582 **null model, covariates (X_{TEMP} , X_{PDO} etc.) are sampled at random without replacement from**
 583 **the set of 59 possible hypotheses and included in the statistical model. The model is then fit**
 584 **to abundance data and the difference in AICc values between the old and new models**
 585 **dictates whether that covariate is kept or discarded, and the next iteration begins.**

586 The result of one round of forward stepwise AICc model building, or fitting the null
 587 model and 59 alternative models sequentially, is one realization of a best-fit model based upon
 588 the AICc criteria. However, experience indicates that given even small correlations among some
 589 environmental covariates, the order in which covariates are introduced has a subtle influence on
 590 the resulting model. Therefore, in order to more fully explore the uncertainty in model selection,
 591 we repeated the forward stepwise AICc process 1,000 times. By evaluating the frequency with
 592 which specific covariates appear in best-fit models across these 1,000 realizations, it is possible
 593 to determine which covariates are most important in explaining historical variation in Chinook
 594 survival. Furthermore, by repeating the stepwise AICc process 1,000 times, we are thoroughly
 595 exploring the model space and among these independently built models can determine the single
 596 model that has the lowest AICc among the candidate best-fit models.

597 *Markov Chain Monte-Carlo Estimation Methods*

598 The second critical piece of uncertainty in our analysis is estimation uncertainty.
 599 Estimation uncertainty describes variation in the estimated value of model parameters, and is a
 600 function of how well model parameters are informed by the available data. In order to quantify
 601 the level of estimation uncertainty in our analyses, particularly as it pertains to estimates of the
 602 coefficients describing the influence of environmental covariates on Chinook survival, we
 603 employed Bayesian estimation methods in addition to the maximum likelihood approach
 604 described above. Bayes' Theorem (Eq. I.21) describes the probability of a hypothesis θ , in our
 605 case a set of parameter values, given the data, which in our case are both adult spawning
 606 abundance ($A_{t,p}$) and juvenile abundance (J_t) observations.

$$607 \quad (I.21) \quad P(\theta | data) = \frac{P(data | \theta)P(\theta)}{\int P(data | \theta)P(\theta)}$$

608 The prior probability on logit transformed coefficients was normal with a mean of zero
 609 and standard deviation equal to 2.5, as per recommendations by King et al. (2010). Bounded
 610 uniform priors were assumed for all other estimated model parameters. Estimated initial (log)
 611 abundances 1967-1969 were bounded on the (0, 100) interval, basal stage productivities ($\beta_{s,p,0}$)
 612 were bounded on the (-25, 25) interval, and basal stage capacities ($\gamma_{s,p,0}$) bounded on the (-100,
 613 100) interval. Bayesian estimation methods allow the posterior probability distribution for
 614 derived and estimated parameters to be calculated, and from it the full range of parameter
 615 uncertainty. The posterior probability distribution for model parameter i (θ_i) describes the
 616 probability that the true value of that parameter is equal to a specific value. Based upon the
 617 posterior probability distributions for model parameters, we are able to calculate the expected
 618 values for model parameters as well the uncertainty in those parameter estimates.

619 Markov Chain Monte-Carlo (MCMC) methods are commonly used numerical algorithms
 620 employed to draw samples from the posterior distributions for parameters in Bayesian models
 621 (Gelman et al. 2004). We employed the Random Walk Metropolis-Hastings (RW-MH) MCMC
 622 algorithm implemented in AD Model Builder (Fournier et al. 2012) to draw samples from
 623 posterior distributions of parameters in population dynamics model. The RW-MH MCMC
 624 algorithm is a widely applicable MCMC algorithm that accounts for correlations among model

625 parameters. As implemented in ADMB, the RW-MH MCMC algorithm begins by finding the
626 parameter values that maximize the complete data likelihood, or posterior modes, and then uses
627 the estimated covariance matrix for model parameters to create a multivariate proposal
628 distribution. Based upon this multivariate proposal distribution randomly drawn parameter sets,
629 or MCMC jumps, are proposed and either accepted or rejected based upon comparison of the
630 ratio of the proposed posterior density to that of the current state, with a random uniform (0,1)
631 deviate. In this way, the RW-MH MCMC algorithm in ADMB begins as the posterior mode and
632 samples the joint posterior.

633 MCMC chains were run for 5,000,000 iterations with a thinning rate of 1/1,000 to reduce
634 posterior correlation. The first 30% of the chain was removed as a burn-in period, during which
635 the chain approached the stationary distribution for model parameters. To ensure MCMC results
636 converged to their stationary distribution, three independent chains were run simultaneously.
637 Model convergence was tested in three separate ways. First, traceplots of MCMC samples were
638 evaluated for the presence of discernable trends that would indicate a lack of convergence to the
639 true stationary distribution. Second, posterior correlations at differing lags were calculated,
640 wherein significant correlation would indicate a lack of convergence. Finally, Gelman and
641 Rubin's convergence diagnostic (Gelman and Rubin 1992, Brooks and Gelman 1998) was used
642 to compare within and among chain variance to determine if all three chains had indeed
643 converged to the same stationary distribution.

644 *RESULTS MODEL FITS*

645 *Model Selection Results*

646 In order to define the set of environmental covariates that best explains historical patterns
647 in abundance for the seven populations of Sacramento Chinook, we employed a process of
648 iterative forward stepwise AICc model selection. This process was meant to test the full range of
649 alternative hypotheses for drivers of Sacramento Chinook survival, and define the most coherent
650 set of covariates with the greatest explanatory power and predictive potential. Each iteration of
651 model selection results in a candidate best-fit model, however in order to fully explore model
652 space it was necessary to repeat this process many times with a randomized order of covariate
653 proposal in each iteration. By comparing the percent of times any particular covariate appeared
654 across the 1,000 candidate best-fit models, we are able to determine which covariates or
655 hypotheses have the greatest support from the data. Table I.3, describes the percentage of
656 candidate best-fit models that incorporated each specific covariate.

657

664

Table I.3. Model selection results. Percent inclusion rate for environmental covariate effects across 1,000 candidate best-fit models, each resulting from one round of forward stepwise-AICc model building. Note the covariate name includes the single population name, or the numbers for multiple populations upon whose survival the effect of the environmental covariate is shared. For reference population numbers are: 1) fall-run mainstem Sacramento wild-run Chinook, 2) fall-run Battle Creek Coleman National Fish Hatchery produced Chinook, 3) fall-run Feather River Hatchery produced Chinook, 4) fall-run American River Nimbus Hatchery produced Chinook, 5) spring-run Deer Creek wild Chinook, 6) spring-run Mill Creek wild Chinook, and 7) spring-run Butte Creek wild Chinook.

665 Results of the iterative forward stepwise-AICc model selection (Table I.3) indicate
 666 that the set of environmental covariates (hypotheses) which best describe historical variation
 667 in Sacramento Chinook abundance encompass a wide range of locations within the life cycle,
 668 populations, and ecological processes. A higher inclusion rate across best-fit models for a
 669 specific covariate by population(s) effect may be interpreted as greater weight of evidence
 670 from the data that this covariate explains variation in survival and therefore may be of
 671 ecological importance (Table I.3). Foremost, it should be noted that the influence of spring
 672 air temperature at the city of Sacramento on survival of the Butte Creek population
 673 (spring.butte – sacAirTemp.spring) was included as an AICc-selected covariate in 998 of
 674 1,000 best-fit models. This covariate represents air temperature during juvenile rearing
 675 (January – March) at the city of Sacramento, and is included as a surrogate for Butte Creek
 676 stream temperature. Additional covariates which were represented in 60% or greater of
 677 iteratively built models include: 1) the combined influence of the size of out-migrating
 678 spring-run juveniles on the survival of Deer, Mill and Butte Creek spring-run populations
 679 (.5.6.7-spring.size.chipps), 2) the combined influence of near-shore upwelling during the
 680 period of ocean entry (April – June) upon the survival of the four fall-run populations
 681 (.1.2.3.4-upwelling.south.early), and 3) the combined influence of the Pacific Decadal
 682 Oscillation during winter (January – May average) of the first year of marine residence
 683 (.1.2.3.4.5.6.7-pdo.early) on the survival of all four fall-run and three spring-run populations.
 684 The 5th most frequently included covariate was the effect of summer (July – September) air
 685 temperature at Sacramento during the brood year, on survival of Butte Creek spring-run
 686 Chinook (spring.butte-sacAirTemp.summer). This covariate was included to test hypothesis
 687 that high over-summer water temperatures may have a negative impact on the survival and
 688 successful spawning of adult spring-run Chinook holding in tributaries.

689 With respect to the representation of anthropogenic drivers of Chinook survival across
 690 the 1,000 forward-AICc built models, covariates describing the influence of water exports on
 691 spring and fall-run survival were the 6th, 7th, and 8th most often included. The combined effect
 692 of average water exports from the Sacramento – San Joaquin Delta between February and
 693 April quantified by the Dayflow QEXPORTS metric on survival of spring-run Chinook
 694 (.5.6.7-spring.dayflow.export), appeared in 54% of forward stepwise-AICc built models.
 695 Similarly, the covariate representing the combined effect of March – May average
 696 Sacramento – San Joaquin water exports on the survival of the four fall-run Chinook
 697 populations (.1.2.3.4-fall.dayflow.export) was included in 48% of stepwise-AICc built
 698 models, with the ratio of water exports to total Delta water inflow (Dayflow: EXPIN) during
 699 this same period (.1.2.3.4-fall.dayflow.expin) following closely with a 37% inclusion rate.
 700 Other covariates highlighting the influence of water routing and supply in the Sacramento –
 701 San Joaquin Delta were included in a smaller subset of stepwise-AICc built models. The
 702 influence of average net channel depletion (Dayflow: QCD) between February and April on
 703 the grouped spring-run Chinook populations (.5.6.7-spring.dayflow.cd) was included in 22%
 704 of the 1,000 stepwise-AICc built models. In addition, the combined influence of the average
 705 flow into Georgiana Slough and the Delta Cross Channel (Dayflow: QXGEO) February –
 706 April on the spring-run populations (.5.6.7-spring.dayflow.geo) was included in 19% of
 707 candidate best-fit models.

708 While the inclusion rate of specific covariate-by-population effects across the 1,000
 709 stepwise-AICc built models provides an indication of the relative weight of evidence from
 710 the data, that each covariate holds some ability to explain historical patterns in survival, we
 711 consider the model with the lowest AICc value to have the best predictive ability. The single

712 model with the lowest AICc value represents the most parsimonious fit to the data, explaining
 713 the greatest amount of observed variation in adult and juvenile abundance, while estimating
 714 the fewest parameters. This lowest AICc or “final” model provides the best basis for
 715 predicting future trends in abundance under alternative climate, marine production, and water
 716 management scenarios. The final model included 14 covariate-by-population effects,
 717 spanning both the freshwater and marine portions of the life cycle (Table I.4). In addition, the
 718 effects incorporated in the final model include both single-population effects as well as
 719 shared effects of environmental covariates across multiple populations. In total five of the
 720 covariates included in the final (lowest AICc) model were related to survival in the 1st
 721 (upriver) stage, six were related to the 2nd stage representing environmental effects on
 722 survival through the Sacramento – San Joaquin Delta, two were related to the 3rd stage
 723 influencing survival in the nearshore environment, and only one covariate was related to
 724 survival during subsequent years of marine residence.

Hypothesis Number	Covariate	Covariate Description	Model Stage	Populations
3	fall.sac.mainstem - keswick.discharge	Average January - March water discharge (cfs) at Keswick Dam	Upstream	Fall Sacramento Mainstem Wild

725
 726 **Table I.4. Fourteen covariate-by-population effects included in the final AICc-**
 727 **selected model.**

728 Of the covariate-by-population effects on upstream survival incorporated in the final
 729 model three were related to atmospheric temperature, used as a proxy for tributary-specific
 730 water temperatures, and two were related to water flow conditions. The three temperature-
 731 related covariate-by-population effects were all based on air temperature at Sacramento, CA
 732 and included: 1) the effect of average spring air temperature (January - March) on survival of
 733 the fall-run Battle Creek population in the year of emergence (fall.battle.creek -
 734 sacAirTemp.spring), 2) the effect of average summer air temperature (July – September)
 735 during the brood year on offspring production and oocyte through juvenile survival for the
 736 Butte Creek spring-run population (spring.butte - sacAirTemp.summer), and 3) the effect of
 737 average spring air temperature (January – March) in the year of emergence on survival of
 738 Butte Creek spring-run Chinook (spring.butte - sacAirTemp.spring). The two upstream
 739 covariate effects related to water flow conditions included, the influence of average water

740 discharge rates (cfs^{-1}) at Keswick Dam during the period between January and March on the
 741 survival of Sacramento mainstem spawning wild fall-run Chinook (fall.sac.mainstem -
 742 keswick.discharge), and the effect of average water discharge in Deer Creek between October
 743 and December on the brood year survival of spring-run Chinook spawning in that tributary
 744 (spring.deer - deer.discharge).

745 The range of covariates which best describe historical patterns in juvenile Chinook
 746 survival through the Sacramento – San Joaquin Delta stage included factors both
 747 anthropogenic and natural in origin. Interestingly, the winter (February-April) concentration
 748 of sediment (mg/L) measured at Freeport, CA was selected based upon the AICc criteria as
 749 an important explanatory covariate for both grouped fall-run (.1.2.3.4-freeport.sed.conc) and
 750 spring-run (.5.6.7-freeport.sed.conc) populations. Two other covariate effects on the
 751 combined survival of fall-run Chinook populations which relate to water flow and
 752 management in the Sacramento – San Joaquin Delta were also identified in the final model,
 753 including average March – May Dayflow metrics for: 1) QCD or net channel depletion for in-
 754 delta consumptive use (.1.2.3.4-fall.dayflow.cd), and 2) EXPIN or the ratio of total delta
 755 exports to freshwater inflows (.1.2.3.4-fall.dayflow.expin) (CDWR 2014). In addition to
 756 sediment concentration, two other covariate effects on the combined survival of the Deer,
 757 Mill, and Butte Creek spring-run populations in the Sacramento – San Joaquin Delta were
 758 present in the AICc-selected final model. These included the influence of average monthly
 759 water exports and diversions from the delta (February – April) as quantified by the Dayflow
 760 metric QEXPORTS (CDWR 2014), which represents the sum of Central Valley Project
 761 exports, State Water Project exports, Contra Costa Water District diversions, and North Bay
 762 Aqueduct exports (.5.6.7-spring.dayflow.export), and the average size of juvenile spring-run
 763 Chinook caught in the Chipps Island Trawl (.5.6.7-spring.size.chipps).

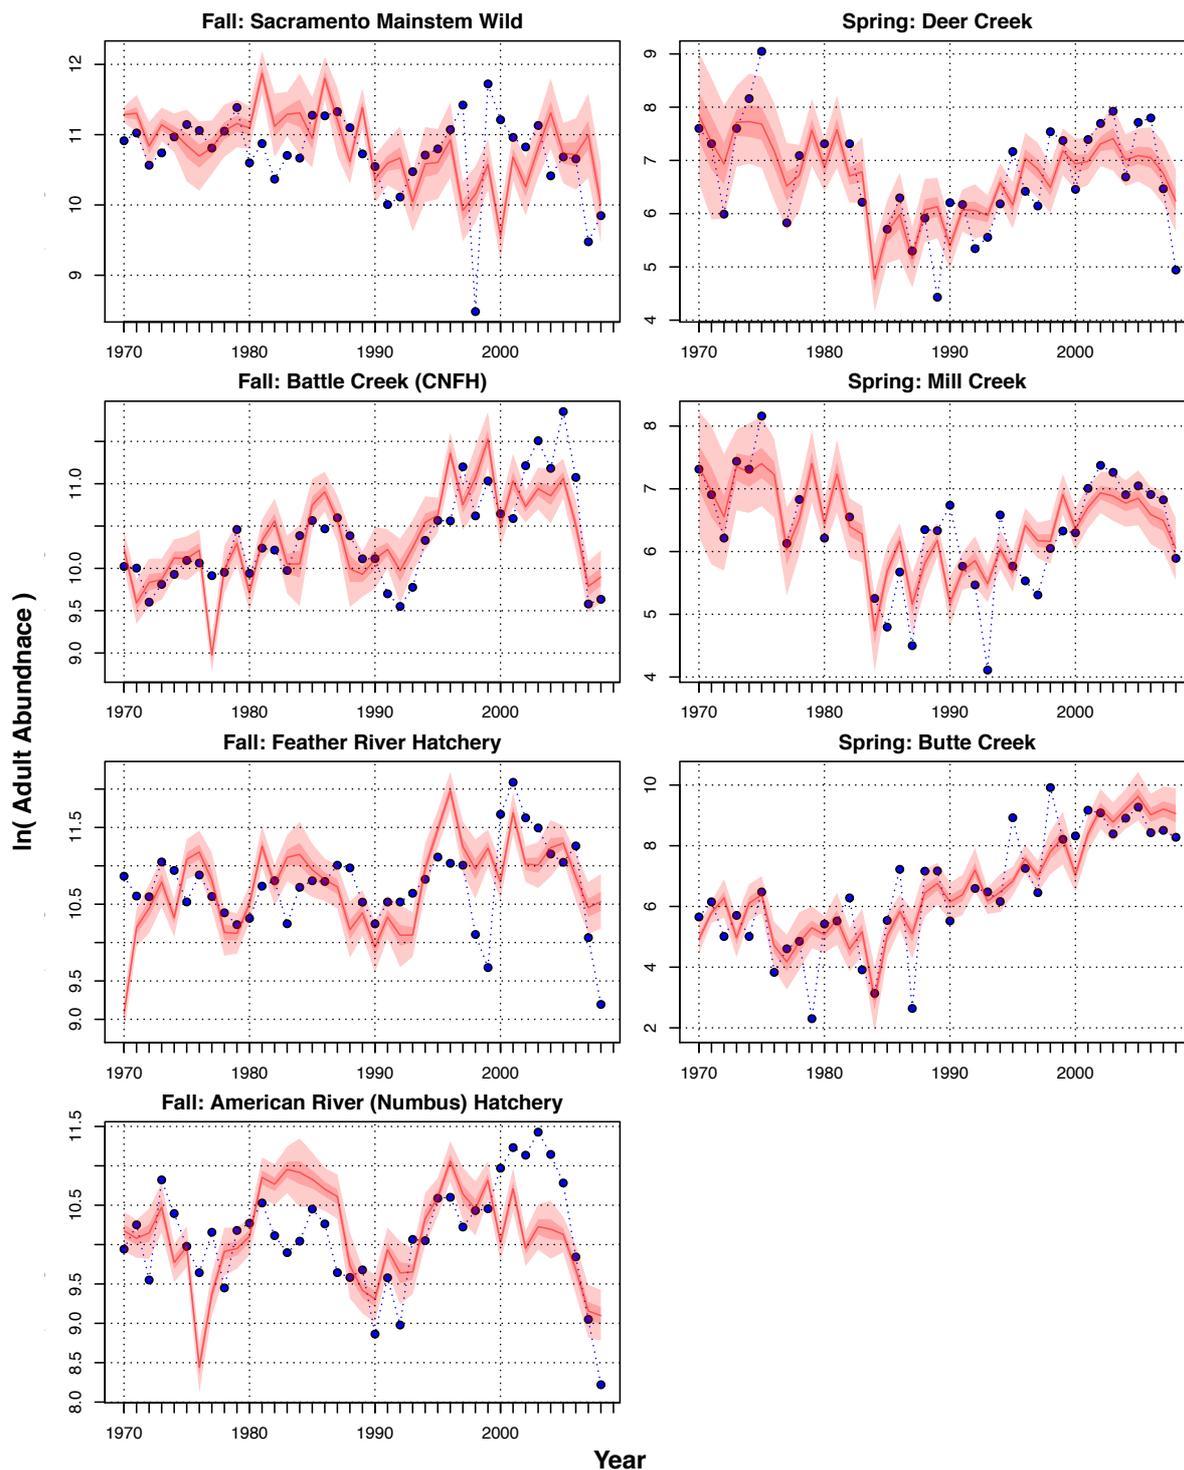

764 Based on the AICc criteria and thorough exploration of model space using replicate
 765 stepwise model building, the final model identified three covariates able to explain some of
 766 variance in Chinook survival in the nearshore region following ocean entry and survival
 767 during subsequent years of marine residency. Survival for the four fall-run Chinook
 768 populations in the nearshore region was explained in part by upwelling patterns during the
 769 spring months (April – June) at the southern NOAA/PFEL monitoring site located at 36°N
 770 latitude and 122°W longitude (.1.2.3.4-upwelling.south.early). Additionally, the effect of
 771 average wind stress curl during July – December of the year of ocean entry on the survival of
 772 all seven combined spring and fall-run populations was included in the final model
 773 (.1.2.3.4.5.6.7-curl.late). The last covariate present in the final model linked to broad-scale
 774 marine climate patterns was the effect of the average Pacific Decadal Oscillation Index
 775 during the winter of the first year at sea (January – May) on the combined survival of all
 776 seven populations (.1.2.3.4.5.6.7-pdo.early).

777 These fourteen population-by-covariate effects, spanning freshwater and marine
 778 portions of the Chinook life cycle and all seven analyzed Chinook populations, represent the
 779 most parsimonious explanation for historical patterns in Chinook survival and observed
 780 juvenile and adult abundance. This final model was used as the basis for the subsequent
 781 Bayesian analysis of the effect of each of these covariates and their realized survival
 782 influence, and used for predicting future trends in abundance under alternative water
 783 management scenarios, predictions for future climate change, and marine production patterns.

784 *Estimation Results*

785 In order to estimate the direction and magnitude of the 14 covariate effects identified
786 by AICc selection criteria across 1,000 stepwise-AICc built models (Table I.4), we have
787 employed Bayesian methods with a MCMC sampler. Separate stage-structured models were
788 used to represent each of the seven populations, however common effects across populations
789 for specific covariates were estimated, and shared capacity constraints in the Sacramento –
790 San Joaquin Delta were assumed for the four fall-run and three spring-run populations
791 separately. Estimation of model parameters was informed by juvenile and adult abundance
792 data, reconstructed to account for observed stray rates between hatchery and wild
793 populations. Figure I.6 displays observed adult abundance data for the four fall-run Chinook
794 populations and three spring-run populations as well as the posterior predictive distribution
795 from the Bayesian population dynamics model. The posterior predictive distribution
796 represented by the red line and shaded regions, describe the median, 50% and 95% credible
797 intervals for the predicted adult spawning abundance or hatchery returns for each population
798 in each year.

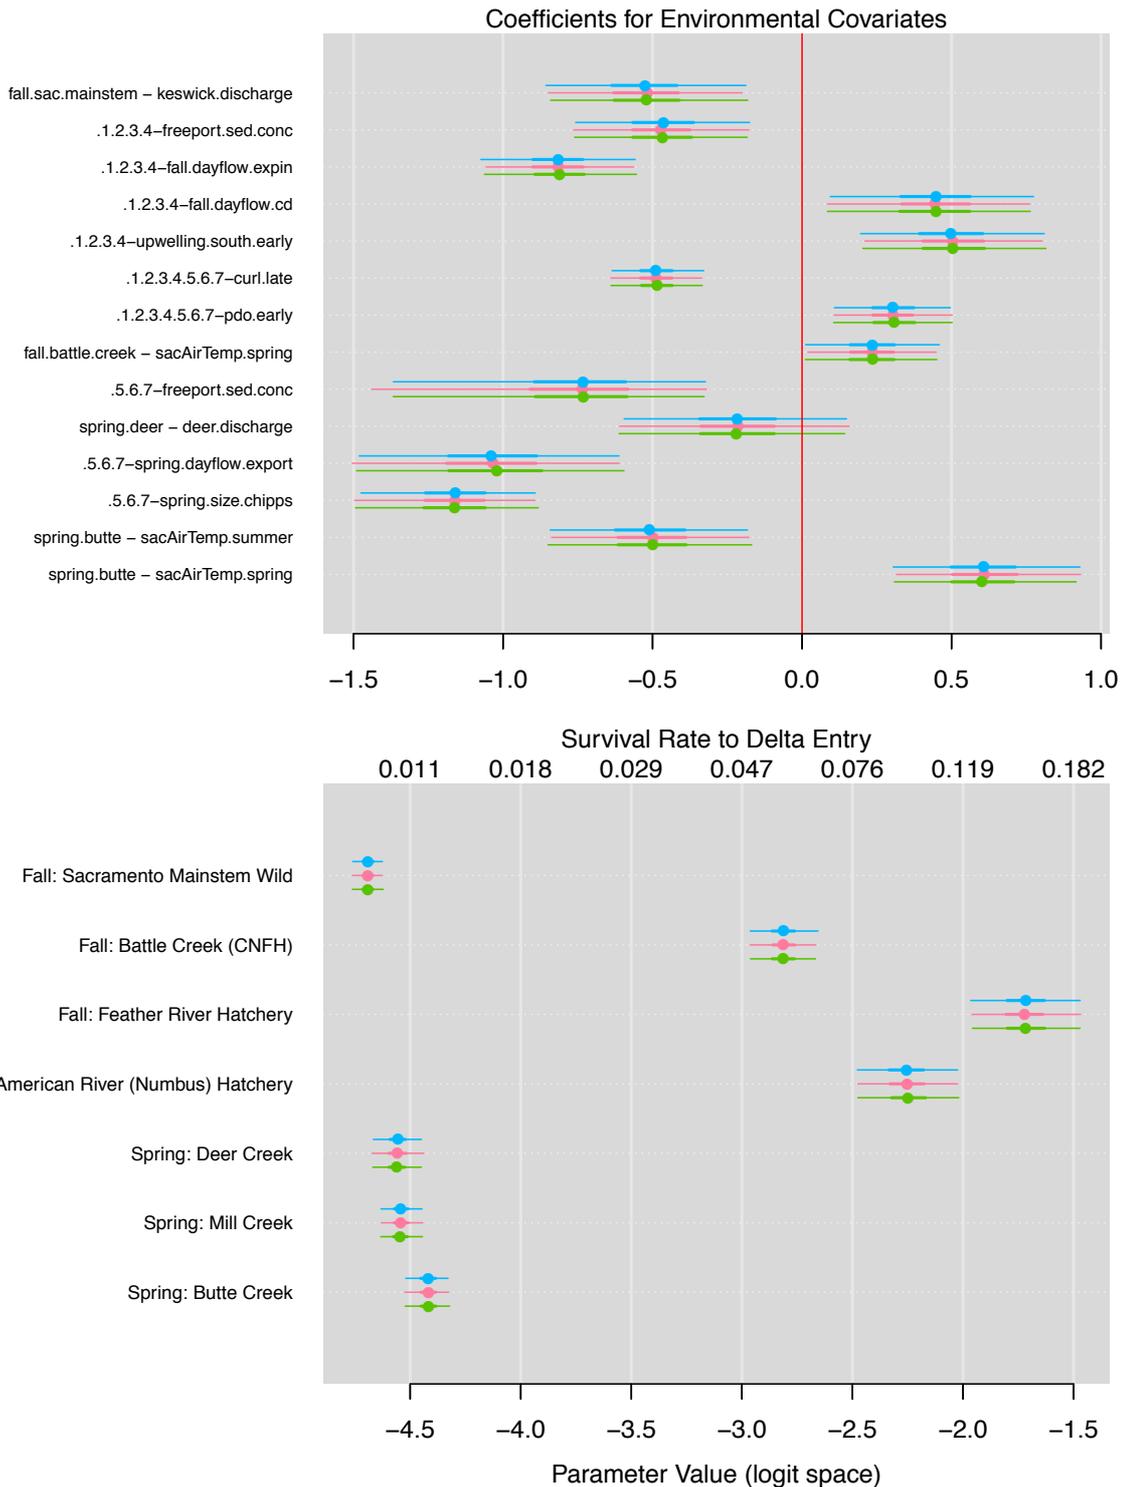

799 Results indicate that the model predicts the pattern for Deer and Mill Creek spring-run
800 populations which exhibit higher adult abundances, relative to the time series, through 1984
801 followed by a period of lower adult abundance through the mid-1990s, followed by higher
802 relative abundances through 2006 (Fig. I.5). Similarly for the Butte Creek spring-run
803 population, the model captures the period of lower spawning abundance prior 1985 followed
804 by a pronounced increase in abundance, ending with a relative plateau in the early 2000's
805 (Fig. I.5). Model predictions for Sacramento Mainstem spawning wild fall-run Chinook and
806 Feather River hatchery fall Chinook both fail to capture the low returns in 1998 – 1999, but
807 capture the reduction in abundance observed in 2007 – 2008. In general for all seven
808 populations of spring and fall-run Chinook included in the analysis, model predictions do not
809 explicitly capture interannual variation, but explain much of the general trend in abundance
810 across the time series (Fig. I.5).
811

812
 813 **Figure I.5.** Bayesian population dynamics model fit to adult abundance data. Blue
 814 points and dashed lines indicate the observed adult abundance in each year on the
 815 spawning grounds or at the hatchery, reconstructed to account for average stray rates
 816 observed from coded wire tagging data (Kormos et al. 2012, Palmer-Zwahlen and
 817 Kormos 2013). Red shaded regions are the 95% and 50% credible intervals for the
 818 model predicted abundance in each year, and the red line describes the median of the
 819 posterior predictions for abundance in each year. Observed and predicted abundances
 820 are presented in natural log space.

821 Posterior distributions for coefficients describing the direction and magnitude of
822 influence each environmental covariate has on a specific population or group of populations
823 were sampled, along with those for other model parameters including survival rate during the
824 first (upstream) life-stage. Bayesian posterior distributions describe the estimated probability
825 that a particular estimated or derived model parameter has a specific value. Figure I.6
826 displays posterior distributions for coefficients describing the influence of environmental
827 covariates on survival, as well as those for parameters describing the base survival rate to
828 Sacramento – San Joaquin Delta entry. In this figure, samples from posterior distributions
829 arising from the three separate MCMC chains are drawn in different colors. Each parameter
830 estimate is illustrated as a caterpillar plot whose median is described by a point, 50% credible
831 interval by a thick line, and 95% credible interval by a thin line. The concordance of the
832 parameter medians and credible intervals across the three MCMC chains, along with Gelman-
833 Rubin test statistic values for all parameters ≤ 1.05 , provide evidence that all three chains
834 have converged to the same stationary distribution.

835 The bottom panel of figure I.6 displays model predictions for the value of the basal
836 productivity parameter ($\beta_{s,p,0}$) in the upstream stage (Eq. I.5), or maximum survival rate to
837 Sacramento – San Joaquin Delta entry. It should be noted that for the four wild-spawning
838 populations (i.e. Mainstem Sacramento fall-run, and Deer, Mill, and Butte Creek spring runs),
839 this parameter represents the maximum survival rate from egg to Delta entry, while for the
840 three hatchery produced populations (Battle Creek (CNFH), Feather River, and American
841 River (Nimbus) fall-run) this parameter represents the maximum survival rate from hatchery
842 release to Delta entry. Parameter values in logit space are listed on the x-axis below the lower
843 panel, while back transformed maximum survival rate values appear above the lower panel.
844 Several things are clear from this figure I.6. First, the similarity in posterior distributions
845 from each of the three chains again indicates that all three have converged to the same
846 stationary distribution despite differing random walk trajectories through parameter space.
847 Second, basal productivity or maximum survival rate for the upstream stage is both
848 significantly higher and more variable for the three hatchery-reared populations. Higher
849 maximum survival rates for these populations are to be expected given that they only
850 represent mortality incurred after release, not mortality from fertilization to the date of
851 release. However, the greater variance in maximum survival rate for the hatchery populations
852 is easily discernable.

860

Figure I.6. Posterior probability distributions for coefficients describing the influence of environmental covariates on survival (top) and the maximum survival rate from egg (or hatchery release) to Sacramento – San Joaquin Delta entry. Caterpillar plots describe the median (dot), 50% credible interval (thick line), and 95% credible interval (thin line) of each posterior. Posteriors from each of the independent MCMC chains are depicted with different colours.

861 Posterior estimates for the value of the coefficients ($\beta_{s,p,c}$) describing the influence of
 862 each environmental covariate on a specified population, or group of populations, provide an
 863 indication of whether each covariate has a positive or negative influence on survival (Fig. 6,
 864 top panel). Table I.5 shows the estimated value for each of the coefficients along with their
 865 variance, and quantile range for each posterior distribution. These results indicate that of the
 866 14 covariates included in the final model, 8 covariates were estimated to have a negative
 867 impact on stage-specific productivity (maximum survival rate), 5 were estimated to have a
 868 positive influence, and 1 was estimated to have a negative influence on average but with a
 869 95% credible interval range overlapping zero. The covariates whose survival impact is
 870 estimated to be negative include the effect of: 1) water discharge (cfs-1) from Keswick Dam
 871 on Mainstem Sacramento spawning fall-run Chinook (fall.sac.mainstem - keswick.discharge),
 872 2) sediment concentration at Freeport, CA (mg/L) on the combined survival of the four fall-
 873 run populations (.1.2.3.4-freeport.sed.conc), 3) the export to inflow ratio in the Sacramento –
 874 San Joaquin Delta on combine survival of the fall-run populations (.1.2.3.4-
 875 fall.dayflow.expin), 4) wind stress curl on the combined survival of all seven populations of
 876 spring and fall-run Chinook (.1.2.3.4.5.6.7-curl.late), 5) spring Freeport, CA sediment
 877 concentrations on the combined survival of the three spring-run Chinook populations (.5.6.7-
 878 freeport.sed.conc), 6) water exports from the Sacramento – San Joaquin Delta on the
 879 combined survival of the three spring-run populations (.5.6.7-spring.dayflow.export), 7) the
 880 average size of juvenile spring-run Chinook on combined spring-run survival (.5.6.7-
 881 spring.size.chipps), and 8) Sacramento air temperature during summer months of the brood
 882 year on survival of Butte Creek spring-run Chinook (spring.butte - sacAirTemp.summer).

884

885 **Table I.5. Values for the posterior probability distributions for coefficients**
 886 **describing the influence of environmental covariates ($\beta_{s,p,c}$) on productivity (maximum**
 887 **survival rate).**

888 Five of the coefficient values were estimated to be positive (Table I.5), indicating that
 889 an increase in the value of those covariates leads to an increase in the maximum survival rate
 890 for the associated population or group of populations. These covariates which are estimated
 891 to positively influence survival include the effect of: 1) upwelling in the nearshore region
 892 during spring of the ocean entry year on the combined survival of the fall-run Chinook
 893 populations (.1.2.3.4-upwelling.south.early), 2) spring air temperature at Sacramento, CA on
 894 the survival of fall-run Battle Creek (CNFH) Chinook (fall.battle.creek - sacAirTemp.spring),
 895 3) spring air temperature at Sacramento, CA on the survival of Butte Creek spring-run
 896 Chinook (spring.butte - sacAirTemp.spring), 4) net channel depletion in the Sacramento –
 897 San Joaquin Delta resulting from within-delta consumptive use as quantified by the Dayflow

898 metric QCD on the combined survival of the four fall-run Chinook populations (.1.2.3.4-
 899 fall.dayflow.cd), and 5) the magnitude of the Pacific Decadal Oscillation during winter
 900 (January – May) of the first year at in the ocean on the combined survival of all seven spring
 901 and fall-run Chinook populations (.1.2.3.4.5.6.7-pdo.early). For the 13 covariates classified
 902 above as having either a distinct positive or negative effect on survival, the posterior
 903 distribution describing the probability of the true value for each coefficient had a 95%
 904 credible interval that was completely above or below zero. Although the estimated median
 905 value for the coefficient describing the effect of Deer Creek discharge (cfs⁻¹) on Deer Creek
 906 spring-run Chinook survival (spring.deer - deer.discharge) is less than zero (i.e. -0.22, Table
 907 I.5) indicating an negative influence on survival, the 95% credible interval overlaps with zero
 908 indicating a significant probability (p=0.121) of the covariate having either no influence or a
 909 positive influence on survival.

910 While posterior probability distributions for coefficients representing the influence of
 911 each environmental covariate on stage and population-specific productivity ($\beta_{s,p,c}$) describe
 912 the model estimate for how much an increase or decrease in the value of that covariate is
 913 expected to change stage-specific productivity parameter of the Beverton-Holt equation (Eq.
 914 I.4), it is difficult to directly compare these estimated coefficient values for several reasons.
 915 First, the basal productivity rate ($\beta_{s,p,0}$) for each stage is population-specific, meaning that
 916 the magnitude of estimated coefficients ($\beta_{s,p,c}$) is always relative to the to the basal
 917 productivity rate for the population of interest. Second, coefficient values and basal
 918 productivity rates are estimated in logit space to ensure the resultant productivity value is
 919 smoothly scaled between 0 and 1 (Eq. I.5), and comparing coefficients and basal productivity
 920 rates in logit space may be difficult to interpret. Therefore, we have endeavored to translate
 921 the magnitude of the estimated environmental covariate effects into more easily interpretable
 922 changes in survival.

923 In order to translate the value of estimated coefficients describing the influence of
 924 environmental covariates into predictions for realized changes in survival, we calculated the
 925 survival rate for the seven populations from egg, or hatchery release, through adults returning
 926 to freshwater under a range of scenarios. Survival rates for each population were calculated
 927 by tracking a set number of individuals forward in time across life-stages, assuming no
 928 harvest mortality, and using parameter values sampled from the joint posterior for the
 929 estimation model. One thousand independent sets of model parameter values were sampled
 930 from their joint posterior in order to preserve posterior correlation, and used to quantify the
 931 variation in predictions for the influence of each environmental covariate on survival, arising
 932 from estimation uncertainty. Survival rate was calculated as the sum of spawning adults
 933 across return years, divided by the number of eggs or hatchery releases. The spawning
 934 abundance, used as the basis for calculating survival rates, was the 1970 – 2010 average for
 935 the wild-spawning populations (i.e. mainstem Sacramento fall-run, as well as Deer, Mill, and
 936 Butte Creek spring-run) and the average release numbers for the most recent 10 years for the
 937 Battle Creek (CNFH), Feather River, and American River (Nimbus) hatchery populations.
 938 Likewise, the most recent 10-year average was used for capacity of wild juvenile fall-run
 939 Chinook in the Sacramento mainstem and for the total capacity for spring-run and fall-run
 940 Chinook rearing in the Sacramento – San Joaquin Delta.

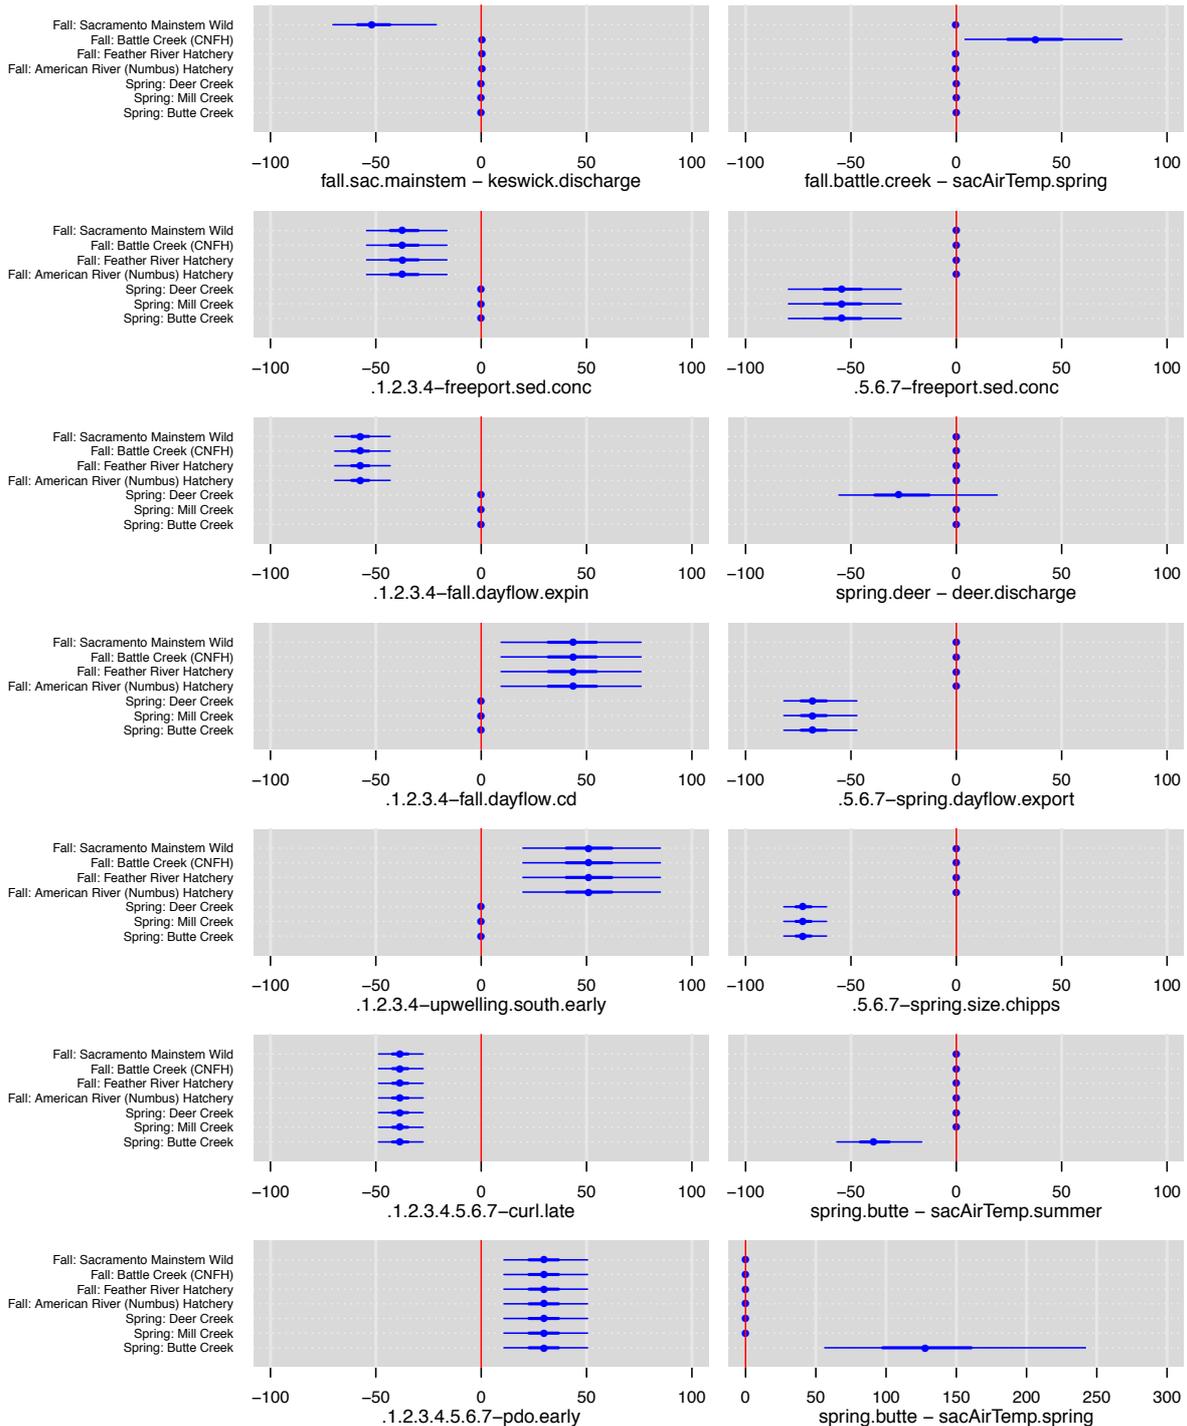

941 The distribution of survival rate predictions for each population (p), across the 1,000
 942 independent sets of parameter values (i), was first calculated for a base case ($S_{base,p,i}$).
 943 Under the base case the value for all environmental covariates was set at zero, which for z-
 944 standardized covariates is equal to the long-term average. Subsequently the covariate-specific

945 survival ($Scov_{p,i,c}$) of each population across the 1,000 parameter sets was determined, as
 946 each covariate (c) was sequentially changed to have a value of 1. Covariate-specific survival
 947 ($Scov_{p,i,c}$) thus represents the population (p) and sample (i) specific survival rate when
 948 covariate c is increased in value to 1 standard deviation above the long-term mean. From this,
 949 the percentage difference in survival for each population resulting from an increase in the
 950 value of an environmental covariate was calculated as: % *difference in Survival* $_{p,i,c} =$
 951 $\frac{(Scov_{p,i,c} - Sbase_{p,i})}{Sbase_{p,i}} * 100$. Table I.6 displays the mean and standard deviation for the expected
 952 percentage change in survival for each population across the sampled parameter sets, when
 953 each covariate is increased in value by 1 SD from the mean.

954
 955
 956 **Table I.6. Percentage change in egg (or hatchery release) to adult survival resulting**
 957 **from covariate variation. Values in the table are the mean (sd) differences in survival**
 958 **between the base case and a scenario where the value of a specific covariate (row) is**
 959 **increased by 1 standard deviation from the long-term mean.**
 960

961 Figure I.7 displays the effect of each environmental covariate on each Chinook
 962 population, as the distribution of percentage change in egg (or hatchery release) to adult
 963 survival, expected when the value of a specific covariate is 1 SD above the long-term mean.
 964 Each panel in figure I.7 describes the influence of a single covariate, while each row within a
 965 panel is the survival change expected for a specific population. Within each panel the seven
 966 population-specific caterpillar plots describe the distribution of expected survival difference,
 967 with the point demarking the median, and the thick and thin lines defining the 50% and 95%
 968 credible intervals for the prediction. Two aspects of this analysis are important to consider.
 969 First, the figure describes the difference in survival between the base case (all covariates at
 970 the mean) and that when a single covariate value is changed, and although the survival
 971 differences may be the same across populations, this should not be not be taken as evidence
 972 that population-specific survival rates are also estimated to be the same. Second, an estimated
 973 survival difference at or near zero does not imply there is no survival effect, only that this
 974 interaction was not included in the final AICc-selected model. Any small, but non-zero
 975 survival effects are the result of changes in the survival of another population in response to
 976 the covariate, with which the focal population shares a capacity constraint at some point in
 977 the life cycle.
 978

% Difference in Survival when Covariate Increased by 1 StDev

979
980

981 **Figure I.7. Percentage change in egg (or hatchery release) to adult survival resulting**
 982 **from a 1 standard deviation increase in covariate values. Each panel represents the**
 983 **outcome of increasing the value of a specific covariate (listed below the x-axis), with**
 984 **each caterpillar plot describing the effect on each population (y-axis). Plotted values are**
 985 **the difference in survival between a scenario where the covariate value is increased and**
 986 **a base case where all covariates are equal to their long-term mean. Caterpillar plots**
 987 **describe the median (dot), 50% interval (thick line), and 95% interval (thin line) for**
 988 **each survival difference accounting for estimation uncertainty.**

989 Results of this analysis of the environmental drivers of survival for Sacramento River
 990 fall and spring-run Chinook salmon indicate that several factors have the potential to
 991 significantly influence survival in the upstream portion of juvenile migration. Keswick Dam
 992 discharge is predicted to reduce egg to adult survival by 52.2%, for each increase in discharge
 993 rate of 1 SD. Increased air temperatures in the spring months following emergence are
 994 expected to increase the survival of Battle Creek (CNFH) fall-run Chinook by 37.5%,
 995 although the 95% credible interval for this predictions ranges from a moderate a modest 4.4%
 996 increase to a 79.8% increase indicating significant uncertainty in this prediction. Spring time
 997 air temperatures are expected to influence the early juvenile survival of Butte Creek spring-
 998 run Chinook in a similar direction but to a much greater extent with a predicted 124.7%
 999 increase. Conversely, increased summertime air temperatures during the period of adult
 1000 upstream holding and egg development are expected to reduce survival by 39.4%, indicating
 1001 that summertime temperatures may be reaching lethal levels or affecting adult fertility. The
 1002 final environmental variable linked to the upstream stage and early juvenile survival is water
 1003 discharge in Deer Creek, which is expected to reduce survival for Deer Creek spring-run
 1004 Chinook by a modest 26.2%. However, it is important to note that there is significant
 1005 uncertainty in this prediction with an increase in Deer Creek discharge by 1 SD predicted to
 1006 have result in anywhere between a 59.4% reduction in survival and a 27% increase in
 1007 survival 95% of the time.

1008 Later in the life cycle for Sacramento River Chinook, several factors are expected to
 1009 significantly influence juvenile survival in the Sacramento – San Joaquin Delta. A 1 SD
 1010 increase in the concentration of sediment (mg/L) at Freeport, CA is expected to result in a
 1011 37.1% reduction in the survival of the four fall-run Chinook populations. Sediment
 1012 concentration is predicted to have a slightly larger influence on survival of the three spring-
 1013 run populations, with a 54.3% reduction in egg to adult survival. Water exports from the
 1014 Sacramento – San Joaquin Delta, although quantified through different metrics, are expected
 1015 to reduce survival of both spring and fall-run juvenile Chinook. An increase in total exports
 1016 of 1 SD from the 1967-2010 average is predicted to result in a 68.1% reduction in the
 1017 survival of Deer, Mill, and Butte Creek spring-run Chinook. Similarly, an increase in the ratio
 1018 of Delta water exports to Delta inflow of 1 SD is expected to reduce survival of the four fall-
 1019 run populations by 57.8%. Interestingly however, net channel depletion or the quantity of
 1020 water removed from Delta channels to meet consumptive needs (Dayflow: QCD) is predicted
 1021 to increase the survival of fall-run Chinook by 43.7%. The final covariate linked to survival
 1022 of spring-run Chinook in the Sacramento – San Joaquin Delta is the average size of spring-
 1023 run Chinook in the Chipps Island Trawl survey. Each increase in the average size of juvenile
 1024 Chinook by 1 SD from the mean (1967-2010) is predicted to reduce survival by 72.9%.

1025 Environmental conditions in the nearshore and marine portions of the Chinook life
 1026 cycle were also found to have a significant impact on survival to adulthood. An increase in
 1027 average nearshore upwelling during late spring (April – June) in the region south of San
 1028 Francisco Bay of 1 SD above the mean, is expected to increase survival to adulthood by
 1029 51.2% for the four wild and hatchery-reared fall-run Chinook populations. Also related to
 1030 marine patterns of nutrient transport and productivity, an increase average wind stress curl
 1031 during the fall (July – December) of the first year of marine residency was estimated to
 1032 reduce survival for the seven populations of spring and fall-run Chinook by 39%. The final
 1033 covariate linked to Chinook survival in the marine environment was the Pacific Decadal
 1034 Oscillation index during winter (January – May) of the first year of marine residence. An
 1035 increase in PDO value of 1 SD above the 1967 – 2010 mean is predicted to increase survival
 1036 of the seven populations of spring and fall-run Chinook by 30%, however there exists

1037 significant uncertainty in this prediction with the 95% credible interval ranging from 10.1 -
 1038 51% increase in egg or hatchery release to adult survival.

1039 *PART I DISCUSSION*

1040 This evaluation of the putative environmental drivers of survival for seven
 1041 populations of spring and fall-run Chinook spawning within the Sacramento River watershed
 1042 was comprised of two essential components. The first component was model selection or the
 1043 process of determining the weight of evidence from the data for which subset of the 59
 1044 hypothesized covariate-by-population effects were able to best explain historical variation in
 1045 Chinook salmon survival, and are therefore informative for predicting future trends in
 1046 abundance. One thousand potential best-fit models were built using forward stepwise based
 1047 upon AICc as the selection criteria. The percentage of the 1,000 best-fit models resulting
 1048 from stepwise-AICc building which included a specific covariate provide a good indication
 1049 of the relative amount of support each of these competing hypotheses had from the adult and
 1050 juvenile abundance data (Table I.3). The fact that a range of covariates influencing both
 1051 grouped and single Chinook populations at all points in the life cycle were present amongst
 1052 those with a high inclusion rate provide evidence that there not exist a single population
 1053 bottleneck within the life cycle. This indicates that variation in environmental factors a
 1054 multiple points within the life cycle play a role in determining interannual survival to
 1055 adulthood. Of further importance is the observation that both natural covariates, including
 1056 temperature, water flow, and marine productivity patters, as well as those of anthropogenic
 1057 origin (i.e. water exports, export/inflow ratio, and water routing) appear amongst the set with
 1058 the highest inclusion rate. This finding indicates that variation in survival of Sacramento
 1059 River Chinook population in not driven by natural or anthropogenic processes in isolation.
 1060 The final model (Table I.4), chosen based on having the lowest AICc value amongst the
 1061 1,000 candidate best-fit models, likewise includes a range of covariates throughout the life
 1062 cycle representing both natural and anthropogenic processes are statistically important
 1063 predictors of survival.

1064 The influence of striped bass (*Morone saxatilis*) on survival of spring-run Chinook
 1065 was of particular interest given findings by Lindley and Mohr (2003), which indicated that
 1066 higher future abundances of striped bass were likely to lead to greater extinction potential for
 1067 winter-run Chinook. While the effect of striped bass on survival on spring-run Chinook was
 1068 included in 36% candidate best-fit models, it did not appear in the final (lowest AICc) model.
 1069 When included alongside other covariates in the final model, the estimated effect of striped
 1070 bass abundance was centered near zero, indicating an inability to estimate a distinctly
 1071 negative impact on grouped survival of spring-run Chinook. This result indicates that while
 1072 striped bass abundance does explain some of the variation in spring-run Chinook survival,
 1073 other explanatory covariates provide a better alternative explanation for historical abundance
 1074 observations.

1075 The estimated effect that water exports from the Sacramento – San Joaquin Delta on
 1076 juvenile Chinook survival through this region was also of importance. While the effect of
 1077 average water export levels on spring-run Chinook survival and the influence of
 1078 export/inflow ratio on fall-run Chinook survival both appear in the final model, these two
 1079 covariate effects have a 54% and 37% inclusion rates across the 1,000 candidate best-fit
 1080 models. The fact that these export-related covariate effects do not appear at the top of the list
 1081 of most often included covariates, indicates that while they have substantial potential to

1082 explain historical patterns in spring and fall-run Chinook survival, as indicated by distinctly
 1083 negative survival effects whose 95% credible intervals do not overlap zero (Figure I.7 and
 1084 Table I.6), there are other environmental covariate which explain a greater proportion of
 1085 variation in historical abundance.

1086 The second component of this evaluation was to estimate the direction and magnitude
 1087 of change in survival rates resulting from variation in each of the covariates in the final model
 1088 using Bayesian methods. When evaluating population dynamics model estimates for the
 1089 effect of environmental covariates on survival, it is important to place each result in the
 1090 proper biological context and determine if there exists a rational mechanistic explanation.
 1091 The effect of Sacramento air temperatures on several populations appeared as AICc-selected
 1092 explanatory covariates for several populations. Sacramento air temperature was employed as
 1093 a proxy for water temperatures in upstream regions of the Sacramento River watershed for
 1094 two reasons. First, significant and often linear relationships exist for between stream
 1095 temperatures and air temperatures in most regions. Second, stream temperature data were not
 1096 available continuously for the requisite time series (1967 – 2010) for all locations, resulting
 1097 in the necessity for interpolation based on the relationship with air temperature. Therefore,
 1098 for consistency in the covariate time-series and to reduce the risk of introducing additional
 1099 uncertainty into the estimation process, we elected to use air temperatures as covariates in
 1100 place of interpolated water temperatures. Results indicate a positive influence of increased
 1101 spring (January - March) air temperatures on the survival of Battle Creek (CNFH) fall-run
 1102 Chinook and Butte Creek spring-run Chinook. This temperature metric coincides with the
 1103 period prior to and during which juvenile Chinook are rearing. The estimated positive
 1104 influence of spring temperatures on Chinook survival could result indirectly from the increase
 1105 in primary production fostered by increased water temperatures and subsequent effects on
 1106 food availability. In this way growth potential for juvenile Chinook in freshwater depends
 1107 indirectly on temperature in the rearing environment through food availability, and directly
 1108 through effects on metabolism as warmer conditions allow juveniles to approach their
 1109 bioenergetic optimum. Finally, there is some evidence that acclimation to higher
 1110 temperatures early in life may facilitate higher thermal tolerance later in life, although research
 1111 in this area has primarily focused on Great Lakes rainbow trout and has not been explicitly
 1112 evaluated in Chinook (Myrick and Chech 1998). While spring time temperatures were
 1113 estimated to have a positive influence at this point in the lifecycle, it is important to note that
 1114 higher temperatures experienced later in the lifecycle during summer months may approach
 1115 upper tolerance limits, resulting in negative survival impacts. However, the effect of
 1116 increased summertime temperatures on juvenile survival was not evaluated as part of this
 1117 analysis.

1118 Contrary to the estimated positive effect of spring temperatures, air temperature
 1119 during the summer months (July - September) of the brood year were found to have a
 1120 negative impact on the survival of Butte Creek spring-run Chinook (Table I.6). For Butte
 1121 Creek spring-run Chinook this time period coincides with the point in the life-cycle when
 1122 adults are holding in freshwater prior to spawning. Prior to the creation of impassable barriers
 1123 to upstream migration, the life history of spring-run Chinook was adapted to make use of
 1124 high spring runoff events from snowmelt to migrate upstream into high elevation streams
 1125 with tolerable temperature regimes where they could successfully mature during the summer
 1126 months and await spawning when waters cooled to below 14 – 15°C (Williams 2006).
 1127 However, in Butte Creek mortality rates during the holding period were observed to exceed
 1128 20-30% in 2002 and 65% in 2003 during high temperature events (Ward et al. 2003). This is
 1129 likely the result of the increased metabolic demands for adult spring-run Chinook while

1130 holding in freshwater during high temperature events, and the increased rate of disease onset
 1131 and parasite load observed in other members of the *Oncorhynchus* genus exposed to high
 1132 temperatures (Kocan et al. 2009).

1133 Water flow conditions during juvenile rearing were also found to be important
 1134 predictors of Chinook survival. Water discharge rates at Keswick Dam were found to
 1135 negatively influence survival of mainstem spawning wild fall-run Chinook, and water
 1136 discharge in Deer Creek was found to reduce survival of the Deer Creek spring-run
 1137 population although to a lesser extent (Table I.6). While it is reasonable to assume that higher
 1138 discharge rates could lead to greater access to valuable off-channel rearing habitat, water flow
 1139 conditions additionally have the potential to influence foraging ability by juveniles through
 1140 the availability of drifting food sources (Neuswanger et al. 2014). None the less the finding
 1141 that fall-run Chinook survival was negatively influenced by increased water flow contradicts
 1142 findings by Stevens and Miller (1983) and Newman and Rice (2002). With respect to the
 1143 influence of water discharge on the survival of Deer Creek spring-run Chinook, this tributary
 1144 is prone to concentrated high flow events due to flood control levees and a lack of riparian
 1145 vegetation in its lower reaches (Tompkins 2006). For Deer Creek this may indicate that high
 1146 water flow rates reduce foraging opportunities for juvenile Chinook, rather than enhancing
 1147 them, as would be the case in a system with greater floodplain connectivity.

1148 Findings related to the influence of environmental covariates on survival of fall and
 1149 spring-run Chinook in the Sacramento – San Joaquin Delta are of particular interest in this
 1150 study. First, the effect of sediment concentration in waters at Freeport, California appeared in
 1151 the final AICc-selected model, and increases in sediment concentration were estimated to
 1152 have a substantial negative influence on the survival of both spring and fall-run populations.
 1153 This finding is contrary to a priori expectations that increased sediment concentrations might
 1154 provide a survival benefit, if they limit the efficacy of visual predators such as striped bass.
 1155 We remain limited in our ability to explain the estimated negative effect of sediment
 1156 concentrations save for the fact that increased sediment influx might be linked to production
 1157 potential for phytoplankton and the benthic periphyton which form the basis for the aquatic
 1158 food web. Similarly, the estimated negative influence of average juvenile spring-run
 1159 Chinook size on the common survival of the three spring-run populations appears contrary to
 1160 a priori expectations. In the review of size selective mortality in teleost fishes Sogard (1997)
 1161 found general support for the “bigger is better” hypothesis across taxa. Claiborne et al. (2011)
 1162 also found that juvenile to adult survival of yearling Chinook from the Willamette River
 1163 Hatchery increased with size at ocean entry. However, in an evaluation of the effect of size
 1164 on survival from analysis of scale samples from Chinook returning to the same hatchery,
 1165 Ewing and Ewing (2002) found either no significant size difference between juveniles at the
 1166 hatchery and those at ocean entry, or in the case of the 1989 – 1990 brood years evidence for
 1167 greater survival of smaller individuals. It is important to note that spring-run juvenile size
 1168 data was unavailable until 1976. As a result we were forced to assume the long-term average
 1169 for this covariate prior that year which may have influenced results related to this particular
 1170 covariate.

1171 Results of this analysis related to the influence of water exports from the Sacramento
 1172 – San Joaquin Delta indicate a negative influence of the export/inflow ratio on the combined
 1173 survival of the four fall-run Chinook populations and a negative influence increased total
 1174 Delta exports on the combined survival of spring-run Chinook populations (Table I.6). These
 1175 findings indicate that higher export rates lead to reduced survival for Sacramento River
 1176 Chinook on average, however a mechanistic explanation remains elusive. Direct entrainment

1177 mortality seems an unlikely mechanism given the success of reclamation and transport
1178 procedures, even given increased predation potential at the release site. Changes to water
1179 routing may provide a more reasonable explanation for the estimated survival influence of
1180 Delta water exports. Higher exports, or export/inflow ratio, result in greater water diversion
1181 into the interior delta where survival has been observed to be substantially lower than that in
1182 the Sacramento River mainstem (Perry et al. 2010), potentially resulting from an increased
1183 encounter rate with predators or prolonged residence in areas with suboptimal feeding
1184 opportunities or dissolved oxygen concentrations.

1185 In conjunction with freshwater drivers of survival for spring and fall-run Chinook
1186 populations of the Sacramento River watershed, results of this analysis indicate that several
1187 attributes of the marine environment have a significant influence on survival. Two covariates
1188 related to nearshore and offshore ocean current patterns and resultant nutrient movement
1189 within the water column were included as part of the final AICc-selected model. These
1190 covariates were the strength of nearshore upwelling and wind stress curl. Nearshore
1191 upwelling results in deep, cooler, and nutrient rich waters moving toward limnetic zone, with
1192 onshore transport and convergence fostering higher nearshore productivity during spring and
1193 summer. Conversely, wind stress curl is associated with offshore divergent transport (Wells
1194 et al. 2008). Our results indicate that increased nearshore upwelling during April – June of
1195 the year of ocean entry results in an increase in the combined survival of the four fall-run
1196 Chinook populations. Four alternative covariates quantifying upwelling patterns were
1197 evaluated as competing hypotheses for fall-run Chinook survival at different locations and
1198 quantifying time periods. Covariates were constructed using information from PFEL/NOAA
1199 monitoring sites both north and south of San Francisco Bay and for both the spring (April –
1200 June) and fall (July – December) periods. The AICc-selected covariate that appeared in the
1201 final model used the upwelling index data for spring time-period and at the southern location.
1202 Interestingly, although the effect of upwelling at the southern location in the spring months
1203 on the combined survival of spring-run Chinook appeared in 22% of candidate best-fit
1204 models, it did not appear in the final (lowest AICc) model, indicating that while upwelling
1205 may also be an important predictor of spring-run Chinook survival it appears to explain more
1206 variation in fall-run Chinook survival.

1207 Wind stress curl was found to have a negative influence on the combined survival of
1208 all seven spring and fall-run Chinook populations. These results are not unexpected given
1209 findings by Wells et al. (2007) that indicate greater Chinook growth in the first year of life
1210 with increased nearshore upwelling and decreased wind stress curl. Wells et al. (2008)
1211 likewise found that reductions in wind stress curl were linked to increased production of
1212 rockfish species although they note this may be more related to dispersal of juvenile rockfish.
1213 The estimated reduction in survival for Chinook associated with greater wind stress curl is
1214 likely explained by trophic interactions, with findings by Macias et al. (2012) indicating that
1215 biomass concentrations for phytoplankton and zooplankton are likely to be substantially
1216 higher with coastal upwelling as opposed to wind stress curl driven upwelling offshore.

1217 The Pacific Decadal Oscillation (PDO) describes a persisting periodicity in sea
1218 surface temperature, mixed layer depth, and strength and direction of ocean currents (Mantua
1219 and Hare 2002). Estimates for the influence of the PDO during January – May of the first
1220 year at sea indicating for the seven spring and fall-run Chinook populations, indicate
1221 increased survival is likely to be observed in during positive PDO events. This result is
1222 contrary to findings by Hare et al. (1999) which indicate positive PDO conditions favor
1223 production in Alaskan salmon stocks and disfavor the productivity of West Coast stocks, as

1224 well as findings by Wells et al. (2006) which highlight the negative covariation between size
1225 of Columbia River Chinook size and PDO values.

1226 **PART II SIMULATION OF FUTURE ABUNDANCE UNDER ALTERNATIVE** 1227 **CLIMATE, OCEANOGRAPHIC, AND WATER USE SCENARIOS**

1228 *INTRODUCTION*

1229 The purpose of conducting forward population projections was to simulate future
1230 survival for Sacramento River Chinook under alternative climate, oceanographic, and water
1231 management scenarios. Simulating the four populations of fall-run and three populations of
1232 spring-run Chinook forward in time, provides a means for weighing differences in future
1233 survival under alternative water export levels, relative to the uncertainty in future climate
1234 change and ocean productivity. In order to generate predictions for future survival, we
1235 integrated results from the Bayesian estimation model with expectations for future
1236 environmental conditions under two alternative future ocean production trends, two
1237 predictions for future climate change, and at four potential levels of future water exports (see
1238 Appendix B). In addition to differences in future Chinook survival arising from natural and
1239 anthropogenic environmental factors, we have also propagated both estimation and process
1240 uncertainty forward in our predictions for future abundance and realized survival rates.

1241 Future climate scenarios were based upon the U.S. Bureau of Reclamation's (USBR)
1242 Operations and Criteria Plan (OCAP) Study (USBR 2008). Two alternative scenarios for
1243 overland climate change were evaluated, the OCAP Study 9.2 and 9.5. The OCAP Study 9.2
1244 (referenced as: **cc92**) describes a wetter and cooler prediction for future climate change, with
1245 a mean increase in temperature of 0.42° C and an increase in precipitation of 12.5%.
1246 Conversely, the OCAP Study 9.5 (referenced as: **cc95**) describes a dryer and warmer outlook
1247 for future climate change in the Central Valley, with a mean increase in temperature of 1.56°
1248 C and a decrease in precipitation of 12%. In addition to differing scenarios regarding climate
1249 change, two alternative predictions for future ocean conditions were explored. These two
1250 scenarios, one representing traditional perceptions of positive growth conditions for Chinook
1251 (referenced as **oceanUP**) and the other representing negative growth conditions (referenced
1252 as **oceanDOWN**), describe alternative patterns in nearshore upwelling and temperature, and
1253 future trends in broad-scale ocean currents.

1254 Paired with these alternative scenarios for future climate change and ocean
1255 production, were four scenarios related to the magnitude of future water exports from the
1256 Sacramento-San Joaquin Delta. The four future scenarios for total water exports included: 1.
1257 **expAVG** (future exports equal to the 1967 – 2010 average), 2. **expZERO** (zero future water
1258 exports), 3. **expUP30** (an increase in future exports to 30% above the historical average), and
1259 4. **expDOWN30** (a decrease in future exports to 30% below the historical average). While it
1260 is clear that some of these water export scenarios are economically infeasible (i.e. expZERO)
1261 they were included as part of the population projections to bound the range of potential
1262 biological outcomes from management actions. All export scenarios are based upon the
1263 historical export values calculated as the average of March – May Dayflow (QEXPORT)
1264 values for fall-run Chinook, and the average of February – April values for spring-run
1265 Chinook.

1266 In total, these 2 onshore climate change scenarios, 2 ocean production scenarios, and
 1267 4 water export scenarios, resulted in 16 different realizations of the future environment for
 1268 Chinook populations of the Sacramento River watershed. These sixteen environmental
 1269 scenarios were subsequently translated into future covariate values (see Appendix B), for use
 1270 as inputs in projecting the populations forward in time and determining realized future
 1271 survival rates.

1272 *SIMULATION METHODS*

1273 Realized future survival rates were simulated by projecting all seven populations of
 1274 Sacramento River Chinook forward in time for 50 years (2007 – 2057). The structure of the
 1275 population dynamics model utilized to estimate stage-specific survival rates and the direction
 1276 and magnitude of response by populations (or groups of populations) to environmental
 1277 covariates, formed the basis for these forward population projections. Population and brood
 1278 year specific cohorts of Chinook were tracked forward in time through the same six spatio-
 1279 temporal life-stages (i.e. upstream/tributaries, Sacramento-San Joaquin Delta, nearshore, and
 1280 the 1st, 2nd, and 3rd years in the ocean). In the same way as the estimation model, both the
 1281 wild-spawning and hatchery production life cycles were represented in population
 1282 projections, with wild-spawning populations linked to future cohort production through a
 1283 fixed fecundity per individual, and hatchery production fixed at the population-specific
 1284 average of releases from the most recent 10-year period. Stage-specific capacities for
 1285 Sacramento mainstem-spawning fall-run Chinook in the upstream stage, and the grouped
 1286 spring-run and fall-run populations in the Sacramento-San Joaquin Delta, were fixed at the
 1287 average of estimates from Hendrix et al. (2014) for the most recent 10-year period. Estimated
 1288 values for population dynamics model parameters including stage and population-specific
 1289 productivity rates, and coefficients describing the direction and magnitude of influence that
 1290 environmental covariates have on stage-specific productivity (maximum survival) rates, were
 1291 used when simulating future trends in abundance.

1292 When simulating future trends in Chinook abundance in order to evaluate differences
 1293 in realized survival, it was necessary to account the two major sources of uncertainty in our
 1294 analysis and propagate this uncertainty forward into predictions under alternative
 1295 environmental and export scenarios. The first source of uncertainty in generating robust
 1296 predictions for future abundance is uncertainty in the estimates of population dynamics model
 1297 parameters. This includes uncertainty in the estimated value of life-stage and population
 1298 specific basal productivity rates, as well as coefficients describing the influence of
 1299 environmental covariates on survival. Estimation uncertainty arises when estimated values
 1300 for model parameters are poorly informed by the available data, leading to broad posterior
 1301 probability distributions indicating a broad range of parameter values with similar
 1302 probabilities of being correct given the data. To account for estimation uncertainty in model
 1303 parameters, we drew 1,000 independent sets of model parameter values from the joint
 1304 posterior sampled by the Bayesian estimation model. By drawing parameter sets from the
 1305 joint posterior, and repeating the 50-year forward projection of the seven populations using
 1306 each of the independent parameter sets, we are able to capture the influence of both the true
 1307 uncertainty in parameter values and posterior correlations between estimated parameters.

1308 The second source of uncertainty that was integrated into forward projects was
 1309 process uncertainty, or temporal variation in the state of future population dynamics. For each

1310 of the 1,000 replicate forward simulations, a random process deviate was introduced in the
 1311 calculation for initial abundance in the first model stage (Eq. II.2, II.3).

$$1312 \quad (II.2) \quad N_{y,s=1,p,e,i} = A_{t=y,p,a,e,i} * fec * \exp\left(\varepsilon_{y,p,i} - \frac{\sigma_p^2}{2}\right)$$

$$\varepsilon_{y,p,i} \sim N\left(0, \sigma_p\right)$$

1313 Equation II.2 describes how process uncertainty is introduced into the wild-spawning
 1314 life cycle used to represent the Sacramento mainstem fall-run, and Deer, Mill, and Butte
 1315 Creek spring-run Chinook populations. The number of individuals entering the upstream (1st)
 1316 model stage ($N_{y,s=1,p,e,i}$), of brood year y , population p , in simulation i of environmental
 1317 scenario e , is a function of the number of spawning adults returning in calendar year $t = y$ of
 1318 population p ($A_{t=y,p,e,i}$), the fixed fecundity rate of 2,000 eggs/individual ($fec = 2,000$), and
 1319 the exponentiated brood year y , population p , and simulation i specific process deviate
 1320 ($\varepsilon_{y,p,i}$). Conversely, equation II.3 describes how initial abundance in the first model stage was
 1321 calculated with process errors for the three populations of hatchery-produced fall-run
 1322 Chinook, where RH_p is the fixed level of hatchery releases for each population.

$$1323 \quad (II.3) \quad N_{y,s=1,p,e,i} = RH_p * \exp\left(\varepsilon_{y,p,i} - \frac{\sigma_p^2}{2}\right)$$

$$\varepsilon_{y,p,i} \sim N\left(0, \sigma_p\right)$$

1324 Process deviates ($\varepsilon_{y,p,i}$) for each brood year y , population p , and replicate simulation
 1325 i , were generated as random draws from a normal distribution with mean equal to 0, and
 1326 population-specific standard deviations (σ_p). The standard deviations for the process error
 1327 distributions (σ_p) were the maximum likelihood estimates for the residual observation
 1328 uncertainty from fitting the original population dynamics model to historical abundance data.
 1329 In total 1,000 randomly drawn process deviates, corresponding to the replicate simulations
 1330 using parameter sets drawn from the joint posterior, were generated for each population in
 1331 each of the 50 years of the forward simulation. To ensure comparability, the same set sets of
 1332 brood year and population specific process deviates were used across environmental
 1333 scenarios.

1334 When simulating future trends in Sacramento Chinook abundance and evaluating
 1335 realized survival rates, it was necessary to incorporate the likely impact of future fishery
 1336 removals. Fishing mortality was simulated based upon the current Reasonable and Prudent
 1337 Alternative (RPA) management scheme for Central Valley Chinook (see “Simulation of
 1338 Harvest Rates” below). Annual allowable harvest rates for fall-run Chinook are established
 1339 based upon the Sacramento Index (SI), however maximum harvest rates are further
 1340 contingent upon minimum abundance requirements for ESA listed winter-run Chinook.
 1341 When projecting populations forward in time, it was necessary to simultaneously model the
 1342 future dynamics of winter-run Chinook in response to the 16 environmental scenarios under
 1343 evaluation. Results from the evaluation of Sacramento River winter-run Chinook using the
 1344 OBAN model (see Appendix D) which was run in parallel with the spring and fall run model,
 1345 were used to simulate the future abundance of Sacramento River winter-run Chinook across
 1346 the same 50-year time-series in response to differences in future climate change, marine

1347 production, and water exports across scenarios. Moving forward in time, future harvest rates
 1348 depended on the model-predicted abundance of fall-run Chinook and winter-run Chinook
 1349 (see “Simulation of Harvest Rates”). Spring-run harvest rates were scaled at 95% of fall-run
 1350 harvest rates.

1351 *SIMULATION OF FUTURE HARVEST RATES*

1352 *Background*

1353 The Pacific Fisheries Management Council (Council) manages the harvest of salmon
 1354 on the coasts of California, Oregon, and Washington. The ocean salmon fishery targets
 1355 Chinook, coho, and pink salmon species, which include Sacramento River Chinook salmon.
 1356 The Sacramento River Chinook stocks overlap with Klamath River Chinook salmon in a
 1357 mixed stock fishery. Furthermore, the Sacramento River fall Chinook (SRFC) is an indicator
 1358 stock for the Central Valley Fall complex and Klamath River fall Chinook (KRFC) is an
 1359 indicator stock for the Oregon/Northern California Chinook complex. As indicator stocks,
 1360 the Council calculates both acceptable biological catches (ABC) and annual catch limits
 1361 (ACL) for the SRFC and KRFC.

1362 Both Sacramento River and Klamath River Chinook are composed of stocks
 1363 supported by hatchery production and stocks that are listed as a conservation concern under
 1364 the Endangered Species Act (ESA). In the Sacramento River and Klamath River mixed
 1365 fishery, the Sacramento winter-run (federally listed as threatened in 1990 and as endangered
 1366 in 1994 under ESA), Central Valley spring-run (listed as threatened under ESA in 1999) and
 1367 the California coastal (listed in 1999) may limit harvest rates. Target harvest rates for the
 1368 Sacramento fall run are determined annually via a forecast of abundance indexes of Chinook
 1369 salmon to both rivers. Management of the fishery occurs through a series of spatially explicit
 1370 openings and closures to structure the harvest effort in such a manner to ensure conservation
 1371 of portions of the stocks that may be at low abundances while allowing harvest of those
 1372 stocks that are healthy. There are a series of Council meetings to review the forecasted
 1373 abundance and possible management alternatives.

1374 NMFS developed a Biological Opinion in 2010 (2010 Opinion) to evaluate the effects
 1375 of the ocean salmon fishery on winter run stock (Biological Opinion on the Authorization of
 1376 Ocean Salmon Fisheries Pursuant to the Pacific Coast Salmon Fishery Management Plan and
 1377 Additional Protective Measures as it affects the Sacramento River Winter Chinook Salmon
 1378 (winter-run) Evolutionary Significant Unit (NMFS 2010)). In the 2010 Opinion, NMFS
 1379 identified that winter-run cohorts could be reduced (i.e., decrease in the number of spawners
 1380 relative to the number of spawners in the absence of the fishery) by 10 to 25% due to the
 1381 ocean salmon harvest with an average rate of 20%. Most of the impacts occur south of Point
 1382 Arena, CA from contacts with the recreational fishery (O’Farrell 2012).

1383 To avoid a jeopardy conclusion on the operation of the ocean salmon fishery, NMFS
 1384 developed a Reasonable and Prudent Alternative (RPA) to allow explicit control of the
 1385 management process to reduce impacts when extinction risk of winter run increases (e.g., due
 1386 to low stock size or periods of decline). After the issuance of the 2010 Opinion, the Council
 1387 was given options to either increase size limits or enact seasonal closures to reduce the
 1388 fishery impacts on winter-run in 2010 and 2011.

1389 In 2012, NMFS performed a Management Strategy Evaluation (MSE) for different
 1390 control rules based on the abundance of winter-run Chinook for setting the allowable harvest
 1391 rate on the mixed stock fishery (Winship et al. 2012). The control rules set allowable impacts
 1392 of age-3 winter-run south of point Arena as: 1) 0 impact (a closed fishery south of Point
 1393 Arena); 2) 25% impact, which is the historical estimate of impact rate; 3) 20% impact, which
 1394 is the current rate; and four alternatives (4-7) that reduce impact rates at certain winter-run
 1395 thresholds. These MSE compared the impact rate under each of the control rules relative to
 1396 the potential for increasing extinction risk of winter-run Chinook.

1397 *Management of Sacramento River Chinook*

1398 ***Fall-run***

1399 The fishery impact rate for SRFC is set by evaluating the Sacramento Index (SI) in
 1400 each year. The SI is calculated as the sum of a) harvest south of Cape Falcon, OR; b) SRFC
 1401 impacts due to non-retention in ocean fisheries; c) harvest in the recreational fishery in the
 1402 Sacramento River basin; and d) SRFC spawner escapement. The SI is forecasted each year
 1403 using a regression model with an autocorrelated error term that uses the number of SRFC
 1404 jacks from the previous year as the dependent variable.

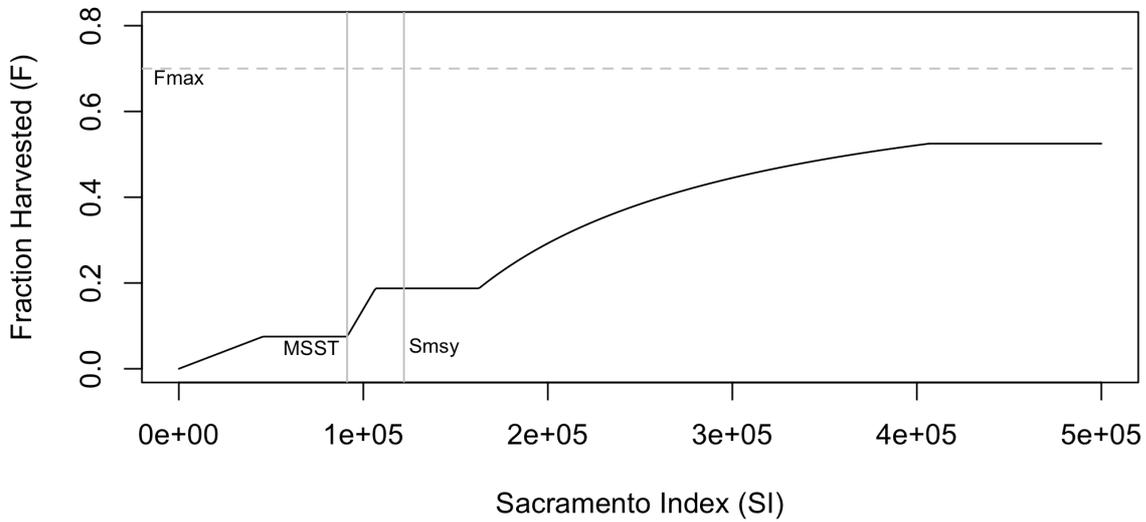

1405 The estimates of the SI are subsequently used to determine the status of the fishery as
 1406 overfished, approaching overfished, rebuilding, or rebuilt. The important metrics for
 1407 determining the status are the minimum stock size threshold (MSST) (91,500 for SRFC) and
 1408 the stock size at maximum sustainable yield (122,000). Given the status of the fishery, the
 1409 allowable biological catch, annual catch limit, and the overfished limit can then be calculated.

1410 The determination of the fishing rate is described as follows (PFMC 2014). The
 1411 discrete fishing rate (F) at the overfishing limit, F_{OFL} , is defined as being equal to F_{MSY} (or the
 1412 maximum fishery mortality threshold) and the spawner size (S) at the overfishing limit, S_{OFL}
 1413 $= N \times (1 - F_{MSY})$. Because, SRFC is a Tier-2 fishery, the fishing rate consistent with the
 1414 allowable biological catch $F_{ABC} = F_{MSY} \times 0.90$ and $S_{ABC} = N \times (1 - F_{ABC})$, where N is the
 1415 spawner equivalent units. Finally, the fishing rate consistent with the allowable catch limits,
 1416 F_{ACL} , is equivalent to F_{ABC} and $S_{ACL} = N \times (1 - F_{ACL})$, which results in $S_{ACL} = S_{ABC}$. The impact
 1417 rate is determined by the SRFC control rule as a function of the potential spawner abundance
 1418 (in this case the spawner abundance is the Sacramento Index = SI) (Figure II.1).

1419 ***Winter-run***

1420 The current RPA (NMFS 2012) uses a fishery control rule with a reduction in fishery
 1421 impact as a function of 3-year geometric average of winter-run escapement. The escapement
 1422 is defined as the total male and female, natural-origin and hatchery-origin escapement as
 1423 estimated by an annual carcass survey (USFWS 2011). The fishery control rule has the
 1424 following threshold definitions (Figure II.1): A) from escapement of 0 to 500, the allowable
 1425 impact rate south of Point Arena is 0; B) from escapement of 501 to 4000, the impact rate is
 1426 linearly increasing from 0.1 to 0.2; C) from escapement of 4000 to 5000, the impact rate is
 1427 0.2. The impact rate for escapement > 5000 is undefined. For purposes of the MSE, NMFS
 1428 assumed that the impact rate would be 0.2 for any 3-year geometric mean of escapement $>$
 1429 4000 as described on pg. 57 of Winship et al. (2012). We assumed the same upper bound of
 1430 0.2 for age-3 impact when the 3-year geometric average escapement was > 5000 .

1431

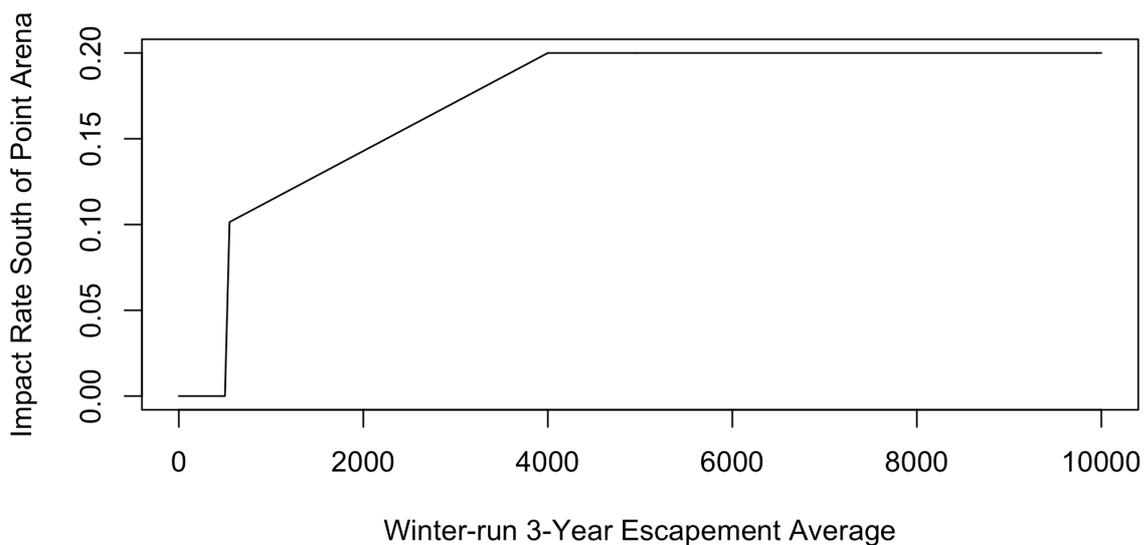

1432
1433
1434
1435

Figure II.1. Fishery control rule as a function of the potential spawner abundance (Sacramento Index) used for setting impact rates for Sacramento River fall-run Chinook.

1436
1437
1438
1439

The fishery control rule defines the impact rates south of Point Arena, which largely encompasses the winter-run marine distribution. Fall-run Chinook are found north of Point Arena, and the fishery control rule for those areas is dependent upon the abundance index for fall run.

1440
1441
1442

Figure II.2. Fishery control rule as a function of the trailing 3-year geometric average of winter-run abundance.

1443 For example, the SI forecast in 2014 was 634,650 (PFMC 2014). The spawner
 1444 escapement associated with overfishing in 2014 is 139,623, which is calculated as a function
 1445 of F_{MSY} (0.78) and the SI abundance forecast of 634,650. The SRFC is a Tier 2 stock, so the
 1446 $F_{ABC} = F_{MSY} * 0.90 = 0.70$, and the spawner escapement associated the allowable biological
 1447 catch was forecasted to be $S_{ABC} = N(1 - F_{ABC}) = 190,395$.

1448 In 2014, the 3-year geometric mean of winter-run abundance was 2,380, which
 1449 resulted in a maximum forecasted impact rate on age-3 winter-run of 15.4% (in comparison it
 1450 was 13.7% in 2012 and 12.9% in 2013).

1451 Reducing the maximum impact rate on age-3 winter-run may have important
 1452 consequences for the actual harvest rates on SRFC. Recently, Satterthwaite et al. (2013)
 1453 compared the ocean distribution of fall-run, winter-run, and spring-run during the summer
 1454 and fall, which provides some understanding of the spatial differences in the relative contacts
 1455 per unit effort of the fishery, which is a proxy for the spatial distribution of each run.
 1456 Sacramento River fall-run have relative contacts per unit effort of approximately 0.2 for
 1457 management areas located south Latitude 42 N at the CA OR border, and 0.1 north of
 1458 Latitude 42 N and Cape Falcon at the OR WA border. These results suggest that the closing
 1459 of fishing south of Point Arena, as would be required for winter-run 3-year average
 1460 escapement of less than 500, can have potential consequences for the total fall-run impact
 1461 rate. For more information, please see PFMC (2014).

1462 *Spring Run*

1463 There are no explicit fishery management rules for spring run, though it has been
 1464 noted in past NMFS Biological Opinions (e.g., NMFS 2010) that protections for winter run
 1465 are likely to be beneficial for spring run. Comparisons of ocean and river impact rates of
 1466 spring-run relative to SRFC by US Fish and Wildlife Service for the purposes of meeting the
 1467 goals of the Central Valley Project Improvement Act (CVPIA) indicated equivalent ocean
 1468 fishery rates were assumed for spring-run and fall-run, whereas river impact rates were
 1469 consistently lower for spring-run (Chinookprod_032011.xlsx obtained from
 1470 <http://www.fws.gov/stockton/afpr/>). Overall, total fishing impact rates for spring-run were
 1471 approximately 0.95 of fall-run.

1472 *Harvest Model*

1473 The management of SRFC requires annual management rules to optimize the fishery
 1474 due to changing abundances of winter-run and Klamath River stock sizes in addition to the
 1475 status of other stocks (e.g., PFMC 2014). The management process can be simplified by
 1476 making several assumptions about the fishery management dynamics:

- 1477 • Klamath River Fall Chinook do not limit the values of F_{ABC} calculated annually for
 1478 SRFC.
- 1479 • The Klamath River fall age 4 harvest rate limits, intended to protect California
 1480 Coastal Chinook, do not limit the values of F_{ABC} calculated annually for SRFC.
- 1481 • Abundance of age-3 SRFC and winter-run are obtained from the spring-run & fall-run
 1482 life cycle model and the winter-run models, respectively. In the actual management
 1483 of SRFC, estimates of an adult (age 3-5) abundance index in year t are calculated
 1484 from regressions to age-2 abundances in year $t-1$.

1485 • The fishery acts without error; thus, management overfishing (i.e., total annual
 1486 exploitation rate exceeds the maximum fishing mortality threshold of 0.78) cannot
 1487 occur.

1488 The following steps were developed for calculating the annual impact rate for SRFC
 1489 (F_{FR}), and Sacramento winter-run Chinook (F_{WR}).

- 1490 1. Calculate an estimate of the Sacramento Index as the sum of the four components
 1491 identified previously.
- 1492 2. Determine the fall-run impact rate F_{FR} based on the fishery control rule for SRFC
 1493 (Figure II.1). The control rule specifies that even if the stock is approaching an
 1494 overfished condition (the SRFC stock has a 3 year geometric average (t-2, t-1, current
 1495 year) that is below the threshold of 91,500), a *de minimis* fishery will occur at the rate
 1496 defined by the fisheries control rule.
- 1497 3. Calculate the trailing 3-year geometric average of winter-run abundance.
- 1498 4. Depending upon the 3-year geometric value, set the fishery impact rate for winter-run
 1499 (Figure II.2). If the winter-run impact rate is 0, reduce F_{FR} by 25% to account for lost
 1500 fishing opportunities south of Point Arena.
- 1501 5. Set the impact rate for spring-run $F_{SR} = 0.95F_{FR}$ to reflect reduced river impact rates.
 1502

1503 *RESULTS*

1504 Future trends in abundance for seven populations of fall and spring-run Chinook
 1505 spawning in tributaries of the Sacramento River watershed were simulated under different
 1506 scenarios for future climate change and ocean productivity, and alternative levels of water
 1507 export from the Sacramento-San Joaquin Delta. Results from a Bayesian multi-stock
 1508 population dynamics model, fit to historical abundance data, were used to parameterize
 1509 forward simulations. In addition, future trends in abundance for Sacramento winter-run
 1510 Chinook were also simulated to allow for implementation of the current fishery management
 1511 process. All eight populations were simulated forward in time for 50 years in response to the
 1512 16 alternative environmental scenarios (combinations of future climate, ocean productivity,
 1513 and water exports), subject to capacity interactions arising from juvenile competition, and
 1514 accounting for estimation uncertainty and process error in future predictions. The forward
 1515 simulation for each environmental scenario was replicated 1,000 times with randomly drawn
 1516 process deviates and model parameter values.

1517 Differences in future outcomes for these populations in response to the 16 scenarios
 1518 are best quantified through comparison of realized survival rates within populations and
 1519 across scenarios. Realized survival rate was calculated in two ways depending on the life
 1520 history of the individual populations. First, for wild-spawning Chinook stocks (mainstem
 1521 Sacramento fall-run, and Deer, Mill and Butte Creek spring-run), realized survival was
 1522 calculated as the survival rate from egg to spawning adult, or the sum of spawning
 1523 adults from a brood year across return years, divided by the spawning abundance producing
 1524 that cohort multiplied by the assumed fecundity (Eq. II.4).

$$1525 \quad (II.4) \quad RS_{y,p,e,i} = \frac{\sum_{a=1}^{Nages} A_{t,p,a,e,i}}{E_{y,p,e,i}}$$

$$t = y + \tau_a$$

1526 In equation II.4, realized survival ($RS_{y,p,e,i}$) from brood year y , of population p , for
 1527 environmental scenario e , and simulation i , is a function of the adult abundance surviving
 1528 both natural and fishing mortality and returning to spawn ($A_{t,p,a,e,i}$) in calendar year t , of
 1529 population p and age a , resulting from simulation i of environmental scenario e , and the
 1530 number of eggs ($E_{y,p,e,i}$) resulting from brood year y for that population, scenario and
 1531 simulation. τ_a represents the difference between brood year y and the calendar year of return
 1532 t , for individuals returning at each age a .

1533 Realized survival for the hatchery-produced populations (Battle Creek (CNFH),
 1534 Feather River, and American River (Nimbus) fall-run) is determined by the ratio of returning
 1535 adult spawners ($A_{t,p,a,e,i}$) to the number of hatchery for that population (RH_p), which is
 1536 assumed constant in the future (Eq. II.5)

$$1537 \quad (II.5) \quad RS_{y,p,e,i} = \frac{\sum_{a=1}^{Nages} A_{t,p,a,e,i}}{RH_p}$$

$$t = y + \tau_a$$

1538 Predictions for future realized survival rates for the three spring-run (Fig. II.3) and
 1539 four fall-run (Fig. II.4) populations across years and replicate scenarios, accounting for future
 1540 fishing mortality, across environmental and export scenarios show some consistent patterns.
 1541 As expected, survival rates for the hatchery-produced Chinook populations were much higher
 1542 than those predicted for the wild-spawning populations, given that realized survival was
 1543 measured as survival from release to spawning adult, as opposed to egg to adult survival
 1544 (Table II.1). For the fall-run Chinook populations, the final model estimated a net positive
 1545 impact of nearshore upwelling on survival, as a result these four populations show higher
 1546 average survival rates for scenarios which included a 10% increase in upwelling (oceanUP)
 1547 across both future climate change and water export scenarios. Across fall-run populations,
 1548 simulated positive upwelling conditions in the future resulted in an average increase in
 1549 realized survival of between 12% and 67% (mean: + 44%) across export scenarios, when
 1550 compared with those scenarios incorporating a 20% reduction in nearshore upwelling
 1551 (oceanDOWN, Table II.1). With respect to the spring-run Chinook populations, substantially
 1552 smaller differences in realized survival rates in response to the oceanUP scenarios were
 1553 observed, with 5 – 17% decreases in average realized egg to adult survival (Fig. II.3). Winter-
 1554 run Chinook on the other hand, were predicted to exhibit higher survival in response to the
 1555 increased upwelling under the oceanUP scenario, with 7 – 36% higher survival (Table II.1)

1556 Predictions for differences in realized survival rate across water export scenarios
 1557 indicated similar general trends across both populations and potential differences in future
 1558 climate change. For all populations realized survival rates were predicted to be highest under
 1559 the zero export scenario, followed by scenarios simulating a 30% reduction in exports,
 1560 average exports, and a 30% increase in water exports (Fig. II.3, II.4). When compared to
 1561 scenarios simulating future survival in response to water export levels at the 1967 – 2010
 1562 average, spring-run Chinook populations are expected to exhibit a higher average realized
 1563 survival in response to a 30% reduction in export volumes, with survival 27 – 48% higher for
 1564 Deer Creek, 29 – 51% higher for Mill Creek, and 19 – 38% higher for Butte Creek Chinook,
 1565 across environmental scenarios. Fall-run Chinook populations are predicted to exhibit
 1566 somewhat smaller increases in survival under a 30% export reduction (expDOWN30) relative
 1567 to average water exports in the future (expAVG), with realized survival higher by 12 – 26%
 1568 for Sacramento mainstem wild-spawning Chinook, and between 14% and 27% for the three
 1569 hatchery-produced fall-run Chinook populations across environmental scenarios (Table II.2).
 1570 Winter-run Chinook are predicted to respond to a 30% reduction in future water exports, with
 1571 only a 3 – 9% increase in survival relative to the average export scenario (Table II.2).

1572 When future dynamics of Sacramento Chinook populations were simulated with a
 1573 30% increase in water exports (expUP30), compared to the average export scenario the
 1574 mainstem Sacramento wild-spawning Chinook were predicted to experience 16 – 28% lower
 1575 median realized survival rates from egg to spawning adult, while the three hatchery-produced
 1576 populations were predicted to exhibit a 14 – 25% reduction in future survival from release to
 1577 adulthood, depending on the climate change and ocean production scenario (Fig II.4, Table
 1578 II.2). Simulation of future Deer, Mill, and Butte Creek survival indicated that, relative to the
 1579 average water export scenario, average realized egg to adult survival was predicted to be 39 –
 1580 53% lower in the presence of a 30% increase in future water exports (Fig. II.3, Table II.2).
 1581 The simulation results again indicate that the response by winter-run Chinook to altered
 1582 export levels is minimal, with a 0 – 3% reduction in average realized egg to adult survival,
 1583 across environmental scenarios.

1584 Predictions for realized survival under the zero future export scenario (expZERO)
 1585 were higher for all populations, however the magnitude of the difference in survival between
 1586 this and the average export scenario (expAVG) was largely contingent upon the climate
 1587 change scenario and population of interest. The Deer and Mill Creek spring-run populations
 1588 exhibited the largest difference in realized survival between the zero and average export
 1589 scenarios, under the OCAP 9.2 climate change prediction and positive ocean conditions
 1590 (cc92.oceanUP) (Fig. II.3). Predicted survival in the absence of exports was 79% higher for
 1591 Deer Creek, 85% higher for Mill Creek, and 59% higher for Butte Creek Chinook, compared
 1592 to average exports (Table II.2). Interestingly, the Butte Creek spring-run Chinook population
 1593 also showed one of the smallest responses to the zero export scenario across populations,
 1594 with only 27% higher survival compared to the average export scenarios under the OCAP 9.5
 1595 climate change and lower ocean production environmental scenario (cc95.oceanDOWN).
 1596 This increase in predicted survival is quite minimal when compared to the 62 – 83% higher
 1597 survival predicted for the fall-run Chinook populations with zero exports, under the same
 1598 environmental scenario (Table II.2). In general however, average realized survival for fall-run
 1599 Chinook under the zero export scenario is expected to be 28 – 62% higher for the mainstem
 1600 Sacramento wild-spawning population and 44 – 83% higher for the hatchery-produced
 1601 populations, when compared to expectations under the average export scenario. While results
 1602 indicated that realized winter-run Chinook survival would be minimally influenced by a 30%
 1603 increase or reduction in future exports, the zero export scenario is predicted to increase
 1604 survival by 28 – 91%, most appreciably when combined with a cooler and wetter future
 1605 climate change scenario and positive future marine conditions (cc92.oceanUP).

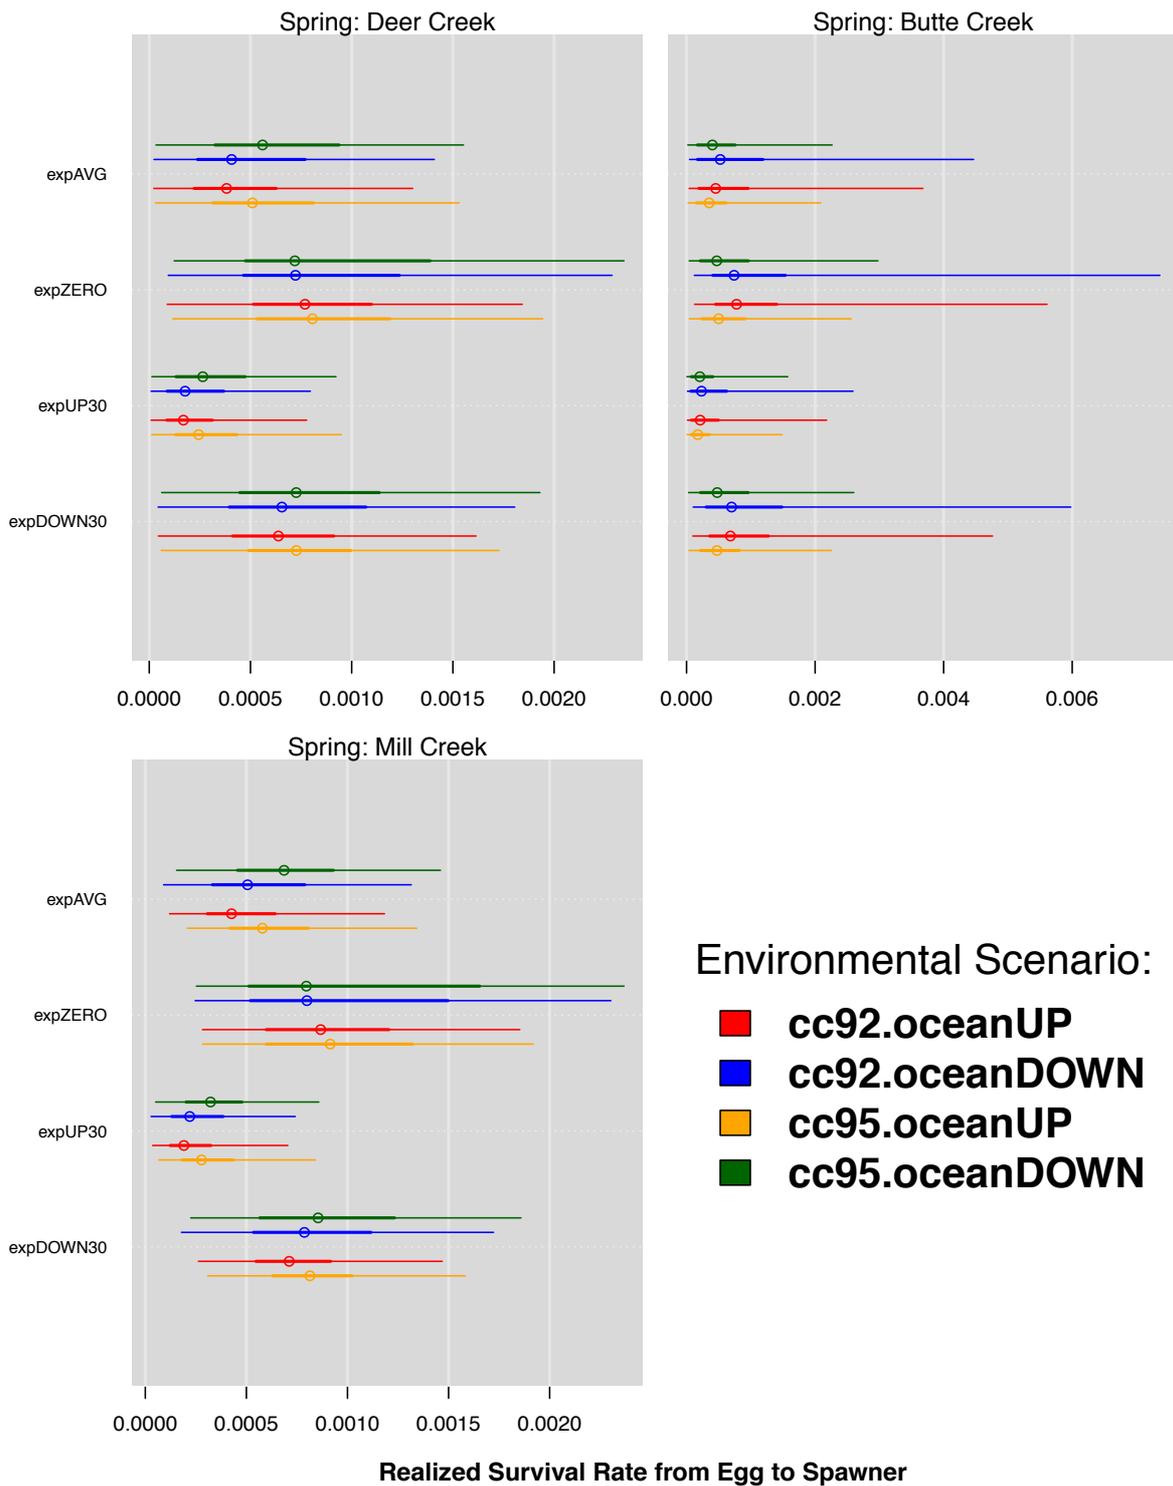

1606 In addition to higher median realized survival rates, the zero export scenario is also
 1607 predict to also produce more variable survival in the future. While most pronounced for the
 1608 spring-run Chinook populations, when the variability in realized survival is compared across
 1609 export scenarios it is consistently higher for the zero export case, across all populations (Fig.
 1610 II.3, Fig. II.4). The Butte Creek population exhibits the greatest variation in future survival,
 1611 specifically under the zero export scenario, and for the OCAP 9.2 climate change pathway
 1612 across export scenarios (Fig. II.3).

1613 While these forward simulation results suggest that higher and more variable realized
 1614 survival can be expected under the zero export scenario, across populations, climate change
 1615 trajectories, and ocean productivity patterns, it is also evident that a 30% reduction in water
 1616 exports (expDOWN30) is likely to achieve an increase in realized survival of a substantial
 1617 magnitude in many cases. For example, on average across environmental scenarios the Butte
 1618 Creek population is expected to exhibit a 41% increase in average realized survival under the
 1619 zero export scenario, and a similarly large increase of 27%, with a 30% reduction in spring
 1620 export volumes (Fig. II.3, Table II.2). This amounts to a difference of only a 14 percentage
 1621 points in the predicted survival rate increase; between the zero export and 30% export
 1622 reduction scenarios. Results are similar for the other spring-run populations, with a difference
 1623 of 25 percentage points for Mill and Deer Creek spring-run Chinook. Improvements in
 1624 survival under the zero export scenario, relative to the 30% export reduction scenario
 1625 (expDOWN30), are on average greater for the hatchery-produced fall-run Chinook
 1626 populations, but likewise suggest that on average across environmental scenarios, a
 1627 difference in survival of only 26 – 43 percentage points is likely to be observed (Table II.2).

1628 The percentage difference in realized survival increase, for the zero export and 30%
 1629 reduction scenarios, relative to the average export scenario, is most variable for the winter-
 1630 run Chinook population. The percentage increase in survival difference between expZERO

1631 and expDOWN30 is smallest under cc95.oceanDOWN scenario at 25, and greatest under the
1632 cc92.oceanUP scenario. This indicates that under a cooler and wetter future climate with
1633 greater upwelling (cc92.oceanUP), the ceasing all exports (expZERO) is likely to have a
1634 substantially higher survival benefit relative to reducing exports by 30% (expDOWN30).
1635 While, in the face of a hotter and drier future climate with reduced nearshore upwelling
1636 (cc95.oceanDOWN) where survival is severely limited by natural processes, both before and
1637 after the delta, the benefits of a 30% reduction and zero exports are more similar (Table II.2).
1638 This same pattern is predicted for the spring-run Chinook populations, but not the fall-run
1639 populations.

1640 With respect to the influence of climate change on predictions for future realized
1641 survival, differences in outcomes amongst climate change scenarios differed across
1642 populations and were smaller on average when compared differences resulting from
1643 alternative export scenarios. The Butte Creek spring-run Chinook population is predicted to
1644 have consistently higher realized survival under the OCAP 9.2 climate change forecast,
1645 which represents a slightly slower rate of warming paired with increased precipitation (Fig.
1646 II.3). Conversely, both the spring-run Deer Creek and fall-run Sacramento mainstem wild-
1647 spawning populations show slightly, but consistently, higher survival under the OCAP 9.2
1648 climate change trajectory which describes a greater increase in temperature paired with lower
1649 levels of future precipitation (Table II.1).

1679

Table II.2. Percent difference in median realized survival from average export (expAVG) scenario, across environmental scenarios. Values shaded from red (low) to green (high) for ease of interpretation.

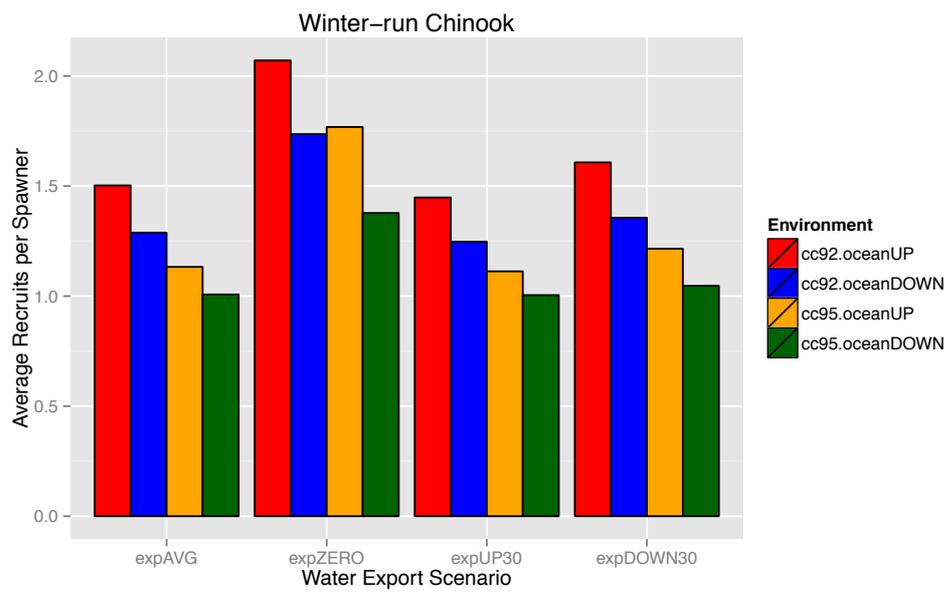

1680 In addition to estimates for future realized survival rates, for wild-spawning
1681 populations the average productivity of populations across years and replicate scenarios was
1682 also evaluated. Figure II.6, displays the average number of recruits per spawner for the
1683 Sacramento mainstem wild-spawning fall-run Chinook population, and the Deer, Mill, and
1684 Butte Creek spring-run populations and winter run, under alternative water export scenarios
1685 and environmental conditions. Scenarios that predict average productivity of less than 1
1686 recruit-per-spawner, indicate that those populations are unlikely to remain viable in the future
1687 and will tend toward extinction in the presence of environmental stochasticity. Forward
1688 simulation results for the mainstem Sacramento fall-run Chinook population indicate that
1689 under the average (expAVG) and 30% increase (expUP30) water export scenarios, average
1690 productivity in the face unfavorable ocean conditions producing a 20% reduction in future
1691 upwelling (oceanDOWN) is expected to be less than one recruit-per-spawner (Fig. II.6).
1692 However, under both of these future export scenarios average recruits-per-spawner is
1693 expected to expected to exceed one under favorable future ocean conditions (oceanUP).

1694 Predicted future realized productivity (recruits-per-spawner) for the Deer, Mill, and
1695 Butte Creek spring-run populations is predicted to be significantly lower under the scenario
1696 representing a 30% increase in future exports (expUP30). For both the Deer Creek and Mill
1697 Creek populations, average realized productivity (recruits-per-spawner) is predicted to be less
1698 than one with a 30% increase in water exports (expUP30), across all four combinations of
1699 future climate change and marine conditions (Fig. II.6). Predictions for future productivity of
1700 the Butte Creek population indicate that with the more gradual climate warming and greater
1701 future precipitation under the OCAP 9.2 scenario indicate that even with a 30% increase in
1702 water exports (expUP30) the population may be expected to produce at or near 1 recruit-per-
1703 spawner, and therefore remain viable.

1704 Average future productivity (recruits-per-spawner) is expected to be highest across
1705 environmental scenarios under the zero export (expZERO) and 30% reduction in future
1706 exports (expDOWN30). However, realized productivity is predicted to vary across
1707 populations in response to future climate change and ocean production scenarios. For the
1708 mainstem Sacramento wild-spawning fall-run population, future productivity in the face of
1709 positive ocean conditions and specifically increased nearshore upwelling (oceanUP) is
1710 predicted to be highest and exceed one recruit-per-spawner, independent of the climate
1711 change or export scenario. The form of future climate change is predicted to have the greatest
1712 impact on the Butte Creek spring-run Chinook population, with higher productivity, in terms
1713 of recruits-per-spawner, under the OCAP 9.2 scenario (Fig. II.6). This results from the fact
1714 that this population was found to be particularly sensitive to summertime temperatures, which
1715 are predicted to increase more precipitously under the OCAP 9.5 climate change scenario
1716 leading to reduced over-summer survival of adults holding prior to spawning. Spring run
1717 stocks are much more sensitive to exports than fall and winter run, but both fall and winter do
1718 see slight improvement under export restrictions.

1723

Figure II.6. Average number of realized recruits per spawner, across populations, environmental and export scenarios

1724 *PART II DISCUSSION*

1725 Results from a Bayesian population dynamics model estimating the stage and
1726 population specific maximum survival rates and changes in survival in response to natural
1727 and anthropogenic environmental covariates were used to parameterize simulations for future
1728 trends in population-specific abundance under alternative water export, climate change, and
1729 ocean production scenarios. Both estimation and process uncertainty were incorporated into
1730 future predictions by, first sampling model parameter values from the joint posterior, and
1731 second incorporating stochastic process deviations into the first modeled life-stage. One
1732 thousand replicate simulations of the 50-year future time series were used to fully quantify
1733 the influence of these two sources of uncertainty. The likely impact from future ocean harvest
1734 of Chinook was incorporated by simultaneously modeling the future trends in abundance for
1735 winter-run Chinook in the Sacramento system and replicating the current fishery management
1736 decision rules. We did not explore the impacts of modifying the harvest regime, but
1737 obviously any change in the fraction of fish harvested would have an analogous impact to
1738 increasing survival via changing exports or other environmental factors.

1739 Results from these forward simulations in the form of estimates for future realized
1740 survival rates from egg, or hatchery release, to spawning adult, and estimates for realized
1741 productivity (recruits-per-spawner) indicate that while all populations are sensitive to
1742 differences in future water exports from the Sacramento-San Joaquin Delta, differences in the
1743 future environment are likely to have substantial population-specific impacts. The
1744 observation that predicted realized survival and productivity are generally higher for the fall-
1745 run populations and equal or lower for the spring-run populations under the oceanUP
1746 scenario results from several characteristics of the forward simulation model. The oceanUP
1747 scenario represents a 10% increase in future nearshore upwelling, paired with a smaller
1748 increase in future water temperatures at the Farallon Islands. While nearshore upwelling was
1749 found by the estimation model to significantly increase survival in the nearshore region for
1750 fall-run Chinook populations, this covariate was not AICc-selected for the spring-run
1751 populations. As a result, predictions for future realized survival for the fall-run Chinook
1752 populations show as consistently higher survival and productivity patterns in response to the
1753 oceanUP scenario. This prediction for higher realized survival for fall-run Chinook
1754 populations agrees with insights by Lindley et al. (2009) pointing to unusually low nearshore
1755 upwelling patterns as one of the proximate causes of the failure of the 2004 – 2005 fall-run
1756 brood years. In addition, the grouped survival of all seven Chinook populations was found to
1757 have a positive relationship with the Pacific Decadal Oscillation. The oceanUP scenario
1758 described an initial negative PDO phase, followed by a positive PDO phase, resulting in
1759 lower marine survival initially followed by higher marine survival in later years for the
1760 populations. The opposite pattern in marine survival was observed for the seven Chinook
1761 populations under the oceanDOWN scenario in response to the PDO pattern simulated in the
1762 opposite direction.

1763 Future climate change scenarios had mixed impacts across populations as a result of
1764 the estimated response by populations to the environmental covariates impacted by the OCAP
1765 9.2 and 9.5 predictions. The cooler and wetter OCAP 9.2 scenario had a particularly strong
1766 influence on the Butte Creek population, because a strong negative influence of high
1767 summertime temperatures was predicted for this population. However, the increase in water
1768 flow associated with the OCAP 9.2 scenario resulted in increased sediment concentration at
1769 Freeport, CA. Given the negative relationship between sediment concentration at this location

1770 and survival for both fall and spring-run Chinook, this aspect of the OCAP 9.2 scenario did
1771 result in some reduction in survival for all populations, although in some cases this effect was
1772 outweighed by the interaction with temperature.

1773 Across all combinations of future export and environmental scenarios predictions for
1774 both realized survival and productivity (recruits-per-spawner) were highly variable. While we
1775 have focused on predicted differences in median survival and average productivity, the 95%
1776 credible intervals for these predictions overlap in almost all cases. This indicates that the
1777 combination of both estimation and process uncertainty introduced in the forward simulation
1778 process leads to significant variability in future abundance and our quantified metrics. This is
1779 particularly pronounced in future predictions of realized survival for the Butte Creek
1780 population, which are extremely right skewed (Fig. II.3).

1781 Quantifying results of forward simulations for wild-spawning Chinook populations in
1782 terms of average productivity (recruits-per-spawner) provided an efficient means for
1783 determining under what water export scenarios and environmental conditions specific
1784 populations are expected to persist (recruits-per-spawner > 1), or decline toward extinction
1785 (Fig. II.5). For several of the populations under the 30% increase in future water export
1786 scenario (expUP30), and for the fall-run mainstem Sacramento wild-spawning population
1787 under the average export scenario paired with decreased future upwelling (oceanDOWN),
1788 average productivity was predicted at less than one. While this result suggests that under
1789 those conditions specific populations may be expected to decline in abundance, it is important
1790 to fully understand the assumptions involved in this prediction. First, the forward simulations
1791 assume that future fishing mortality rates will vary in accordance with current management
1792 practices, as influenced by the Sacramento Index and harvest limitations based upon the
1793 abundance of winter-run Chinook. A reduction in future fishing mortality rate may be
1794 sufficient to increase the productivity of these populations above 1 recruit-per-spawner and
1795 facilitate persistence. Second, predictions for future productivity do not account for the stray
1796 rates amongst hatchery and wild populations leading to source-sink dynamics (Johnson et al.
1797 2012). These effects may be most important for the Sacramento mainstem wild-spawning
1798 fall-run Chinook population, which was found in 2010 and 2011 to have 20 – 27% of its
1799 observed spawning abundance resulting from hatchery-reared strays (Kormos et al. 2012,
1800 Palmer-Zwahlen and Kormos 2013). Whether the contribution of straying individuals may be
1801 enough to facilitate persistence of populations under environmental and export scenarios that
1802 are predicted by these analysis to lead to decline (recruits-per-spawner < 1), remains
1803 unknown.

1936 *BACKGROUND*

1937 The National Marine Fisheries Service (NMFS) Southwest Fisheries Science Center
 1938 (SWFSC) initiated a project to develop life-cycle models of salmon populations in the
 1939 Central Valley. The project objective is to build a framework to quantitatively evaluate how
 1940 the management and operation of the Federal Central Valley Project (CVP) and California
 1941 State Water Project (SWP) affect Central Valley salmon populations. The modeling
 1942 framework will evaluate the current operations of the CVP and SWP, i.e., Operational Plan
 1943 and Criteria (OCAP), and evaluate future water conveyance structures as proposed in the Bay
 1944 Delta Conservation Plan (BDCP). The NMFS Central Valley Life Cycle Model (CVCLCM)
 1945 targeted winter-run as the first race of Chinook for model development (Hendrix et al. 2014).

1946 The CVCLCM framework is a stage-structured model. Stages in the model were
 1947 based on developmental state as well as geographic location (e.g., smolts in the delta, smolts
 1948 in the mainstem river, or smolts in a floodplain). State transitions among life-history stages
 1949 are defined by a modified Beverton-Holt (Beverton 1957) that allows individuals exceeding
 1950 the capacity of a habitat to move to a different geographic location rather than die in that
 1951 habitat (Greene and Beechie 2004). The Beverton-Holt with movement function is defined
 1952 by a survival rate, capacity, and movement rate (Figure A.1). Each of these parameters can
 1953 be modeled as a function of environmental or anthropogenic factors that may be influenced
 1954 by management (e.g., spatial extent of floodplain habitat as it affects capacity) and
 1955 operational actions (e.g., flow as it affects movement or water temperature as it affects
 1956 survival).

1957 Capacity estimates for the river and delta habitats from the CVCLCM were used in
 1958 the current fall-run and spring-run model. In addition, there are several products from the
 1959 current model that will be useful to the CVCLCM, which is developing fall-run and spring-
 1960 run life cycle models.

1961
 1962 **Figure A.1. Beverton-Holt with movement transition function. Outgoing abundance**
 1963 **(thin solid line) is composed of migrants (thick dashed line) and residents (thick solid**
 1964 **line), which are affected by the resident capacity (dotted horizontal line). Those fish**
 1965 **that are not residents leave as migrants. The 1:1 line (thin dashed) is also plotted for**
 1966 **reference.**

1967

1968 *PRODUCTS FROM THE CVCLCM USED IN THE FALL-RUN AND SPRING-RUN MODEL*

1969 *Capacities*

1970 The CVCLCM developed estimates of monthly capacities for use in the Beverton-
 1971 Holt transition function. The capacities were estimated in four habitats/geographic areas: 1)
 1972 Sacramento River from headwaters to the city of Sacramento (river), 2) Yolo bypass
 1973 (floodplain), 3) delta (city of Sacramento to Chipps Island) and 4) Chipps Island to the
 1974 Golden Gate Bridge (bay). Two of these areas were used in the current fall-run and spring-
 1975 run life-cycle model. The Sacramento River monthly capacity estimates were used for the
 1976 Sacramento River mainstem spawning fall-run population in Stage 1 and the delta capacity
 1977 estimates were used in fall-run (average delta capacity March to May) and spring-run
 1978 (average delta capacity February to April) capacities for Stage 2.

1979 Capacities for the river, floodplain, delta, and bay habitats were calculated in the
 1980 CVCLCM as a function of habitat-specific capacity models (Hendrix et al. 2014). We
 1981 provide details on the river and delta calculations and habitat capacity estimates, because they
 1982 were included in the fall-run and spring-run model. In particular, the calculation of River
 1983 capacity was modified since the publishing of the methods in Hendrix et al. (2014).
 1984 Although the initial model development in the CVCLCM was focused on winter-run, the
 1985 estimates of capacity are applicable to all races of Chinook in the Central Valley.

1986 ***River Capacities***

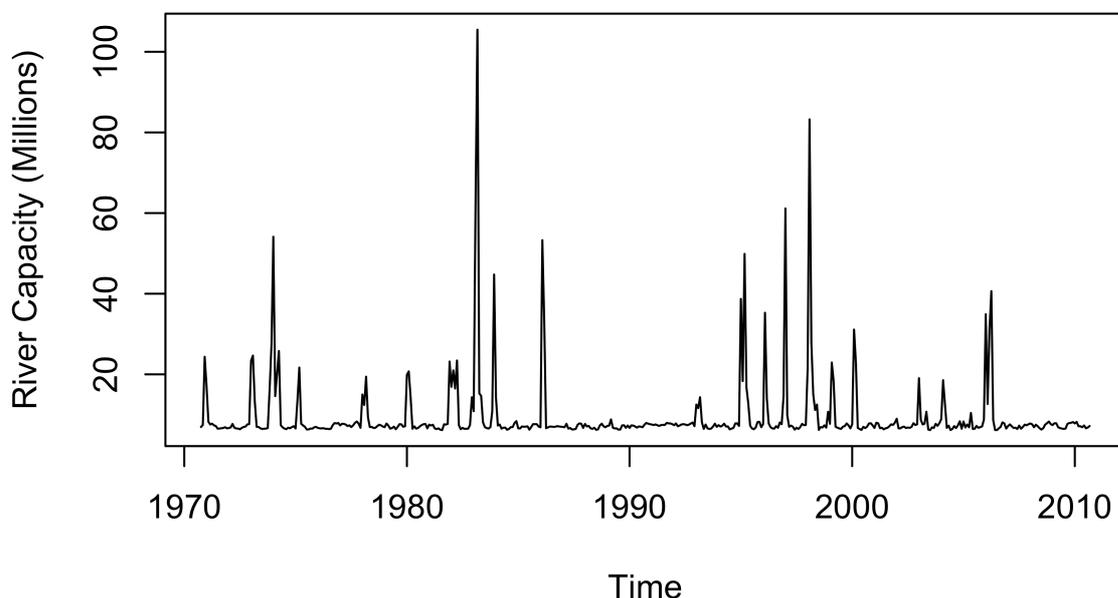

1987 The River capacities were defined as a function of velocity and depth. For each
 1988 variable preferred versus not-preferred categories were defined (Table A.1). The possible
 1989 combinations of the 2 levels of 2 variables provided 4 categories of habitat quality for rearing
 1990 Chinook salmon. The Central Valley is primarily a hatchery-dominated system with fish
 1991 released at smolt size for rapid migration to the ocean, and natural stocks are at historically
 1992 low levels; therefore, current estimates of fish density from the Central Valley may not be
 1993 indicative of densities at capacity. As a result, densities from the Skagit River, WA were
 1994 used to inform the maximum density estimates for each category (Greene et al. 2005). Two
 1995 densities were used to calculate capacities: the 90th percentile and the 95th percentile of the
 1996 distribution of densities by habitat category in the Skagit River.

1997

1998 **Table A.1. Habitat variables used to define the River capacity.**

Variable	Preferred or Not-preferred	Range
Velocity	Preferred	≤ 0.15 m/s
	Not preferred	> 0.15 m/s
Depth	Preferred	> 0.2 m and ≤ 1 m
	Not preferred	≤ 0.2 m or > 1 m

1999 Areas of habitat under each of the 4 categories were calculated by running the HEC-
 2000 RAS model on a series of Sacramento River cross-sections that define cells. Each cell in the
 2001 cross-section has a depth and velocity, and altering the flow changes the depth and velocity of
 2002 a particular cell. The area of each cell that corresponded to a specific combination of
 2003 velocity and depth category was tabulated for each monthly flow associated with a cross-
 2004 section. The appropriate density of Chinook salmon for each of the 4 categories was applied
 2005 to arrive at a density estimate for the Sacramento River in each month (Figure A.2).

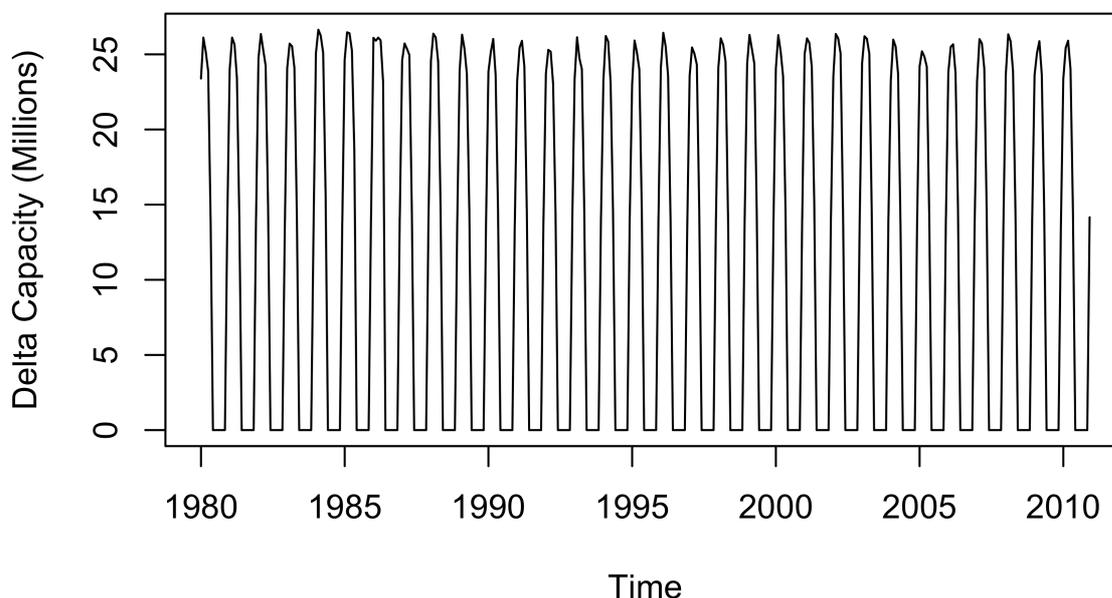

2006
2007
2008
2009

Figure A.2. Monthly capacity of Chinook salmon in the Sacramento River using a 90th percentile estimate of fish density.

2010 *Delta Capacities*

2011 The monthly capacities in the delta were defined as a function of several habitat
2012 attributes including: channel type, cover, shoreline type, blind channel area, salinity and
2013 vegetated cover along riverbanks. Analysis was conducted by using Geographic Information
2014 System (GIS) data layers. Habitat quality was determined by defining binary High/Low
2015 ranges for each axis of habitat quality, similar to the Preferred and Not-preferred approach
2016 used in the river habitat. In the delta, 8 categories of habitat quality were defined, each with
2017 an associated maximum density. Because not all habitats are accessible by rearing Chinook,
2018 a subsequent analysis was conducted to restrict habitat areas based on connectivity. Using
2019 beach seine data collected by US Fish and Wildlife Service (Speegle et al. 2013), a
2020 generalized linear model was used to estimate the probability of juvenile habitat use by
2021 seining location. This model was subsequently used to restrict habitat use by juvenile
2022 salmonids throughout the delta. Monthly estimates of capacity in the delta reflected the
2023 restricted access to particular areas of the delta and the seasonal absence of juvenile
2024 salmonids during the summer months (Figure A.3). Additional details on the capacity
2025 calculations can be found in Hendrix et al. (2014).

2026

2028 **estimate of fish density.**

2029 *PRODUCTS FROM THE FALL-RUN AND SPRING-RUN MODEL THAT COULD BENEFIT THE*
2030 *CVCLCM*

2031 In the current project, we are using a model for fall and spring-run that incorporates
2032 competition through density dependence via a Beverton-Holt transition. This interaction
2033 effectively removes some capacity for each of the interacting races. Initial model evaluations
2034 indicated that an external capacity value improves the ability to estimate an interaction effect
2035 e.g., between fall-run and spring-run or between hatchery and natural. Although the
2036 Beverton-Holt function in the CVCLCM incorporates a movement component, understanding
2037 the importance of both of these interactions is important in the context of the CVCLCM
2038 models for fall-run and spring-run Chinook.

2039 The NMFS scientists developing the fall-run and spring-run CVCLCM models will
2040 benefit from interacting with the current fall-run and spring-run model. The current model
2041 uses the CVCLCM capacities for certain stages, but these can also be modeled as functions of
2042 covariates to allow further hypothesis evaluation. In addition, the time series of observations
2043 is greater for the current model than the CVCLCM, which is restricted to 1980 to 2010. Thus
2044 earlier escapement data can be used to help parameterize the CVCLCM. Finally, the speed
2045 with which alternative hypotheses can be developed and fit to the fall-run and spring-run
2046 escapement data provides a useful tool for model construction in the CVCLCM. Hypotheses
2047 can be developed and tested on the order of minutes to hours, whereas running the full
2048 CVCLCM under a new set of environmental drivers can take on the order of days.

2065 **APPENDIX B CLIMATE CHANGE SCENARIO PROJECTIONS**

2066 Climate change scenario projections were used to explore the level of impact that
 2067 California's Central Valley Project (CVP) and State Water Project (SWP) operations can
 2068 have on spring, fall and winter run Chinook under favorable and unfavorable climate
 2069 forecasts. Model covariates were divided into three categories: overland covariates (river
 2070 flows, river temperatures, air temperatures), nearshore ocean covariates (upwelling, PDO,
 2071 wind stress curl, Farallon ocean temperatures), and anthropogenic water use covariates
 2072 (exports, export/inflow ratios). Overland model covariates reflected two climate change
 2073 scenarios: a warmer/drier scenario, and a cooler/wetter scenario. Nearshore ocean covariates
 2074 explored two situations: favorable nearshore conditions for Chinook at ocean entry (increases
 2075 in upwelling, PDO in negative phase, less warming of nearshore oceans), and unfavorable
 2076 conditions (decreases in upwelling, PDO in positive phase, greater warming of nearshore
 2077 oceans). Anthropogenic water use levels were modified with regard to exports to create four
 2078 options: 1. future exports=mean historical exports; 2. future exports=mean historical exports
 2079 +30%; 3. future exports=mean historical exports – 30%, and 4. future exports=0. A total of
 2080 16 climate change scenarios were generated using all combinations of overland covariates,
 2081 nearshore ocean covariates and anthropogenic water use covariates (Table B.1).

2082 *METHODS*

2083 As the basis for our climate change scenarios, we used the United States Bureau of
 2084 Reclamation's (USBR) Operations Criteria and Plan (OCAP) Study 9.2 and 9.5 (USBR
 2085 2008). OCAP Study 9.2 reflects a mean increase in temperature of 0.75° F (=0.42° C) and an
 2086 increase of 12.5% in precipitation. OCAP Study 9.5 reflects a mean increase in temperature
 2087 of 2.8° F (=1.56° C) and a decrease in precipitation of 12%. These temperature and
 2088 precipitation changes represent a mean 30-year change between 1971-2000 and projected
 2089 2011-2040 levels. Study 9.2 and 9.5 are the extreme corners of a bounding box that captures
 2090 the 10th and 90th percentiles for temperature increase and precipitation change that were
 2091 predicted by 112 climate projections from a variety of climate models and greenhouse gas
 2092 emission levels (USBR 2008). USBR used the following methodology to generate OCAP
 2093 Study 9.2 and 9.5:

- 2094 1. Plot temperature change (ΔT) vs. precipitation change (ΔP) over central California for
 2095 each of 112 archived Downscaled CMIP3 Climate Projections (Downscaled CMIP3
 2096 Climate Projections Archive website).
- 2097 2. Determine the 10th and 90th percentiles for predicted temperature and precipitation
 2098 change.
- 2099 3. Identify the levels of ΔT and ΔP associated with the 10th and 90th percentiles in the
 2100 climate projections. The intersection of the 10th and 90th percentiles for ΔT with the
 2101 10th and 90th percentiles for ΔP form a bounding box with four corners.
- 2102 4. Choose climate projections that most closely reflect the four corners of the bounding
 2103 box. OCAP Study 9.2 reflects the mildest climate change conditions over central
 2104 California (less warming/ wetter), while OCAP Study 9.5 reflects the most dramatic
 2105 climate change conditions over central California (more warming/ drier).
- 2106 5. Modify CalSim-II hydrology inputs and Sacramento River Water Quality Model
 2107 (SRWQM) inputs based on temperature and precipitation values generated by the
 2108 climate projections.

2109 6. Run CalSim-II and SRWQM models using historical data that has been modified to
2110 reflect climate change, but is still run retrospectively.

2111 We used CalSim-II and SRWQM outputs for OCAP Study 9.2 and 9.5 (USBR 2008
2112 Appendix R zipped data), but projected the hindcast covariate values from 1946-2002 onto
2113 years 2007-2063 to obtain a forward projection, while retaining year-to-year variability in
2114 covariate values and the covariance structures present in the natural system. OCAP Study 9.2
2115 and 9.5 provided two types of scenario outputs:

- 2116 1. Streamflows and controlled discharges from dams and weirs: The CalSim-II model
2117 predicts mean monthly streamflows and discharges at various points throughout the
2118 Sacramento River system and the Delta, including the following covariates from the
2119 spring, fall and winter run Chinook models:
 - 2120 a. **Keswick Dam discharge** (fall run): CalSim-II channel flows at C5 from
2121 OCAP Study 9.2 and 9.5 were used for years 1946-2002, averaged over
2122 January-March. Averaged values were then projected forward to become
2123 scenario values for 2007-2063 (Fig. B.1, Table B.2D).
 - 2124 b. **Deer Creek discharge** (spring run): CalSim-II channel flows for Deer Creek
2125 were not available in OCAP Study 9.2 and 9.5. Instead, CalSim-II channel
2126 flows at C11305 (just past the confluence of Mill Creek, Deer Creek, Antelope
2127 Creek and discharge point D11305) from OCAP Study 9.2 and 9.5 were used
2128 for years 1946-2002, averaged over October-December. Deer Creek was
2129 separated from the other constituents of C11305 using the following
2130 methodology:
 - 2131 i. CalSim-II channel flows at C11309 (Deer Creek), C11305 and D11305
2132 were obtained from OCAP scenario NAA_Existing (no action
2133 alternative) for years 1946-2002, averaged over October-December.
2134 Deer Creek flow C11309 was divided by the sum of D11305 and
2135 C11305 to determine which proportion of Deer + Mill + Antelope
2136 Creek flows should be attributed to Deer Creek.
 - 2137 ii. CalSim-II values C11305 + D11305 from OCAP Study 9.2 and 9.5
2138 were multiplied by the vector of proportions for Deer Creek, one for
2139 each year (mean over all years=0.42, sd=0.05). These values were
2140 then projected forward to become scenario values for 2007-2063 (Fig.
2141 B.2, Table B.2D).
 - 2142 c. **Exports / Inflow Ratio** (fall run): CalSim-II delta inflows (INFLOW-
2143 DELTA parameter) from OCAP Study 9.2 and 9.5 for 1946-2002, averaged
2144 over March-May, were used as the denominator in the Exports/Inflow ratio,
2145 while the four export scenarios (see 8. *CVP and SWP Dayflow Exports*; and
2146 8b. *Mean Daily Exports March-May*, below) formed the numerator (Fig. B.3,
2147 Table B.2E).
 - 2148 d. **Bend Bridge minimum monthly flow** (winter run): CalSim-II channel flows
2149 at C109 from OCAP Study 9.2 and 9.5 were used over years 1946-2002,
2150 selecting the minimum monthly flow between August-November. Minimum
2151 flow values were then projected forward to become scenario values for 2007-
2152 2063 (Fig. B.4, Table B.3A).
 - 2153 e. **Freeport sediment concentration as a function of Freeport flow** (spring
2154 and fall run): Sediment concentrations at Freeport, averaged annually over
2155 February-April, were modelled as a linear function of Freeport flows (also
2156 averaged annually over February-April) from CalSim-II scenario

2157 NAA_Existing at C169. The linear model equation, with intercept set to zero,
2158 is:

$$2159 \text{ Freeport sediment conc.} = \text{CalSim-II flow at Freeport} * 0.0022487$$

2160

2161 The R-squared value for the regression is 0.834 (Fig. B.5). Freeport flows
2162 from OCAP Study 9.2 and 9.5 for years 1946-2002, averaged over February-
2163 April, were then used in conjunction with the linear model to generate
2164 sediment concentrations. These were projected forward to years 2007-2063
2165 (Fig. B.6, Table B.2D).

2166 2. River temperatures: SRWQM generates mean monthly river temperatures at various
2167 nodes along major rivers in the Sacramento River system (USBR 2008 Appendix R
2168 zipped data)

2169 a. **Sacramento River temperature at Bend Bridge** (winter run): SRWQM
2170 outputs for OCAP Study 9.2 and 9.5 were extracted along the Sacramento
2171 River at Bend Bridge for 1946-2002. Model predictions were averaged for
2172 months July-September and projected onto years 2007-2063 (Fig. B.7, Table
2173 B.3B).

2174 In addition to the OCAP Study 9.2 and 9.5 scenario outputs, we also used several
2175 other sources of data to generate scenario covariates:

2176

2177 3. Nearshore ocean upwelling estimates: Upwelling indices were obtained from
2178 NOAA's Pacific Fisheries Environmental Laboratory (PFEL Upwelling website). We
2179 increased and decreased historic values (1946-2002) of upwelling by +10% and -20%
2180 to account for a range of changes to upwelling that might occur under climate change
2181 (N. Mantua pers. comm., 12/8/14). These altered historic values were then projected
2182 onto years 2007-2063.

2183 a. **Upwelling at 36° N, 122° W** (spring and winter run): NOAA upwelling index
2184 values at 36° N, 122° W (southwest of Monterey, CA) were averaged over
2185 April-June for years 1946-2002, and adjusted up or down before being
2186 projected onto 2007-2063 (Fig. B.8, Tables B.2B & B.3A).

2187 4. Pacific Decadal Oscillation (PDO) index: PDO indices were obtained from the Joint
2188 Institute for the Study of the Atmosphere and Oceans (Mantua and Hare). Over the
2189 last century, the PDO has displayed a 20-30 year autocorrelation pattern (Mantua et
2190 al. 1997). To capture the future impact of positive (warm) and negative (cold) PDO
2191 cycles on Chinook populations, we used two ranges of historic PDO data and
2192 projected them forward to years 2007-2063: one was a sequence that began with a
2193 positive PDO phase before flipping to a negative PDO phase, while the other began
2194 with a negative PDO phase and then flipped to a positive PDO phase. Pacific
2195 Northwest and West coast salmon production is enhanced during the negative phase
2196 of the PDO, and tends to decline during positive phases of the PDO (Mantua et al.
2197 1997, Hare et al. 1999).

2198 a. **PDO** (spring and fall run): PDO values between 1900 and 2013 were
2199 averaged annually over January-May, and two sequences with opposite
2200 patterns were selected for future scenarios (Fig. B.9). The sequence of years
2201 between 1922-1978 began with a positive PDO phase, flipping to a negative
2202 phase around 1947. The sequence of years between 1946-2002 began with a
2203 negative PDO phase, flipping to a positive phase around 1977 (Fig. B.10,
2204 Table B.2B).

- 2205 5. Wind Stress Curl Index: Calculated values for NOAA wind stress curl index for
 2206 upwelling at Northern Location (39° N, 125° W) were obtained from NOAA's Pacific
 2207 Fisheries Environmental Laboratory (PFEL Derived Winds website).
 2208 a. **Curl Index** (spring and fall run): Historic curl index values from 1946-2002
 2209 averaged over July-December were increased or decreased by 20% and plotted
 2210 as forward projections for 2007-2063 (Fig. B.11). Curl trajectories from 1967-
 2211 2063 suggested a long-term autocorrelation pattern (Fig. B.11). Because we
 2212 did not have compelling reasons to believe that future curl values would
 2213 follow the same pattern as historic values, we set the future scenario curl index
 2214 equal to mean curl from 1967-2010 (standardized curl index = 0) (Table
 2215 B.2B).
 2216 6. Farallon Islands ocean temperature: Water temperature data at the Farallon Islands
 2217 (37° 41.8' N, 122° 59.9' W) were not available for all years between 1946 and 2002,
 2218 so the methodology of projecting covariate values from 1946-2002 under climate
 2219 change onto years 2007-2063 could not be used. Instead, we calculated the mean
 2220 water temperature over February-April for 1967-2012, and increased it by 0.42° C
 2221 (=0.75° F) to correspond with OCAP Study 9.2, and by 1.56° C (=2.8° F) to
 2222 correspond with OCAP Study 9.5.
 2223 a. **Farallon Islands ocean temperature** (winter run): Mean water temperature
 2224 from February-April during years 1967-2012 was 11.8° C. This was increased
 2225 to 12.3° C and 13.4° C to match with OCAP Study 9.2 and 9.5, respectively
 2226 (Fig. B.12, Table B.3B).
 2227 7. Sacramento air temperatures: Sacramento air temperature projections for 2007-2063
 2228 were obtained from the Downscaled CMIP3 Climate Projections archive (Downscaled
 2229 CMIP3 Climate Projections Archive website) for the same climate projections that
 2230 were used to generate OCAP Study 9.2 and 9.5. Air temperatures were obtained for
 2231 the modelled grid cell containing Sacramento's latitude/ longitude (38.5556° N,
 2232 121.4689° W). OCAP Study 9.2 was based on climate model mri cgcm2.3.2a with
 2233 A2 emissions, simulation #5, and OCAP Study 9.5 was based on climate model ukmo
 2234 hadcm3 with A2 emissions, simulation #1.
 2235 a. **Sacramento air temperature - spring** (spring and fall run): Climate
 2236 projections for the modelled cell over Sacramento were averaged annually
 2237 over January-March and adjusted up by 4.55 °F to spatially downscale climate
 2238 projections to match with historic Sacramento air temperature data. The
 2239 adjustment factor was obtained for each climate projection by subtracting
 2240 mean projected air temperature between 1960-2010 (averaged over January-
 2241 March) from mean historical Sacramento air temperature over the same
 2242 period. Resulting differences were averaged for the two scenarios to obtain an
 2243 adjusting value of 4.55 °F (Fig. B.13, Table B.2A).
 2244 b. **Sacramento air temperature - summer** (fall run): Climate projections for
 2245 the modelled cell over Sacramento for July-September were adjusted up by
 2246 8.82° F to spatially downscale climate projections to match with historic
 2247 Sacramento air temperature data. Methodology for obtaining the adjustment
 2248 factor was the same as for spring Sacramento air temperatures (see above)
 2249 (Fig. B.13, Table B.2A).
 2250 8. CVP and SWP Dayflow Exports: Dayflow data for exports from the Delta were
 2251 obtained from California's Department of Water Resources (CA DWR Dayflow
 2252 website). Average daily exports were calculated for 1967-2010 and modified to
 2253 generate four future export scenarios: 1. future exports = mean historical exports; 2.

- 2254 future exports = mean historical exports +30%; 3. future exports = mean historical
 2255 exports – 30%; and 4. future exports = 0.
- 2256 a. **Mean daily exports February-April** (spring run): Dayflow exports were
 2257 averaged annually over February-April for years 1967-2010 to form the
 2258 historical export level, which was then modified for scenarios (Fig. B.14,
 2259 Table B.2C).
- 2260 b. **Mean daily exports March-May, for Export/Inflow ratio** (fall run):
 2261 Dayflow exports were averaged annually over March-May for years 1967-
 2262 2010 to form the historical export level for the Export/Inflow ratio (see Fig.
 2263 B.3 and Table B.2E for the Export/Inflow ratio).
- 2264 c. **Total daily exports December-June** (winter run): Dayflow exports were
 2265 summed over all days between December and June, then averaged over 1967-
 2266 2007 to form the mean historical export level, which was then modified for
 2267 scenarios (Fig. B.15, Table B.3A).
- 2268 9. Daily stream flows: Streamflow data are collected daily at select locations by USGS
 2269 (USGS National Water Information System website). In order to generate future
 2270 predictions for OCAP Study 9.2 and 9.5, the daily stream flow data had to be
 2271 correlated to an appropriate CalSim-II output using linear models.
- 2272 a. **Number of days Sacramento River flow at Verona > 56,000 cfs** (winter
 2273 run): A linear model was generated to relate CalSim-II monthly flows at
 2274 Verona (C160 from OCAP scenario NAA_Existing) for 1967-2003 averaged
 2275 over December-March, to the total number of days between December and
 2276 March that Sacramento River flow at Verona exceeded 56,000 cfs (data from
 2277 USGS National Water Information System website). The linear model is:
- 2278
$$\# \text{ Days flow} > 56,000 = -25.19 + \text{CalSim-II flow at Verona} * 0.001646$$
- 2279 with R-squared = 0.9285. This relationship was used in conjunction with
 2280 CalSim-II flows at Verona (C160) for December 1946-March 2003, averaged
 2281 over December-March, to generate future scenario values (projected onto
 2282 2007-2063) for number of days that Sacramento River flow at Verona exceeds
 2283 56,000 cfs (Fig. B.16, Table B.3B)
- 2284 10. Water management operations: Discharges from dams, weirs and gates are managed
 2285 in California to optimize diverse interests, including efforts to increase winter run
 2286 Chinook populations.
- 2287 a. **Proportion of time Delta Cross Channel gate is open, December-March**
 2288 (winter run): The current operations plan is to close the Delta Cross Channel
 2289 (DCC) gate while winter run Chinook are out-migrating. As a result, future
 2290 scenarios assume that the proportion of time that the DCC gate is open
 2291 between December and March is zero (Table B.3B).
- 2292 11. Parameters for which no future conditions could be generated:
- 2293 a. **Channel Depletion** (fall run): The net channel depletion is the quantity of
 2294 water removed from the Delta channels to meet consumptive use, averaged
 2295 over March-May. Since future population growth may be countered by water-
 2296 saving technologies and measures, we set the future value of channel depletion
 2297 equal to the mean value over 1967-2010 (or a standardized value of 0) (Table
 2298 B.2A).
- 2299 b. **Smolt Size at Chipps Island** (spring run): For this parameter, we assumed
 2300 that size of out-migrating smolt caught at Chipps Island will not change over

2301 future years, so smolt size for the scenario projections was set equal to mean
2302 size over 1967-2010 (standardized value of 0) (Table B.2A).
2303

2304 *ACKNOWLEDGEMENTS*

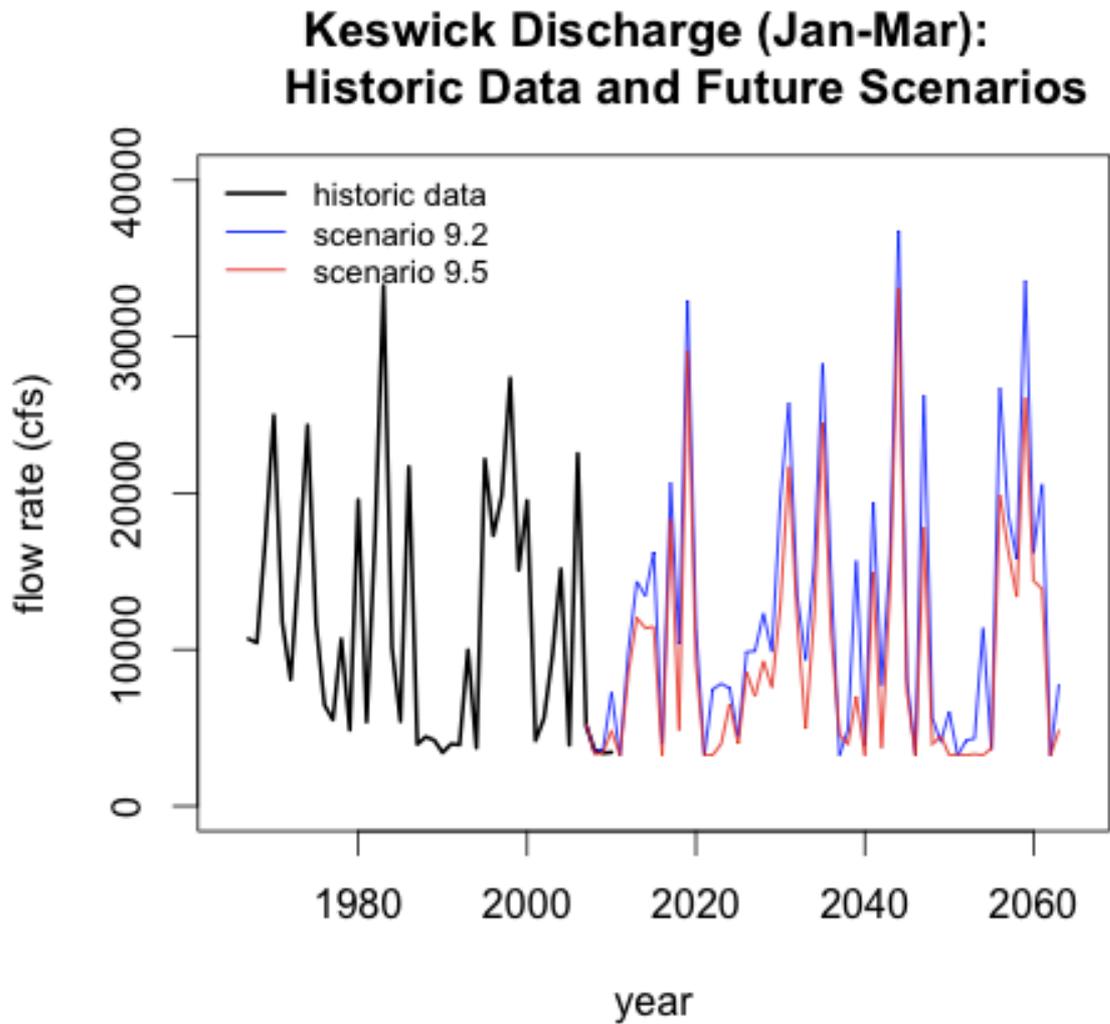

2305 We would like to thank Nate Mantua (NMFS – SWFSC) for advice on climate change
2306 impacts to physical characteristics of oceans, and Andrew Pike (NMFS – SWFSC) for his
2307 assistance with understanding and obtaining CalSim-II and SRWQM OCAP model outputs.
2308 For climate projection outputs that were used for scenario covariates, we acknowledge the
2309 modeling groups, the Program for Climate Model Diagnosis and Intercomparison (PCMDI)
2310 and the WCRP's Working Group on Coupled Modelling (WGCM) for their roles in making
2311 available the WCRP CMIP3 multi-model dataset. Support of the CMIP3 dataset is provided
2312 by the Office of Science, U.S. Department of Energy. Lastly, we thank Nate Mantua and
2313 Steve Hare for access to their historic PDO index values.

2350 FIGURES

2351

2352

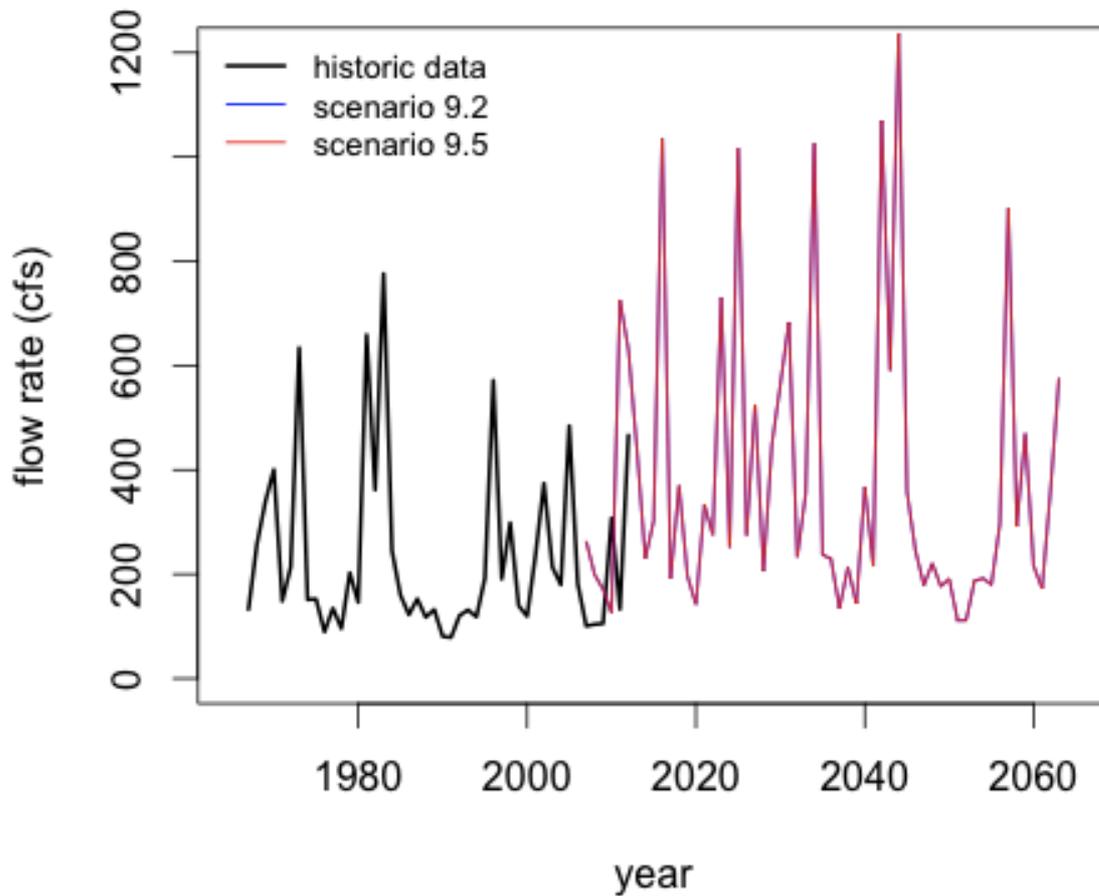

2353 **Figure B.1.** Mean annual discharge (cubic feet per second, cfs) from Keswick Dam for
 2354 January-March: historic data from 1967-2010 and climate change scenarios 9.2 and 9.5.
 2355 Climate change scenarios were based on CalSim-II OCAP Study 9.2 and 9.5 values from
 2356 1946-2002, which were projected forward to 2007-2063.

2357

2358

2359

Deer Creek Discharge (Oct-Dec): Historic Data and Future Scenarios

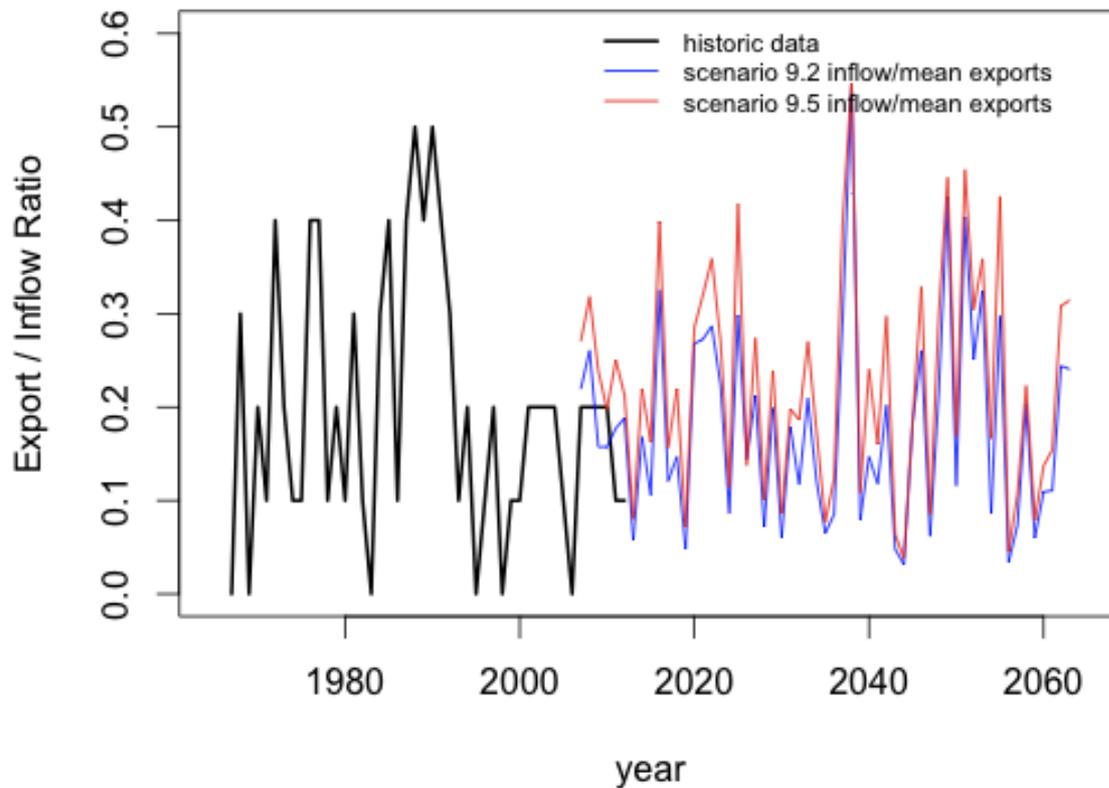

2360

2361 **Figure B.2.** Mean annual discharge (cfs) from Deer Creek for October-December: historic
 2362 data from 1967-2012 and climate change scenarios 9.2 and 9.5. Climate change scenarios
 2363 were based on CalSim-II OCAP Study 9.2 and 9.5 values from 1946-2002, which were
 2364 projected forward to 2007-2063. Note that there is no difference in projection values
 2365 between scenarios 9.2 and 9.5.

2366

2367

Ratio of Exports to Delta Inflow (Mar-May): Historic Data and Future Scenarios (Mean Exports)

2368

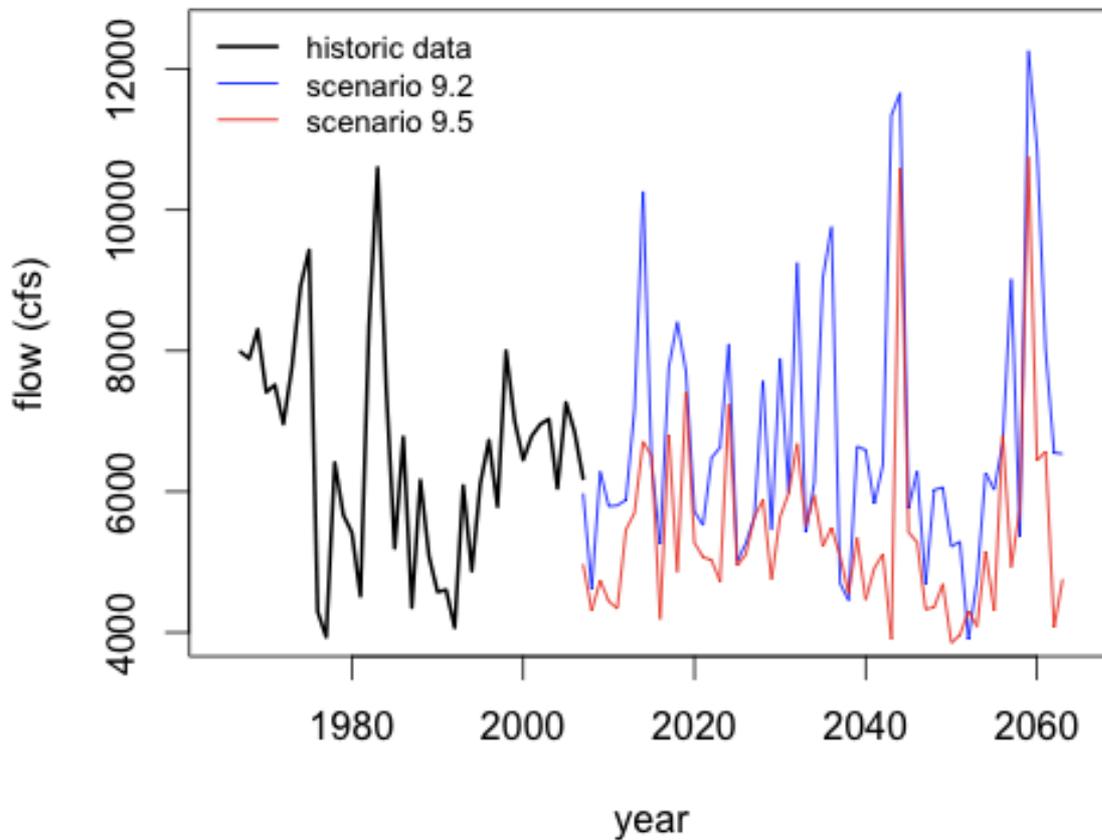

2369 **Figure B.3.** Exports to inflow ratio for the Delta, averaged over March-May: historic data
 2370 from 1967-2012 and climate change scenarios 9.2 and 9.5. Historic values are based on
 2371 Dayflow data $((QCVP + QSWP - BBID) / QTOT)$. Climate change scenarios use mean
 2372 exports from 1967-2010 for the numerator, and CalSim-II Delta inflow values from OCAP
 2373 Study 9.2 and 9.5 for the denominator. The CalSim-II Delta inflow values were from years
 2374 1946-2002, projected forward to 2007-2063.

2375

2376

2377

Bend Bridge Minimum Monthly Flow (Aug-Nov): Historic Data with Future Scenarios

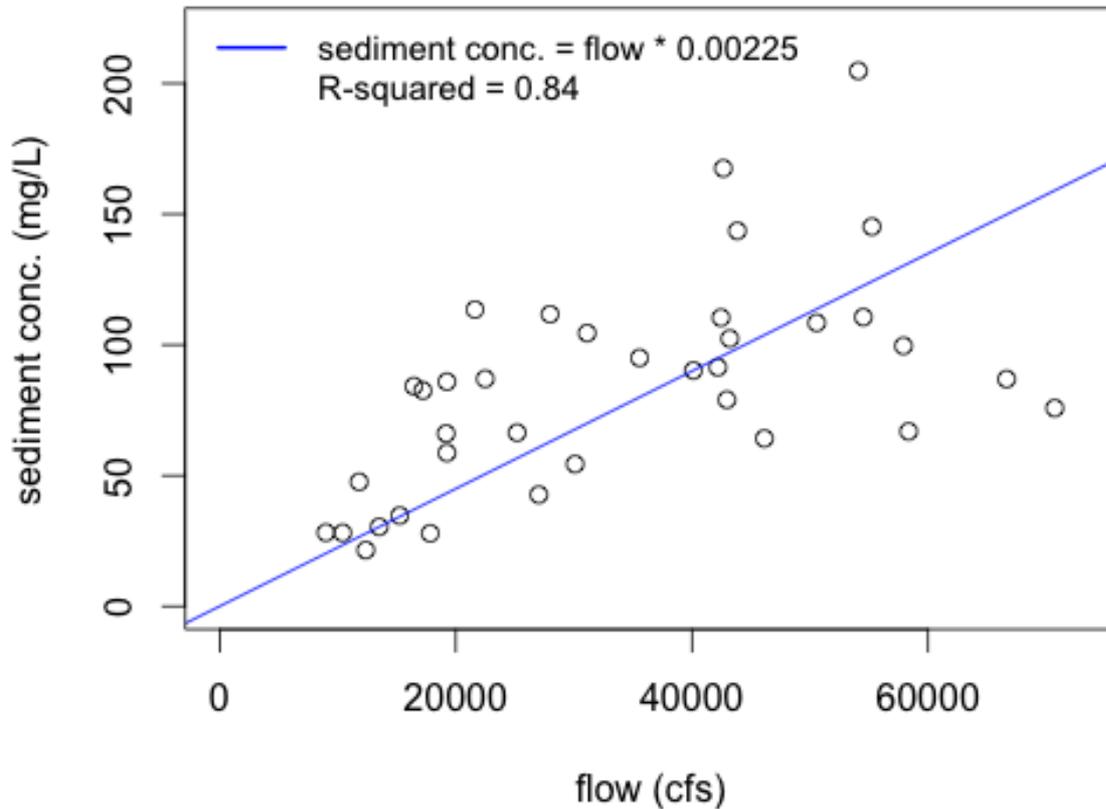

2378

2379 **Figure B.4.** Minimum monthly flow (cfs) at Bend Bridge for August-November: historic
 2380 data from 1967-2007 and climate change scenarios 9.2 and 9.5. Climate change scenarios
 2381 were based on CalSim-II OCAP Study 9.2 and 9.5 values from 1946-2002, which were
 2382 projected forward to 2007-2063.

2383

Freeport Monthly Sediment Concentration vs. Freeport Flow (Feb-Apr)

2384

2385

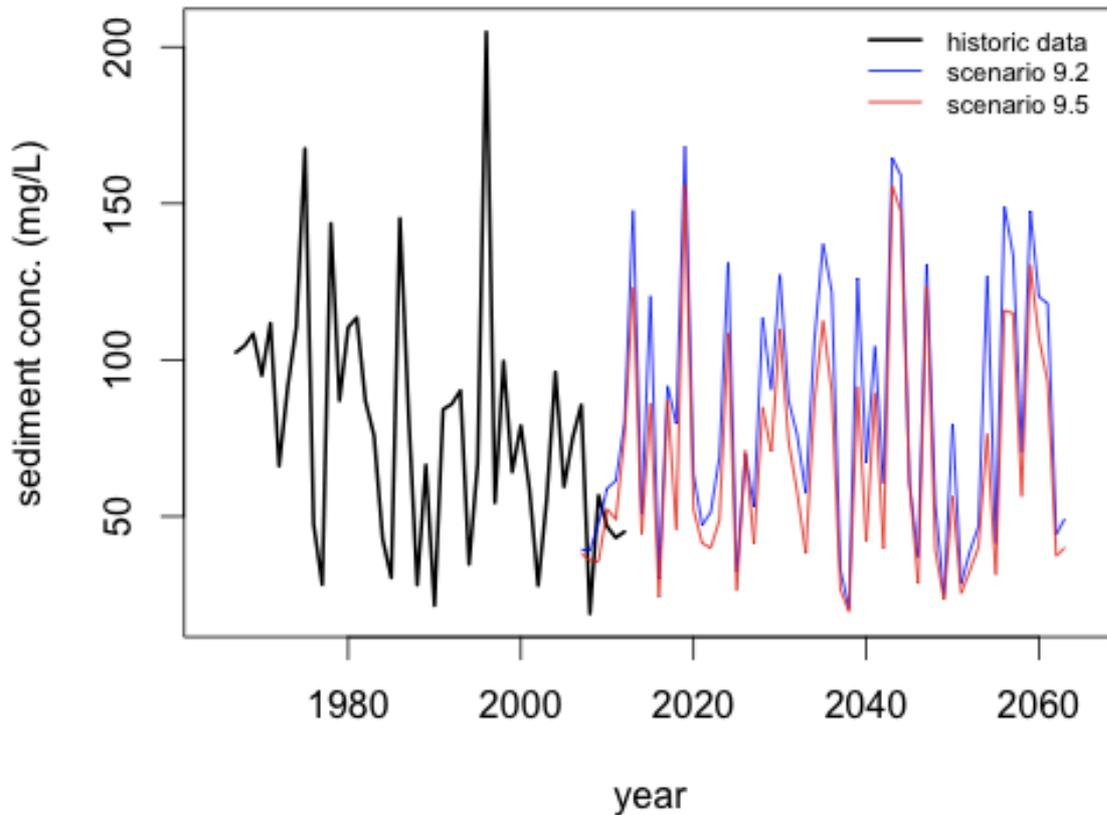

2386 **Figure B.5.** Average monthly sediment concentration (mg/L) at Freeport for years 1967-
 2387 2002, as a function of modelled Freeport flows (cfs) from CalSim-II OCAP scenario
 2388 NAA_Existing at node C169. Each point represents one year of data, averaged over months
 2389 February-April. A linear model was fit to the points, with a specified intercept of 0 (blue
 2390 line):

2391 $\text{Freeport sediment concentration} = \text{Freeport flow} * 0.0022487$

2392 The adjusted R-squared for the linear model is 0.84.

2393

Freeport Sediment Concentration (Feb-Apr): Historic Data and Future Scenarios

2394

2395 **Figure B.6.** Freeport sediment concentrations (mg/L) averaged over February-April: historic
 2396 data from 1967-2012 and climate change scenarios 9.2 and 9.5. Climate change scenario
 2397 values were obtained using Freeport flow predictions (at C169) from CalSim-II OCAP Study
 2398 9.2 and 9.5 for 1946-2002, and multiplying these values by 0.0022487 to correlate them to
 2399 sediment concentrations (see Fig. B.5). The 1946-2002 climate change scenario sediment
 2400 predictions were then projected forward to 2007-2063.

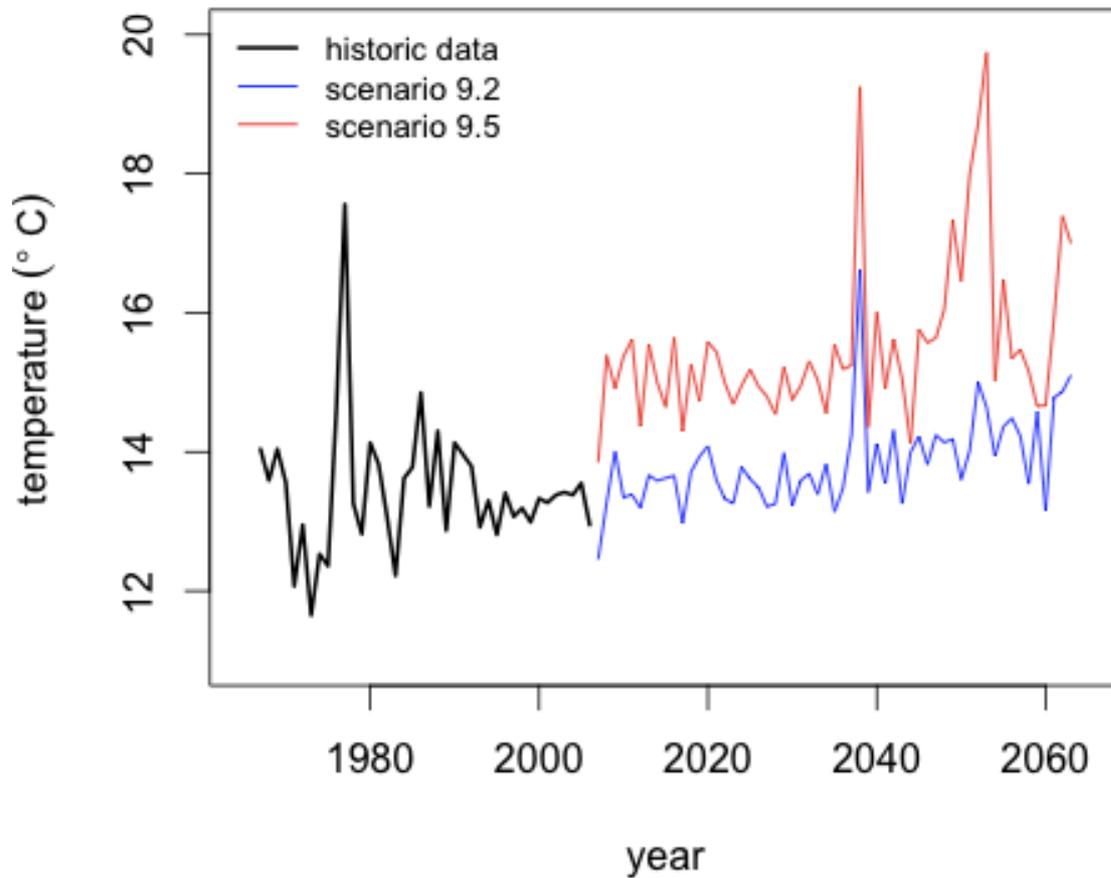

2401

2402

2403

2404

Bend Bridge Temperature (Jul-Sep): Historic Data with Future Scenarios

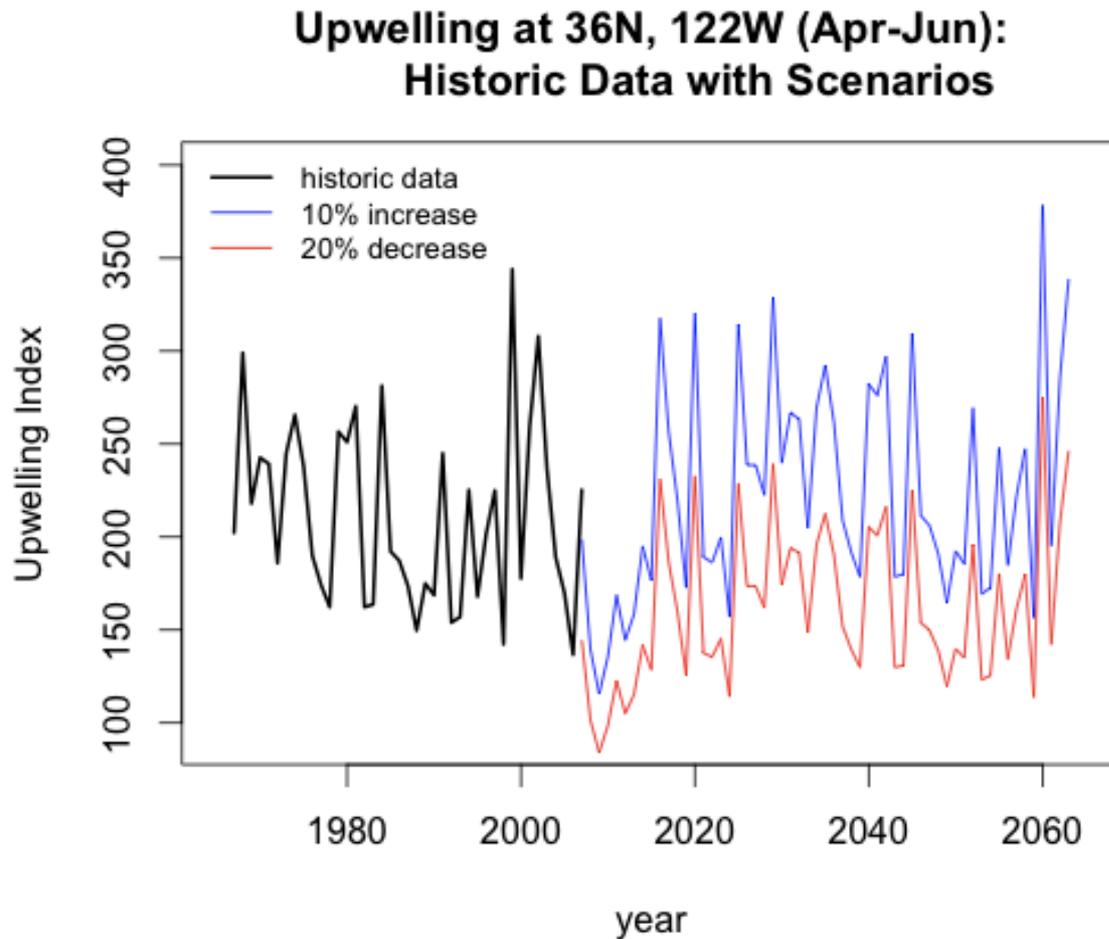

2405

2406 **Figure B.7.** Sacramento River average water temperature (° C) at Bend Bridge, averaged
 2407 over July-September: historic data from 1967-2006 and climate change scenarios 9.2 and 9.5.
 2408 Climate change scenarios were based on the SRWQM OCAP Study 9.2 and 9.5 values from
 2409 1946-2002, which were projected forward to 2007-2063.

2410

2411

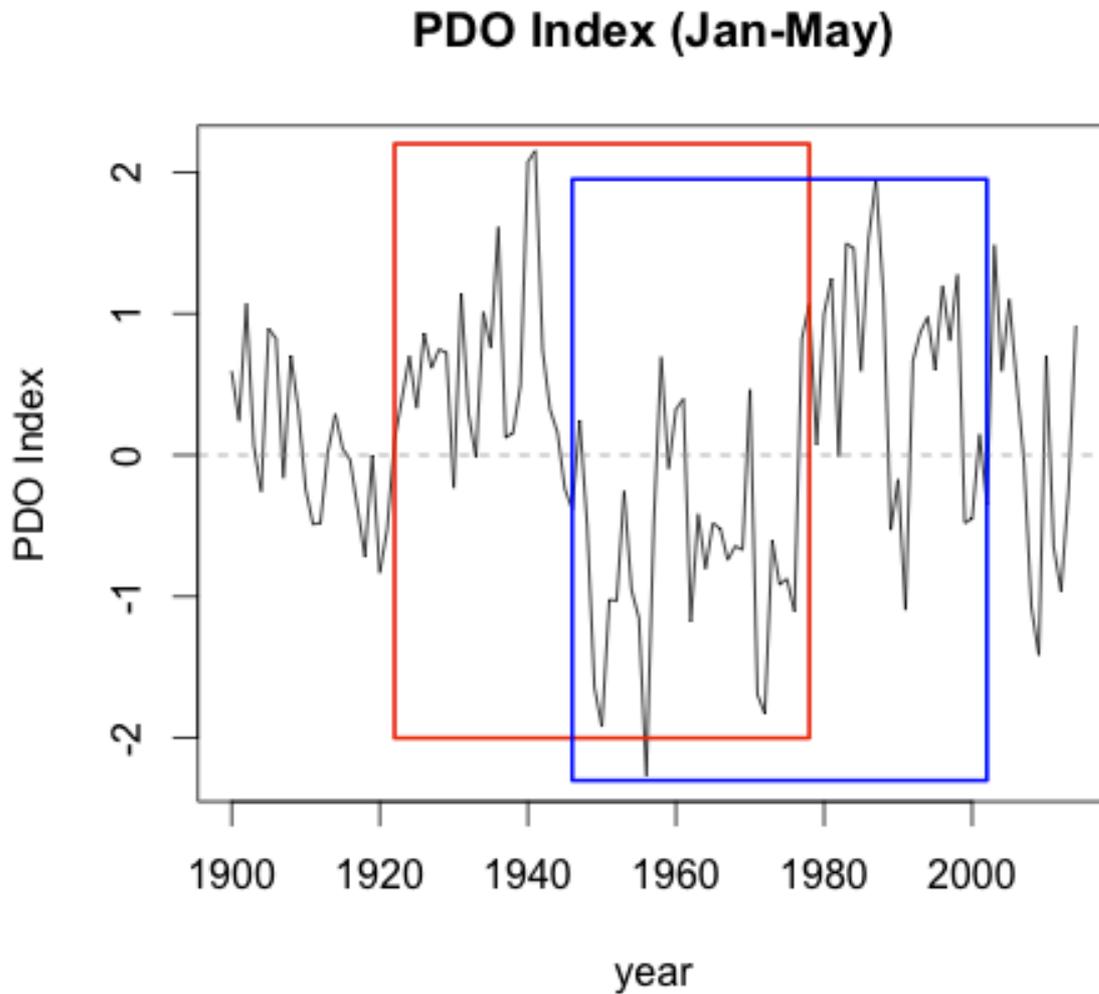

2412

2413 **Figure B.8.** NOAA upwelling index at station 36° N, 122° W averaged over April-June:
 2414 historic data from 1967-2007 and two climate change scenarios. Climate change scenarios
 2415 were based on historic upwelling values from 1946-2002, which were adjusted up (+20%) or
 2416 down (-10%) and projected forward to 2007-2063.

2417

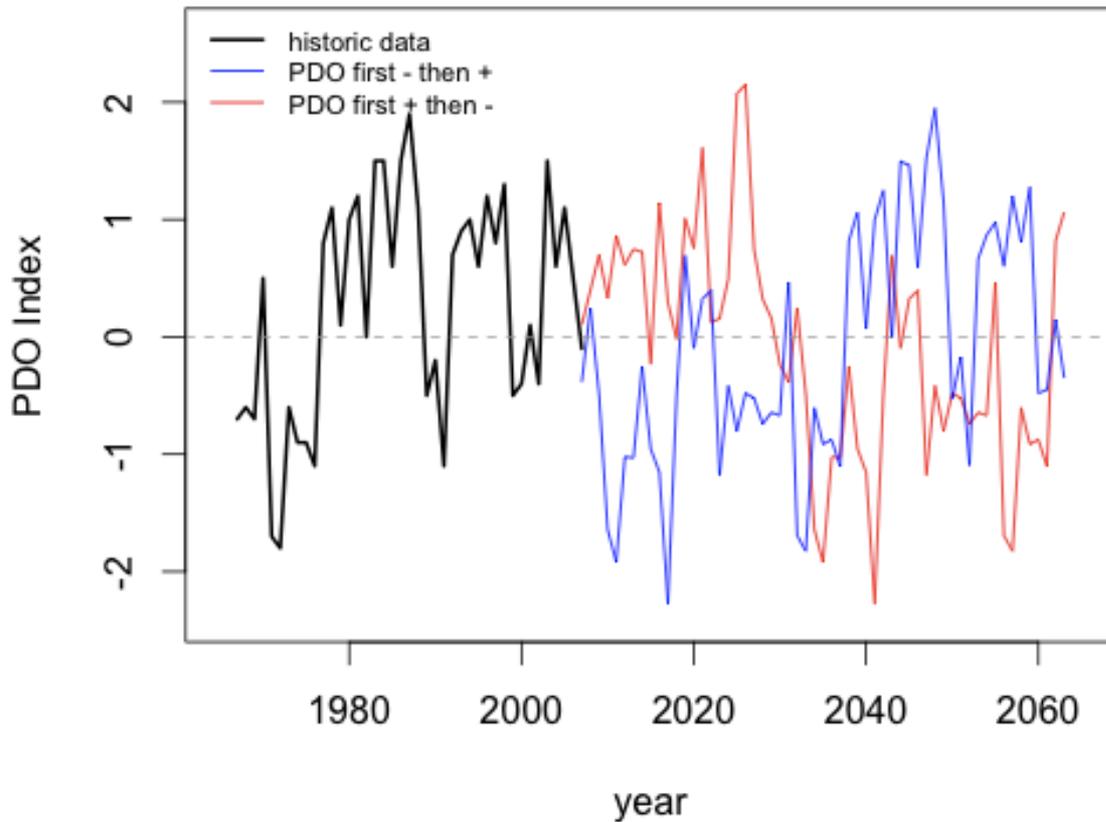

2418

2419

2420 **Figure B.9.** Historic values of the PDO index, averaged annually over January-May. West
 2421 coast salmon stocks have higher productivity during negative (cool) phases of the PDO, and
 2422 lower productivity during positive (warm) phases. The sequence of years from 1922-1978
 2423 (red box) was projected forward to 2007-2063 to represent a scenario where the PDO begins
 2424 in a positive cycle, while the sequence of years from 1946-2002 (blue box) was projected
 2425 forward to represent a scenario where the PDO begins in a negative cycle.

PDO Index (Jan-May): Historic Data and Future Scenarios

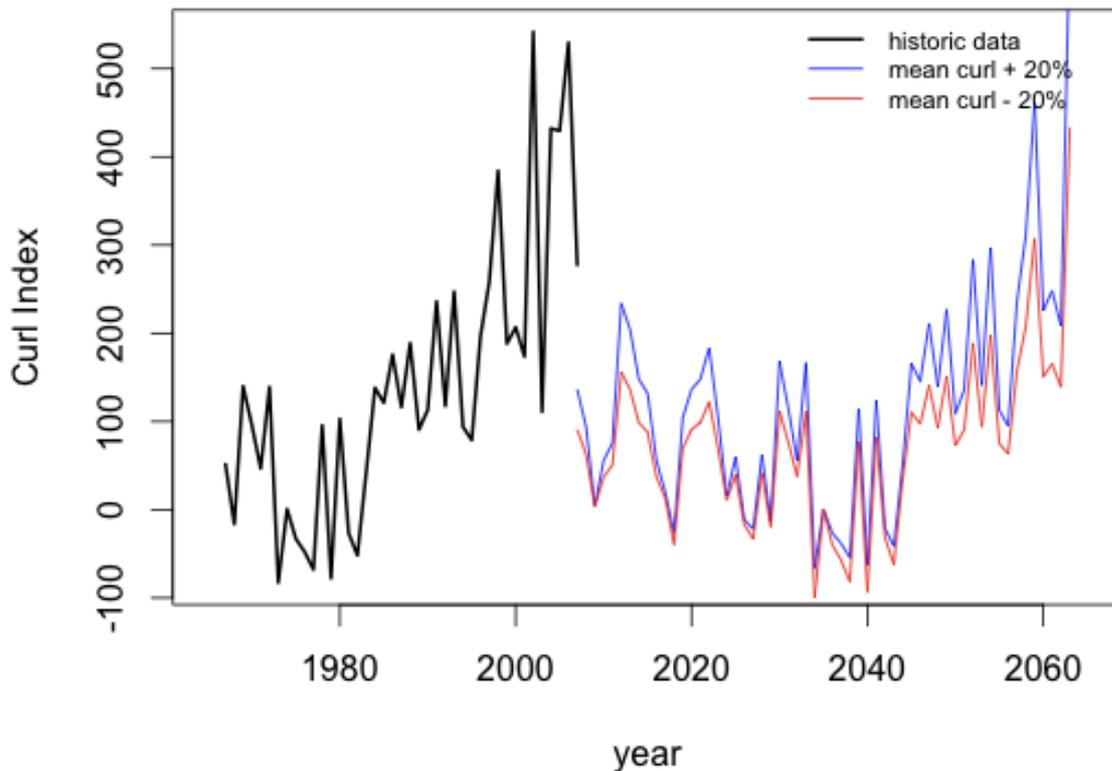

2426

2427 **Figure B.10.** PDO index averaged annually over January-May: historic data from 1967-2007
 2428 and two future scenarios. Future scenarios were projected onto 2007-2063 and consist of: 1.)
 2429 a historic sequence that begins with a negative PDO index, then flips to a positive PDO index
 2430 halfway through the time series (blue line: historic values from 1922-1978); and 2.) a historic
 2431 sequence that begins with a positive PDO index, then flips to a negative PDO index (red line:
 2432 historic values from 1946-2002).

2433

NOAA Wind Stress Curl Index (Jul-Dec): Historic Data and Potential Future Scenarios

2434

2435 **Figure B.11.** NOAA wind stress curl index averaged over July-December: historic data for
 2436 1967-2007 and potential scenario values. Potential scenario values were generated by
 2437 increasing (+20%) or decreasing (-20%) curl data from 1946-2002 according to the equations
 2438 below, then projecting the values onto 2007-2063:

2439
$$\text{Curl} + 20\% = \text{historic curl} + \text{abs value}(\text{historic curl}) * 0.2$$

2440
$$\text{Curl} - 20\% = \text{historic curl} - \text{abs value}(\text{historic curl}) * 0.2$$

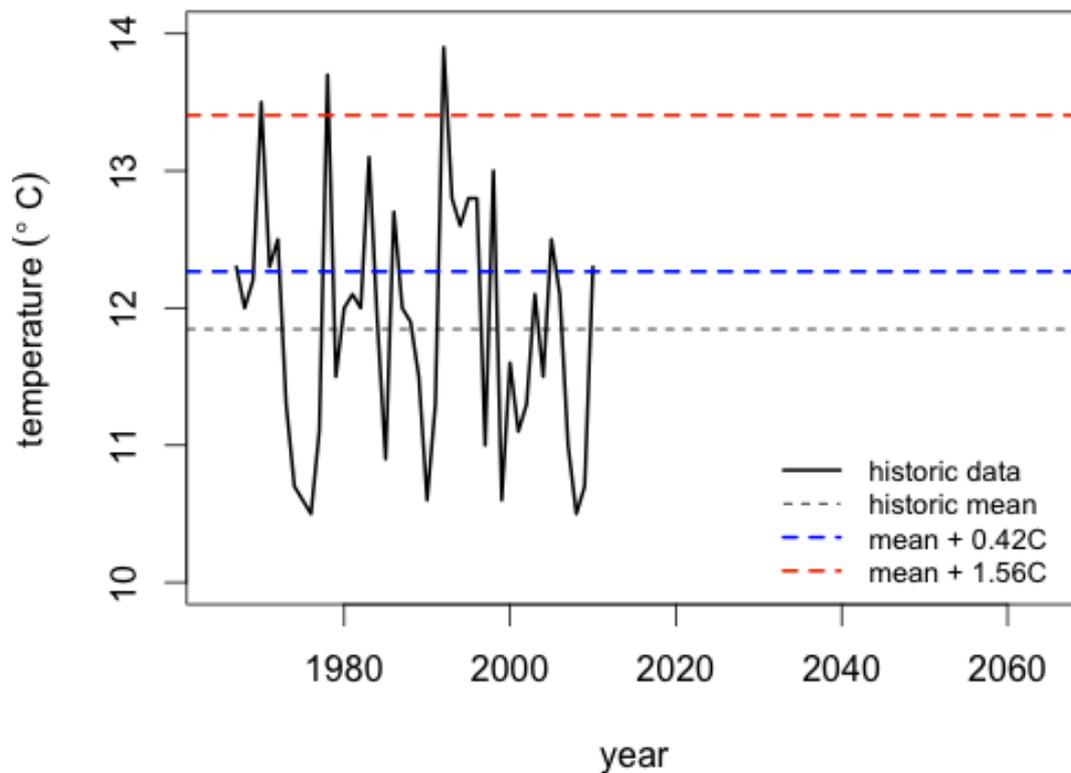

2441 Curl index trajectories from 1967-2063 suggest a long-term autocorrelation pattern. Because
 2442 we did not have compelling reasons to believe that future curl values would follow the same
 2443 pattern as historic values, we set the standardized curl projections for future scenarios to 0.

2444

2445

2446

Farallon Islands Ocean Temperature (Feb-Apr): Historic Data with Mean and Future Scenarios

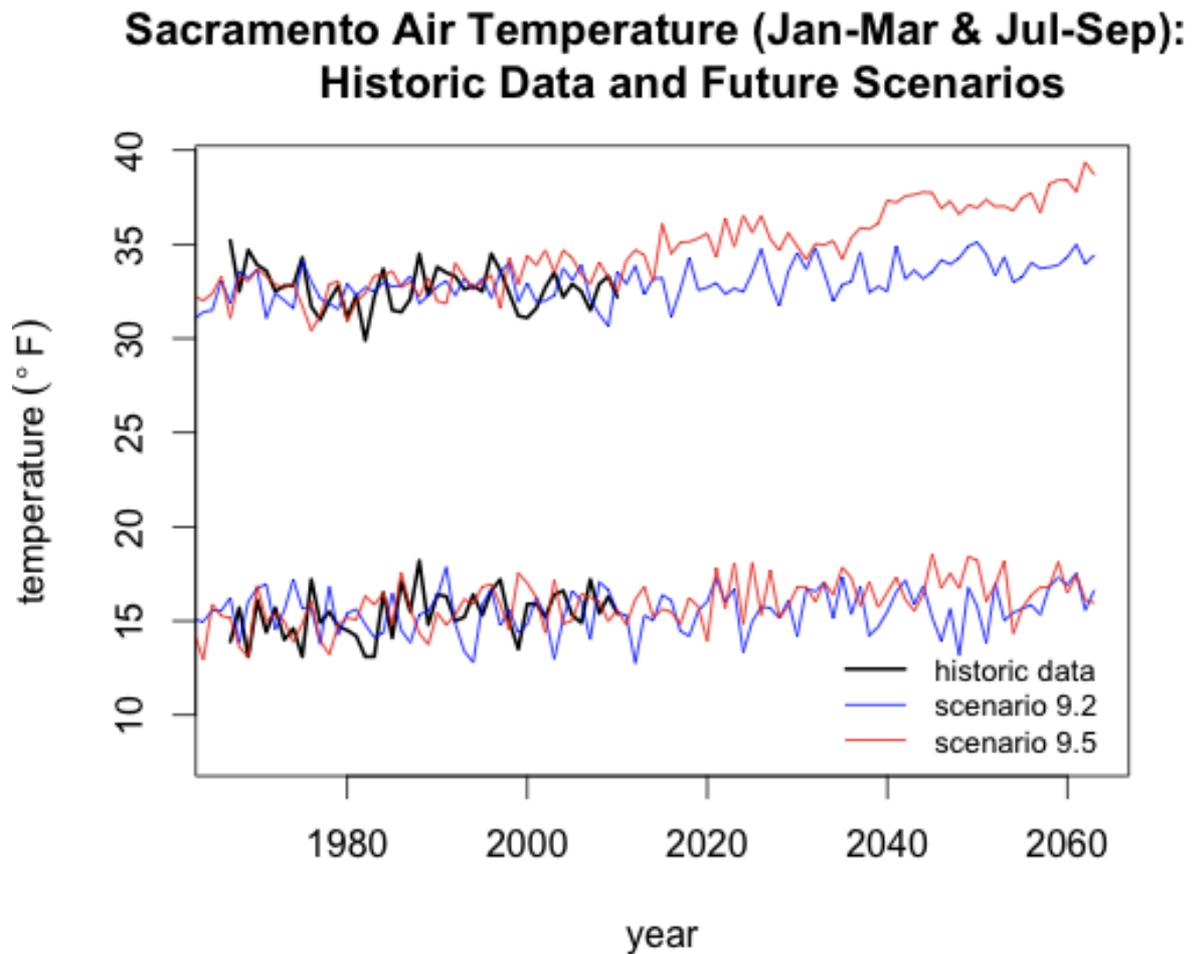

2447

2448 **Figure B.12.** Ocean temperature at the Farallon Islands averaged over February-April:
 2449 historic data with mean for 1967-2010, and two climate projections: mean +0.42° C (=0.75°
 2450 F, the average temperature increase for OCAP Study 9.2), and mean +1.56° C (=2.8° F, the
 2451 average temperature increase for OCAP Study 9.5).

2452

2453

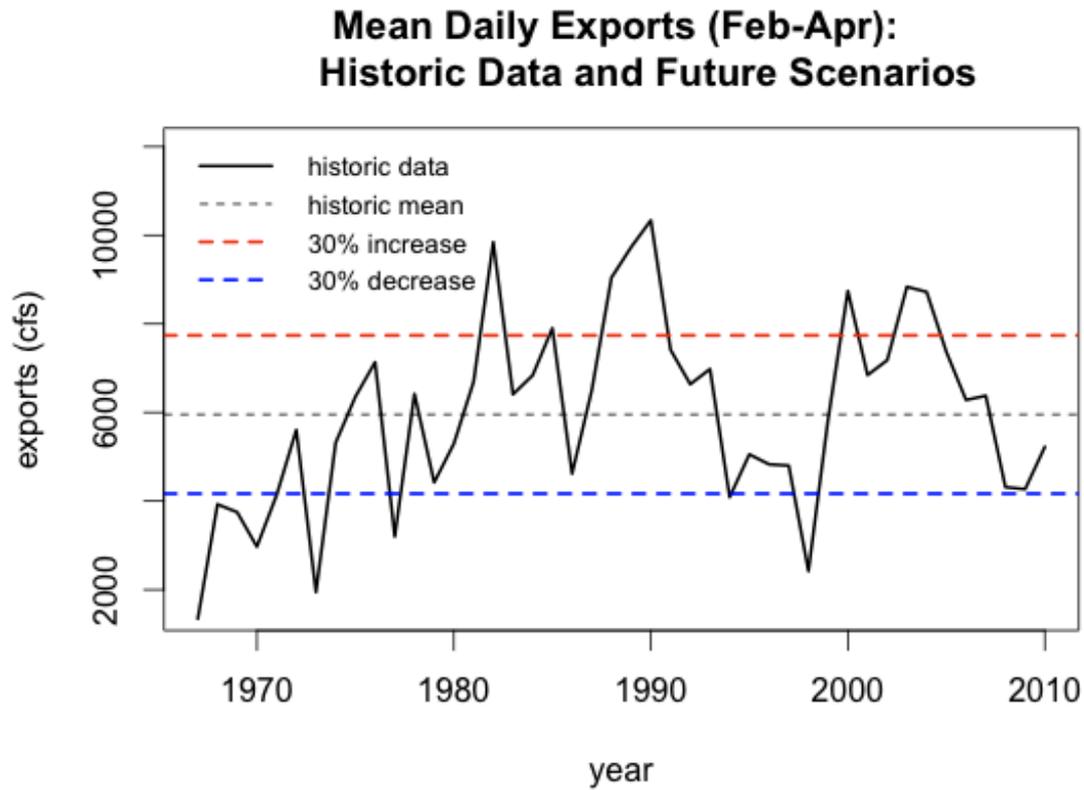

2454

2455

2456 **Figure B.13.** Sacramento air temperature averaged over spring months (January-March,
 2457 bottom lines) and summer months (July-September, top lines): historic data for 1967-2010,
 2458 and future climate change predictions based on CMIP3 climate projections. CMIP3 air
 2459 temperature predictions for the model cell over Sacramento were adjusted by + 4.55° F for
 2460 the spring, and + 8.82° F for the summer, to spatially downscale climate projections from
 2461 1967-2010 to match the range of historic Sacramento air temperature data.

2462

2463

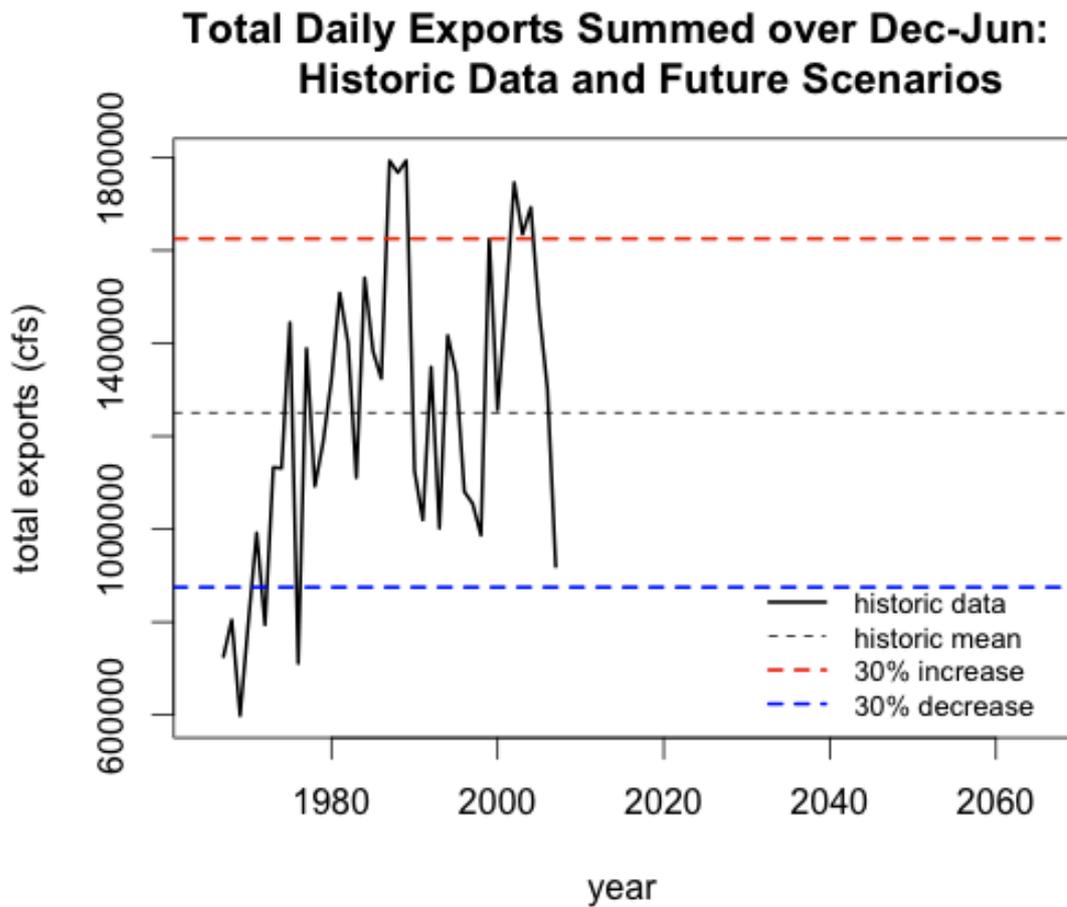

2464 **Figure B.14.** Mean daily exports (cfs) averaged annually from February-April: historic data
 2465 and future scenarios. Scenarios represent the following options: mean exports (1967-2010),
 2466 zero exports, mean exports + 30%, mean exports - 30%.

2467

2468

2469

2470

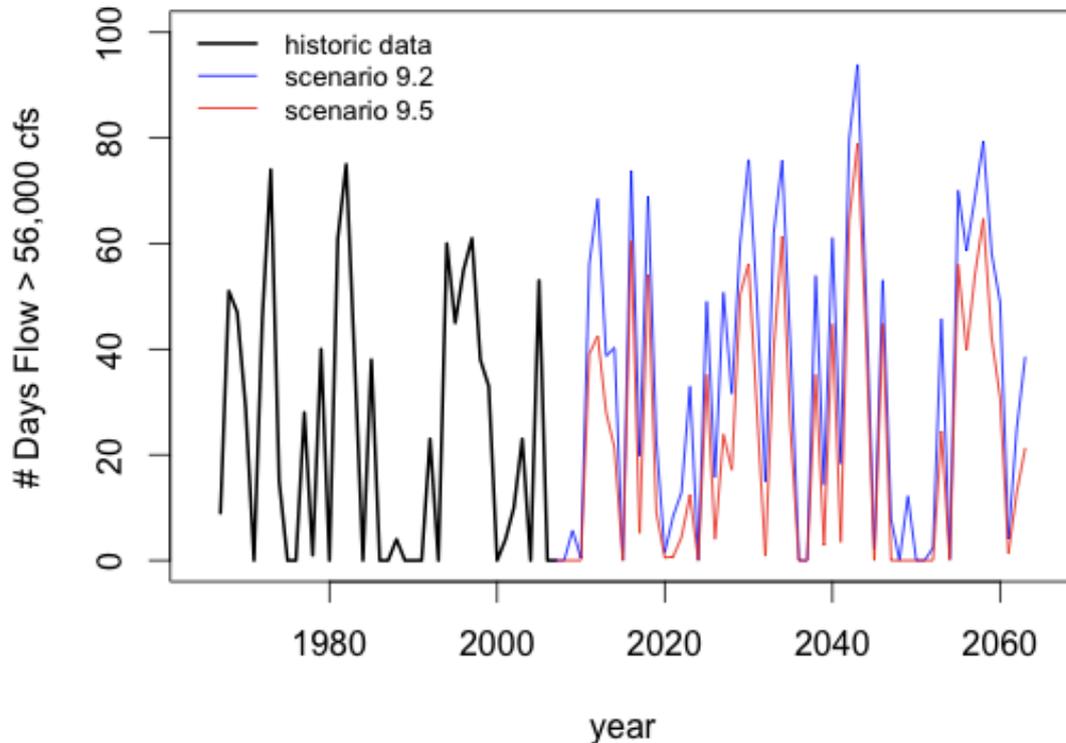

2471

2472 **Figure B.15.** Total daily exports summed over December-June: historic data and future
 2473 scenarios. Scenarios represent the following options: mean total exports (1967-2010), zero
 2474 exports, mean total exports + 30%, mean total exports - 30%.

2475

Number of Days Flow at Verona > 56,000 cfs (Dec-Mar): Historic Data with Future Scenarios

2476

2477 **Figure B.16.** Total number of days from December-March that Sacramento River flow at
 2478 Verona exceeds 56,000 cfs: historic data from 1967-2007 and climate change scenarios 9.2
 2479 and 9.5. Climate change scenario values were obtained using Verona flow predictions (at
 2480 C160) from CalSim-II OCAP Study 9.2 and 9.5 for 1946-2002 averaged over December-
 2481 March, and adjusting these values per the linear model:

2482
$$\# \text{ Days flow} > 56,000 = -25.19 + \text{CalSim-II flow at Verona} * 0.001646$$

2483 to correlate them to the number of days that flow exceeds 56,000 cfs. The 1946-2002 climate
 2484 change scenario predictions were then projected forward to 2007-2063.

2485

2486

2487

2488 **TABLES**2489 **Table B.1.** Scenario list with values drawn for each category of covariate.

2490

	OCAP Study	Upwelling	Farallon Temp	PDO Index	Exports
Scenario 1	9.2	+ 10%	+ 0.42° C	- then +	Mean Level
Scenario 2	9.2	- 20%	+ 1.56° C	+ then -	Mean Level
Scenario 3	9.2	+ 10%	+ 0.42° C	- then +	Zero
Scenario 4	9.2	- 20%	+ 1.56° C	+ then -	Zero
Scenario 5	9.2	+ 10%	+ 0.42° C	- then +	Mean + 30%
Scenario 6	9.2	- 20%	+ 1.56° C	+ then -	Mean + 30%
Scenario 7	9.2	+ 10%	+ 0.42° C	- then +	Mean - 30%
Scenario 8	9.2	- 20%	+ 1.56° C	+ then -	Mean - 30%
Scenario 9	9.5	+ 10%	+ 0.42° C	- then +	Mean Level
Scenario 10	9.5	- 20%	+ 1.56° C	+ then -	Mean Level
Scenario 11	9.5	+ 10%	+ 0.42° C	- then +	Zero
Scenario 12	9.5	- 20%	+ 1.56° C	+ then -	Zero
Scenario 13	9.5	+ 10%	+ 0.42° C	- then +	Mean + 30%
Scenario 14	9.5	- 20%	+ 1.56° C	+ then -	Mean + 30%
Scenario 15	9.5	+ 10%	+ 0.42° C	- then +	Mean - 30%
Scenario 16	9.5	- 20%	+ 1.56° C	+ then -	Mean - 30%

2491

2492

2493

2494

2495

2496 **Table B.2A.** Fall and spring covariate values for Sacramento air temperature, channel
 2497 depletion and smolt size at Chipps Island.
 2498

Year	Sacramento Air Temp (°F, Jan-Mar)		Sacramento Air Temp (°F, Jul-Sep)		Channel Depletion (cfs, Mar-May)	Size at Chipps Island (mm, Jan)

2572

2573 **APPENDIX C: GROWTH ANALYSIS AND MODELLING**

2574 In this appendix we provide a description of the methods we used to collect and
 2575 analyze length information from various state and federal collection facilities in the
 2576 Sacramento drainage. We assembled time series of lengths, both upstream and downstream,
 2577 for both hatchery fish and combined hatchery and wild aggregates. Where possible, we used
 2578 upstream and downstream lengths to obtain annual growth estimates. In the absence of a
 2579 downstream growth measurement, we assembled a time series of downstream lengths. We
 2580 performed regressions on growth and length estimates, evaluating impacts of environmental
 2581 conditions on growth.

2582 *INTRODUCTION*

2583 The life-cycle modeling analysis in this project attempts to attribute variability in
 2584 survival to environmental factors during different parts of the life history. Survival can be
 2585 affected by the environment in complex ways, and can be mediated through biotic and abiotic
 2586 processes. We posit that size can play a role in predicting survival, and that growth itself can
 2587 be an indicator of survival as well. An obvious mechanism for size effects on survival would
 2588 be that larger fish are less vulnerable to predation than smaller fish. A mechanism for growth
 2589 being a predictor of survival would be that faster growing fish are likely to be experiencing
 2590 better feeding conditions and bioenergetic advantages, and therefore should survive better.

2591 In this appendix we look for relationships between environmental conditions and
 2592 growth, but because growth requires two measurements (a capture and a recapture, or a
 2593 release and recapture), we are not always able to get an estimate of a growth increment. Some
 2594 length estimates obtained from survey data cannot be connected to later surveys, and
 2595 therefore a growth estimate can't be derived from the measurements. An example of this
 2596 occurs with rotary screw traps operating in tributaries, where juvenile size samples are
 2597 obtained during rearing and migration. Those sizes are not directly comparable to later
 2598 samples obtained downstream, because the downstream samples are aggregates of all the
 2599 independent upstream sampled lengths. We might be able to document a pattern in upstream
 2600 sizes over the years, but growth to the downstream measurement can't be inferred. We
 2601 therefore treat size as a surrogate for growth, with the assumption that annual variability in
 2602 juvenile size is in actual fact a measurement of annual variability in growth since all fish must
 2603 at some point have emerged from the gravel at roughly the same sizes.

2604 *METHODS*

2605 We performed an analysis of length and growth patterns for Spring and Fall run
 2606 Chinook in the Sacramento River in relation to environmental factors. We collected size at
 2607 release and recapture data from state and federal agencies. We compiled records into average
 2608 sizes at release for several different stock aggregates that provided adequate sample sizes for
 2609 the years the data were available. In some case, it was possible to associate the length of a
 2610 downstream recaptured fish with a known upstream release size to obtain a growth increment

2611 estimate, but in other cases only the downstream size record was available. Upstream length
 2612 records were obtained from hatchery release information, from screw traps operated in
 2613 tributaries, and from seine surveys operated throughout the Sacramento drainage. The farthest
 2614 downstream sizes were obtained from Chipps Island, where mid-water trawl surveys
 2615 collected size information and recorded the race of the fish based on the presence of a CWT
 2616 or a length based estimated based on the length of the fish at the time the sample was
 2617 obtained.

2618 *Data compilation*

2619 *Length data*

2620 The Pacific States Marine Fisheries Commission manages and supports the Regional
 2621 Mark Processing Center (RMPC; <http://www.rmpc.org/>), which in turn manages the Regional
 2622 Mark Information System (RMIS). Agencies and organizations throughout the Western
 2623 United States report CWT data directly to the RMIS. The Delta Juvenile Fish Monitoring
 2624 Program (DJFMP) was initiated in the 1970s and is managed by the US Fish and Wildlife
 2625 Service (USFWS, 2014). The program has a stated objective to monitor the effects of water
 2626 projects in the Bay Delta on juvenile Chinook.

2627 The number of juvenile salmon leaving freshwater during the spring has been sampled
 2628 annually since 1978 by means of mid-water trawling in the estuary near Chipps Island
 2629 (Brandes and McLain 2001). The Trawl site in Suisun Bay is sampled three days per week
 2630 year round. It is sometimes sampled daily and at times two shifts per day for a total of 20
 2631 tows per day during May and June. During December and January, trawls occur 7 days per
 2632 week with ten 20 minute trawls conducted daily. Catch limits are imposed when Delta Smelt
 2633 catches exceed 8 individual Delta Smelt. The trawl survey records fish length at capture and
 2634 creates a record of the race, origin and release location if a coded wire tag is detected.

2635 We used data that had been collected since 1979 in mid-water boat trawls at Chipps
 2636 Island, Suisun Bay (Zone 10 S UTM, 4211218N, 595531E). Data from the DJFMP is
 2637 available online (<http://www.fws.gov/stockton/jfmp/>). USFWS tables available online
 2638 contained metrics of juvenile Chinook salmon that had been marked with CWTs, released
 2639 throughout the Sacramento - San Joaquin Basin and then recovered near Chipps Island in
 2640 Suisun Bay (*Coded Wire Tag 1978 -2011.xls* and *Coded Wire Tag 2012 -2013.xls*). Survey
 2641 records not containing CWTs can be found in the spreadsheets *Chipps Island Trawls 1976-*
 2642 *2011.xlsx* and *Chipps Island Trawls 2012-2014.xlsx*.

2643 We used the records from the Chipps Island trawls to create a database of fish lengths
 2644 and growths increments for all fish with CWTs (referred to as the CWT table). Each fish with
 2645 a CWT is of a known origin, so the race and the source (hatchery or wild stock origin) are
 2646 also known. We used the remaining records from the Chipps Island survey to construct a
 2647 database table of Chinook known to be of a given race, but where the origin is not known.
 2648 These records were assembled into a table we refer to as the TRAWL table, which only
 2649 distinguishes between Fall and Spring runs.

2650 We compiled juvenile salmon length data from the Sacramento watershed and the San
 2651 Francisco Bay Delta into a relational database in order to determine growth of hatchery Fall
 2652 Chinook and hatchery and wild juvenile Spring Chinook. Wild Spring stocks included Deer,
 2653 Mill and Butte creeks. Butte Creek fish were release and recaptured in Butte Creek, the Sutter

2654 Bypass or near Chipps Island in Suisun Bay. Release and recovery data were compiled from
 2655 three sources: California Department of Fish and Wildlife (CDFW), US Fish and Wildlife
 2656 Service's Delta Juvenile Fish Monitoring Program (DJFMP) and the Regional Mark
 2657 Processing Center (RMPC).

2658 From 1995 to 2001, the CDFW captured, measured, marked, and released wild
 2659 spring-run Chinook on Butte Creek (CDFG, 1999; CDFG, 2004-2; CDFG, 2004-3). The
 2660 purpose of the CDFW program was to estimate adult escapement, monitor timing and
 2661 abundance of juvenile outmigration, and monitor relative growth rates in the Butte Creek
 2662 system. Fish were captured and marked with adipose fin clips and coded wire tags at the
 2663 Parrot-Phelan Diversion Dam (PPDD; Zone 10 S UTM, 4396287N, 611463E). Releases
 2664 took place at three locations, but varied from year to year. Release sites were: PPDD,
 2665 Baldwin Construction Yard (approximately one mile downstream of the PPDD) and Adams
 2666 Dam (approximately 7 miles downstream of PPDD). After release, marked fish were subject
 2667 to recapture and sacrifice at downstream locations in Butte Creek, the Sutter Bypass and the
 2668 Sacramento Delta near Chipps Island. Rotary screw traps were used to recapture fish at all
 2669 locations and an off-stream fish screen outfitted with a trap box was used to collect fish at the
 2670 PPDD site. Recaptured fish were sacrificed, measured for fork length and their CWTs were
 2671 extracted and read. We received programmatic data formatted in a Microsoft Access
 2672 database directly from the CDFW (C. Garman, personal communication, 1/30/2014).

2673 We queried the RMIS database for juvenile Chinook that had been marked and
 2674 released at any location in the Sacramento drainage. The RMIS table was then related by
 2675 CWT code to Chipps Island mid-water trawl and Sacramento River recoveries. In this way,
 2676 we queried recoveries with release locations only within the Sacramento Basin.

2677 We obtained tributary measurements of juvenile lengths from rotary screw traps
 2678 (RSTs) operating in Butte creek, Mill creek and Deer creek. Rotary screw traps were operated
 2679 by the US Fish and Wildlife Service in Mill and Deer creeks, and by the California
 2680 Department of Fish and Wildlife in Butte creek. Screw trap operation spanned 1995-2010 in
 2681 the records used in this analysis. We used samples obtained from January to June of each
 2682 year to obtain estimates of tributary outmigration size.

2683 ***Environmental data***

2684 We compiled time series of environmental variables that pertain to the experiences of
 2685 downstream migration juveniles. For Spring Run, we used discharge at the three creeks
 2686 (Deer, Mill and Butte), flow, exports volumes and other export indices, and a CPUE index of
 2687 bass abundance. Flow temperature and discharge were obtained from USGS gauging stations
 2688 (<http://waterdata.usgs.gov/nwis/inventory>). Exports and other dayflow parameters were
 2689 obtained from water project data available on the California department of water resources
 2690 website (<http://www.water.ca.gov/dayflow/output/Output.cfm>). Environmental variables
 2691 were normalized by subtracting the mean and dividing by the standard deviation. The
 2692 variables are summarized in Table C.1 for Spring run and in Table C.2 for Fall run.

2698 *Length and Growth analysis*

2699 We examined environmental factors affecting length at recapture at Chipps Island of
 2700 fish with known and unknown release lengths. Where length at release was known, we
 2701 examined growth rates. We associated each size and growth record with environmental
 2702 factors experienced by each race of salmon each year the sizes were recorded. We compared
 2703 fall and spring length at capture at Chipps Island from two separate surveys. The CWT table
 2704 provided an estimate of growth for fall and spring hatchery releases. The mid-water trawls
 2705 did not distinguish between wild and hatchery fish, so those analyses pertain to the race as a
 2706 whole, without distinction about release locations or wild/hatchery distinctions. We also
 2707 obtained sizes from DJFMP seines in Region 1 (upstream from the Delta) and compared
 2708 those sizes with Chipps Island size information. Since seine samples do not distinguish
 2709 between populations, growth obtained from subtracting upstream seine sizes from Chipps
 2710 Island trawl sizes provide estimates of aggregate Fall and Spring run sizes, but cannot
 2711 distinguish between release locations or between wild and hatchery releases.

2712 **SEINE/TRAWL - growth by race from mid-Sacramento to Chipps Island.**

2713 We queried the DJFMP seine database to obtain estimates of growth for Spring and
 2714 Fall runs. Region 1 of the DJFMP beach seine runs from Colusa State Park to Elkhorn. We
 2715 averaged lengths of Spring and Fall seine lengths for each year for fish collected between
 2716 January and June, and compared those to Chipps Island midwater trawl sizes. The trawl
 2717 survey assigned fish to Fall and Spring runs based on size ranges and records indicated that
 2718 all collections occurred in May and June. We calculated the growth for each race of fish each
 2719 year as the difference between the average trawl length and the average seine length. We
 2720 refer to these growth estimates as the SEINE/TRAWL dataset.

2721 We examined growth patterns in relation to environmental variables listed in Tables
 2722 C.1 and C.2. We performed stepwise linear regressions of growth in relation to each variable,
 2723 adding variables according to best p-value, and stopping when no further significant variables
 2724 were found.

2725 **CWT –growth and length by hatchery source.**

2726 When hatchery fish are released, the average size of a sample of the release batch is
 2727 used as the release length of record for fish in the batch. When recaptures occur at Chipps
 2728 Island, a record for each fish recaptured can be compared to a release length record on the
 2729 basis of CWT codes. To get reasonable sample sizes for recaptures, we were forced to
 2730 aggregate hatchery releases such that release locations were ignored. We aggregated all
 2731 release locations within the Sacramento drainage for each hatchery source. Since a release
 2732 batch contains a range of lengths, it is possible for the smallest recaptured fish to be smaller
 2733 than the average released fish. The growth record for each year was calculated as the average
 2734 of all the recapture lengths minus the average release length. The average of release length
 2735 was calculated as the weighted release length, weighted by the number released at each
 2736 location at each time of release. We refer to the length and growth estimates from this method
 2737 as the CWT dataset.

2738 We tested for statistical relationships between size at recapture and environmental
 2739 variables for Spring and Fall hatchery releases from Coleman National Fish Hatchery
 2740 (CNFH) and Feather Fish Hatchery (FFH). We examined growth and length patterns in
 2741 relation to environmental variables listed in Tables C.1 and C.2. We performed stepwise
 2742 linear regressions of growth and length in relation to each variable, adding variables
 2743 according to best p-value, and stopping when no further significant variables were found.

2744 **TRAWL – length by race at Chipps Island.**

2745 We selected records that were not limited to CWT tagged fish (the TRAWL dataset in
 2746 this analysis) from Chipps Island, and assembled all records of Spring and Fall chinook to
 2747 look at the size. By not being limited to CWT matches, the sample size was much larger than
 2748 for the CWT matched database, but for the TRAWL dataset, the origin of fish could not be
 2749 determined. The race of the fish was assigned by a length/timing criteria established by the
 2750 DJFMP (the “Race Table” found at www.fws.gov/stockton/jfmp). Using these records we
 2751 looked for temporal trends, comparisons between Spring and Fall runs, and relationships
 2752 between size at capture and environmental factors. Annual average size records for Spring
 2753 and Fall Chinook do not distinguish between hatchery and wild, and there is no growth
 2754 estimate because the size at release is not known, and there is no way to distinguish between
 2755 Butte, Mill, and Deer creeks. The TRAWL dataset provides an aggregate estimate of length
 2756 at Chipps Island by race alone.

2757 We examined growth patterns in relation to environmental variables listed in Tables
 2758 C.1 and C.2. We performed stepwise linear regressions of length in relation to each variable,
 2759 adding variables according to best p-value, and stopping when no further significant variables
 2760 were found. We treat length as a surrogate for growth on the assumption that some initial
 2761 length can be treated as a constant across and all variability can be thought of as occurring
 2762 after that initial length.

2763 **RST – Lengths in tributaries**

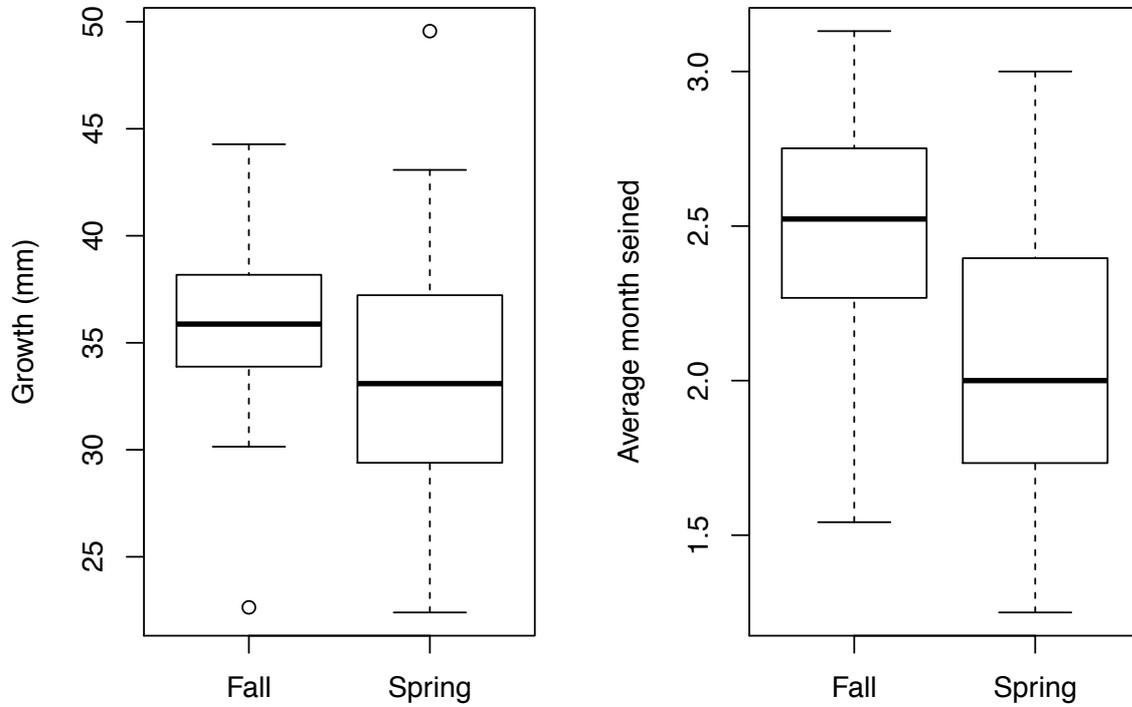

2764 Deer, Mill, and Butte creek rotary screw trap records were queried to obtain estimates
 2765 of out-migrating juvenile sizes. We took the average size of all samples obtained from the
 2766 traps between January and June of each migration year. We attempted to match CWT
 2767 releases from Butte Creek each year to recoveries within the Sacramento basin to obtain
 2768 growth estimates at various sample locations, but found that recoveries were too few to
 2769 obtain good estimates of growth. Butte Creek CWT release records with Chipps Island
 2770 recapture events began in 1996, but recaptures amounted to fewer than 10 fish per year at
 2771 Chipps Island. It was not possible to relate RST lengths to downstream lengths at Chipps
 2772 Island for a growth estimate. We therefore limited our examination of RST data to showing
 2773 temporal trends of sizes of Deer, Mill and Butte creeks.

2774 *RESULTS*

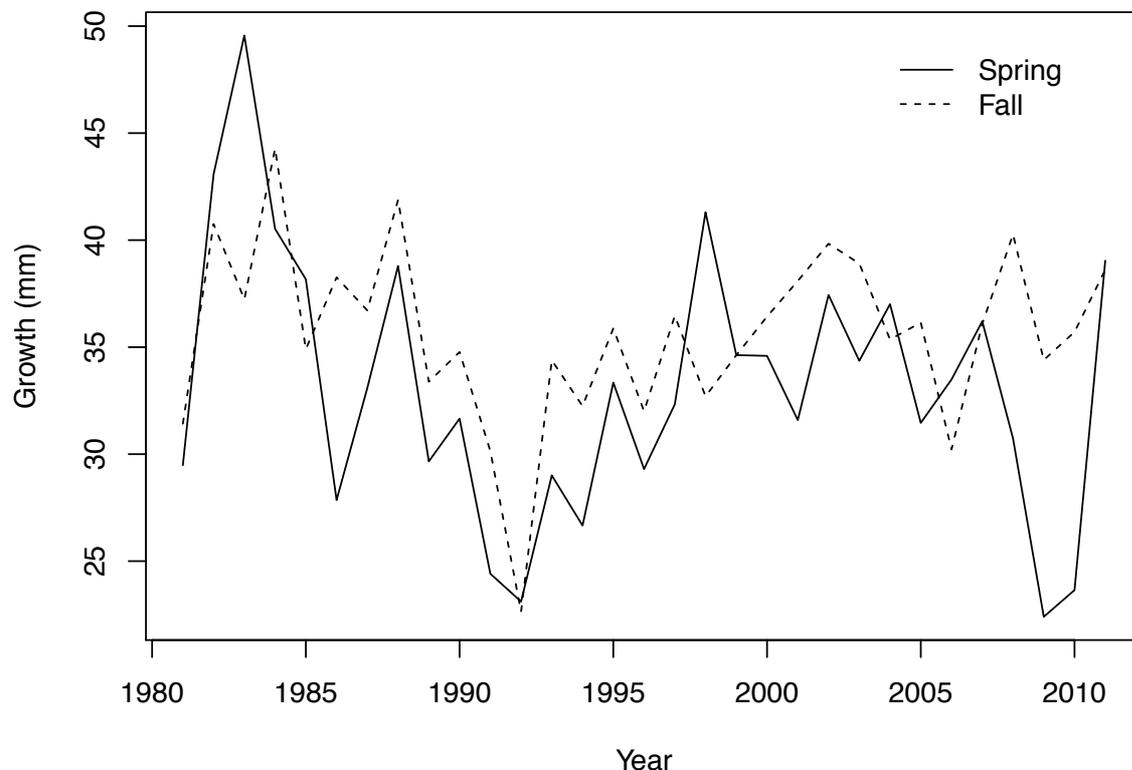

2775 **SEINE/TRAWL - growth by race from mid-Sacramento to Chipps Island.**

2776 The average growth of Spring and Fall Chinook are shown in Figure C.1 along with
 2777 the time elapsed between Seine surveys and mid-water trawls. The temporal trend in growth
 2778 is shown in Figure C.2. Fall Chinook appear to be slightly larger and on average seen in seine
 2779 surveys about half of a month later. Predominantly, Fall Chinook appear to grow slightly

2780 more between Seine and mid-water trawl surveys, which is noteworthy, since they do so in
 2781 less time as seen in the average month seined calculation.

2782 **Figure C.1 Growth between release and sampling at Chipps Island (left panel) and**
 2783 **month at which Region 1 seine was sampled (right panel).**
 2784

2785
2786 **Figure C.2 Temporal trends in Spring and Fall Chinook growth evaluated from beach**
2787 **seine and mid-water trawl surveys.**

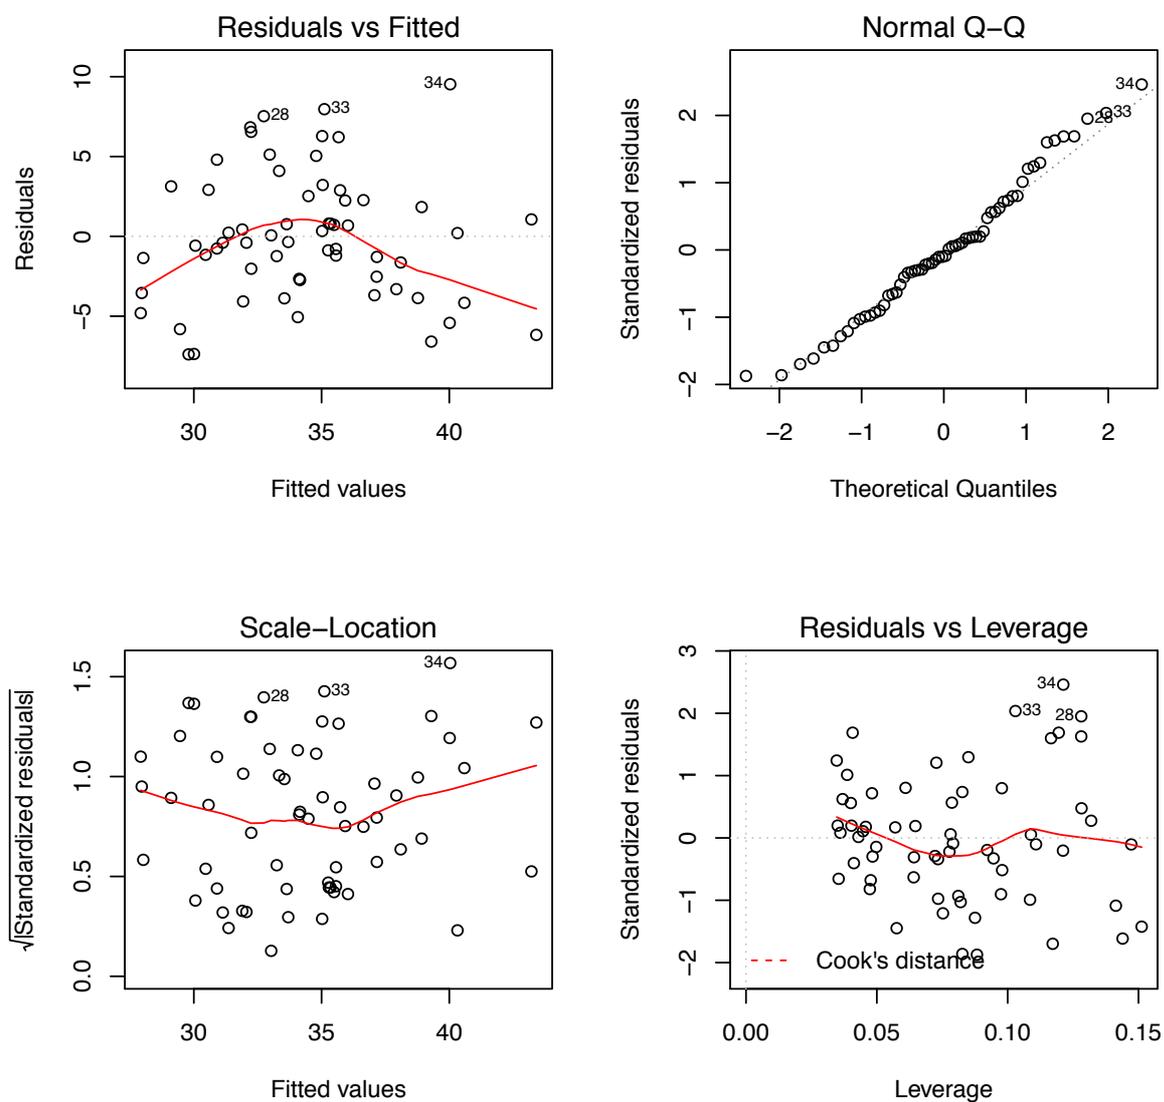

2788 Table C.3 shows the results of stepwise linear regressions. The regression results
2789 show that there are significant effects of Bass, Central Valley Project exports, race (spring or
2790 fall run), and the export to inflow ratio (EXPIN). The bass index shows a positive effect on
2791 growth. Central Valley Project exports also show a positive effect, but the export to inflow
2792 ratio shows a negative effect. The adjusted R-squared value for the fit was 0.4068. The
2793 diagnostic plot of the fit is shown in Figure C.3.

2794

2800

2801 **CWT –growth and length by hatchery source.**

2802 Feather Fish Hatchery (FFH) spring Chinook and Coleman National Fish Hatchery
2803 (CNFH) fall Chinook growth and lengths at Chippis Island are shown in Figure C.4. We see
2804 that there is considerable variability in growth, and that Spring run fish appear to have grown
2805 faster than Fall run until the early 1990's, but are now growing less than Fall run (see Figure
2806 C.4 upper panel). Table C.4 shows the results of stepwise regressions of length against all
2807 Spring and Fall run covariates. The export to inflow ratio was the only significant predictor of
2808 catch length in the Chippis Island trawl, with EXPIN having a positive effect. The adjusted R-
2809 squared for the best fitting model shown was 0.3414. Diagnostic plots of the best fit are
2810 shown in Figure C.5, where we can see that the residuals are normal. Regressions show a

2811 hatchery effect, finding that FFH fish arrive at Chipps Island 3.5 mm larger than CNFH fish,
 2812 but FFH fish included Spring run, which were larger. Despite growth of Spring run recoveries
 2813 appearing to decline from 1985, the lengths of Spring run fish at Chipps Island appears to be
 2814 relatively constant. We found no significant relationships between growth and environmental
 2815 variables.

2816

2824 **Figure C.5 Diagnostic plots of best fit of length at recapture at Chipps Island to**
 2825 **environmental variables.**
 2826

2827 **TRAWL – length by race at Chipps Island.**

2828 Unlike the CWT lengths from hatchery specific releases, the aggregated relative
 2829 Spring and Fall lengths remain consistent from the 1980's until present. Spring run appear to
 2830 be consistently larger than Fall run (see Figure C.6). Regression results are shown in Table
 2831 C.5 and indicate that Yolo flow, the Central Valley Project exports, the export to inflow ratio,
 2832 water passing via the Delta Cross Channel, and the bass index are all significant predictors of
 2833 size. The Adjusted R-squared of the best fit shown is 0.785. The diagnostic plots of the best

2834 fit is shown in Figure C.7. The TRAWL dataset had the largest samples, and despite being
 2835 aggregated wild and hatchery fish, and despite not identifying source drainages, the
 2836 regression results yield the highest R-squared. The diagnostics show normality in residuals as
 2837 well as the majority of residuals concentrated on predicted theoretical quantiles.

 2844 **Island mid-water trawl and environmental variables.**

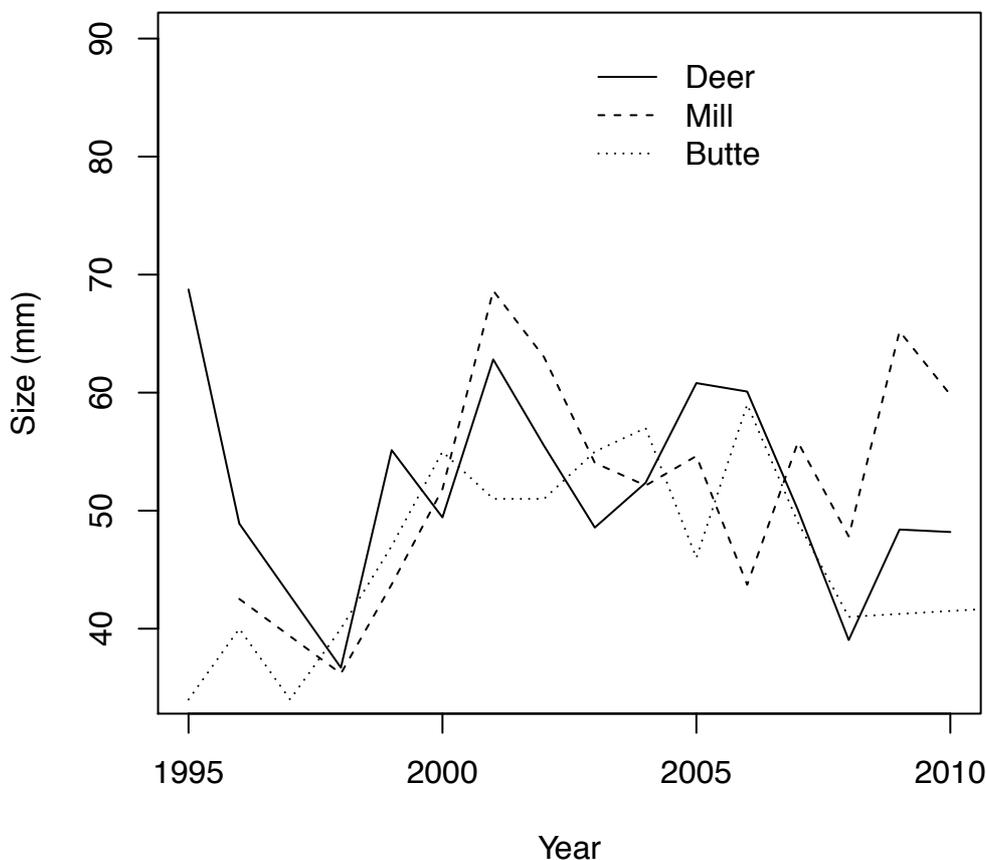

2845 **RST – Lengths in tributaries**

2846 Mill, Deer, and Butte creek Spring run average fish sizes from rotary screw trap
 2847 operations are shown in Figure C.8. We see that Mill, Deer and Butte creeks are on average
 2848 about 45-55 mm in length between January and June when records were aggregated for
 2849 outmigration estimates. The temporal pattern in sizes is shown in Figure C.9. We see no
 2850 major trend in size in tributaries between January and June, only that Butte creek fish appear
 2851 to run a bit smaller.

2858 *DISCUSSION*

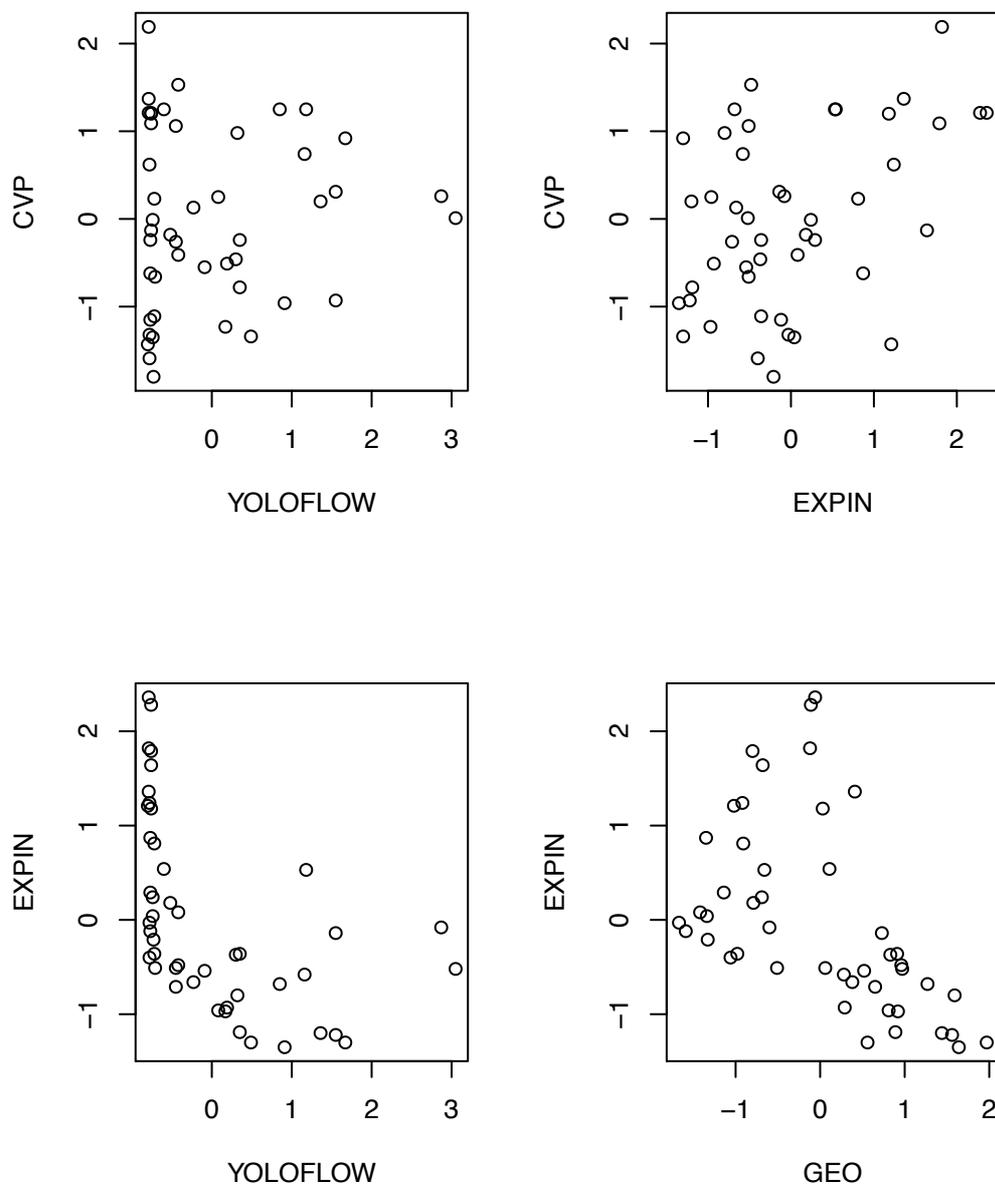

2859 This analysis drew upon varied sources of fish length information in the Sacramento
 2860 River drainage. The summary of rotary screw trap lengths indicates that Spring run out-
 2861 migrating Chinook from Deer, Mill and Butte creeks are approximately the same size, and
 2862 have been stable at approximately 55 mm in recent years. Regression analysis of recoveries
 2863 from mid-water trawl surveys at Chipps Island indicates that growth of fish from North of the
 2864 Delta to Chipps Island, as well as the length at recapture in Chipps Island trawls varied in
 2865 relation to environmental variables. Regression analyses showed that the length at Chipps
 2866 Island from the perspective of two different types of length statistics proved to be related to
 2867 environmental variables regardless of the data source of the length estimates.

2868 We used two different growth metrics. One growth metric came from lengths of CWT
 2869 recoveries and releases of hatchery fish, and the other came from seine and trawl surveys.
 2870 The CWT growth was derived from average recovery length at Chipps Island and average
 2871 release lengths at various release locations and times. The average recovery length is a
 2872 statistic based on a very small sample size relative to the release length statistic. If you

2873 consider the how many fish are released relative to recaptured, and if you consider that
2874 tagged fish are released at various locations and at different times, it is easy to see how biased
2875 the growth estimate might be. The SEINE/TRAWL growth estimate made no distinction
2876 between hatchery and non-hatchery fish and it represents an estimate of the growth of all Fall
2877 or Spring run fish between Region 1 seines and Chipps Island. In comparison to the CWT
2878 estimate, it will be more complex in it's stock composition (with hatchery and non-hatchery
2879 fish of all origins), but it is much simpler in upstream capture and release size sampling. All
2880 stocks were sampled from the same locations for sizing regardless of origin. We found a
2881 relationship between SEINE/TRAWL growth and environmental variables, but no
2882 relationship between CWT growth and environmental variables. This may be due to the
2883 complexity of how the release length was calculated for the CWT growth estimate.

2884 The environmental predictors that best explained growth were the Central Valley
2885 Project exports (CVP), the ratio of combined state and federal exports to the total Delta
2886 inflow (EXPIN), and the bass index. CVP and EXPIN are both related to flows in complex
2887 ways. CVP is related to flow because exports would tend to be less restricted at higher flows,
2888 but would have its highest impact when flows are low. We would expect that juvenile salmon
2889 growth could be high when CVP is highest under that logic. EXPIN is related to flow by a
2890 similar logic, but since EXPIN is a ratio, we would expect the largest fraction of flows to be
2891 exported when flows are low (for a given level of exports). We would expect juvenile salmon
2892 growth to be lowest when EXPIN is highest at the lowest flows.

2893 Figure C.10 illustrates some the general patterns in environmental covariation. In the
2894 upper left panel we see that CVP has the greatest degree of variability at the lowest flows
2895 (with Yolo flow being used as a surrogate for average flow at export locations). Across a
2896 range of flow values we can see that the lower bound of CVP increases. This is consistent
2897 with a general tendency of reducing exports at lower flows. The relative impact of exports at
2898 a given flow is seen with EXPIN, which we see (lower left) diminishes at higher flows. We
2899 also see that more water reaches downstream to the Mokelumne river when EXPIN is lower
2900 (lower right panel). Finally, there is a general pattern of CVP being larger when EXPIN is
2901 higher, but recall that the highest EXPIN may coincide with low flows.

2902
2903

Figure C.10 Covariation between significant environmental predictors.

2904 EXPIN was a significant predictor of length when both CWT and TRAWL datasets
 2905 were used. It was significant with $p < 0.01$ in both cases. EXPIN was also a significant
 2906 predictor ($p < 0.01$) of growth estimates of Fall and Spring aggregates obtained from the
 2907 SEINE/TRAWL dataset. The CWT length regression is in conflict with the SEINE/TRAWL
 2908 growth regression and the TRAWL length regression though. The CWT result predicts a
 2909 positive effect of EXPIN, versus a negative effect for the other two regression analyses. A
 2910 possible reason for this would be that the CWT dataset was exclusively measuring hatchery
 2911 fish (although hatchery fish would also have been present in the other two analyses). If
 2912 EXPIN has a positive effect on hatchery fish length at Chipps Island as shown in the CWT
 2913 length regression, and a negative effect on the aggregate of both hatchery and non-hatchery
 2914 fish seen in the TRAWL length and SEINE/TRAWL growth analysis, it might suggest that
 2915 that the negative effect on non-hatchery growth is even stronger than seen in the TRAWL

2916 surveys. It could also be a size related issue. If hatchery fish are smaller and more vulnerable
 2917 to entrainment, removal of the smaller fish from the out-migrating cohort would make it
 2918 appear as if they grew on average, when in fact it was just the smaller ones that did not make
 2919 it into the downstream survey sample.

2920 The relationship between flows and exports, and resulting growth and survival are
 2921 complex. We found that growth and length are negatively related to EXPIN, but positively
 2922 related to CVP. A possible mechanism, is that there is a threshold flow/export relationship
 2923 where in smaller fish become more vulnerable to entrainment. Such a mechanism would
 2924 predict that more larger fish than smaller fish make it downstream to be sampled at Chipps
 2925 Island, which has the effect of making the growth appear larger on the basis of the average
 2926 recovery size. This would appear to be favorable growth conditions despite the fact that all
 2927 individuals did not grow better on those conditions. If a relatively high CVP export year were
 2928 where to coincide with an average flow year, and if more small fish were entrained, it would
 2929 appear that fish were larger at Chipps Island.

2930 Results also indicated that Spring run were longer at Chipps Island, despite the fact
 2931 that the SEINE/TRAWL regression showed that Spring run growth was less than Fall run.
 2932 Total Central Valley Projects (combined state and federal) exports showed positive effect
 2933 on growth in the SEINE/TRAWL regression and length in the TRAWL analysis. Since there
 2934 was a negative effect from the export to inflow ratio, it may be suggest that total flows have a
 2935 positive effect, and that there may be a relationship between exports and flows that is dictated
 2936 by water extraction policies.

2937 It is interesting that regression results show that bass has a positive effect on the
 2938 growth estimates evaluated from the SEINE/TRAWL, yet has a negative effect on lengths
 2939 estimated from the TRAWL data. Since the bass index is not standardized to effort, it can't
 2940 imply a direct predation rate change on a size class of Chinook juveniles, but depending on
 2941 the relationship between the index and the size of the bass caught, it might imply a shift in the
 2942 size of Chinook vulnerable to bass predation at a given abundance of bass. It could be that
 2943 smaller fish are more vulnerable and predation biases the growth estimate by removing
 2944 smaller fish.

2945 Our examination of length/growth sensitivity to environmental variation points to a
 2946 few results. First, EXPIN is a statistically significant predictor of size and growth, with a
 2947 negative effect on both. Our samples conflate the story a bit, but if you consider that the only
 2948 positive effect was seen in the length of hatchery fish, and if you consider that the CWT
 2949 dataset had race and hatchery factors, the positive effect of EXPIN in the regression result of
 2950 the CWT data should not detract from the regression results found in both the
 2951 SEINE/TRAWL and TRAWL dataset. It should be noted however, that the highest regression
 2952 coefficient value for an environmental effect in any of our regressions was about 5, meaning
 2953 that about 5 mm per standard deviation was the maximum variability in size predicted by
 2954 variability in an environmental effect. This implies that at the extreme of 2 standard
 2955 deviations, only 10 mm of net difference in size at Chipps Island would be predicted. Still,
 2956 two standard deviations explains about 95% of the variation in environmental factors, and 10
 2957 mm explains 10-15% of the variability in length at Chipps Island (assuming 85 mm length at
 2958 Chipps Island). Since the same environmental variables explain significant variation in
 2959 rearing survival, it is feasible that length may be an instrumental in the mechanism of rearing
 2960 survival.

1893 **APPENDIX C: GROWTH ANALYSIS AND MODELLING**

1894 In this appendix we provide a description of the methods we used to collect and
 1895 analyze length information from various state and federal collection facilities in the
 1896 Sacramento drainage. We assembled time series of lengths, both upstream and downstream,
 1897 for both hatchery fish and combined hatchery and wild aggregates. Where possible, we used
 1898 upstream and downstream lengths to obtain annual growth estimates. In the absence of a
 1899 downstream growth measurement, we assembled a time series of downstream lengths. We
 1900 performed regressions on growth and length estimates, evaluating impacts of environmental
 1901 conditions on growth.

1902 *INTRODUCTION*

1903 The life-cycle modeling analysis in this project attempts to attribute variability in
 1904 survival to environmental factors during different parts of the life history. Survival can be
 1905 affected by the environment in complex ways, and can be mediated through biotic and abiotic
 1906 processes. We posit that size can play a role in predicting survival, and that growth itself can
 1907 be an indicator of survival as well. An obvious mechanism for size effects on survival would
 1908 be that larger fish are less vulnerable to predation than smaller fish. A mechanism for growth
 1909 being a predictor of survival would be that faster growing fish are likely to be experiencing
 1910 better feeding conditions and bioenergetic advantages, and therefore should survive better.

1911 In this appendix we look for relationships between environmental conditions and
 1912 growth, but because growth requires two measurements (a capture and a recapture, or a
 1913 release and recapture), we are not always able to get an estimate of a growth increment. Some
 1914 length estimates obtained from survey data cannot be connected to later surveys, and
 1915 therefore a growth estimate can't be derived from the measurements. An example of this
 1916 occurs with rotary screw traps operating in tributaries, where juvenile size samples are
 1917 obtained during rearing and migration. Those sizes are not directly comparable to later
 1918 samples obtained downstream, because the downstream samples are aggregates of all the
 1919 independent upstream sampled lengths. We might be able to document a pattern in upstream
 1920 sizes over the years, but growth to the downstream measurement can't be inferred. We
 1921 therefore treat size as a surrogate for growth, with the assumption that annual variability in
 1922 juvenile size is in actual fact a measurement of annual variability in growth since all fish must
 1923 at some point have emerged from the gravel at roughly the same sizes.

1924 *METHODS*

1925 We performed an analysis of length and growth patterns for Spring and Fall run
 1926 Chinook in the Sacramento River in relation to environmental factors. We collected size at
 1927 release and recapture data from state and federal agencies. We compiled records into average
 1928 sizes at release for several different stock aggregates that provided adequate sample sizes for
 1929 the years the data were available. In some case, it was possible to associate the length of a
 1930 downstream recaptured fish with a known upstream release size to obtain a growth increment

1931 estimate, but in other cases only the downstream size record was available. Upstream length
 1932 records were obtained from hatchery release information, from screw traps operated in
 1933 tributaries, and from seine surveys operated throughout the Sacramento drainage. The farthest
 1934 downstream sizes were obtained from Chipps Island, where mid-water trawl surveys
 1935 collected size information and recorded the race of the fish based on the presence of a CWT
 1936 or a length based estimated based on the length of the fish at the time the sample was
 1937 obtained.

1938 *Data compilation*

1939 *Length data*

1940 The Pacific States Marine Fisheries Commission manages and supports the Regional
 1941 Mark Processing Center (RMPC; <http://www.rmhc.org/>), which in turn manages the Regional
 1942 Mark Information System (RMIS). Agencies and organizations throughout the Western
 1943 United States report CWT data directly to the RMIS. The Delta Juvenile Fish Monitoring
 1944 Program (DJFMP) was initiated in the 1970s and is managed by the US Fish and Wildlife
 1945 Service (USFWS, 2014). The program has a stated objective to monitor the effects of water
 1946 projects in the Bay Delta on juvenile Chinook.

1947 The number of juvenile salmon leaving freshwater during the spring has been sampled
 1948 annually since 1978 by means of mid-water trawling in the estuary near Chipps Island
 1949 (Brandes and McLain 2001). The Trawl site in Suisun Bay is sampled three days per week
 1950 year round. It is sometimes sampled daily and at times two shifts per day for a total of 20
 1951 tows per day during May and June. During December and January, trawls occur 7 days per
 1952 week with ten 20 minute trawls conducted daily. Catch limits are imposed when Delta Smelt
 1953 catches exceed 8 individual Delta Smelt. The trawl survey records fish length at capture and
 1954 creates a record of the race, origin and release location if a coded wire tag is detected.

1955 We used data that had been collected since 1979 in mid-water boat trawls at Chipps
 1956 Island, Suisun Bay (Zone 10 S UTM, 4211218N, 595531E). Data from the DJFMP is
 1957 available online (<http://www.fws.gov/stockton/jfmp/>). USFWS tables available online
 1958 contained metrics of juvenile Chinook salmon that had been marked with CWTs, released
 1959 throughout the Sacramento - San Joaquin Basin and then recovered near Chipps Island in
 1960 Suisun Bay (*Coded Wire Tag 1978 -2011.xls* and *Coded Wire Tag 2012 -2013.xls*). Survey
 1961 records not containing CWTs can be found in the spreadsheets *Chipps Island Trawls 1976-*
 1962 *2011.xlsx* and *Chipps Island Trawls 2012-2014.xlsx*.

1963 We used the records from the Chipps Island trawls to create a database of fish lengths
 1964 and growths increments for all fish with CWTs (referred to as the CWT table). Each fish with
 1965 a CWT is of a known origin, so the race and the source (hatchery or wild stock origin) are
 1966 also known. We used the remaining records from the Chipps Island survey to construct a
 1967 database table of Chinook known to be of a given race, but where the origin is not known.
 1968 These records were assembled into a table we refer to as the TRAWL table, which only
 1969 distinguishes between Fall and Spring runs.

1970 We compiled juvenile salmon length data from the Sacramento watershed and the San
 1971 Francisco Bay Delta into a relational database in order to determine growth of hatchery Fall
 1972 Chinook and hatchery and wild juvenile Spring Chinook. Wild Spring stocks included Deer,
 1973 Mill and Butte creeks. Butte Creek fish were release and recaptured in Butte Creek, the Sutter

1974 Bypass or near Chipps Island in Suisun Bay. Release and recovery data were compiled from
 1975 three sources: California Department of Fish and Wildlife (CDFW), US Fish and Wildlife
 1976 Service's Delta Juvenile Fish Monitoring Program (DJFMP) and the Regional Mark
 1977 Processing Center (RMPC).

1978 From 1995 to 2001, the CDFW captured, measured, marked, and released wild
 1979 spring-run Chinook on Butte Creek (CDFG, 1999; CDFG, 2004-2; CDFG, 2004-3). The
 1980 purpose of the CDFW program was to estimate adult escapement, monitor timing and
 1981 abundance of juvenile outmigration, and monitor relative growth rates in the Butte Creek
 1982 system. Fish were captured and marked with adipose fin clips and coded wire tags at the
 1983 Parrot-Phelan Diversion Dam (PPDD; Zone 10 S UTM, 4396287N, 611463E). Releases
 1984 took place at three locations, but varied from year to year. Release sites were: PPDD,
 1985 Baldwin Construction Yard (approximately one mile downstream of the PPDD) and Adams
 1986 Dam (approximately 7 miles downstream of PPDD). After release, marked fish were subject
 1987 to recapture and sacrifice at downstream locations in Butte Creek, the Sutter Bypass and the
 1988 Sacramento Delta near Chipps Island. Rotary screw traps were used to recapture fish at all
 1989 locations and an off-stream fish screen outfitted with a trap box was used to collect fish at the
 1990 PPDD site. Recaptured fish were sacrificed, measured for fork length and their CWTs were
 1991 extracted and read. We received programmatic data formatted in a Microsoft Access
 1992 database directly from the CDFW (C. Garman, personal communication, 1/30/2014).

1993 We queried the RMIS database for juvenile Chinook that had been marked and
 1994 released at any location in the Sacramento drainage. The RMIS table was then related by
 1995 CWT code to Chipps Island mid-water trawl and Sacramento River recoveries. In this way,
 1996 we queried recoveries with release locations only within the Sacramento Basin.

1997 We obtained tributary measurements of juvenile lengths from rotary screw traps
 1998 (RSTs) operating in Butte creek, Mill creek and Deer creek. Rotary screw traps were operated
 1999 by the US Fish and Wildlife Service in Mill and Deer creeks, and by the California
 2000 Department of Fish and Wildlife in Butte creek. Screw trap operation spanned 1995-2010 in
 2001 the records used in this analysis. We used samples obtained from January to June of each
 2002 year to obtain estimates of tributary outmigration size.

2003 ***Environmental data***

2004 We compiled time series of environmental variables that pertain to the experiences of
 2005 downstream migration juveniles. For Spring Run, we used discharge at the three creeks
 2006 (Deer, Mill and Butte), flow, exports volumes and other export indices, and a CPUE index of
 2007 bass abundance. Flow temperature and discharge were obtained from USGS gauging stations
 2008 (<http://waterdata.usgs.gov/nwis/inventory>). Exports and other dayflow parameters were
 2009 obtained from water project data available on the California department of water resources
 2010 website (<http://www.water.ca.gov/dayflow/output/Output.cfm>). Environmental variables
 2011 were normalized by subtracting the mean and dividing by the standard deviation. The
 2012 variables are summarized in Table C.1 for Spring run and in Table C.2 for Fall run.

2018 *Length and Growth analysis*

2019 We examined environmental factors affecting length at recapture at Chipps Island of
2020 fish with known and unknown release lengths. Where length at release was known, we
2021 examined growth rates. We associated each size and growth record with environmental
2022 factors experienced by each race of salmon each year the sizes were recorded. We compared
2023 fall and spring length at capture at Chipps Island from two separate surveys. The CWT table
2024 provided an estimate of growth for fall and spring hatchery releases. The mid-water trawls
2025 did not distinguish between wild and hatchery fish, so those analyses pertain to the race as a
2026 whole, without distinction about release locations or wild/hatchery distinctions. We also
2027 obtained sizes from DJFMP seines in Region 1 (upstream from the Delta) and compared
2028 those sizes with Chipps Island size information. Since seine samples do not distinguish
2029 between populations, growth obtained from subtracting upstream seine sizes from Chipps
2030 Island trawl sizes provide estimates of aggregate Fall and Spring run sizes, but cannot
2031 distinguish between release locations or between wild and hatchery releases.

2032 **SEINE/TRAWL - growth by race from mid-Sacramento to Chipps Island.**

2033 We queried the DJFMP seine database to obtain estimates of growth for Spring and
2034 Fall runs. Region 1 of the DJFMP beach seine runs from Colusa State Park to Elkhorn. We
2035 averaged lengths of Spring and Fall seine lengths for each year for fish collected between
2036 January and June, and compared those to Chipps Island midwater trawl sizes. The trawl
2037 survey assigned fish to Fall and Spring runs based on size ranges and records indicated that
2038 all collections occurred in May and June. We calculated the growth for each race of fish each
2039 year as the difference between the average trawl length and the average seine length. We
2040 refer to these growth estimates as the SEINE/TRAWL dataset.

2041 We examined growth patterns in relation to environmental variables listed in Tables
2042 C.1 and C.2. We performed stepwise linear regressions of growth in relation to each variable,
2043 adding variables according to best p-value, and stopping when no further significant variables
2044 were found.

2045 **CWT –growth and length by hatchery source.**

2046 When hatchery fish are released, the average size of a sample of the release batch is
2047 used as the release length of record for fish in the batch. When recaptures occur at Chipps
2048 Island, a record for each fish recaptured can be compared to a release length record on the
2049 basis of CWT codes. To get reasonable sample sizes for recaptures, we were forced to
2050 aggregate hatchery releases such that release locations were ignored. We aggregated all
2051 release locations within the Sacramento drainage for each hatchery source. Since a release
2052 batch contains a range of lengths, it is possible for the smallest recaptured fish to be smaller
2053 than the average released fish. The growth record for each year was calculated as the average
2054 of all the recapture lengths minus the average release length. The average of release length
2055 was calculated as the weighted release length, weighted by the number released at each
2056 location at each time of release. We refer to the length and growth estimates from this method
2057 as the CWT dataset.

2058 We tested for statistical relationships between size at recapture and environmental
 2059 variables for Spring and Fall hatchery releases from Coleman National Fish Hatchery
 2060 (CNFH) and Feather Fish Hatchery (FFH). We examined growth and length patterns in
 2061 relation to environmental variables listed in Tables C.1 and C.2. We performed stepwise
 2062 linear regressions of growth and length in relation to each variable, adding variables
 2063 according to best p-value, and stopping when no further significant variables were found.

2064 **TRAWL – length by race at Chipps Island.**

2065 We selected records that were not limited to CWT tagged fish (the TRAWL dataset in
 2066 this analysis) from Chipps Island, and assembled all records of Spring and Fall chinook to
 2067 look at the size. By not being limited to CWT matches, the sample size was much larger than
 2068 for the CWT matched database, but for the TRAWL dataset, the origin of fish could not be
 2069 determined. The race of the fish was assigned by a length/timing criteria established by the
 2070 DJFMP (the “Race Table” found at www.fws.gov/stockton/jfmp). Using these records we
 2071 looked for temporal trends, comparisons between Spring and Fall runs, and relationships
 2072 between size at capture and environmental factors. Annual average size records for Spring
 2073 and Fall Chinook do not distinguish between hatchery and wild, and there is no growth
 2074 estimate because the size at release is not known, and there is no way to distinguish between
 2075 Butte, Mill, and Deer creeks. The TRAWL dataset provides an aggregate estimate of length
 2076 at Chipps Island by race alone.

2077 We examined growth patterns in relation to environmental variables listed in Tables
 2078 C.1 and C.2. We performed stepwise linear regressions of length in relation to each variable,
 2079 adding variables according to best p-value, and stopping when no further significant variables
 2080 were found. We treat length as a surrogate for growth on the assumption that some initial
 2081 length can be treated as a constant across and all variability can be thought of as occurring
 2082 after that initial length.

2083 **RST – Lengths in tributaries**

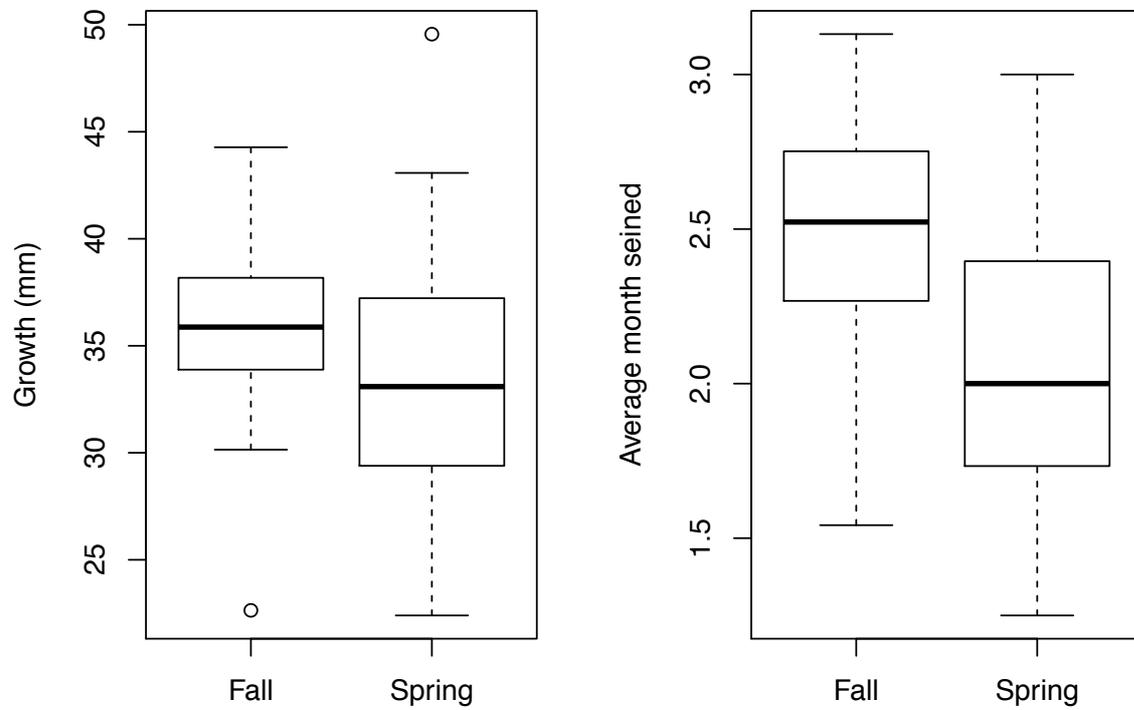

2084 Deer, Mill, and Butte creek rotary screw trap records were queried to obtain estimates
 2085 of outmigrating juvenile sizes. We took the average size of all samples obtained from the
 2086 traps between January and June of each migration year. We attempted to match CWT
 2087 releases from Butte Creek each year to recoveries within the Sacramento basin to obtain
 2088 growth estimates at various sample locations, but found that recoveries were too few to
 2089 obtain good estimates of growth. Butte Creek CWT release records with Chipps Island
 2090 recapture events began in 1996, but recaptures amounted to fewer than 10 fish per year at
 2091 Chipps Island. It was not possible to relate RST lengths to downstream lengths at Chipps
 2092 Island for a growth estimate. We therefore limited our examination of RST data to showing
 2093 temporal trends of sizes of Deer, Mill and Butte creeks.

2094 *RESULTS*

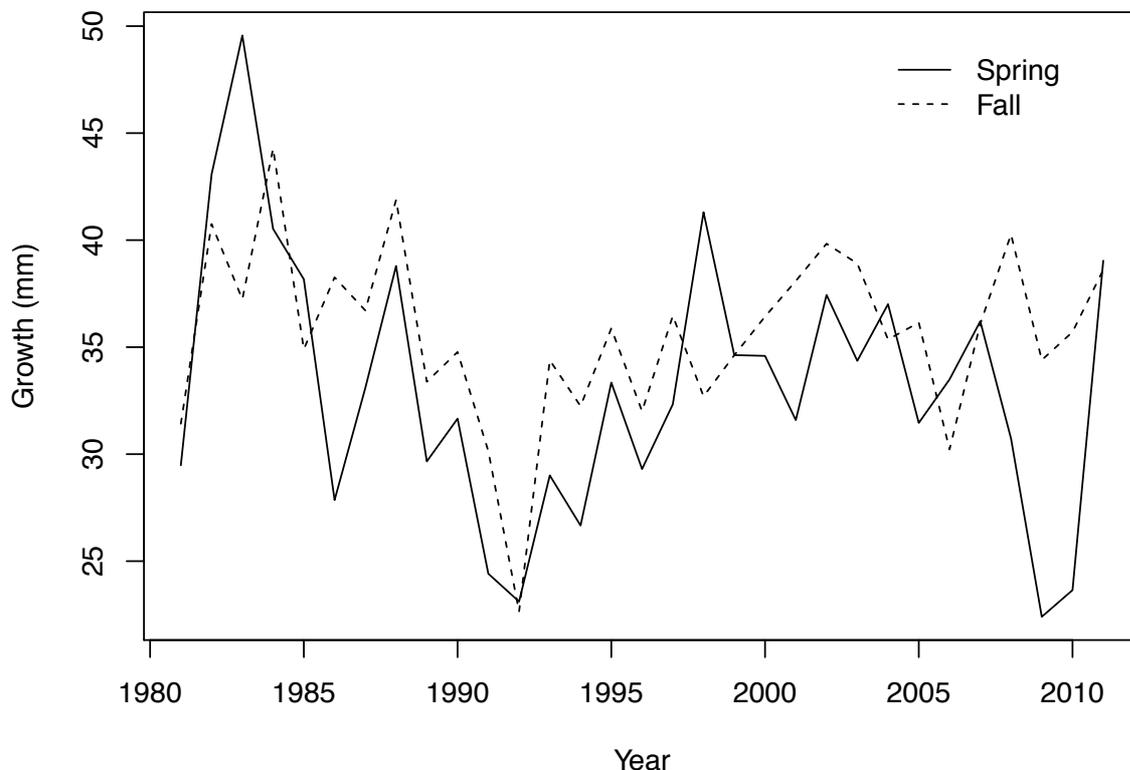

2095 **SEINE/TRAWL - growth by race from mid-Sacramento to Chipps Island.**

2096 The average growth of Spring and Fall Chinook are shown in Figure C.1 along with
 2097 the time elapsed between Seine surveys and mid-water trawls. The temporal trend in growth
 2098 is shown in Figure C.2. Fall Chinook appear to be slightly larger and on average seen in seine
 2099 surveys about half of a month later. Predominantly, Fall Chinook appear to grow slightly

2100 more between Seine and mid-water trawl surveys, which is noteworthy, since they do so in
 2101 less time as seen in the average month seined calculation.

2102 **Figure C.1 Growth between release and sampling at Chipps Island (left panel) and**
 2103 **month at which Region 1 seine was sampled (right panel).**
 2104

2105
2106 **Figure C.2 Temporal trends in Spring and Fall Chinook growth evaluated from beach**
2107 **seine and mid-water trawl surveys.**

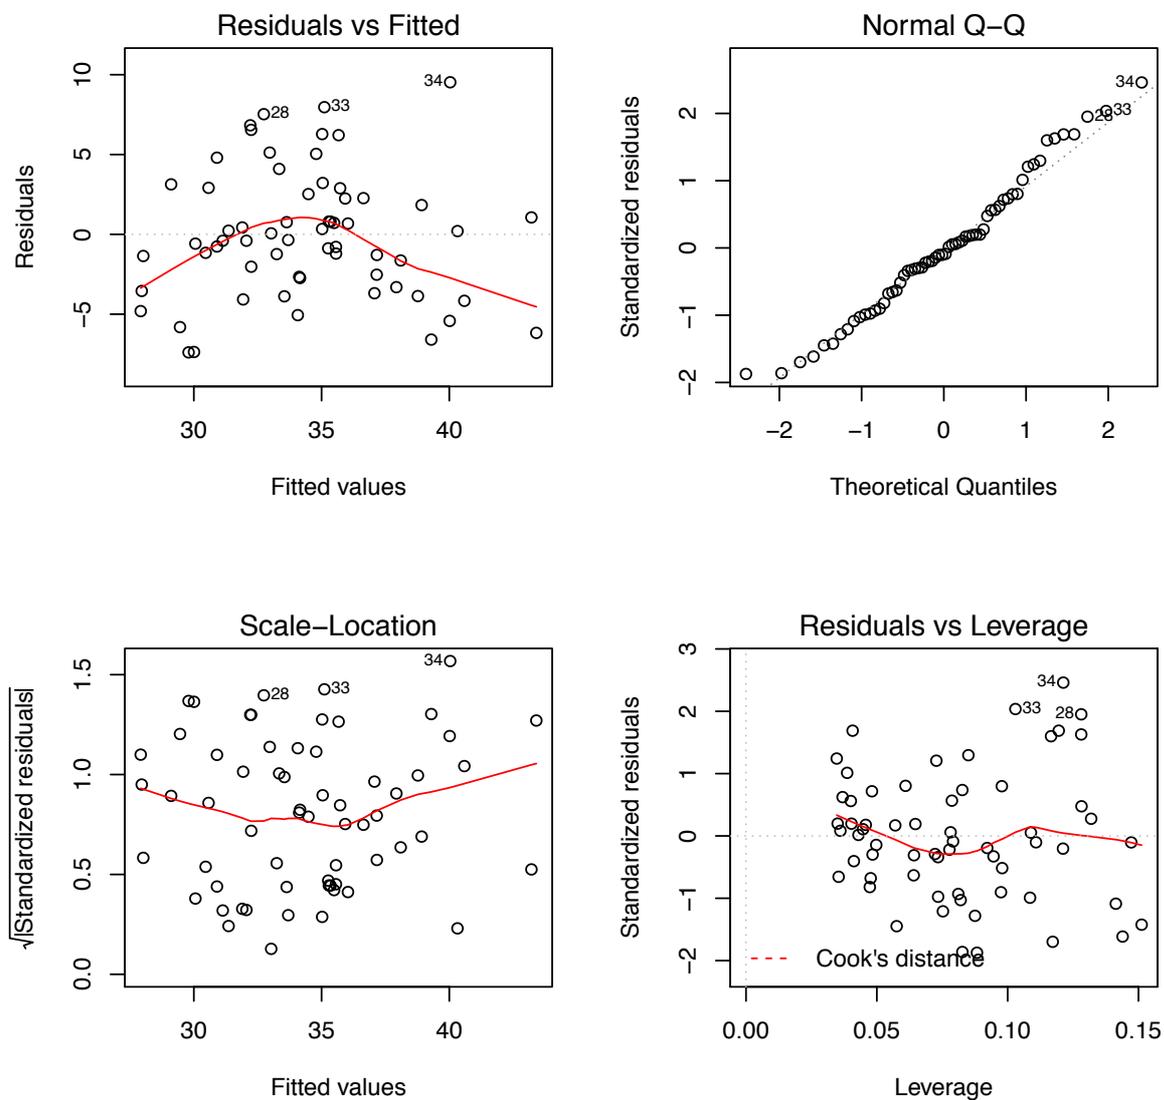

2108 Table C.3 shows the results of stepwise linear regressions. The regression results
2109 show that there are significant effects of Bass, Central Valley Project exports, race (spring or
2110 fall run), and the export to inflow ratio (EXPIN). The bass index shows a positive effect on
2111 growth. Central Valley Project exports also show a positive effect, but the export to inflow
2112 ratio shows a negative effect. The adjusted R-squared value for the fit was 0.4068. The
2113 diagnostic plot of the fit is shown in Figure C.3.

2122 Feather Fish Hatchery (FFH) spring Chinook and Coleman National Fish Hatchery
 2123 (CNFH) fall Chinook growth and lengths at Chippis Island are shown in Figure C.4. We see
 2124 that there is considerable variability in growth, and that Spring run fish appear to have grown
 2125 faster than Fall run until the early 1990's, but are now growing less than Fall run (see Figure
 2126 C.4 upper panel). Table C.4 shows the results of stepwise regressions of length against all
 2127 Spring and Fall run covariates. The export to inflow ratio was the only significant predictor of
 2128 catch length in the Chippis Island trawl, with EXPIN having a positive effect. The adjusted R-
 2129 squared for the best fitting model shown was 0.3414. Diagnostic plots of the best fit are
 2130 shown in Figure C.5, where we can see that the residuals are normal. Regressions show a

2131 hatchery effect, finding that FFH fish arrive at Chipps Island 3.5 mm larger than CNFH fish,
 2132 but FFH fish included Spring run, which were larger. Despite growth of Spring run recoveries
 2133 appearing to decline from 1985, the lengths of Spring run fish at Chipps Island appears to be
 2134 relatively constant. We found no significant relationships between growth and environmental
 2135 variables.

2147 **TRAWL – length by race at Chipps Island.**

2148 Unlike the CWT lengths from hatchery specific releases, the aggregated relative
 2149 Spring and Fall lengths remain consistent from the 1980's until present. Spring run appear to
 2150 be consistently larger than Fall run (see Figure C.6). Regression results are shown in Table
 2151 C.5 and indicate that Yolo flow, the Central Valley Project exports, the export to inflow ratio,
 2152 water passing via the Delta Cross Channel, and the bass index are all significant predictors of
 2153 size. The Adjusted R-squared of the best fit shown is 0.785. The diagnostic plots of the best

2154 fit is shown in Figure C.7. The TRAWL dataset had the largest samples, and despite being
 2155 aggregated wild and hatchery fish, and despite not identifying source drainages, the
 2156 regression results yield the highest R-squared. The diagnostics show normality in residuals as
 2157 well as the majority of residuals concentrated on predicted theoretical quantiles.

2165 **RST – Lengths in tributaries**

2166 Mill, Deer, and Butte creek Spring run average fish sizes from rotary screw trap
 2167 operations are shown in Figure C.8. We see that Mill, Deer and Butte creeks are on average
 2168 about 45-55 mm in length between January and June when records were aggregated for
 2169 outmigration estimates. The temporal pattern in sizes is shown in Figure C.9. We see no
 2170 major trend in size in tributaries between January and June, only that Butte creek fish appear
 2171 to run a bit smaller.

2178 *DISCUSSION*

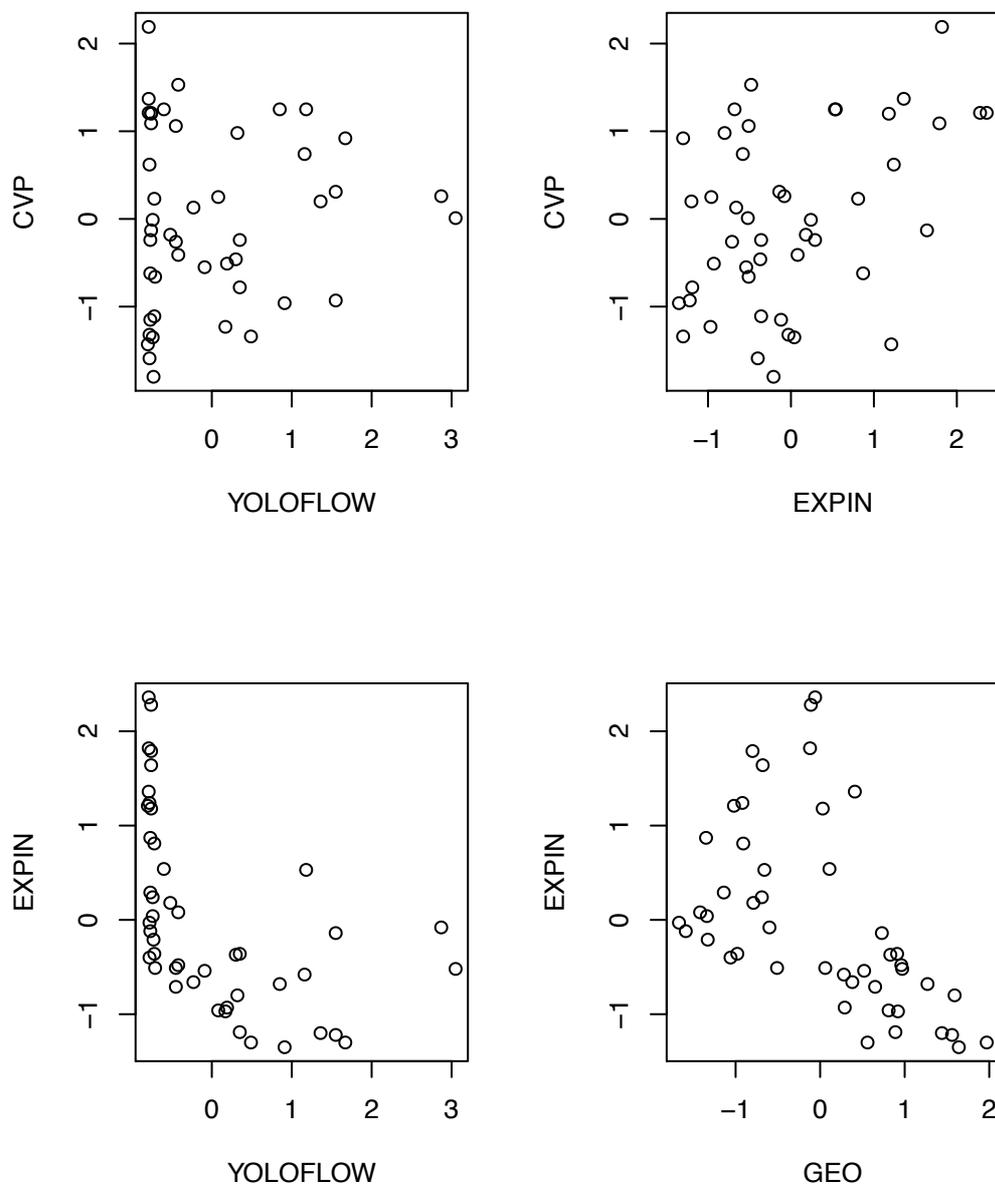

2179 This analysis drew upon varied sources of fish length information in the Sacramento
 2180 River drainage. The summary of rotary screw trap lengths indicates that Spring run out-
 2181 migrating Chinook from Deer, Mill and Butte creeks are approximately the same size, and
 2182 have been stable at approximately 55 mm in recent years. Regression analysis of recoveries
 2183 from mid-water trawl surveys at Chipps Island indicates that growth of fish from North of the
 2184 Delta to Chipps Island, as well as the length at recapture in Chipps Island trawls varied in
 2185 relation to environmental variables. Regression analyses showed that the length at Chipps
 2186 Island from the perspective of two different types of length statistics proved to be related to
 2187 environmental variables regardless of the data source of the length estimates.

2188 We used two different growth metrics. One growth metric came from lengths of CWT
 2189 recoveries and releases of hatchery fish, and the other came from seine and trawl surveys.
 2190 The CWT growth was derived from average recovery length at Chipps Island and average
 2191 release lengths at various release locations and times. The average recovery length is a
 2192 statistic based on a very small sample size relative to the release length statistic. If you

2193 consider the how many fish are released relative to recaptured, and if you consider that
2194 tagged fish are released at various locations and at different times, it is easy to see how biased
2195 the growth estimate might be. The SEINE/TRAWL growth estimate made no distinction
2196 between hatchery and non-hatchery fish and it represents an estimate of the growth of all Fall
2197 or Spring run fish between Region 1 seines and Chipps Island. In comparison to the CWT
2198 estimate, it will be more complex in it's stock composition (with hatchery and non-hatchery
2199 fish of all origins), but it is much simpler in upstream capture and release size sampling. All
2200 stocks were sampled from the same locations for sizing regardless of origin. We found a
2201 relationship between SEINE/TRAWL growth and environmental variables, but no
2202 relationship between CWT growth and environmental variables. This may be due to the
2203 complexity of how the release length was calculated for the CWT growth estimate.

2204 The environmental predictors that best explained growth were the Central Valley
2205 Project exports (CVP), the ratio of combined state and federal exports to the total Delta
2206 inflow (EXPIN), and the bass index. CVP and EXPIN are both related to flows in complex
2207 ways. CVP is related to flow because exports would tend to be less restricted at higher flows,
2208 but would have its highest impact when flows are low. We would expect that juvenile salmon
2209 growth could be high when CVP is highest under that logic. EXPIN is related to flow by a
2210 similar logic, but since EXPIN is a ratio, we would expect the largest fraction of flows to be
2211 exported when flows are low (for a given level of exports). We would expect juvenile salmon
2212 growth to be lowest when EXPIN is highest at the lowest flows.

2213 Figure C.10 illustrates some the general patterns in environmental covariation. In the
2214 upper left panel we see that CVP has the greatest degree of variability at the lowest flows
2215 (with Yolo flow being used as a surrogate for average flow at export locations). Across a
2216 range of flow values we can see that the lower bound of CVP increases. This is consistent
2217 with a general tendency of reducing exports at lower flows. The relative impact of exports at
2218 a given flow is seen with EXPIN, which we see (lower left) diminishes at higher flows. We
2219 also see that more water reaches downstream to the Mokelumne river when EXPIN is lower
2220 (lower right panel). Finally, there is a general pattern of CVP being larger when EXPIN is
2221 higher, but recall that the highest EXPIN may coincide with low flows.

2222
2223

Figure C.10 Covariation between significant environmental predictors.

2224 EXPIN was a significant predictor of length when both CWT and TRAWL datasets
 2225 were used. It was significant with $p < 0.01$ in both cases. EXPIN was also a significant
 2226 predictor ($p < 0.01$) of growth estimates of Fall and Spring aggregates obtained from the
 2227 SEINE/TRAWL dataset. The CWT length regression is in conflict with the SEINE/TRAWL
 2228 growth regression and the TRAWL length regression though. The CWT result predicts a
 2229 positive effect of EXPIN, versus a negative effect for the other two regression analyses. A
 2230 possible reason for this would be that the CWT dataset was exclusively measuring hatchery
 2231 fish (although hatchery fish would also have been present in the other two analyses). If
 2232 EXPIN has a positive effect on hatchery fish length at Chipps Island as shown in the CWT
 2233 length regression, and a negative effect on the aggregate of both hatchery and non-hatchery
 2234 fish seen in the TRAWL length and SEINE/TRAWL growth analysis, it might suggest that
 2235 that the negative effect on non-hatchery growth is even stronger than seen in the TRAWL

2236 surveys. It could also be a size related issue. If hatchery fish are smaller and more vulnerable
 2237 to entrainment, removal of the smaller fish from the outmigrating cohort would make it
 2238 appear as if they grew on average, when in fact it was just the smaller ones that did not make
 2239 it into the downstream survey sample.

2240 The relationship between flows and exports, and resulting growth and survival are
 2241 complex. We found that growth and length are negatively related to EXPIN, but positively
 2242 related to CVP. A possible mechanism, is that there is a threshold flow/export relationship
 2243 where in smaller fish become more vulnerable to entrainment. Such a mechanism would
 2244 predict that more larger fish than smaller fish make it downstream to be sampled at Chipps
 2245 Island, which has the effect of making the growth appear larger on the basis of the average
 2246 recovery size. This would appear to be favorable growth conditions despite the fact that all
 2247 individuals did not grow better on those conditions. If a relatively high CVP export year were
 2248 where to coincide with an average flow year, and if more small fish were entrained, it would
 2249 appear that fish were larger at Chipps Island.

2250 Results also indicated that Spring run were longer at Chipps Island, despite the fact
 2251 that the SEINE/TRAWL regression showed that Spring run growth was less than Fall run.
 2252 Total Central Valley Projects (combined state and federal) exports showed positive effect
 2253 on growth in the SEINE/TRAWL regression and length in the TRAWL analysis. Since there
 2254 was a negative effect from the export to inflow ratio, it may be suggest that total flows have a
 2255 positive effect, and that there may be a relationship between exports and flows that is dictated
 2256 by water extraction policies.

2257 It is interesting that regression results show that bass has a positive effect on the
 2258 growth estimates evaluated from the SEINE/TRAWL, yet has a negative effect on lengths
 2259 estimated from the TRAWL data. Since the bass index is not standardized to effort, it can't
 2260 imply a direct predation rate change on a size class of Chinook juveniles, but depending on
 2261 the relationship between the index and the size of the bass caught, it might imply a shift in the
 2262 size of Chinook vulnerable to bass predation at a given abundance of bass. It could be that
 2263 smaller fish are more vulnerable and predation biases the growth estimate by removing
 2264 smaller fish.

2265 Our examination of length/growth sensitivity to environmental variation points to a
 2266 few results. First, EXPIN is a statistically significant predictor of size and growth, with a
 2267 negative effect on both. Our samples conflate the story a bit, but if you consider that the only
 2268 positive effect was seen in the length of hatchery fish, and if you consider that the CWT
 2269 dataset had race and hatchery factors, the positive effect of EXPIN in the regression result of
 2270 the CWT data should not detract from the regression results found in both the
 2271 SEINE/TRAWL and TRAWL dataset. It should be noted however, that the highest regression
 2272 coefficient value for an environmental effect in any of our regressions was about 5, meaning
 2273 that about 5 mm per standard deviation was the maximum variability in size predicted by
 2274 variability in an environmental effect. This implies that at the extreme of 2 standard
 2275 deviations, only 10 mm of net difference in size at Chipps Island would be predicted. Still,
 2276 two standard deviations explains about 95% of the variation in environmental factors, and 10
 2277 mm explains 10-15% of the variability in length at Chipps Island (assuming 85 mm length at
 2278 Chipps Island). Since the same environmental variables explain significant variation in
 2279 rearing survival, it is feasible that length may be an instrumental in the mechanism of rearing
 2280 survival.

1 Abstract

2 We developed a general state-space modeling framework to evaluate the influence of factors on trends in
3 abundance of multiple life-history stages of salmon. The model utilizes Beverton-Holt transitions among
4 life stages, and incorporates factors into the transitions by modeling the dependence of the Beverton-Holt
5 productivity p (survival) and capacity K parameters as functions of driving factors. We estimated model
6 coefficients in a Bayesian framework to provide inference on factors hypothesized to affect the population
7 dynamics by fitting to indices of abundance. We call the modeling framework *Oncorhynchus* Bayesian
8 Analysis (OBAN), and we applied it to winter run Chinook in the Sacramento River, California, a salmon
9 run listed as endangered in 1994. Using the OBAN framework we were able to place probability statements
10 on the relationships between certain environmental and anthropogenic factors and winter-run population
11 dynamics. We found that temperatures and minimum flow in the spawning reaches and ocean productivity
12 had a high probability of affecting survival (≥ 0.8), whereas water diversions and water routing had lower

13 probabilities of affecting survival. The OBAN framework provides a means for understanding how historical
14 management of hydrology and harvest coupled with environmental variability shape the trends in abundance,
15 and thus facilitates understanding how future management actions may affect population recovery.

16 Keywords: state-space, WinBUGS, Bayesian, winter-run, California, water management

17 Introduction

18 Recovery of endangered animals requires an analysis of the factors responsible for affecting the population
19 dynamics historically and modifying those factors to facilitate recovery of the population. This is particularly
20 true of salmon populations that have seen decreases in their abundances through the majority of their range,
21 but particularly in the southerly portions of their distribution (NMFS 2014). Understanding what factors
22 have lead to the decline in abundances is an important step toward developing future management actions.
23 Incorporation of uncertainty is important when evaluating these factors to be able to identify the level of
24 confidence that one has in the relationship between historical factors and changes in population abundance.
25 An additional complication arises when abundance measurements are made with relatively poor accuracy.
26 Furthermore, natural variability in the population dynamics (i.e., spawner recruitment relationships) may
27 obfuscate the signal between causative factors and the response of the population to such factors. To address
28 these needs, we developed a state-space modeling framework that is capable of reflecting uncertainty in the
29 factors affecting salmon population dynamics.

30 The population dynamics uses stages to structure the chronology of factors affecting different portions of
31 the life cycle with density dependence among stages described by Beverton-Holt transitions (Moussalli and
32 Hilborn 1986, Scheuerell et al. 2006, Greene and Beechie 2004). The dynamics incorporate process noise
33 to reflect natural variability in the dynamics of the population and an observation process that describes
34 a state-space modeling framework (Newman et al. 2014). Although the parameters of such models can be
35 estimated using maximum likelihood methods (Maunder et al. 2011) we estimate the model parameters in a
36 Bayesian framework to allow prior knowledge and the observation process to inform the parameter estimates
37 (i.e., using posterior distributions to integrate information from these two sources). Fitting such non-linear
38 state-space models in a Bayesian context is becoming relatively commonplace (King et al. 2010, Newman
39 and Lindley 2006) and this is an extension of those methods.

40 The development of this modeling framework arises from a practical problem related to a population that

41 may have a moderate probability of extinction (Lindley et al. 2007, Botsford and Brittnacher 1998). The
42 Sacramento River winter-run Chinook (*Oncorhynchus tshawytscha*) currently listed as endangered under
43 the Federal and California Endangered Species Acts, and it has seen a decline in escapement since the
44 1970's. Like many salmon populations in decline, a list of factors that could potentially affect winter-run
45 (and other salmon transiting the Sacramento River and the San Francisco Delta) have been compiled. Some
46 of these factors include: 1) thermal mortality of eggs and alevin in the spawning reaches; 2) flow related
47 survival after emergence; 3) rearing in off-channel areas such as the Yolo bypass (Sommer et al. 2005); 4)
48 entrapment into the interior delta due to positioning of channel flow gates (Perry et al. 2010); 5) alterations
49 in the outmigration flow vectors due to exportation of water from the system (Newman and Brandes 2010;
50 Newman 2003); 6) predation from piscivorous fishes such as striped bass (*Morone saxatilis*) (Newman and
51 Lindley 2006). Salmon exiting the Bay-Delta ecosystem enter the Gulf of the Farallones and transition to a
52 near-shore environment with annual variability in productivity tied to the strength and location of upwelling
53 (Wells et al. 2007). Once winter-run attain an age of 3 years (2-ocean), they are vulnerable to the west coast
54 salmon fishery that primarily targets fall-run Chinook from the Klamath River, OR and Sacramento Rivers
55 but also catches winter-run (O'Farrell 2012); however, timing and area closures to minimize fishery impacts on
56 winter-run have been in place since the late 1990's (O'Farrell 2012). Yet, the ability to quantitatively evaluate
57 the importance of all of these factors for explaining trends in winter-run escapement has not occurred.

58 The objectives of our work is to provide a general overview of the *Onchorhynchus* Bayesian Analysis
59 (OBAN) modeling framework and to provide an analysis of the winter-run Chinook in the Sacramento River
60 as an example of how the framework was utilized.

61 **Methods**

62 **Population Dynamics Model**

63 The OBAN modelling framework provides a quantitative tool to evaluate historical patterns in salmon
64 abundance as a function of hypothesized explanatory factors. Specifically, the model: 1) estimates model
65 coefficients by fitting predictions of the population dynamics model to observed indices of abundance; 2)
66 evaluates factors that may explain dynamic vital rates; 3) accounts for mortality during all phases of the
67 salmon life history; and 4) incorporates uncertainty in the estimation of model coefficients by fitting in a
68 Bayesian framework.

69 The first step to the modeling framework is to define the life-history stages. The OBAN model structure

70 can define life-history stages based on management objectives, such as important locations of anthropogenic
 71 or environmental driving factors by the locations where indices of abundance are observed. The number of
 72 life-stages is application specific, but it has to incorporate at least two stages for freshwater (egg and juvenile
 73 stages), and an ocean stage for each age of returning adult (e.g., a stage for each of the age 2, ..., L ages of
 74 escaping adults). The OBAN model uses temporally implicit stage durations. Each freshwater stage may be
 75 defined such that it reflects the duration that the salmon are within that stage, thus stages do not need to be
 76 the same duration. As a consequence, inference on the population vital rates for that stage are predicated
 77 on its duration.

78 The OBAN framework begins with eggs as the first stage and defines the egg abundance as a function of
 79 the escapement.

$$N_{1,t} = E_t \times f_t \quad (\text{D.1})$$

80 where $N_{1,t}$ is the first stage (egg) abundance, E_t is the escapement, and f_t is the fecundity at time t . If
 81 only females are being modeled, then the fecundity reflects estimates of eggs per female. Alternatively, if
 82 escapement is not sex-specific then fecundity can be defined in terms of fecundity per adult.

83 The OBAN framework uses Beverton-Holt transitions to calculate the density-dependent transition in
 84 abundance among freshwater life stages ($1, \dots, M$) after the egg stage.

$$N_{i,t+1} = N_{i,t} \times \frac{p_{i,t}}{1 + \frac{p_{i,t}N_{i,t}}{K_{i,t}}} \quad (\text{D.2})$$

85 where $p_{i,t}$ is the productivity parameter, $K_{i,t}$ is the capacity parameter of the Beverton Holt transition and
 86 $K_{i,t}$ is the capacity parameter for stage $i = 2, \dots, Q$ in year t . Because the production of eggs is captured
 87 in equation (1), productivities are equivalent to survival rates in the absence of density dependence and are
 88 confined to the range $(0, 1)$. If density dependence is not expected to occur between two stages, the $K_{i,t}$
 89 parameter can be set to a large value to effectively remove the density-dependent portion of the equation.

90 The productivity parameter ($p_{i,t}$) and capacity parameter ($K_{i,t}$) in a given life stage i from brood year t
 91 can be modeled as 1) a constant value; 2) as a constant value with annual variation via random effects; or 3) as
 92 a dynamic rate with dependence on a set of time-varying covariates ($X_{j,t}$ for factor j in year t). By using the
 93 final formulation, the influence of anthropogenic and environmental factors on specific life history stages can
 94 be evaluated. The productivity parameter can be influenced by independent factors acting simultaneously
 95 on the life history stage to drive demographic rates, for example environmental variables that represent

96 water conditions such as temperature or flow, biotic factors such as predator abundance, food abundance,
 97 or anthropogenic factors such as diking, water diversions, and harvest.

98 The dynamic productivities are modeled as a function of various factors by using a logit transformation,
 99 which ensures that the productivities remain between 0 and 1.

$$\text{logit}(p_{i,t}) = \sum_{j=1}^F \beta_j X_{j,t} \quad (\text{D.3})$$

100 where β_j is the coefficient associated with factor $X_{j,t}$.

101 Likewise, there may be processes occurring that affect annual stage-specific capacities, such as the amount
 102 of available spawning area or the amount of flooded off-channel rearing habitat. To model the dynamic
 103 capacities, a log transformation is used, which causes the capacities to remain between 0 and ∞ , which is
 104 the appropriate parameter space for capacity.

$$\log(K_{i,t}) = \sum_{j=1}^F \gamma_j X_{j,t} \quad (\text{D.4})$$

105 where γ_j is the coefficient associated with factor $X_{j,t}$.

106 After Chinook enter the ocean, they mature and can return to spawn after a single summer or after
 107 overwintering in the ocean for multiple years (Healey 1991). When Chinook enter the ocean, we shift the
 108 notation to O_{age} to reflect the fact that some Chinook will remain in the ocean, while others will mature
 109 and migrate back to freshwater after escaping the fishery. The transition from juvenile rearing to ocean
 110 stages occurs via the following transition equation

$$O_{2,t} = N_{M,t} \times \frac{p_{M,t}}{1 + \frac{p_{M,t} O_{i,t}}{K_{M,t}}} \quad (\text{D.5})$$

Maturation of ocean stages for ages $2, \dots, L$ are calculated using the following equation:

$$M_{t+age} = O_{age,t} \phi_{age} z_{age} \quad (\text{D.6})$$

111 where M_{age} is the maturation of the adults at a specific age returning to freshwater according to the
 112 conditional maturation rate ϕ_{age} . The number of fish remaining in the ocean $O_{age,t}$ is a function of those
 113 that remain and survive to the following year. Because harvest is one of the major sources of mortality in
 114 the ocean stages, the above formulation assumes that harvest occurs before maturation; however, this order
 115 could be altered to reflect the specific dynamics of the stock of Chinook being modeled.

$$O_{age+1,t} = (1 - h_{age,t})(1 - \phi_{age})O_{age,t} \times \frac{p_{age,t}}{1 + \frac{p_{i,t}O_{age,t}}{K_{age,t}}} \quad (\text{D.7})$$

116 In the final stage, all Chinook of age L return, thus $M_{t+L} = O_{L,t}$. Survival and capacities can be modelled
 117 in the ocean stages just as in the freshwater stages to reflect the effects of localized nearshore productivity.
 118 Furthermore the conditional maturation rates may also be modeled as a function of factors using logistic
 119 regression. For example, due to differential size at ocean entry or size at release in the case of modeling a
 120 hatchery population.

$$\text{logit}(\phi_{age,t}) = \sum_{j=1}^F \delta_j X_{j,t} \quad (\text{D.8})$$

121 where δ_j is the coefficient associated with factor $X_{j,t}$.

122 Finally, the escapement in calendar year y is the sum of the mature fish returning from the ocean at ages
 123 $2, \dots, L$ from brood years $y - 2, \dots, y - L$.

$$E_y = \sum_{age=2}^L M_{age,t} \quad (\text{D.9})$$

124 Process noise can be added to the stage-specific survivals and capacities by allowing them to vary as
 125 a random effect. For example, extra variability could be incorporated through a residual error term in
 126 either equation (1) or equation (2) to add variability in the production (fecundity) relationship or in the
 127 stage transitions, respectively. To implement process noise, stage-specific random effects, e.g., $Z_{i,t} \sim N(0, \sigma_{i,p}^2)$
 128 can be added to the equation to express annual variation, where $\sigma_{i,p}^2$ reflects the variance due to process
 129 noise in stage i . The amount of process noise may require some additional structure (e.g., through prior
 130 specification), otherwise, all the observed data may ostensibly be fitted exactly by allowing the variance in
 131 the process noise to be sufficiently large.

132 Finally, the timing of the influence of factors has to be matched with the timing of the life stages such
 133 that the factors are affecting the appropriate cohort. The time subscript t refers to the brood year, thus
 134 the covariates, which are typically provided by calendar year y , are lagged appropriately for the population
 135 under study.

136 Bayesian Estimation

137 Estimation of the model parameters occurs by comparing model predictions to observed data across multiple
 138 competing "states of nature" or parameter values. This is achieved through Bayesian estimation of the
 139 likelihood of observing the data times the prior probability of the model parameter values (Gelman et al.
 140 2004). The general framework described above is used to compute predicted abundances that are then
 141 compared with observed abundances obtained through some sampling method. As a result, a sampling
 142 model is defined for each observation. The stage abundances are related to the observed indices of abundance
 143 through a sampling model $g()$. The framework is relatively flexible in that any type of sampling data can
 144 be incorporated by specifying an appropriate sampling model. Multiple types of abundance indices, $I_{i,k,y}$
 145 for stage i of index type k in year y , can be included in the modeling framework by defining the observation
 146 process $g()$ as a function of the sampling model and observation error σ_k^2 . For example, the observation
 147 process $g()$ could be defined as a lognormal for abundances or biomass, Poisson or negative binomial for
 148 counts, or Binomial for capture-recapture studies. Note that if the observation process is modeled with
 149 lognormal errors, the variance can be defined in terms of the coefficient of variation (CV = mean/standard
 150 deviation) as $\sigma_k^2 = \log(CV_k^2 + 1)$.

$$I_{i,k,t} \sim g(N_{i,t}, \sigma_k^2) \quad (\text{D.10})$$

151 Priors

152 Prior probability distributions are required for all model coefficients that are estimated within the modeling
 153 framework. For example the coefficients of the logistic regression to define stage-specific survival rates (β_j 's)
 154 and coefficients of the log-linear model (γ_j 's) to define stage-specific capacities will require prior probability
 155 distributions; normal distributions can be used to define the prior probabilities for both of these coefficients
 156 due to the transformations used in equations (3) and (4). Care should be taken in specifying the priors for
 157 the β coefficients given their inclusion into a logit() transformation, however. King et al. (2010) suggest
 158 that $N(0,2.5)$ priors may be used in the coefficients of logistic regression to ensure that excessive mass is not
 159 placed in the values near 0 and 1 (as might be the case with a more diffuse normal prior). The conditional
 160 maturation rates ϕ_{age} are required to be in the interval (0,1); therefore, Beta distributions can be used as
 161 priors for these coefficients. Finally, the variance of the measurement error on the observation process (σ_k^2)
 162 and the variance of any process noise ($\sigma_{i,p}^2$ for stage i) will also require a prior and can be specified as either

163 inverse gamma on the variance or alternatively as a uniform prior on the standard deviation of the variance
 164 (Gelman et al. 2006).

165 *Implementation of Bayesian Estimation*

166 The posterior distributions of the model parameters can be estimated by drawing samples from the full
 167 conditional distributions of each parameter given values of all other parameters through a Metropolis within
 168 Gibbs Markov Chain Monte Carlo (MCMC) approach (Gelman et al. 2004, Gilks and Spiegelhalter 1996). If
 169 conjugate priors are used, then the Gibbs sampler can be employed; however, if posterior distributions for the
 170 parameters can not be updated using the Gibbs sampler (Roberts and Polson 1994), they can instead updated
 171 by using distribution-free adaptive rejection Metropolis steps (Gilks and Spiegelhalter 1996, Spiegelhalter
 172 et al. 2003) which is the approach adopted in WinBUGS (Spiegelhalter et al. 2003).

173 To evaluate if the posterior draws were arising from a stationary target distribution, multiple chains were
 174 run from dispersed initial values for each model and the scale reduction factor (SRF, Gelman et al. 2004)
 175 was computed for all monitored quantities (model coefficients and abundance estimates). The diagnostics
 176 were implemented using the R2WinBUGS package (Sturtz et al. 2005) in R (R Core Team 2013). Monitored
 177 parameters in all models had SRF values that indicated samples were being drawn from the target distribution
 178 (i.e. $SRF \approx 1$) by 75,000 samples (Gelman and Rubin 1992). The initial 50% of the samples were used to
 179 reach the stationary target distribution and were discarded with the subsequent samples thinned to produce
 180 approximately 1,000 draws from the stationary target distributions. The 1,000 draws were used to compute
 181 the posterior mean and symmetric 95% probability intervals or credible intervals (95% CrI).

182 **Application of Model to Winter Run Chinook**

183 We defined 7 life-history stages in the winter-run OBAN model including 6 freshwater and marine transition
 184 stages and 3 annual ocean stages: 1) eggs, 2) fry 3) juveniles in the Delta (delta), 4) juveniles in the Gulf of
 185 the Farallones (gulf) 5) age 2 in the ocean, 6) age 3 in the ocean, and 7) age 4 in the ocean. The escapement
 186 was composed of mature individuals that returned at age 2, 3, and 4 (Table D.1).

187 Fecundity was assumed to vary annually, and the annual values were sampled from probability distribu-
 188 tion, i.e., $f_t \sim \log N(\mu_f, \sigma_p^2)$. This formulation allowed process noise to be incorporated into the population
 189 dynamics, but empirical information on fecundity restricted the range of process noise in the model. Multiple
 190 environmental and anthropogenic factors were incorporated into the winter-run model at different stages in
 191 the life-history based on hypotheses about factors affecting (Table D.2). The mean fecundity is calculated

192 by assuming that each adult spawner produces 2,450 eggs (Williams 2006, Winship et al. 2014).

193 *Winter Run Abundance Indices*

194 Estimates of winter-run escapement in the Central Valley have been conducted since 1967, and we used an
195 escapement abundance index from 1967 to 2008. Different methods were used to estimate escapement over
196 this period, which may affect the precision of the spawner escapement estimates (Williams 2006, Botsford
197 and Brittnacher 1998). Prior to 1987, all returning spawners passed via a counting ladder at Red Bluff
198 Diversion Dam (RBDD, Figure D.1). From 1987 onward the gates of the diversion dam have been opened
199 to enhance upstream survival of winter-run Chinook salmon, but also likely improved access to areas above
200 RBDD. The current operation of RBDD makes counts of winter-run Chinook salmon after closing the gates
201 on May 15. On average, 15% of the winter run passed RBDD by May 15, but the specific percentage in
202 a given year was as low as 3% or as high as 48% (Snider et al. 2000). Since 2001 the annual escapement
203 estimates have been calculated using a Jolly-Seber estimator derived from the carcass count data (California
204 Department of Fish and Game 2004). Juvenile production indices were calculated from rotary screw trap
205 samples and trap capture probabilities at Red Bluff Diversion Dam for 1995 through 1999 and 2002 through
206 2008 (Poytress and Carrillo 2011).

207 *Winter Run Factors*

208 Several environmental and anthropogenic factors were used to help describe variability in winter-run juvenile
209 and adult abundance indices (Table D.2). Because the abundance indices occur at RBDD, which coincides
210 with the fry stage, a basal survival rate could be estimated for the egg to fry stages and a second basal rate
211 for the fry to escapement stages. Explanatory factors were incorporated into the survival during the fry
212 stage, delta stage, and gulf stages (Table D.2). We provide a short rationale for the inclusion of each of the
213 factors here.

214 Water temperatures in the spawning reach above RBDD can sometimes reach stressful levels, thus July
215 through September mean daily water temperature (C) in the Sacramento River at Bend Bridge (TEMP)
216 was used to explain annual variability in egg to fry survival. In addition, low flow can affect survival rates of
217 alevin, so August through November minimum monthly flow in the Sacramento River at Bend Bridge was
218 also used to affect egg to fry survival. In addition, an interaction term of TEMP:FLOW was incorporated
219 into the model to determine if there was some additional mortality associated with either high temperatures
220 or low flow.

221 In the delta stage, several factors may affect winter-run survival rates. Access to the Yolo bypass, a large
 222 floodplain that provides the potential for increased survival and growth of fall-run Chinook (Sommer et al.
 223 2005), may also provide similar benefits for winter-run via bypassing the delta. The Yolo bypass floods when
 224 flows on the Sacramento River surpass 56,000 cfs; each day when flows were great enough to enter the Yolo
 225 bypass between December and March was a potential opportunity for winter-run to enter the floodplain
 226 habitat (YOLO). The Delta Cross Channel is a dual gate structure that conveys water to the interior delta,
 227 and late-fall Chinook salmon that enter the interior delta have lower survival rates relative to those that
 228 migrate down the Sacramento River (Perry et al. 2010). In the southern delta, the Central Valley Project
 229 and State Water Project export water from the delta to supply agricultural and municipal water needs.
 230 The levels of exports can vary annually and have been associated with differential survival rates of fall run
 231 Chinook (Newman and Brandes 2010, Newman 2003).

232 Finally, nearshore ocean processes can have important consequences for Chinook salmon (Wells et al.
 233 2007, Woodson et al. 2013), and here we evaluated upwelling in a region south of the entrance to San
 234 Francisco Bay (UPW) and the sea surface temperature in the Gulf of the Farallones (FARA).

235 The ocean stages were modeled as a function of maturation rates and age-3 impact rates. Information for
 236 the maturation rates were taken from an analysis of 1998, 1999, and 2000 coded wire tag (CWT) data (Grover
 237 et al. 2004) and more recent analyses of maturation rates (O'Farrell et al. 2012). Age-3 impact rates for
 238 winter-run were calculated for 1978 - 2011 from a combination of estimated impact rates from CWT returns
 239 (1998 - 2008) and from a hindcast of impact rates given spatial allocation of fishing effort (O'Farrell, M.,
 240 NMFS unpublished data). Until 1987, there was little regulation of the Central Valley Chinook salmon shery
 241 and estimates of the mortality rate on winter-run Chinook salmon in the ocean shery were approximately
 242 0.7 of the mortality rate experienced by fall-run Chinook salmon.

243 Most winter-run Chinook salmon return to spawn as 3-year-olds; however, the winter-run age-4 oceanstages
 244 are more likely to be captured in the commercial fishery because of their larger size. Grover et al. (2004)
 245 found that the harvest-related mortality of age-4 winter-run Chinook salmon was 2.5 to 3.7 times the rate
 246 of age-3. The age-4 impact rate in a calendar year y was assumed to be double the instantaneous rate of
 247 age-3 ($h_{4,y} = \exp(\log(h_{3,y}/2))$).

Results

Observed winter-run escapement was on the order of several tens of thousands in the late 1960's and early 1970's and declined to levels in the low thousands during the 1980's with a low abundance estimate of 194 in 1994. Since the mid-1990's the population has recovered to some degree with escapements in the mid 2000's on the order of several thousands. The winter-run OBAN model captured this declining trend and recovery in escapement (Figure D.2). In particular, the model was able to capture the decline in the late 1970's (along with the spike in escapement in 1980), the continued decline through the mid-1990s, and the subsequent increase through early 2000. The three different sampling methods had median estimated CV's ranging from 0.68 for the early period, 1.34 for the middle period, and 0.97 for the later period. As a result, the model was more sensitive to those sampling methods with higher precision (lower CV). In particular, the model fits to the intermediate period (in which counts were expanded assuming 15% passed RBDD by May 15) indicated that the escapement in 1990, 1991, and 1994 was underestimated relative to model predictions (Figure D.2). In contrast, the winter-OBAN model predictions of escapements during the early period (1967 - 1987) and the later period (2001-2008) fit the annual variability in escapement estimates more closely. The winter-OBAN model also fit well to patterns in the juvenile abundance index at RBDD from 1995 to 2007. The median estimated CV on the juvenile index data was 1.2, indicating that the model had intermediate sensitivity to the juvenile indices relative to escapement. The winter-run model predictions of juveniles at RBDD captured the relatively low production of fry during the late 1990's, subsequent increase in early 2000's due to higher escapements, and the decline in the index in 2007 (Figure D.3).

Annual patterns in stage-specific survivals

To predict escapement and juvenile index values, stage-specific survivals were estimated as a function of the environmental and anthropogenic factors. The estimated survival from egg to fry at RBDD averaged 0.24 95%CrI(0.11, 0.48) (Table D.3); however, survival from the 1970's to mid-1990's was highly variable. There were two years in the late 1970's where median survival was predicted to be approximately zero and periods in the early 1980's and early 1990's when survival in the alevin stage was also low (Figure D.4). Since the mid-1990's the survival rates for alevin have been more stable relative to the prior periods. Survival through the delta stage, which spans fry at RBDD to the nearshore ocean, was 0.0097 (95%CrI: 0.0041, 0.022) (Table D.3). Within the delta, annual variability was less pronounced with median survival ranging from a high of 0.017 in 1969 to a low of 0.0063 in 2004. Median delta survivals were relatively stable at approximately 0.009 through the 1980's and 1990's with slightly lower survivals during 2001 to 2004 of approximately

278 0.006 (Figure D.4). Average survival in the gulf stage was assumed to be 0.5 and variability in survival
279 among years was reflective of ocean productivity. For winter-run Chinook the mid 1980's and mid 1990's
280 were periods of poor survival, whereas 1998 and 2000 - 2001 were years of relatively good survival. Finally,
281 patterns in age-3 survival rates (which were a deterministic function of harvest rates and annual survival
282 rate of 0.8) indicated relatively low survival rates for brood years through the mid-1990's, with improving
283 ocean survival for brood years after 1995 (Figure D.4).

284 Although the magnitude of the effect from each factor cannot be evaluated directly via the magnitude
285 of the coefficient estimate (due to dependence on the stage-specific intercept), the sign of the coefficients
286 associated with factors provide an indication of the effect of the factor: positive values increase survival
287 relative to the average and negative values decrease survival. Because the winter-run OBAN model was fit
288 in a Bayesian framework, the coefficients are described by posterior distributions and the probability that
289 the coefficient value was positive was calculated (Table D.3). In the egg to fry stage, temperatures in the
290 spawning reaches (TEMP) had a consistent negative effect on survival, whereas minimum flows (FLMIN)
291 had a consistent positive effect on survival (Table D.3). A positive TEMP:FLMIN interaction term of
292 flow and temperature would exacerbate the negative effect of high temperatures and low minimum flows,
293 and the interaction term had a 0.73 probability of being positive. In the delta stage, access to the Yolo
294 bypass (YOLO) and DCC gate position open (DCC) had a positive effect on survival, whereas export levels
295 (EXPT) were negative. Finally, in the gulf stage, high temperatures in the Farallone Islands (FARA) had a
296 negative effect on winter-run survival, whereas upwelling south of the entrance to San Francisco Bay (UPW)
297 had a positive effect on survival (Table D.3). Several additional parameters were given informative priors
298 to structure the winter-run OBAN model, although if the data were informative on the coefficients, this
299 would be reflected in the posterior. The posteriors on the conditional maturation rates largely reflected the
300 informative priors. as did the CV on the process error (Table D.3).

301 The magnitude of the effect for each of the factors can not be discerned directly from the magnitude
302 of the coefficient estimate (e.g., in Table D.3), because the coefficients associated with the covariates are
303 dependent upon the intercept terms. To understand how the various factors affect the overall survival of
304 winter-run Chinook, we increased each of the covariates one at a time by 1 standard deviation (SD). The
305 survival rates under the one-at-a-time increases were compared to a baseline case, which was the survival
306 rate with all factors at their mean 1967 to 2008 level. The survival rates began at the egg stage and ended
307 at the end of age 2, prior to harvest affecting survival. To facilitate comparison, we calculated the percent
308 change relative to the baseline survival (i.e., $(alt_k - base)/base \times 100\%$), where alt_k describes a model with

309 factor k increased by 1 SD. Minimum flow had the largest effect per unit SD on winter-run survival with a
 310 median increase of 128% (Figure D.5). Temperature also had a strong effect with a negative median effect
 311 of -96.7% per unit SD. The other notable factors were exports which had a negative effect of - 12.4% per
 312 unit SD, Yolo with a median positive effect of 11.3% and upwelling with a positive effect of 42.3% per unit
 313 SD (Figure D.5). The standard deviations are not the same on a percentage basis among factors, however.
 314 For example 1 SD of TEMP is equal to 6.8% of the mean, whereas 1 SD of EXPT is equal to 25.6% of the
 315 mean. Calculations of the effects of each factor on a percent basis indicated that temperature provides the
 316 largest effect with an 11.9% decrease in survival per percent increase in temperature. Minimum flows in the
 317 spawning reach provided a median 5.73% change, temperature in the Farallones provided a median -1.55%,
 318 and upwelling provided a median 1.78% change, whereas all other factors provided a less than 1% change in
 319 survival for a 1% increase in the factor (EXPT -0.48%, YOLO 0.10%, and DCC 0.16%).

320 Correlation among coefficients was generally low with the exception of the two intercept terms β_{alevin} and
 321 β_{delta} (Pearson correlation coefficient on posterior samples = - 0.685). Despite juvenile data being present
 322 for the latter portion of the time series, some negative correlation among these two coefficients was expected
 323 due to the model structure. This correlation did not inhibit the MCMC algorithm from converging, however.
 324 All scale reduction factors on monitored parameters were approximately 1, which indicated that the 3 chains
 325 had converged to a stable distribution.

326 Discussion

327 The winter-OBAN framework provided a means to evaluate the importance of several anthropogenic and
 328 environmental factors hypothesized to affect winter-run Chinook in the Central Valley. The model results
 329 support the importance of the environmental conditions in the natal spawning and rearing area and early
 330 ocean conditions with important but more subtle effects of delta survival. Our results are comparable with
 331 previous models of winter-run Chinook, providing some justification of the overall model structure and its
 332 inference. Our estimate of delta survival can be compared with Winship et al. (2014), who estimated the fry
 333 to end of age 2 survival rate for 1996 - 2008 of 0.4%. In comparison, our delta survival rate was 0.9% times
 334 the average age 2 value of 0.5 equals a 0.45% estimate for our model from fry to the end of age 2.

335 Median egg to fry survivals were slightly lower than estimated by Winship et al. (2014), in which the
 336 median egg to fry survival was 0.30. Furthermore, they found little variability in annual egg to fry survival.
 337 Similar fry data were used for both models; however, the winter-run OBAN model was able to use the

338 1995-2008 survival relationships to improve inference on factors affecting egg to fry survival in the 1970's to
339 mid-1990's, prior to the analysis of Winship et al. (2014). We too found low variability among years in egg
340 to fry survival from 1996 to 2008, but in contrast we found that there was high variability in survival prior
341 to 1995 due to temperature and flow effects, and it played an important role in the decline of winter-run
342 Chinook during the late 1970's and 1980's.

343 The factors leading to the decline in winter-run abundance during the 1970's can be explained by several
344 periods of poor egg to fry survival tied to low flows and high water temperatures in the spawning reaches.
345 While survival through the delta did not vary dramatically, survival at early ocean entry also had several
346 periods with generally poor survival. Concurrent with this period of episodic recruitment failure and variable
347 ocean conditions, impact rates of age-3 winter-run averaged 0.38 from 1969 to 1997. The recovery of winter
348 run beginning in the late 1990's and early 2000 can be attributed to several management actions and good
349 ocean productivity from 2001 - 2003. The installation of a temperature control device in 1991 has generally
350 reduced the variability in temperature with subsequent reduction in variability of egg to fry survival since 1993
351 (Figure D.4). Concurrent with the installation of the temperature control device, harvest rate management
352 reduced the impact rates on winter-run (1998-2009 average of 0.153) (O'Farrell et al. 2012). In addition,
353 survival through the delta was generally better during the 1996 to 1998 period due to lower than average
354 exports and greater than average access to Yolo bypass.

355 *Model Critique*

356 Although the OBAN modeling framework can incorporate density dependence in the model structure, the
357 winter-run implementation here did not include it based on previous work fitting density dependence to
358 winter-run abundance indices. Estimation of the density dependence requires a signal in the data, namely
359 the reduction in survival as a function of abundance. Previous efforts to include density dependence in
360 models of winter-run population dynamics have had mixed results. Newman and Lindley (2006) included
361 density dependence in the egg to fry transition and found little support for density dependence in a model
362 without process noise, but they found strong evidence when process noise was included as a random effect in
363 each stage under a state-space formulation. The information in the data to support the density dependence
364 came from accounting for autocorrelation in the juvenile abundance state variables as well as measurement
365 errors. Winship et al. (2014) found little support for density dependence in the egg to fry stage using a
366 state-space model that estimated process noise, but fixed measurement error based on estimates of CV from
367 sampling design. Based on the similarity of our model design to Winship et al. (2014), we did not include

368 capacity in the model structure. We return to the topic of density dependence below.

369 We also did not include hatchery output explicitly in the winter-run OBAN implementation. We did,
370 however, incorporate a process noise component to the egg production stage, which was able to vary among
371 years. Hatchery supplementation should be reflected in deviations of recruitment variability, if it was in
372 fact improving the productivity of the population. Hatchery supplementation was initiated in 1991 with
373 some releases in 1994 and 1995; however, production began in earnest in 2000 with between 20 to 57 natural
374 origin females removed from the spawning population for hatchery brood stock (Winship et al. 2014). A
375 more direct approach would be to include a dummy factor in the egg production equation that identified
376 years of hatchery production. The hatchery term could be restricted to have a positive value, reflecting a
377 hypothesized expected benefit of hatchery supplementation, or allowed to be positive or negative reflecting
378 the potential for negative hatchery effects on production of natural origin juveniles.

379 *Recovery*

380 Recovery of winter-run is likely to occur through management of factors under human control while being
381 aware of the influence of uncontrollable environmental conditions (e.g., upwelling). Winter-run appear to
382 be particularly sensitive to temperatures and flows in the spawning reaches. Estimates of the temperature
383 during 1977 indicated that it was 4 standard deviations above the mean (17.6 C) during the July to September
384 period. Mortality in the egg to fry stage was similar in 1976, though, when the temperature was only 1.2
385 standard deviations (14.6 C) above the mean. The installation of a temperature control device at Shasta
386 Dam provides the ability to decouple water temperatures from flow out of the dam, and manages temperatures
387 by mixing cold hypolimnetic water with warmer surface water. While this provides a method for controlling
388 temperatures, the operations of the control device may be complicated by the multi-year climate cycles that
389 affect the reservoir storage and thus the amount of cold water available. Still, the winter-run OBAN model
390 results suggest that small deviations in temperature can have substantial impacts on survival from the egg to
391 fry stage, and managing thermal mortality can have important consequences for the population dynamics.

392 Management of factors in the delta appear to also affect winter-run, but to a lesser degree than the
393 temperature and flow effects during egg to fry survival. Within the delta, increasing access to Yolo bypass
394 and reducing exports can have a positive effect on survival. Water flows into the Yolo bypass over an
395 approximately 1.5 mile weir when flows on the Sacramento River exceed 56,000 cfs at Verona. Winter-run
396 juveniles rear above the weir location and their downstream movement is triggered by flow cues (del Rosario
397 et al. 2013). Access to the Yolo bypass occurs when these flow pulses are also substantial enough to overtop

398 the weir. Given the general lack of off-channel rearing area for salmonids in the Central Valley, improving
399 access to Yolo bypass has been identified as an important management action for recovery of Central Valley
400 salmonids, and winter-run in particular (NMFS 2014).

401 For the model with a density dependent effect in Newman and Lindley (2006), a Beverton-Holt model
402 was used and the estimated capacity was on the order of 11.5 million fry. Using these values of capacity
403 for fry, estimated fry to age-2 survival of 0.45% and ocean age 2 and age 3 survival rates of 0.5, and 0.8
404 respectively would suggest a capacity of approximately 20,500 winter-run in the absence of harvest. This
405 capacity level was exceeded every year from 1967 to 1977; thus it may not be an appropriate capacity
406 estimate for that period, but could potentially reflect more recent conditions as the Newman et al. (2006)
407 model focused on 1992 to 2003. More importantly, the existence of a carrying capacity at this level may have
408 important implications for modeling the expected responses to recovery of winter-run. Both the Newman
409 and Lindley (2006) and Winship et al. (2014) models included density dependence in the egg to fry stage,
410 presumably because spawner and juvenile data were available. Yet density dependence could more likely
411 be in the spawning stage given that winter-run are currently spawning below Keswick dam, rather than
412 in their natal tributaries surrounding Mt. Shasta (Yoshiyama et al. 2001). For evaluating the potential
413 for reconnecting winter-run populations to their natal spawning reaches, such an analysis could provide
414 information on potential population sizes under expanded habitat.

415 The state-space modeling framework has proven to be an important component to ecological modeling
416 due to its ability to reflect uncertainties in the biological processes via process noise and in the observation
417 process via measurement error. In most applications, the process noise is ascribed to random effects (e.g.
418 Newman and Lindley 2006, Winship et al. 2014), but some of the variation in process noise may be explained
419 by relationships to anthropogenic and environmental factors. Thus, the OBAN framework attempts to move
420 inference toward evaluating hypotheses by formally laying out a framework by which stage-specific variability
421 can be ascribed to explanatory factors rather than to random effects. This linkage can be particularly
422 powerful if some of the factors affecting the population dynamics can be managed for salmonid recovery.

423 **Acknowledgements**

424 We thank the School of Aquatic and Fisheries Sciences at the University of Washington for providing feedback
425 through their Quantitative Seminar series, Eva Jennings for providing help with data management, and Curry
426 Cunningham for thoughtful discussions on state-space modeling and Chinook population dynamics. Support

⁴²⁷ for this project was received under Grant Agreement 2039 from the Delta Stewardship Council.

Table D.1: Model parameters, state variables, and observable indices of abundance for winter-run OBAN model.

Symbol	Value	Description
Indices		
i	egg, alevin, fry, delta, bay, gulf	freshwater stages
j		covariate index
k		gear type for observation process
t	1967, ..., 2004	brood year
y	1967, ..., 2008	calendar year
age	2, 3, 4	ocean age
State Variables		
$N_{i,t}$		abundance of freshwater stage
$O_{age,t}$		abundance of ocean stage
$M_{age,t}$		abundance of mature fish
Parameters		
$\beta_{i,j}$		coefficient relating factor j to survival in stage i
$\gamma_{i,j}$		coefficient relating factor j to capacity in stage i
$\delta_{age,j}$		coefficient relating factor j to maturation at age
ϕ_{age}	(0,1)	conditional maturation in age
$CV_{E,k}$		coefficient of variation for escapement observation process k
CV_J		coefficient of variation for juvenile observation process k
CV_p		coefficient of variation of process noise
f_t	2450	fecundity per spawner
$h_{age,t}$		impact rate due to harvest
$p_{i,t}$	(0, 1)	productivity in stage i and brood year t
$K_{i,t}$	(0, ∞)	capacity in stage i and brood year t
z_2	0.5	age 2 average natural survival rate
z_3	0.8	age 3 average natural survival rate
z_4	0.8	age 4 average natural survival rate
Observables		
$I_{y,E}$		Escapement 1967 - 2008
$I_{y,J}$		Juvenile abundance at Red Bluff Diversion Dam 1995 - 1999, 2002-2007

520 Figure D.1. Map of the Central Valley (black lines), Sacramento River, San Francisco Estuary, and ocean
521 habitats used by winter-run Chinook.

522 Figure D.2. Model fit to observed winter-run escapement data (squares) from three collection methods:
523 1) Red Bluff Diversion Dam (RBDD) counts, 2) expansion of RBDD counts assuming 15% passage by May
524 15, and 3) carcass mark-recapture. Vertical lines indicate 1 standard deviation. Heavy line is the mean
525 winter-run OBAN prediction, whereas thin lines are the 95% credible interval on model predictions of the

Table D.2: Covariates used in the winter-run OBAN model.

Covariate	Mean	Standard Deviation	Stage	Description
TEMP	13.4	0.9	alevin	Jul - Sept mean temperature at Bend Bridge (C) ¹
FLMIN	6605	1477	alevin	Aug - Nov minimum of monthly average flow at Bend Bridge (cfs) ²
YOLO	22.9	24.7	delta	Dec - Mar number of days where flow is greater than 56,000 on the Sacramento River at Verona ³
DCC	0.46	0.42	delta	Dec - Mar proportion of time when Delta Cross Channel gates are open ⁴
EXPT	1250154	320854	delta	Dec - Jun total exports (cfs) ³
UPW	210.5	49.8	gulf	Apr-Jun upwelling index ⁵
FARA	11.8	0.9	gulf	Feb - Apr mean temperature in the Farallon Islands (C) ⁶

¹ Temperature regressions for 1967 - 1970; modeled temperature data 1970-2005; gage data 2005-2008 CDEC-BND

Table D.3: Prior and posterior distributions in the winter-OBAN model.

Parameter	Prior	Mean	Median	95%CrI	Pr > 0
β_{alevin}	N(0, 2.5)	-1.17	-1.21	(-2.09, -0.09)	0.21
β_{delta}	N(0, 2.5)	-4.63	-4.64	(-5.48, -3.79)	0.00
β_{TEMP}	N(0, 2.5)	-2.00	-1.99	(-3.66, -0.35)	0.004
β_{FLMIN}	N(0, 2.5)	1.48	1.42	(0.42, 2.86)	1.00
$\beta_{TEMP:FLMIN}$	N(0, 2.5)	0.52	0.53	(-0.91, 2.06)	0.73
β_{YOLO}	N(0, 2.5)	0.13	0.11	(-0.54, 0.84)	0.65
β_{DCC}	N(0, 2.5)	0.15	0.14	(-0.37, 0.78)	0.70
β_{EXPT}	N(0, 2.5)	-0.13	-0.13	(-0.95, 0.66)	0.39
β_{UPW}	N(0, 2.5)	0.94	0.90	(-0.71, 2.83)	0.83
β_{FARA}	N(0, 2.5)	-0.24	-0.23	(-1.53, 0.91)	0.35
CV_{E1}	U(0, CV_{E3})	0.71	0.68	(0.46, 1.12)	NA
CV_{E2}	U(CV_{E3} , 2)	1.36	1.34	(0.80, 1.96)	NA
CV_{E3}	U(0, 2)	1.03	0.97	(0.62, 1.79)	NA
CV_J	U(0, 2)	1.20	1.20	(0.42, 1.93)	NA
CV_p	¹ B(2, 6)	0.26	0.25	(0.02, 0.59)	NA
ϕ_2	² B(1, 10)	0.038	0.030	(0.004, 0.128)	NA
ϕ_3	³ B(10, 1)	0.907	0.928	(0.700, 0.997)	NA

¹ Informative prior with a mean of 0.25, 95% interval (0.036, 0.58)

² Informative prior with mean of 0.091, 95% interval (0.0025, 0.31)

³ Informative prior with mean of 0.91, 95% interval (0.69, 0.99)

526 state variable of escapement.

527 Figure D.3. Model fit to observed winter-run juvenile abundance index (squares) at Red Bluff Diversion
528 Dam from 1996 to 2008. Vertical lines indicate 1 standard deviation. Heavy line is the mean winter-run
529 OBAN prediction, whereas thin lines are the 95% credible interval on model predictions of the state variable
530 of fry abundance.

531 Figure D.4. Predicted survival in the egg to fry (alevin) stage above Red Bluff Diversion Dam (A), in
532 the delta (B), in the gulf (C), and as age 3 in the ocean (D). For A - C the dark line represents the median
533 model prediction, whereas thin lines are the 95% credible interval on model predictions. For D the dark line
534 represents the assumed survival rate of age-3 due to natural mortality and harvest.

535 Figure D.5. Analysis of factors affecting winter-run survival to the end of age 2. Factors were increased
536 by 1 standard deviation and the percent change in survival to the end of age 2 relative to a baseline (all
537 factors at their 1967-2008 mean levels) was calculated for each factor. Please see Table D.2 for a description
538 of each factor.

creasing demands of supporting and moving greater weight on land and the benefits of having more upright toe bones but directing some loads away from the toes with the predigits and fat pad, which resulted in the peculiar compromise that persists in the feet of extant elephants.

The recognition of elephant predigits as enlarged sesamoids that perform digit-like functions fuels inspiration for examining the evolution of foot function, terrestriality, and gigantism in other lineages. Sauropod dinosaurs had expansive foot pads, particularly in their pedes (24); however, no evidence of predigits has been found. Considering that the predigits form on the medial border of the feet, they would tend to be lost if digit I is lost or reduced, as it was in early perisodactyls and artiodactyls. This loss might limit foot pad expansion and thereby explain why rhinos and hippos seem to lack predigits [but see (18) for a possible rudimentary pollex in hippos] and have less expanded foot pads than elephants do (8). Regardless, the previously misunderstood and neglected predigits of elephants now deserve recognition as a remarkable case of evolutionary exaptation (4), revealing how elephants evolved their specialized foot form and function.

Global Seabird Response to Forage Fish Depletion—One-Third for the Birds

Philippe M. Cury,^{1*} Ian L. Boyd,^{2*} Sylvain Bonhommeau,³ Tycho Anker-Nilssen,⁴ Robert J. M. Crawford,⁵ Robert W. Furness,⁶ James A. Mills,⁷ Eugene J. Murphy,⁸ Henrik Österblom,⁹ Michelle Paleczny,¹⁰ John F. Piatt,¹¹ Jean-Paul Roux,^{12,13} Lynne Shannon,¹⁴ William J. Sydeman¹⁵

Determining the form of key predator-prey relationships is critical for understanding marine ecosystem dynamics. Using a comprehensive global database, we quantified the effect of fluctuations in food abundance on seabird breeding success. We identified a threshold in prey (fish and krill, termed “forage fish”) abundance below which seabirds experience consistently reduced and more variable productivity. This response was common to all seven ecosystems and 14 bird species examined within the Atlantic, Pacific, and Southern Oceans. The threshold approximated one-third of the maximum prey biomass observed in long-term studies. This provides an indicator of the minimal forage fish biomass needed to sustain seabird productivity over the long term.

Public and scientific appreciation for the role of top predators in marine ecosystems has grown considerably, yet many upper trophic level (UTL) species, including seabirds, marine mammals, and large predatory fish, remain depleted owing to human activities (1–4). Fisheries impacts include direct mortality of exploited species and the more subtle effects of altering trophic pathways and the functioning of marine ecosystems (5). Specifically, fisheries for lower trophic level (LTL) species, primarily small

coastal pelagic fish (e.g., anchovies and sardines), euphausiid crustaceans (krill), and squid (hereafter referred to as “forage fish”), threaten the future sustainability of UTL predators in marine ecosystems (6, 7). An increasing global demand for protein and marine oils contributes pressure to catch more LTL species (8). Thus, fisheries for LTL species are likely to increase even though the consequences of such activity remain largely unknown at the ecosystem level. It remains challenging, however, to assess fishing

impacts on food webs because numerical relationships between predators and prey are often unknown, even for commercially valuable fish (9, 10). Ecosystem models and ecosystem-based fisheries management, for which maintaining

predator populations is an objective (2, 11, 12), will remain controversial until these relationships are more fully quantified.

To improve our understanding of the effects of LTL fisheries on marine ecosystems, more information on predator-prey relationships across a range of species and ecosystems is required (6). Seabirds are conspicuous members of marine ecosystems globally. Many aspects of seabird ecology have been measured consistently for decades, encompassing ecosystem change at multiple scales (13). Substantial long-term data sets on seabird breeding success have been compiled for many taxa in several marine ecosystems around the world (14–16), but for relatively few has independent information on prey availability been obtained concurrently. For those where prey data are available, temporal covariance in predators and their prey suggests that seabirds can be used as indicators of forage fish population fluctuations (7, 16, 17). Here, we used data collected contemporaneously over multiple decades from seabirds and forage fish to test the hypothesis that the form of the numerical response between seabird breeding success and forage fish abundance is consistent across species and ecosystems. We used data from seabird species that have strong dietary dependencies on forage fish prey and where the time series for both the predator and the prey have high spatial and temporal congruence. We compiled data from 19 time series covering seven marine ecosystems, nine sites, and 14 seabird species and their major prey (Fig. 1 and table S1). The data set included 438 data points spanning 15 to 47 colony-years per breeding site (table S1). The abundance of principal prey for each seabird species was estimated independently of the data collected from the birds, usually as part of population assessments conducted in support of fisheries management (table S1).

To examine empirical relationships between seabird breeding success and prey abundance, we used nonparametric statistical methods that facilitate nonlinear modeling by making no a priori assumptions about the form of the relationships (generalized additive models, or GAMs). Initially, each time series (seabird breeding success and prey abundance) was normalized by expressing the measurements as the number of standard deviations from the mean; this enables robust comparisons across species and ecosystems. Once the numerical relationship was established, we used a change-point analysis (sequential *t* tests that find the most likely point at which the slope of breeding success changes in relation to prey abundance) to identify thresholds within nonlinear relationships (18) (Fig. 2A). A bootstrap analysis was used to calculate confidence intervals of the threshold, and the variance in seabird breeding success was calculated for each prey abundance class. Last, a selection of a priori parametric models ranging from linear, sigmoid, asymptotic, to hierarchical (table S2) was fitted to the general relationship. The most parsimonious

model was then used to fit the relationship between seabird breeding success and forage fish population size for each ecosystem (pooling all species) and each seabird species (pooling all ecosystems).

Seabird breeding success showed a nonlinear response to changes in prey abundance (Fig. 2A). The threshold at which breeding success began to decline from the asymptote was not significantly different from the long-term mean of prey abundance (range -0.30 and $+0.13$, standard deviation of the mean, Fig. 2A). The threshold was 34.6% (95% confidence interval 31 to 39%), or approximately one-third of the maximum observed prey abundance. The coefficient of variation between the different thresholds among species and ecosystems was 28% (table S1). All time series were of sufficient duration to identify the threshold (detection is possible after 13 years of observation, fig. S1) and the maximum biomass (detection is possible after 11 years, fig. S2). Variance in breeding success increased significantly (*F* test, $P < 10^{-4}$) below the threshold of prey abundance (Fig. 2B). Fitting parametric models to individual responses showed a similar inflection point and similar asymptotic values across ecosystems and species (Figs. 2, C and D, and 3), indicating that the functional form was a general feature of the seabird–forage fish relationship.

The asymptotic form of the relationship between seabird breeding success and forage

fish abundance has been reported previously (15, 16, 19–24), but the common scaling across species and ecosystems and the consistency of threshold values are new observations. The global pattern shows a threshold below which the numerical response declines strongly as food abundance decreases and above which it reaches a plateau and does not change even as food abundance increases. This pattern is apparently robust to the varying life-history strategies, habitat preferences, and population sizes of the seabird species considered. Nonetheless, we acknowledge that a range of factors may interact to weaken or possibly accentuate the relationship between seabird breeding performance and prey species abundance. Alternative drivers of change in breeding success include changes in habitat characteristics or predation pressures, or complex intercolony dynamics. Predators may also show more or less capacity to switch to alternative prey items, which may buffer productivity against declines in any single prey species (25).

Periods of consistently high or low breeding success, or occasional complete breeding failures, are normal in seabirds, and most species are adapted to fleeting anomalous environmental conditions. However, chronic food scarcity, as potentially defined by prey abundance below the threshold described here for seabirds, will compromise long-term breeding success, and this may affect the trajectory of their populations.

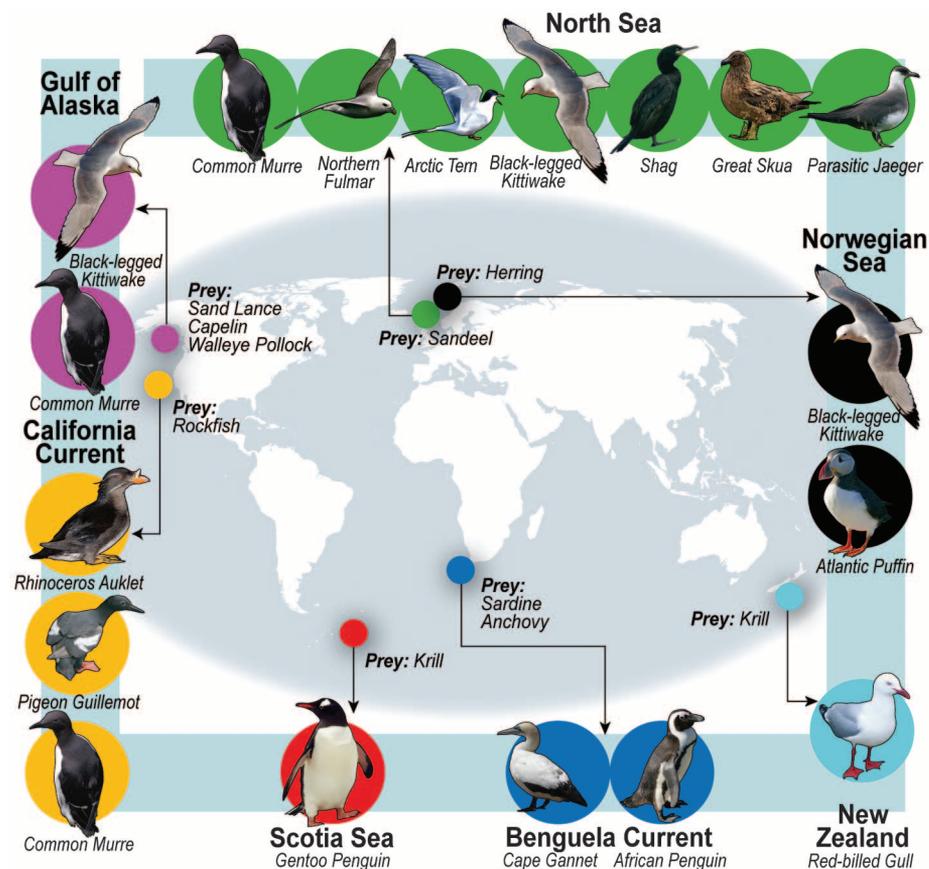

Fig. 1. Map of the distribution of seabird and prey species considered in our analysis.

Fig. 2. (A) Relationship between normalized annual breeding success of seabirds and normalized prey abundance. Each data point from all the time series was plotted with the predictions of a generalized additive model (GAM) (solid line). The gray area represents the 95% confidence interval of the fitted GAM. The threshold in the nonlinear relationship (black solid vertical line) and its 95% confidence interval (black dashed vertical lines) were detected from a change-point analysis. (B) Change in variance across the range of normalized food abundance ranging from -1.5 to 2 standard deviations in eight classes. Variance below the threshold was 1.8 times higher than above it. (C and D) Similar relationships were present when data were pooled (C) for species within ecosystems and (D) for species pooled among ecosystems using the best-fitting asymptotic model (table S2). The Arctic Tern (not shown) model fit was not significant (table S1). The colors in (A) and (C) represent the data set for each ecosystem and in (D) for each seabird species.

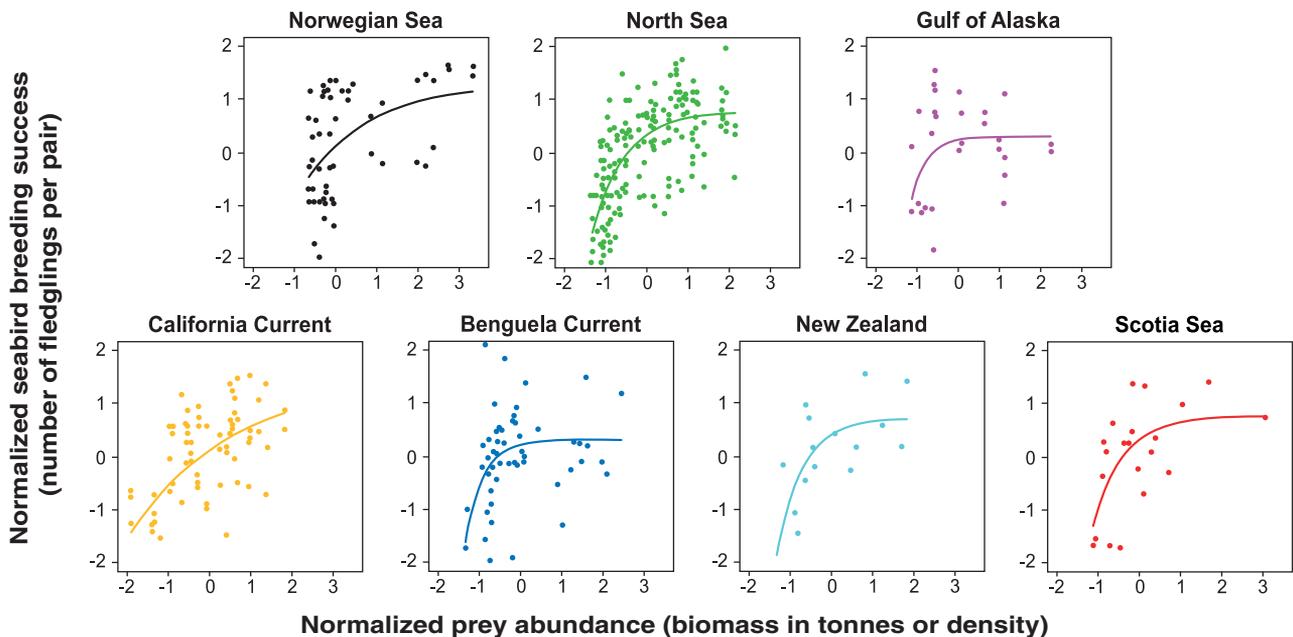

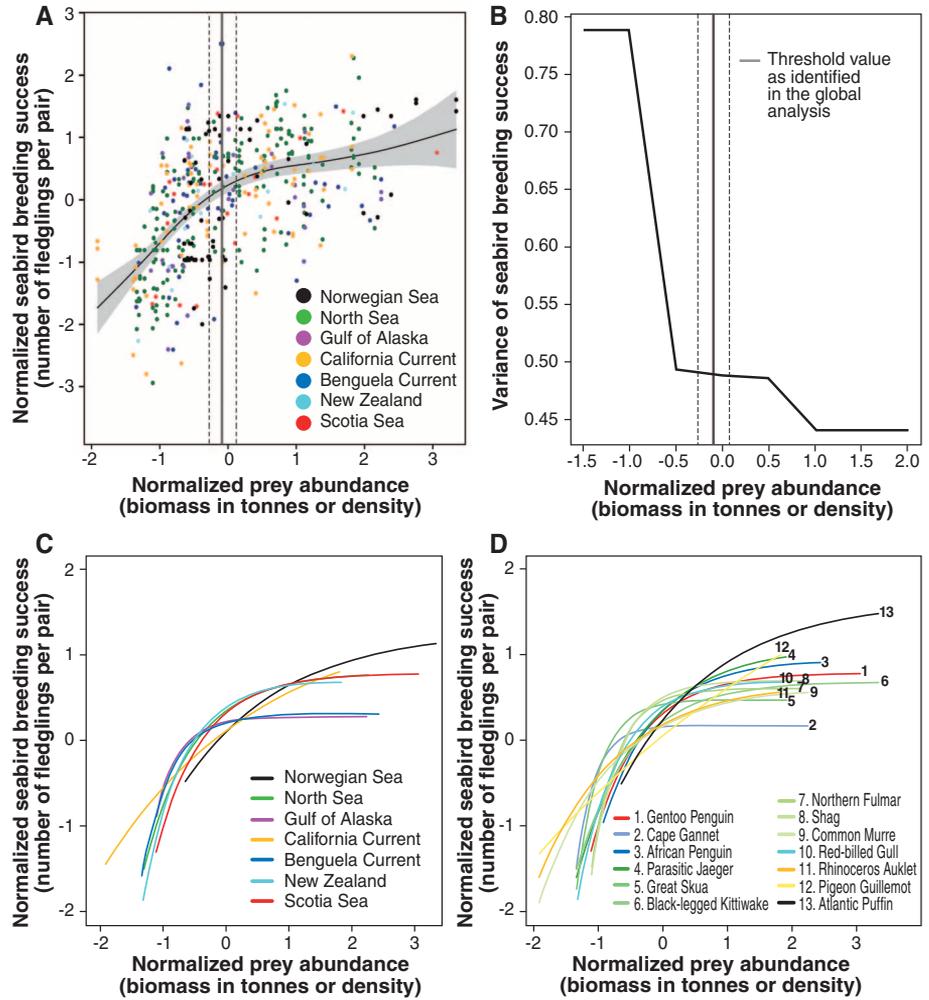

Fig. 3. Relationship between normalized annual breeding success of pooled seabird species and normalized prey abundance for the seven different ecosystems using the most parsimonious asymptotic model (table S2).

Indeed, food scarcity can also reduce adult survival in seabirds (26), with immediate population-level impacts. Whether caused by persistent overfishing, or directional or stochastic environmental change that reduces ecosystem carrying capacity, recruitment and survival will probably have thresholds of prey abundance shifted to the left of that for breeding success (15, 16). Consequently, the threshold for breeding success is likely to provide a precautionary guideline to what level of food reduction might seriously impact seabird populations.

The threshold defined by our study suggests that if management objectives include balancing predator-prey interactions to sustain healthy UTL predator populations and ecosystem functions (2), a practical indicator would be to maintain forage fish biomass above one-third of the maximum observed long-term biomass. The application of such a management guideline will depend upon local circumstances, such as the need to implement spatial management around breeding colonies or the conservation status of species (27). Although we cannot assume similarity between all taxa in the value of the predator-prey threshold, our study demonstrates consistency among a broad range of seabirds. There is also evidence that some marine mammals and predatory fish share the general form of the relationship (17, 19, 25, 28).

Tuning management goals to ensure sufficient biomass of forage fish for seabird reproduction may be a useful step toward ensuring sustainability of predator-prey interactions for other, less well-studied predators in marine ecosystems. Even for predators not showing high dependency on exploited species, this is likely to provide a precautionary step. The “one-third for the birds” guiding principle could be applied widely to help

manage forage fisheries to benefit ecosystem resilience. Indeed, predator responses of this type are already included in some specific management systems (29). Although such a guideline might be difficult to consider for new fisheries, where there are few data to determine the maximum biomass, most of the economically important coastal pelagic fish populations have sufficient data to define the threshold in many ecosystems (e.g., in the Benguela, California, and Humboldt Currents) (figs. S1 and S2).

The generality of the asymptotic form of the predator-prey relationship suggests that it is rooted in fundamental life history and ecological theory (e.g., demographic trade-offs and functional responses). In a practical context, “one-third for the birds” is a simple, empirically derived guiding principle that embraces the ecosystem approach to management aimed at sustaining the integrity of predator-prey interactions and marine food webs for the benefit of both natural predators and humans.

Mouse B-Type Lamins Are Required for Proper Organogenesis But Not by Embryonic Stem Cells

Youngjo Kim,^{1,2} Alexei A. Sharov,³ Katie McDole,^{1,2,4} Melody Cheng,⁵ Haiping Hao,⁶ Chen-Ming Fan,^{1,4} Nicholas Gaiano,⁵ Minoru S. H. Ko,^{3*} Yixian Zheng^{1,2,4*}

B-type lamins, the major components of the nuclear lamina, are believed to be essential for cell proliferation and survival. We found that mouse embryonic stem cells (ESCs) do not need any lamins for self-renewal and pluripotency. Although genome-wide lamin-B binding profiles correlate with reduced gene expression, such binding is not directly required for gene silencing in ESCs or trophoblast cells. However, B-type lamins are required for proper organogenesis. Defects in spindle orientation in neural progenitor cells and migration of neurons probably cause brain disorganizations found in lamin-B null mice. Thus, our studies not only disprove several prevailing views of lamin-Bs but also establish a foundation for redefining the function of the nuclear lamina in the context of tissue building and homeostasis.

The major structural components of the nuclear lamina found underneath the inner nuclear membrane in metazoan nuclei are type V intermediate filament proteins called

lamins (1). Mammals express both A- and B-type lamins encoded by three genes, *Lmna*, *Lmnb1*, and *Lmnb2*. *Lmnb1* and *Lmnb2* express lamin-B1 and -B2, respectively. *Lmnb2* also expresses

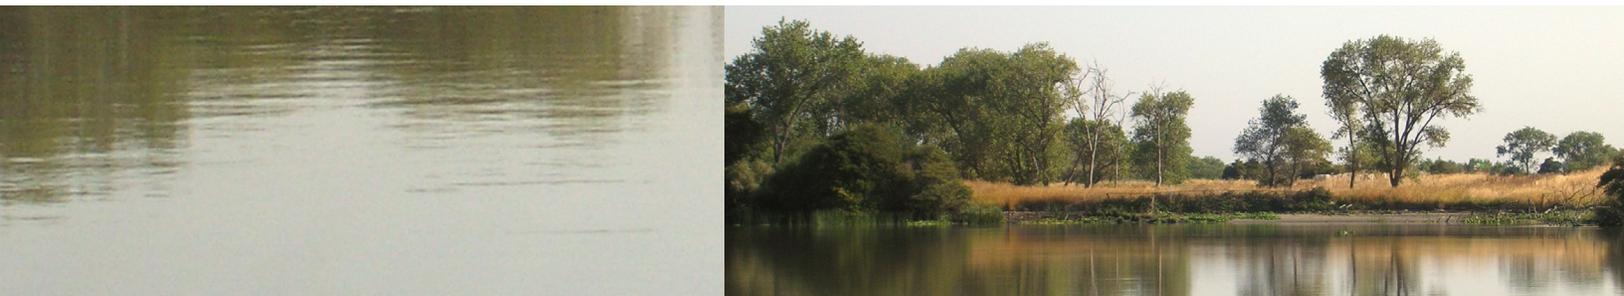

lamin-B3 through alternative splicing in testes. Mutations in lamins have been linked to a number of human diseases referred to as laminopathies (2), although the disease mechanism remains unclear. A-type lamins are expressed only in a subset of differentiated cells and are not essential for basic cell functions (3, 4). By contrast, at least one B-type lamin is found in any given cell type. Because numerous functions, including transcriptional regulation, DNA replication, and regulation of mitotic spindles, have been assigned to B-type lamins, they are thought to be essential for basic cell proliferation and survival (1, 5–8).

Comparative Approach	109
Hydrological Conditions	110
Hypotheses.....	112
Adult Hypotheses.....	112
Hypothesis 1: Hydrology and water exports interact to influence entrainment risk for adult Delta Smelt.	112
Hypothesis 2: Hydrology interacting with turbidity affects predation risk for adult Delta Smelt.	116
Hypothesis 3: Predator distribution affects predation risk of adult Delta Smelt	118
Hypothesis 4: Variability in prey availability during winter and spring affects growth and fecundity (eggs per clutch and number of clutches) of female Delta Smelt.....	118
Larval Hypotheses	120
Hypothesis 1: Delta Smelt larvae numbers are positively affected by increased duration of the temperature spawning window	120
Hypothesis 2: Increased food availability results in increased larval abundance and survival.	122
Hypothesis 3: Distributional overlap of Mississippi Silverside with Delta Smelt and high abundance of Mississippi Silverside increases predation risk/rate on larval Delta Smelt, whereas, increased turbidity, decreases predation risk/rate on larval Delta Smelt.	123
Hypothesis 4: Hydrology and water exports interact with one another to influence direction of transport and risk of entrainment for larval Delta Smelt.	127
Juvenile Hypotheses.....	132
Hypothesis 1: High water temperatures reduce juvenile Delta Smelt growth and survival through lethal and sublethal (bioenergetic stress; reduced distribution) effects.....	132
Hypothesis 2. Distribution and abundance of Striped Bass, temperature, and turbidity influence predation risk/rate on juvenile Delta Smelt.....	132
Hypothesis 3. Juvenile Delta Smelt growth and survival is affected by food availability. ..	135
Hypothesis 4. Juvenile Delta Smelt survival and growth is reduced by harmful algal blooms (HAB) because of direct (habitat quality and toxic effects) and indirect (food quality and quantity) effects.	139

Subadult Hypotheses.....	140
Hypothesis 1. Subadult Delta Smelt abundance, growth, and survival is affected by food availability.....	140
Hypothesis 2. Distribution and abundance of Striped Bass, temperature, and turbidity influence predation risk/rate on subadult Delta Smelt.....	140
Hypothesis 3. Subadult Delta Smelt abundance, survival and growth are reduced by harmful algal blooms (HAB) because of direct (habitat quality and toxic effects) and indirect (food quality and quantity) effects.	141
Hypothesis 4. Subadult Delta Smelt abundance, survival and growth are affected by the size and position of the low salinity zone during fall.	141

- The directed survey (which targeted smelt spawning areas) was discontinued after January 2010. 38
- Figure 18.** Salinity distribution at low outflow. The upper panel shows the area of the low-salinity zone (4,262 hectares) at $X_2 = 85$ km, when positioned mostly between Antioch and Pittsburg. Connections to Suisun Bay and Suisun Marsh are minimal. The lower panel shows the percentage of day that the low-salinity zone occupies different areas. 41
- Figure 19.** Salinity distribution at intermediate outflow. The upper panel shows the area of the low-salinity zone (9,140 hectares) at $X_2 = 74$ km (at Chipps Island). The lower panel shows the percentage of day that the low-salinity zone occupies different areas. 42
- Figure 20.** Modeled volume, area, and depth of the low salinity zone (salinity 0.5 to 6 at various values of X_2 for 9 steady state values of outflow using bottom salinity (green diamonds) and depth-averaged salinity (black diamonds) and for daily values based on variable values from April 1994 through March 1997 (blue circles) (modified from Kimmerer et al. 2013). The top axis gives the Delta outflow corresponding to the 9 steady state scenarios. 43
- Figure 21.** Plot of monthly X_2 (km) values calculated from mean monthly unimpaired Delta outflows from 1921-2003. X_2 values are categorized by water year type for the Sacramento Valley. Also shown are the median X_2 values from 1921-2003 across all water year types (grey circles) C, red dots: critically dry; D, orange dots: dry; BN, yellow dots: below normal; AN, light blue dots: above normal; W, dark blue dots: wet. Water year type data from <http://cdec.water.ca.gov/cgi-progs/iodir/WSIHIST>. Unimpaired flow data from DWR 2007 (available at http://www.waterboards.ca.gov/waterrights/water_issues/programs/bay_delta/bay_delta_plan/water_quality_control_planning/docs/sjrf_sprrinfo/dwr_2007a.pdf). X_2 equation from Jassby et al. 2005. 44
- Figure 22.** Plots of monthly X_2 as a function of the Sacramento River Water Year Index (a measure of runoff) for the years 1956 to 1999 and 2000 to 2013 for: a, winter/spring; b, summer; and c, fall. The regression equation for each set of points is also shown. The index is calculated as: $0.4 * \text{Current April to July Runoff Forecast (in millions of acre feet, maf)} + 0.3 * \text{Current October to March Runoff in (maf)} + 0.3 * \text{Previous Water Year's Index}$ (if the Previous Water Year's Index exceeds 10.0, then 10.0 is used) (see <http://cdec.water.ca.gov/cgi-progs/iodir/WSIHIST> for further detail). 45
- Figure 23.** Plots of the log transformed a) Delta Smelt Summer Towntnet Survey abundance index and b) Delta Smelt Fall Midwater Trawl Survey abundance index, in relation to monthly averaged daily X_2 position from February to June. Lines are either simple linear least squares regression (lines) or quadratic regression (curves). 47
- Figure 24.** Secchi depth data collected during the 20 mm Survey. Surveys are conducted biweekly March-July. See Chapter 3: Data Analyses for explanation of boxplots. 52
- Figure 25.** Average and median Secchi depth in cm from monthly sampling at IEP Environmental Monitoring Program stations. Data are shown for the time period up to the pelagic organism decline (1975-2002) and after the decline (2003-2012). 54
- Figure 26.** A: Total reported October-March salvage for adult Delta Smelt and the corresponding mean salvage density based on the total monthly salvage and water volume exported by CVP and SWP. B: Both salvage and salvage density standardized by the Fall Midwater Trawl (FMWT) index for the previous year. 57

- Figure 27.** Annual time series of Largemouth Bass (top graph) and Bluegill (bottom graph) salvage at the CVP (blue bars) and SWP (green bars) fish protection facilities. Also shown are the annual San Joaquin Valley Water Year Index (SJWY Index) (blue line) and the combined annual (water year) SWP and CVP water export volume (purple line; MAF, million acre feet). 58
- Figure 28.** A: Total reported May-June salvage for juvenile Delta Smelt and the corresponding mean salvage density based on the total monthly salvage and water volume exported by CVP and SWP. B: Both salvage and salvage density standardized by the Fall Midwater Trawl (FMWT) index for the previous year..... 59
- Figure 29.** A: Total reported July-August salvage for juvenile Delta Smelt and the corresponding mean salvage density based on the total monthly salvage and water volume exported by CVP and SWP. B: Both salvage and salvage density standardized by the Fall Midwater Trawl (FMWT) index for the previous year..... 60
- Figure 30.** A: Total reported July-August salvage for sub-adult Delta Smelt and the corresponding mean salvage density based on the total monthly salvage and water volume exported by CVP and SWP. B: Both salvage and salvage density standardized by the Fall Midwater Trawl (FMWT) index for the same year..... 61
- Figure 31.** Flows in cubic feet per second for Qwest (positive values are seaward), Old and Middle River (OMR) (positive values are seaward), and total exports for years since the beginning of the pelagic organism decline (POD). Maximum monthly average Qwest values in 2006 and 2011 omitted to improve graph display, values are 50,086 cfs in April 2006, 35,477 in May 2006, and 32,884 cfs in April 2011 (Qwest and Export data are from 2013 Dayflow, OMR data are from USGS). 64
- Figure 32.** Interquartile ranges (boxes) and medians (lines) for chlorophyll-*a* measured monthly at all IEP EMP stations from 1975-2002 (blue) and 2003-2012 (red). Data from <http://www.water.ca.gov/bdma/>..... 70
- Figure 33.** Density (number/m³) of adult *Eurytemora affinis* (*E. affinis*) by month for three salinity ranges. Each month 16 stations were sampled across all salinity ranges. Horizontal lines represent single samples within a salinity range and boxes without whiskers indicate 2 samples within a salinity range. Data from the IEP Zooplankton Study index stations. See Chapter 3: Data Analyses for explanation of boxplots. 73
- Figure 34.** Density (number/m³) of adult *Pseudodiaptomus forbesi* (*P. forbesi*) by month for three salinity ranges. Each month 16 stations were sampled across all salinity ranges. Horizontal lines represent single samples within a salinity range and boxes without whiskers indicate 2 samples within a salinity range. Data from the IEP Zooplankton Study index stations. See Chapter 3: Data Analyses for explanation of boxplots. 74

An updated conceptual model of Delta Smelt biology: our evolving understanding of an estuarine fish

By Management, Analysis, and Synthesis Team

Executive Summary

The main purpose of this report is to provide an up-to-date assessment and conceptual model of factors affecting Delta Smelt (*Hypomesus transpacificus*) throughout its primarily annual life cycle and to demonstrate how this conceptual model can be used for scientific and management purposes. The Delta Smelt is a small estuarine fish that only occurs in the San Francisco Estuary. Once abundant, it is now rare and has been protected under the federal and California Endangered Species Acts since 1993. The Delta Smelt listing was related to a steep decline in the early 1980s; however, population abundance decreased even further with the onset of the “pelagic organism decline” (POD) around 2002. A substantial, albeit short-lived, increase in abundance of all life stages in 2011 showed that the Delta Smelt population can still rebound when conditions are favorable for spawning, growth, and survival. In this report, we update previous conceptual models for Delta Smelt to reflect new data and information since the release of the last synthesis report about the POD by the Interagency Ecological Program for the San Francisco Estuary (IEP) in 2010. Specific objectives include:

1. Provide decision makers with a practical tool for evaluating difficult trade-offs associated with management and policy decisions.
2. Provide scientists with a framework from which they can formulate and evaluate hypotheses using qualitative or quantitative models.
3. Provide the general public with a new way of learning about Delta Smelt and their habitat.

Our updated conceptual model describes the habitat conditions and ecosystem drivers affecting each Delta Smelt life stage, across seasons and how the seasonal effects contribute to the annual success of the species. The conceptual model consists of two nested and linked levels of increasing specificity. The *general life cycle conceptual model* for four Delta Smelt life stages (adults, eggs and larvae, juveniles, and subadults) includes stationary ecosystem components and dynamic environmental drivers, habitat attributes, and Delta Smelt responses. The more detailed *life stage transition conceptual models* for each of the four Delta Smelt life stages describe relationships between environmental drivers, key habitat attributes, and the responses of Delta Smelt to habitat attributes as they transition from one life stage to the next.

Our analyses and conceptual model show that good larval recruitment is essential for setting the stage for a strong year class; however, increased growth and survival through subsequent life stages are also needed to achieve and sustain higher population abundance. We used our conceptual model to generate 16 hypotheses about the factors that may have contributed to the 2011 increase in Delta Smelt relative abundance. We then evaluated these hypotheses by comparing habitat conditions and Delta Smelt responses in the wet year 2011 to those in the

prior wet year 2006 and in the drier years 2005 and 2010. Larval recruitment was similarly high in both wet years and lower in the drier antecedent years, but juvenile and adult abundance increased only in 2011. In 2005 and 2006, the population was limited by very poor survival from the larval to the juvenile life stage. We found that in 2011, Delta Smelt may have benefitted from a combination of favorable habitat conditions throughout the year, including:

1. Adults and larvae benefitted from prolonged cool spring water temperatures, high 2011 winter and spring outflows which reduced entrainment risk and possibly improved other habitat conditions, and possibly enhanced food availability in late spring.
2. Juveniles benefitted from cool water temperatures in late spring and early summer as well as from improved food availability and low levels of harmful *Microcystis*.
3. Subadults also benefitted from improved food availability and from favorable habitat conditions in the large, low salinity zone (salinity 1-6) located more toward Suisun Bay in 2005-2006 and 2010.

Our comparisons of other habitat attributes either produced inconclusive results or were limited by a lack of suitable data or other necessary information. This was especially true for predation risk and toxicity, and other contaminant effects. Clearly more monitoring and studies are needed on these two topics, but we also found many other data and information gaps. Overall, we did not entirely reject any of our hypotheses. Together with the large amount of published information used to construct our conceptual model, this gives us some confidence that the majority of the elements and linkages of our conceptual model are relevant and (qualitatively) correct. However, the mechanisms they describe are likely variable in the degree to which they drive population outcomes, depending on the conditions in any given year and prior Delta Smelt abundance levels. In addition, the scientific merit of some linkages for which data are sparse (e.g., predation and contaminants effects) is impossible to evaluate without additional information.

Importantly, while this report identifies many data and information gaps that must be filled before some hypotheses can be objectively evaluated, the report includes a very large amount of pertinent data and information that is currently available. The San Francisco Estuary is clearly an intensely monitored and studied ecosystem and Delta Smelt may well be one of the most thoroughly studied endangered fish species in the world. The most critical data for this report came from four long-term Interagency Ecological Program fish monitoring surveys. These surveys provide sound, high-quality data about the annual distribution and relative abundance of Delta Smelt for time periods ranging from one to more than five decades. These four surveys, other monitoring surveys, and numerous research studies provide data about many habitat attributes and ecosystem drivers.

The report ends with key conclusions, a discussion of our hypothesis testing approach, and recommendations for future work and adaptive management applications. The final report Chapter contains many concrete examples of studies, modeling approaches, and management applications that are directly derived from the conceptual model. These examples are not meant to be exhaustive lists. Rather, they are primarily intended to illustrate science and management applications of our conceptual model.

We strongly recommend that analysis, synthesis and modeling efforts, such as this report, be a high priority for the management and science organizations that oversee monitoring and research in the estuary. Without these types of integrative efforts, ongoing and proposed adaptive

management processes must conduct such efforts in an *ad hoc* manner, often driven by unrealistic schedules that are unlikely to be fulfilled. Such adaptive management processes in the estuary include the ongoing adaptive management of fall outflow for Delta Smelt, the new “Collaborative Science and Adaptive Management Program,” the California Delta Stewardship Council’s Delta Plan, and the multi-agency Bay Delta Conservation Plan. On a more basic level, such synthesis efforts identify data gaps that serve to focus research and management efforts on scientifically relevant topics rather than the “crisis of the day.”

The 2011 increase in the Delta Smelt abundance index demonstrated that the species still has the ability to rebound to higher abundance levels. Delta Smelt has often been called an indicator – or canary in the coalmine – for overall ecosystem conditions in the estuary. The 2011 increase suggests that the system has not yet irreversibly shifted into an altered state that will no longer support native species. Given the profound habitat alterations in the San Francisco Estuary, continued study of the environmental drivers and habitat attributes and the subsequent responses of the Delta Smelt population seem critical to the wise management of the species. Some possible topics for future synthesis groups include:

1. Reviews and updates to existing conceptual and mathematical models.
2. Further development of mathematical models of Delta Smelt population abundance drawn specifically from the conceptual models described in this report; applications and extensions of recently published models to help make management decisions and guide new modeling efforts; additional modeling efforts and future research projects to improve resolution and understanding of the particular factors identified as critical to reproduction, recruitment, survival, and growth.
3. Review and refinement of new models such as the emerging comprehensive state-space population model (K. Newman, U.S. Fish and Wildlife Service, personal communication); development of additional models or modules of models specifically aimed at estimating effects of inadequately monitored or difficult to measure and evaluate habitat attributes such as predation risk and toxicity; development of new “nested” and/or “linked” mathematical modeling approaches that can accommodate multiple drivers and their interactive effects across temporal and spatial scales.
4. Interdisciplinary collaboration among scientists, managers, and stakeholders to develop and model management scenarios and strategies based on principles of integrative ecosystem and landscape-based management rather than relatively crude distinctions among categorical “water year types.”

Continued growth of California’s human population, climate change, new species invasions, and other changes will increase management challenges. Science and management have to go hand in hand to constantly identify, implement, evaluate, and refine the best management options for this ever-changing system. We hope that the conceptual model and information in this report will be useful for achieving these goals.

Chapter 1: Introduction

The San Francisco Estuary

Estuarine ecosystems are among the most complex ecosystems on earth (Wilson 1998). They are constantly changing ecosystems that respond to dynamic “drivers” of change (Healey et al. 2008, Baxter et al. 2010). Natural drivers include the geological and geographic setting, climatic and oceanic variability, dynamic hydrological and nutrient regimes, weather and disturbance regimes, biogeochemical processes, species assemblages, and many other biotic and abiotic features. Estuaries also respond to a broad range of human activities. Some of these “human drivers” have negative impacts on ecosystems. These negative human drivers are often called “stressors.” Human stressors on estuarine ecosystems include water and land use, pollutant discharges, species introductions, and fishing (Townend 2004, Lotze et al. 2006, Cloern and Jassby 2012). The interplay of natural and human drivers and their effects on the San Francisco Estuary and in particular on the Delta Smelt (*Hypomesus transpacificus*), an endemic fish species, is the subject of this report.

The San Francisco Estuary (SFE; Fig. 1) is comprised of an upstream region consisting of channels and islands associated with the confluence of the Sacramento and San Joaquin Rivers known as the “Delta” and a series of downstream bays and marshes that are separated from the Pacific Ocean by the “Golden Gate,” the sea passage between the San Francisco and Marin peninsulas. Because of California’s Mediterranean climate, the SFE experiences large interannual and seasonal flow variations, which are modulated by tides and human management of the rivers within the Delta watershed (Moyle et al. 2010). These hydrological variations lead to a dynamic estuarine salinity gradient. In the winter and spring fresh water often extends into San Pablo Bay, while in the summer and fall brackish water can intrude into the western Delta. These seasonal differences are exacerbated by pronounced interannual differences in precipitation in the watershed. Extremely dry years with little precipitation and very wet years with widespread flooding do not occur in predictable patterns (Dettinger 2011).

The SFE has undergone dramatic morphological, hydrological, chemical, and biological alterations since the onset of the California Gold Rush in the middle of the 19th century (Nichols et al. 1986, Arthur et al. 1996, Baxter et al. 2010, Brooks et al. 2012, NRC 2012, Whipple et al. 2012, Cloern and Jassby 2012). These alterations include five human activities that have changed ecological functions and habitats in many riverine and estuarine systems with increasingly dense human populations: diking, draining, dredging, diverting, and discharging. Specifically, diking and draining have reduced the vast wetlands that once covered and surrounded the SFE to small remnants. There has been an 80-fold decrease in the ratio of wetland to open water area in the Delta, from a historical ratio of 14:1 to a current ratio of 1:6 (Whipple et al. 2012, Herbold et al. 2014). Diking and dredging have led to a substantial reconfiguration of the bays, sloughs, and channels, while large-scale water diversions, and discharge of contaminants have altered water quantity and quality. Small water diversions occur throughout the freshwater portion of the estuary, but the largest water diversions are at the pumping facilities of the federal Central Valley Project (CVP) and the State Water Project (SWP) that export water from the southwestern Delta to agricultural and urban areas to the south (Fig. 2). In addition, a wide variety of non-native plants and animals have been introduced and have become established in the SFE (Cohen and Carlton 1998, Light et al. 2005, Winder et al. 2011).

Figure 1. Map of the San Francisco estuary. The inset shows various values of X2, the distance in kilometers from the Golden Gate to the near bottom salinity 2 isohaline.

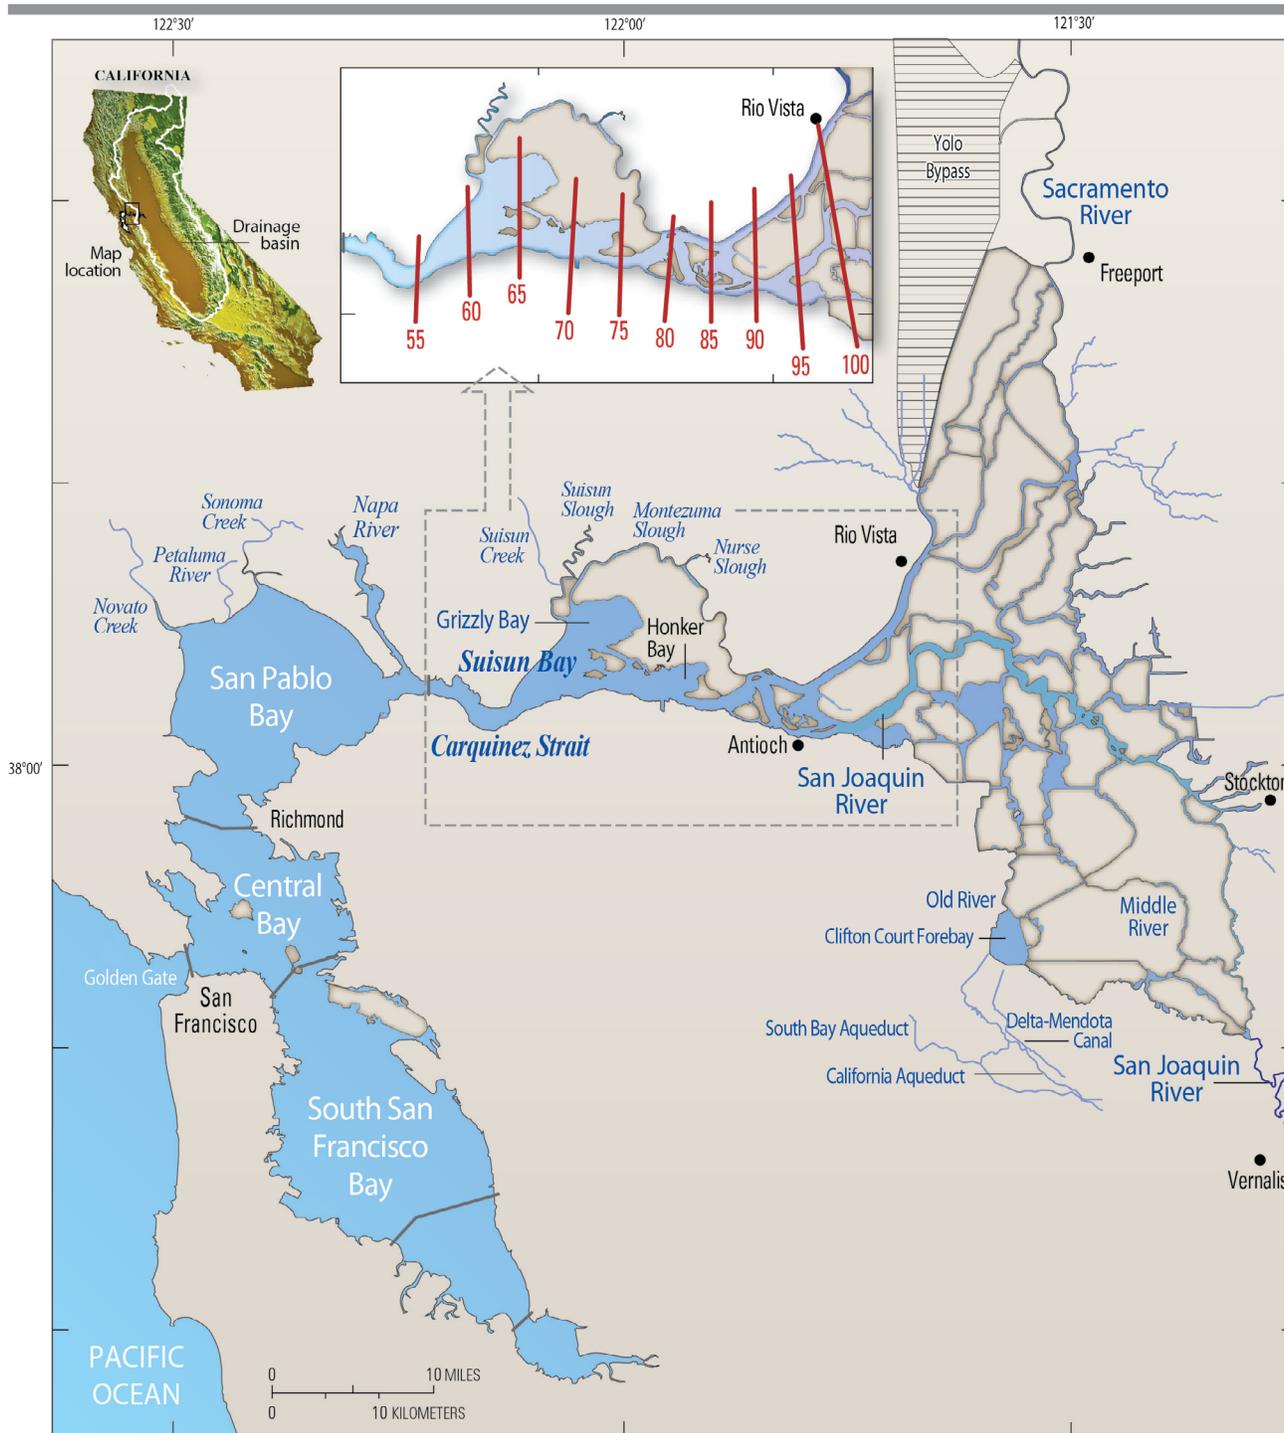

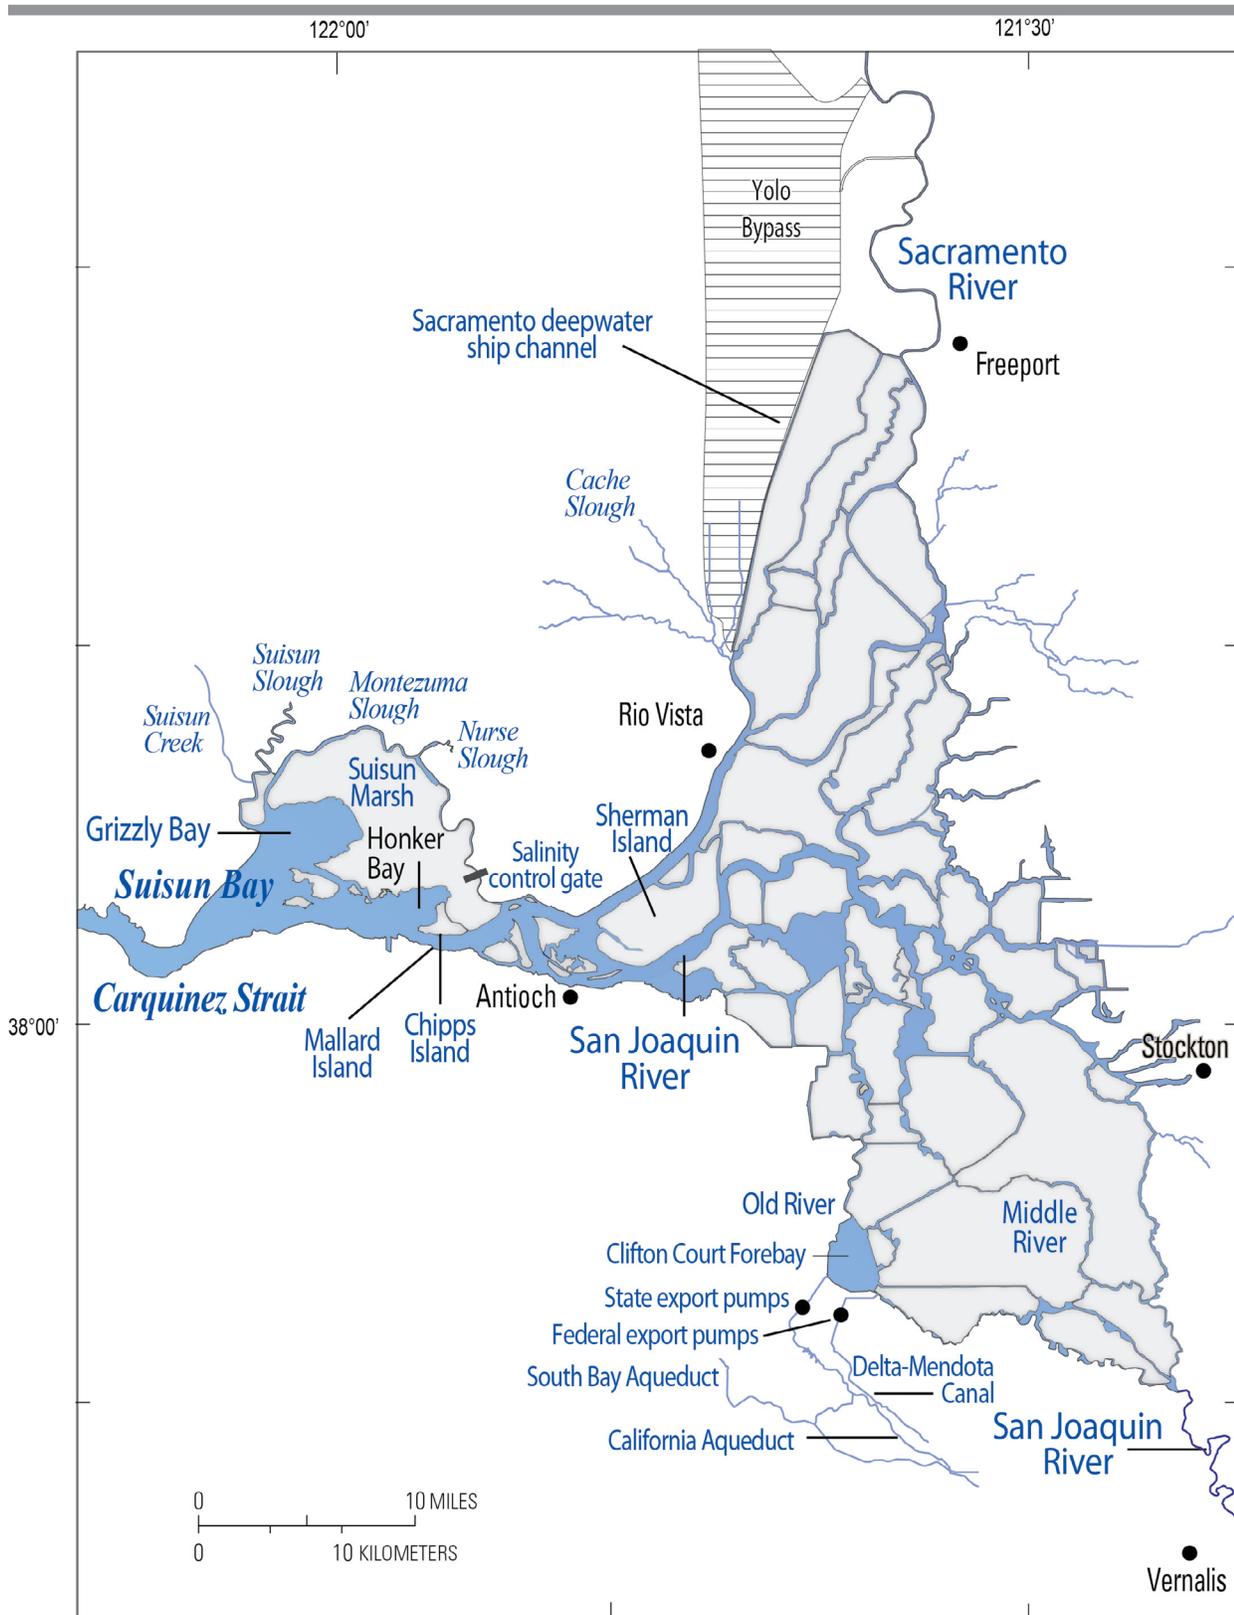

Figure 2. Map of the upper San Francisco estuary. The upper estuary includes the Suisun Bay region and the Sacramento-San Joaquin Delta, which are west and east of Chipps Island respectively. The area from approximately Chipps Island to the west end of Sherman Island is referred to as the “confluence.”

Many of the more recent ecological changes in the SFE have been documented by long-term monitoring surveys. Most of these surveys are conducted under the auspices of the Interagency Ecological Program (IEP), an interagency science consortium with three State and six federal member agencies (<http://www.water.ca.gov/iep/>). Together with monitoring conducted by others, these monitoring surveys provide one of the longest and most comprehensive environmental and biological data records in a U.S. coastal ecosystem. With each additional year of monitoring, this data record serves as an increasingly valuable tool for observing gradual changes or abrupt shifts in ecological conditions and for identifying their underlying causes (Cloern and Jassby 2012).

The modern SFE continues to be a dynamic and complex ecosystem that supports many important ecosystem services (Millennium Ecosystem Assessment 2005), including the provision of fresh water, agricultural crops, commercial and recreational fisheries, and other recreational opportunities. However, it no longer provides adequate habitat for many of its native species as evidenced by severe declines in several of its native fish populations (e.g., Bennett and Moyle 1996, Brown and Moyle 2005, Sommer et al. 2007).

Pelagic fish declines

Among the native fishes of the upper SFE (Fig. 2), the endemic Delta Smelt is of high management concern because of a decline of its annual abundance indices (see Chapter 3 for details of fish surveys and indices), particularly longer term indices for juveniles and subadults, to persistent low levels (Fig. 3). This decline led to its listing under the federal Endangered Species Act in 1993. The Delta Smelt is a slender-bodied pelagic fish with a maximum size of about 120 mm standard length (length from snout to end of vertebral column) and a maximum age of two years. It is the most estuary-dependent of the native fish species in the SFE (Moyle et al. 1992, Bennett 2005). The continued existence of the species is dependent upon its ability to successfully grow, develop, and survive in the SFE.

Delta Smelt is not the only fish species currently in decline in the Delta. Abundance indices of Longfin Smelt (*Spirinchus thaleichthys*), age-0 Striped Bass (*Morone saxatilis*), and Threadfin Shad (*Dorosoma petenense*) declined simultaneously with those of Delta Smelt in about 2002. This simultaneous decline has become known as the pelagic organism decline (POD) (Sommer et al. 2007, Baxter et al. 2008, 2010) (Fig. 4). Given the very different life histories of these four pelagic species, it is unlikely that a single environmental variable could account for the POD declines. In general, researchers have suggested that the POD declines were likely multi-causal (Sommer et al. 2007, Baxter et al. 2008, 2010, Mac Nally et al. 2010, Cloern and Jassby 2012, NRC 2012). Several researchers have suggested that the SFE has undergone an ecological regime shift (Moyle and Bennett 2008, Baxter et al. 2010, Glibert et al. 2011, Cloern and Jassby 2012). In the present system, an invasive aquatic macrophyte (*Egeria densa*) dominates the littoral zone of many areas of the Delta and provides favorable habitat for many invasive fishes (e.g., Largemouth Bass *Micropterus salmoides*; Brown and Michniuk 2007); invasive clams (*Potamocorbula amurensis* and *Corbicula fluminea*) consume a large portion of the available pelagic phytoplankton (Alpine and Cloern 1992, Lopez et al. 2006, Lucas et al. 2002, Lucas and Thompson 2012); agricultural, industrial, and urban discharges transport large quantities of nutrients and a plethora of contaminants into many regions of the estuary; and current management of water for agricultural, industrial and urban purposes is focused on optimizing the reliability of water exports by the CVP and SWP.

Figure 3. Delta Smelt abundance index for life stages of Delta Smelt including the larvae-juveniles (20 mm Survey), juveniles (Summer Townet Survey), subadults (Fall Midwater Trawl), and adults (Spring Kodiak Trawl). The initiation of each individual survey is indicated by the initial bar with subsequent missing bars indicating when an index could not be calculated. See Chapter 3 for details of sampling programs, including geographic coverage, and Appendix B for details of calculating abundance indices.

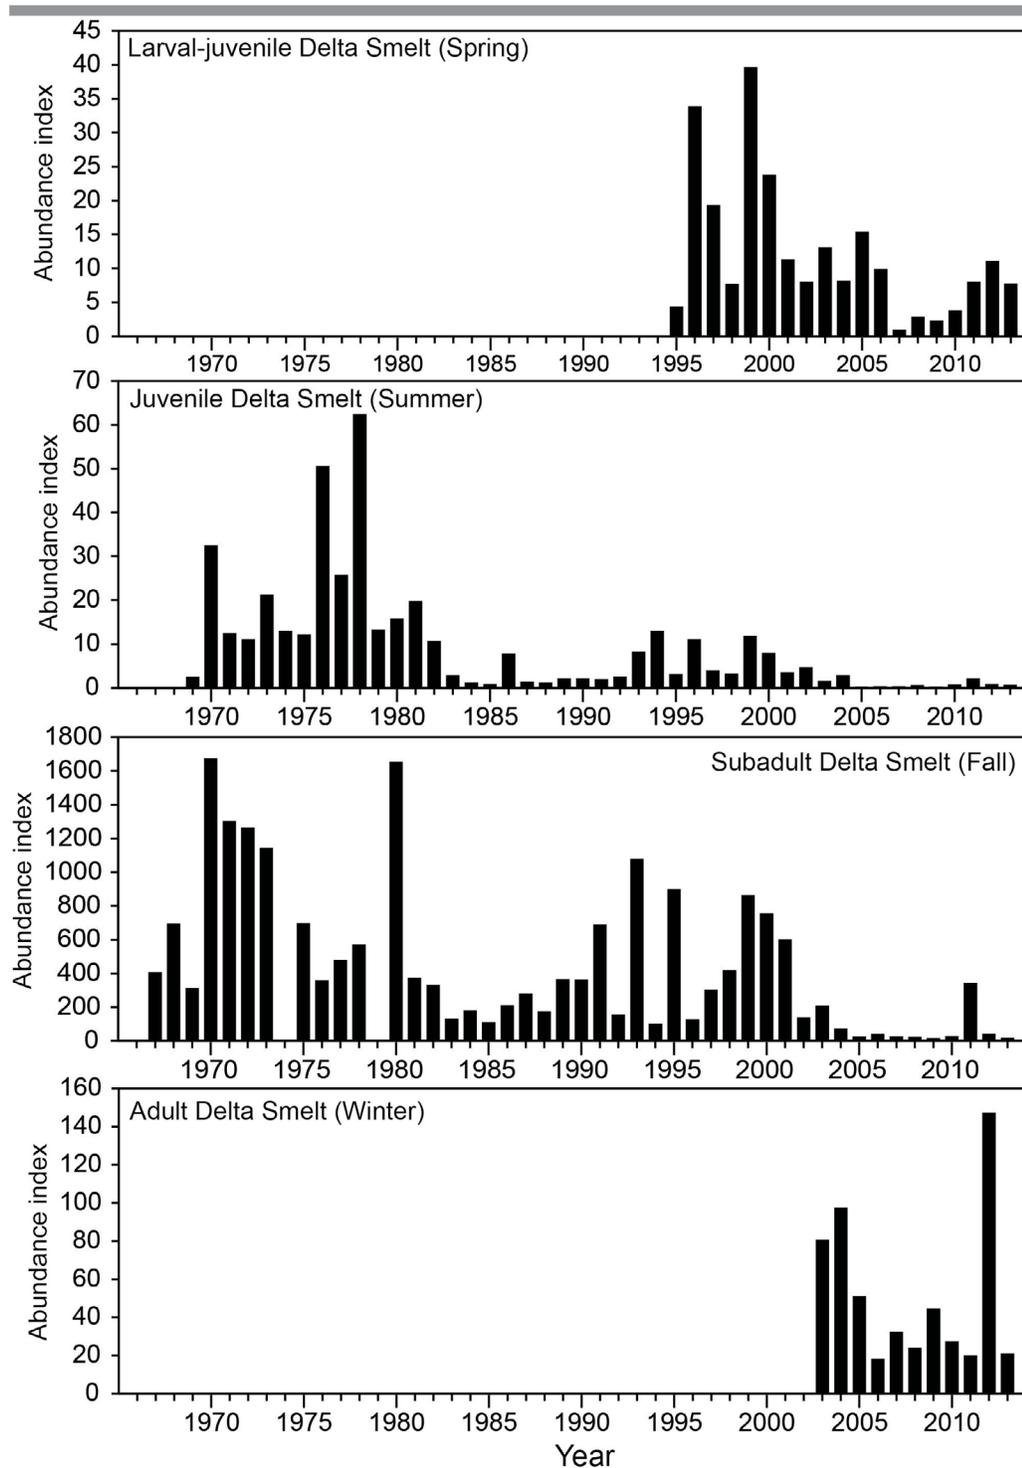

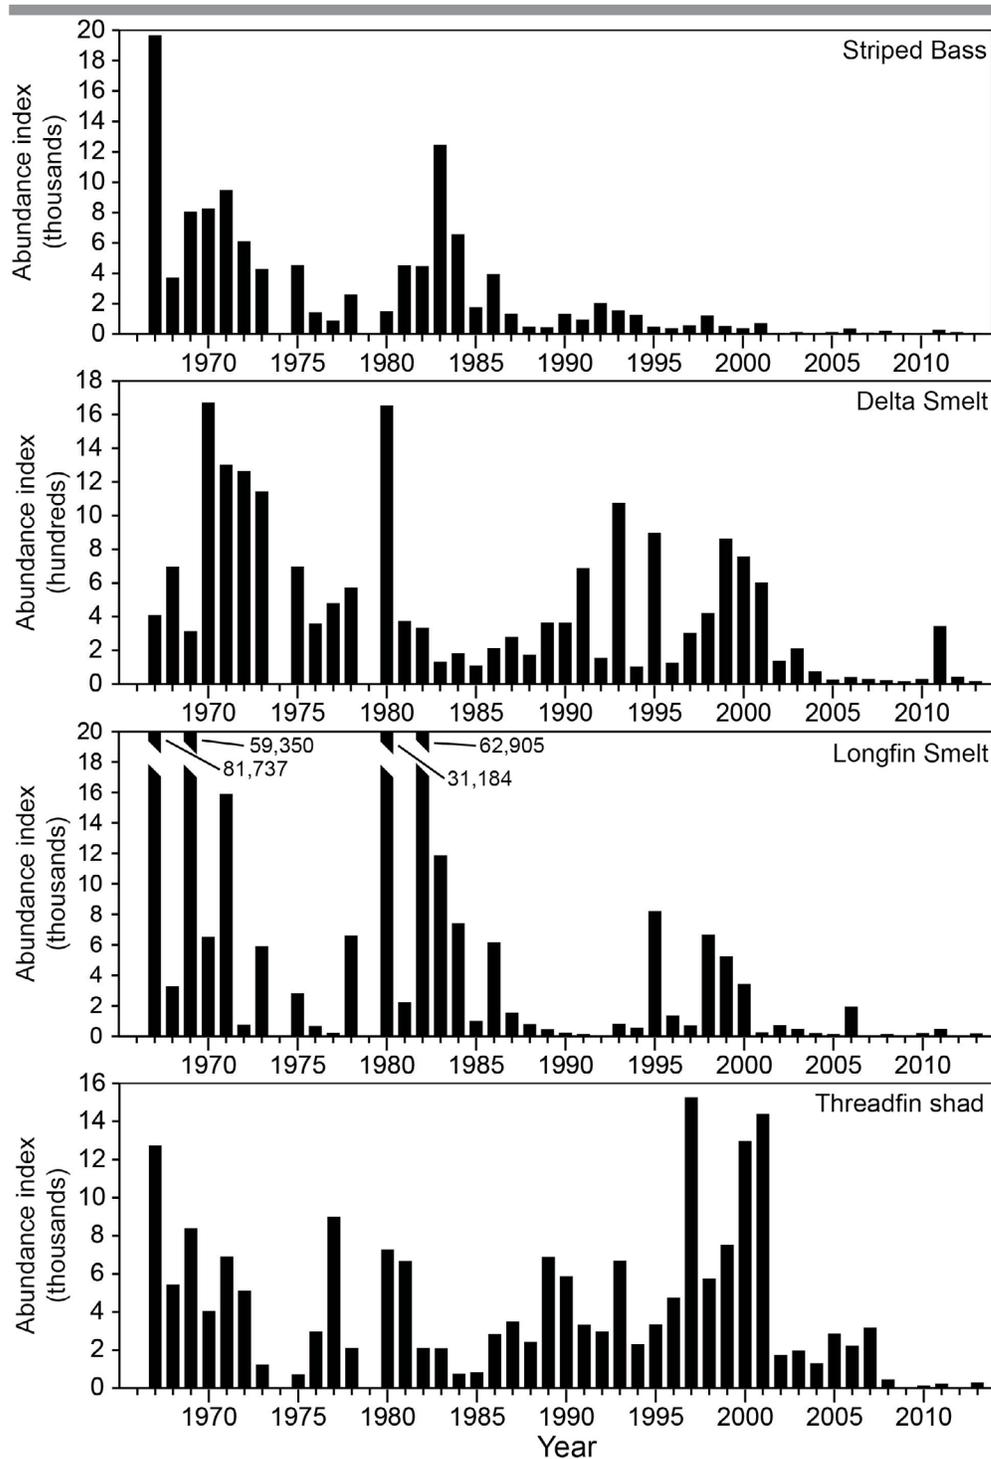

Figure 4. Abundance indices from Fall Midwater Trawl for Delta Smelt, Longfin Smelt, age-0 Striped Bass, and Threadfin Shad. Missing bars indicate when an index could not be calculated. See Chapter 3 for details of sampling programs, including geographic coverage, and Appendix B for details of calculating abundance indices.

Changes in Delta Smelt distribution and abundance

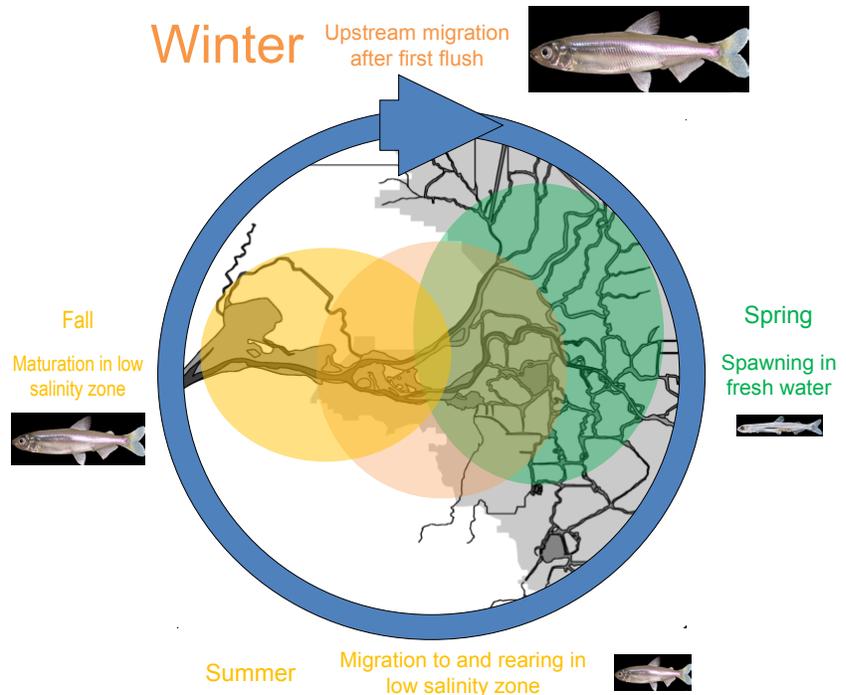

Long-term monitoring surveys conducted by the IEP have documented substantial changes in the distribution and abundance of Delta Smelt in its small native geographic range which extends from the upstream boundaries of tidal influence in the northern, eastern and southern Delta region of the estuary to Suisun and San Pablo Bays in the north-western region of the estuary. The geographic range of Delta Smelt also includes some of the larger tidal sloughs and tributaries adjacent to Suisun and San Pablo Bays, including some Suisun Marsh sloughs and the lower Napa River (Bennett 2005, Hobbs et al. 2007, Sommer et al. 2011, Merz et al. 2011, Sommer and Mejia 2013, Murphy and Hamilton 2013). Delta Smelt are generally considered a pelagic species. While they are commonly found in shallow shoal areas such as Honker and Grizzly Bays in the Suisun Bay region of the estuary and larger marsh sloughs such as Suisun and Montezuma Sloughs in Suisun Marsh and the lower reaches of Cache and Lindsey Sloughs in the northern Delta, they are less commonly encountered in near-shore areas and only rarely in smaller marsh sloughs (Bennett 2005, Merz et al. 2011, Sommer and Mejia 2013).

The Delta Smelt has been characterized as a “semi-anadromous” fish species that spawns in fresh water and rears in fresh to brackish water (Fig. 5; Dege and Brown 2004, Bennett 2005, Sommer et al. 2011, Merz et al. 2011). While Delta Smelt have been documented throughout their geographic range during most months of the year (Sommer et al. 2011, Merz et al. 2011, Murphy and Hamilton 2013), their distribution varies seasonally in response to dynamic abiotic and biotic habitat attributes such as salinity, temperature, turbidity, and presumably food supplies (Bennett et al. 2005, Sommer et al. 2013, Brown et al. 2014). In years with high freshwater discharge in winter and spring, spawning and rearing of larval and early post-larval fish can temporarily extend seaward into San Pablo Bay, while in years with less discharge it usually occurs in the Delta, Suisun Bay and Suisun Marsh. Juveniles and adults are distributed across a broader salinity range (0 to about 18) than larval and post-larval fishes which tend to be most abundant in the low salinity zone (salinity 1-6). Dege and Brown (2004) and Sommer et al. (2011) found that the center of the Delta Smelt distribution is associated with salinities of about 2 during most months and moves with the estuarine salinity gradient as the salinity gradient responds to flow.

Historically, Delta Smelt were commonly observed throughout the fresh and low salinity portions of their geographic range (Erkkila et al. 1950, Radke 1966). Over the last two decades, their geographic distribution has become more constricted during the summer and fall. At present, Delta Smelt are less commonly found in the southern and eastern Delta during the winter and spring and are largely absent from this region in the summer and fall (Nobriga et al. 2008, Sommer et al. 2011). While Delta Smelt continue to be found in the northern Delta year-round and individual catches in this region are sometimes large, particularly during winter and spring, the majority of the population is usually observed in the region near to and west of the Sacramento-San Joaquin River confluence, especially in the summer and fall (Sweetnam 1999, Feyrer et al. 2007, Nobriga et al. 2008, Merz et al. 2011, Sommer et al. 2011, Sommer and Mejia 2013).

In addition to documenting changes in distribution, long-term IEP surveys also reveal that the annual abundance indices of Delta Smelt have greatly declined since the first long-term pelagic fish monitoring survey began in summer 1959 (Fig. 3). Both a gradual, long-term decline and step changes, most recently around 2002, have been described using a variety of qualitative and statistical approaches for subadult Delta Smelt caught in the fall (e.g., Bennett and Moyle 1996, Bennett 2005, Manly and Chotkowski 2006, Thomson et al. 2010). These declines have not been smooth or entirely unidirectional and also include a great deal of interannual variability (Fig. 3).

Figure 5. Simplified life cycle of Delta Smelt (modified from Bennett 2005). Colors correspond to different seasons with the low salinity zone changing position with season.

Since the beginning of the POD in 2002, the Delta Smelt abundance indices have often been at record low levels, leading to concerns about declines in effective population size (Fisch et al. 2011) and a loss of population-level resilience, meaning the ability of the population to recover to higher population abundances when conditions are suitable. For example, population sizes might become too small to produce enough eggs or larvae to outpace predation on eggs and larvae.

Delta Smelt had previously rebounded from low population abundances, most recently in the wet years of the late 1990s (Fig. 3). The lack of increase in Delta Smelt in the wet year of 2006 combined with new evidence for genetic bottlenecks and a significant decline in effective population size from 2003 to 2007 (Fisch et al. 2011) were thus a source of great concern. However, during 2011, the next wet year after 2006, the species did increase in abundance (Fig. 3). Unfortunately, the increase in Delta Smelt abundance was short-lived and did not carry over into the following year-class in 2012, a drier year. Nevertheless, the temporary increase gave some cause for renewed optimism about the resilience of the species and its potential recovery. In addition, the contrasts between habitat conditions and Delta Smelt responses in 2006 and 2011 provided an opportunity to gain new insights into the Delta Smelt habitat requirements that might help better manage this species and its habitat.

Protecting Delta Smelt

Delta Smelt are currently protected under both California and federal endangered species legislation. The protection and recovery of Delta Smelt and its estuarine habitat in the SFE will

likely require the human population of California to reduce its dependence on some of the natural resources provided by the SFE. This will become even more challenging in the future because of climate change and the continued growth of California's human population. California's population has increased by approximately 38 million people compared to the population when California became a state in 1850 and has increased by about 22.5 million compared to 1959 when Delta Smelt monitoring started 55 years ago (U.S. Census Bureau data). More than three quarters of today's 38 million Californians live south of the SFE, and the majority of these Californians and millions of acres of farmland rely on fresh water diverted from the Delta for all or part of their water supply. The conflicts and trade-offs between species protection measures and actions to provide water and other natural resources to California's growing human population have resulted in repeated attempts to reconcile these seemingly irreconcilable objectives through regulatory requirements, new institutional arrangements, and management plans.

Among the regulatory requirements are the State water right decisions issued by the California State Water Resources Control Board, which grant SWP and CVP water rights permits, but also include requirements to protect fish. State regulations also include increasingly more stringent waste discharge permits. For example, the new permit recently issued to the Sacramento Regional County Wastewater Treatment Plant includes new requirements for major treatment upgrades to better protect downstream water uses and the health of the estuary. Federal regulations include water quality requirements under the Clean Water Act and Biological Opinions (BiOps) issued under the federal Endangered Species Act. Two BiOps assess the effects of the coordinated operations of the SWP and CVP on Delta Smelt, Green Sturgeon, and salmonid fish populations, and their designated critical habitat. These BiOps include "reasonable and prudent alternatives" to lessen negative impacts of SWP and CVP operations and avoid jeopardy to the species, while at the same time trying to avoid major reductions in water exports from the Delta.

Recent institutional reconciliation attempts include the multiagency, State and federal CALFED Bay-Delta Program and Authority (CALFED) and the California Delta Stewardship Council (DSC), a new State agency. From 1994 to 2010, CALFED attempted to reconcile water allocation and ecosystem restoration efforts in the estuary in a way that would allow them to "get better together" (Doremus 2009). After the demise of CALFED, the State of California created the DSC to address what the legislature termed the "co-equal goals" of providing a more reliable water supply for California and protecting, restoring, and enhancing the Delta ecosystem (CA Water Code §85054, <http://deltacouncil.ca.gov/>).

Among the many management plans aimed at reconciling species protection and human water and land use objectives are plans by the DSC, SWRCB, and new groupings of multiple agencies and stakeholders. The DSC recently completed and is now starting to implement its comprehensive "Delta Plan" (<http://deltacouncil.ca.gov/delta-plan-0>) to achieve the co-equal goals, while the SWRCB is on track to complete a major update to its "Bay-Delta Plan" which may result in changes to water right permits (http://www.waterboards.ca.gov/waterrights/water_issues/programs/bay_delta/). Three California State agencies recently completed a new California Water Action Plan that includes actions to help achieve the co-equal goals (http://resources.ca.gov/california_water_action_plan/). A multi-agency planning effort that includes State and federal agencies as well as local Public Water Agencies (water contractors) is working to complete the "Bay-Delta Conservation Plan" (BDCP, <http://baydeltaconservationplan.com>). The BDCP is a proposed Habitat Conservation Plan under the federal Endangered Species Act and a Natural Community Conservation Plan under the California Natural Community Conservation Planning Act. It proposes to implement habitat restoration measures, stressor reduction activities,

improved water project operations criteria, and new water conveyance infrastructure. If approved by the regulatory agencies, this plan would provide long-term permits for the various projects and water operations to proceed over a 50-year time frame.

Management actions, regulatory requirements, and institutional arrangements in the SFE have undergone substantial and complex changes over the last 150 years. Hanak et al. (2011) describe a progression from an early disorganized “laissez-faire” era of California and SFE water management followed by increasingly organized and large-scale management schemes, from local water use to state-wide water projects, which led to a current “era of conflict” and the hope for a new “era of reconciliation.” A complete review of these changes is outside the scope of this report and the reader is referred to Hanak et al. (2011) and other existing reports on this topic. It is important to note, however, that increasingly, these changes have been “adaptations” based on the results of monitoring, studies, and other scientific activities in the SFE. Many of these scientific activities have been conducted under the auspices of the IEP (Herrgesell 2013). It can be argued that some of the activities preceding and ultimately leading to the creation of the IEP in 1970 ushered in an era of increasingly intense and formalized “adaptive management” before the term itself was coined.

Adaptive management is a formal approach to natural resource management that closely connects science with management to devise, track, and improve management outcomes. This connection started to become an important aspect of fisheries management in the 1950s (e.g., Beverton and Holt 1957), although the term itself was not coined until 1978 when Holling (1978) and Walters and Hilborn (1978) provided a conceptual framework for adaptive resources management. This framework was later refined to distinguish between “passive” and “active” adaptive management. According to Williams (2011), “active adaptive management actively pursues the reduction of uncertainty through management interventions, whereas passive adaptive management focuses on resource objectives, with learning a useful but unintended byproduct of decision making [...]. In practice this means that a key difference between passive and active adaptive management is the degree to which the objectives that guide decision making emphasize the reduction of uncertainty.” In active adaptive management, management actions are designed as “experimental treatments” with clear hypotheses about outcomes that are tested through rigorous data collection and analyses. This accelerates learning, but can come at the expense of achieving resource objectives because potentially less effective management actions may be included in the experimental design. Moreover, the more intense science efforts needed for active adaptive management can be costly over the short term (Williams 2011). This may explain why passive adaptive management, while not always referred to by this name or implemented in the formal and rigorous way now advocated by the DSC’s Delta Plan (DSC 2013), has been and continues to be common in the SFE, but active adaptive management – viewed by some as the only “real” adaptive management – is still rare.

Of all current management actions and requirements affecting Delta Smelt, the actions required in the 2005 and 2008 BiOps issued by the U.S. Fish and Wildlife Service (FWS) are most directly aimed at the protection of Delta Smelt. The 2008 BiOp takes a life cycle approach to protecting Delta Smelt and includes an explicit requirement for adaptive management of fall outflow. After initial steps to design a passive adaptive management program, the U.S. Bureau of Reclamation (Reclamation) decided to take a more active approach aimed at more rapidly reducing uncertainties about the underlying mechanisms and effects of fall outflow management on Delta Smelt (Reclamation 2011, 2012, Brown et al. 2014). The study component of the fall outflow adaptive management plan, also known as the “fall low salinity habitat” (FLaSH) studies, was developed with the help of a new conceptual model (FLaSH conceptual model, Brown et

al. 2014) and has been implemented by the IEP starting in 2011. The FLaSH studies provided an opportunity to intensely study the increase in the Delta Smelt abundance index observed in 2011. At this initial stage of the adaptive management program and the FLaSH studies, the 2011 data were compared to data gathered in the previous wet year, 2006, during which fall outflow was lower. The initial data analysis effort also considered antecedent conditions in 2010 and 2005, resulting in a simple comparative approach focusing on four years (Brown et al. 2014).

Report Purpose and Organization

It is clear that the recovery of Delta Smelt and other listed and unlisted native species will be a key requirement of any plan to manage the resources of the SFE. Understanding the factors driving Delta Smelt population dynamics is a major goal of resource management agencies. The main purpose of this report is to provide an up to date assessment of factors affecting Delta Smelt throughout its primarily annual life cycle. Specific goals are to provide decision makers with scientific information for evaluating difficult trade-offs associated with management and policy decisions, provide scientists with a resource for formulating and testing hypotheses and mathematical models, and provide the general public with a new way for learning about Delta Smelt and their habitat.

We address these goals through a synthesis of scientific information about Delta Smelt with an emphasis on new information since the release of the last POD synthesis report in 2010 (Baxter et al. 2010). As in previous reports, conceptual models play a key role in this report. Conceptual models are useful tools for organizing and synthesizing information, designing research and modeling studies, and for evaluating potential outcomes of management actions. Here, we revisit previously developed conceptual models for Delta Smelt, and synthesize new information about factors affecting Delta Smelt and Delta Smelt responses to those factors. This comprehensive body of information is then used to construct and populate a Delta Smelt conceptual model, within a new framework.

Numerous conceptual models have been developed to describe the relationships and linkages among environmental drivers of ecosystem change, ecosystem and habitat attributes, and Delta Smelt responses. In Chapter 2 of this report, we provide a brief introduction to conceptual models and review some of the conceptual models developed for the SFE and for Delta Smelt. In Chapter 3, we introduce a new conceptual model framework for Delta Smelt and describe our approach to updating the previously developed Delta Smelt conceptual models. We also describe the data sources and analytical approaches used in this report. In Chapter 4, we review and synthesize recent information about drivers and habitat attributes affecting Delta Smelt and Delta Smelt responses to habitat attributes. In Chapter 5, we present an updated conceptual model for Delta Smelt that include key drivers, habitat attributes, interactions between them, and Delta Smelt responses discussed in Chapter 4. In Chapter 6, we review and synthesize recent information about Delta Smelt population dynamics, life history, and population trends. In Chapter 7, we use the updated conceptual model to formulate hypotheses about Delta Smelt responses and changing habitat conditions and test them using a simple comparative approach similar to the FLaSH approach (Brown et al. 2014), but for all life stages of Delta Smelt. The purpose of Chapter 7 is to put the new conceptual model along with the comparative approach to an immediate test that is of high relevance to the management of Delta Smelt. Chapter 8 presents key results and conclusions from the preceding Chapters. In Chapter 9, we discuss next steps for future conceptual, qualitative, and quantitative modeling as well as the science and management implications of the information contained in this report.

Chapter 2: Conceptual Models

Overview

We learn and think about the world we live in through mental models of how the world looks and how it works. Our mental models guide all our conscious decisions and actions. They are never static; we constantly update them with new information gained by observing the world around us and by assessing the outcomes of our decisions and actions. In our minds, we compare the new information against our existing mental models. Observations that agree with our mental models strengthen them, observations that don't agree with our mental models force us to modify, adjust, and update them.

Conceptual models are formalized versions of mental models that are communicated to others verbally and graphically. Ecologists and environmental managers use them to communicate hypotheses about “how ecosystems work” and to explore how human actions and other drivers change ecosystems. They usually use a combination of narrative text and graphical illustrations about ecosystem components and the relationships among them. More informal narrative conceptual models verbally describe cause-effect relationships, while more formal conceptual models may express them through scientific hypotheses or mathematical equations.

Conceptual model illustrations often take the form of pictures, plots, schematic images or diagrams, matrices, or tables (Fischenich 2008). For example, the IEP Estuarine Ecology Team used elaborate matrices to illustrate and assess the likely mechanisms underlying the statistically determined relationships between SFE fishes and “X2,” an indicator of estuarine salinity dynamics (Estuarine Ecology Team 1997), while Reclamation (2011, 2012) used a table format to illustrate how fall outflow interacts with other features of Delta Smelt habitat and affects Delta Smelt. Schoellhamer et al. (2012) used a series of conceptual X-Y plots to illustrate a conceptual model of sediment supply reduction and downstream propagation in the SFE. Glibert (2012) and Glibert et al. (2011) used schematic images to conceptualize changes in nutrients, flows, biogeochemical processes, and the food web of the SFE. Many schematic conceptual model diagrams use boxes to depict ecosystem components and arrows to illustrate the relationships, flows, and interactions among them. The conceptual models developed by the IEP for its POD investigations (see below) include examples of schematic conceptual model depictions with few boxes and arrows, while some of the conceptual models developed for the “Delta Regional Ecosystem Restoration Implementation Plan” (DiGennaro et al. 2012, see below) and the “effects hierarchy” of factors affecting Delta Smelt abundance developed by Miller et al. (2012) provide examples of more complex schematics with a large number of boxes and arrows.

Conceptual models have become essential tools for summarizing, synthesizing, and communicating scientific understanding of ecosystem structure and functioning. They are also key to successful planning and implementation of ecological research and mathematical modeling as well as to adaptive management, restoration and recovery of ecosystems, and environmental science education (e.g., Thom 2000, Ogden et al. 2005, Fortuin et al. 2011). Conceptual models are also essential tools for identifying management and science priorities and for the selection of key ecological attributes to be used to evaluate the performance of management actions (i.e., performance measures) and assess the present relative to a desired state of an ecosystem (i.e., indicators) (Washington State Academy of Sciences 2012).

Conceptual models have clear limitations. For example, even the most complex conceptual models are highly simplified descriptions of a small part of an ecosystem – they can never tell the “whole” story. Just like our every-day mental models, they are also never final. To remain relevant, ecological conceptual models must evolve and change with the evolution of our knowledge about ecosystems. Furthermore, conceptual models identify key ecosystem components and relationships, but they do not quantify them and unless they are coupled with mathematical models, conceptual models cannot be used to make quantitative predictions.

Conceptual models can be used to make qualitative predictions about changes in ecosystem components and their relationships. These qualitative predictions can serve as testable hypotheses that help design scientific analyses and studies. The creation or revision of the conceptual models themselves usually forces the formulation of hypotheses and their testing with available data and information, as will be demonstrated in the later Chapters of this report. Qualitative predictions and testable hypotheses are also at the heart of active adaptive management. They are needed to design experimental adaptive management actions and the studies and monitoring needed to assess the outcomes from such actions. The fall outflow adaptive management plan (Reclamation 2011, 2012) provides an example of how a conceptual model was used to make qualitative predictions and design a comprehensive set of studies, the FLaSH studies. Finally, the formulation of conceptual models is usually the essential first step for constructing quantitative models. Mathematical models are sets of mathematical expressions that quantify the components and relationships in the conceptual models and can be used to make quantitative predictions about the state of ecosystem components and linkages under specific circumstances (Jackson et al. 2000). The (few) quantitative predictions in the fall outflow adaptive management plan (Reclamation 2011, 2012) are based on such mathematical models.

Ecological conceptual models generally link ecological “drivers” with ecological effects or “outcomes.” Drivers are physical, chemical, or biological factors of human or natural origin (for example, nutrients from natural soils and applied fertilizers). Outcomes can be physical, chemical or biological responses to the drivers (for example, phytoplankton growth and biomass), but can also be social and economic impacts on human components of the ecosystem (for example, harmful algal blooms that affect recreational use or costs of water treatment for drinking water supply). Drivers and outcomes are the components of the system under consideration. They are linked by mechanistic cause-effect relationships. Conceptual models can also be nested within each other, for example, to accommodate different temporal or spatial scales, or conceptual models can be coupled so that the outcome of one conceptual model becomes a driver in the next one. Drivers are often categorized in various ways, including their causal proximity to specific outcomes, whether they are natural or anthropogenic, and whether they can be altered by human management strategies and actions. Graphically, drivers are often arranged in hierarchical tiers that reflect these categories.

For example, Gentile et al (2001) describe a basic three-tiered approach that links environmental outcomes (tier 1) to proximal anthropogenic drivers termed “stressors” (tier 2) and the natural and anthropogenic drivers that act on these stressors (tier 3). Davis et al. (2010) show how different ecological regimes in Australian lakes (outcomes, tier 1) arise from the interplay of stressors (tier 2) and hydrological changes (tier 3) acting on the original ecological regime (tier 4). Carr et al. (2007) review a widely used five-tiered “Driver–Pressure–State–Impact–Response” (DPSIR) framework that focuses on identifying human-caused environmental problems and solutions. In this framework, the ultimate drivers (D) are social processes that result in specific human activities that manifest as proximal “pressures” (P) that change the “state” (S), or condition, of the environment. This can have “impacts” (I) on human well-being that are recognized as

problems. Some impacts are so severe that they require a human response (R), usually in the form of institutional solutions aimed at reducing high-priority impacts. The Puget Sound Partnership Science Panel (2012) recently used the DPSIR framework to develop a conceptual model that links management strategies (i.e., responses; e.g., reduce pollution) to anthropogenic drivers (e.g., human population growth) and pressures (e.g., pollution) that affect the state of ecosystem components (e.g., habitats and species) and impact the provisioning of ecosystem services (e.g., fishing). This model helped identify scientific knowledge gaps and decision-critical issues and questions that needed to be answered in response to management priorities.

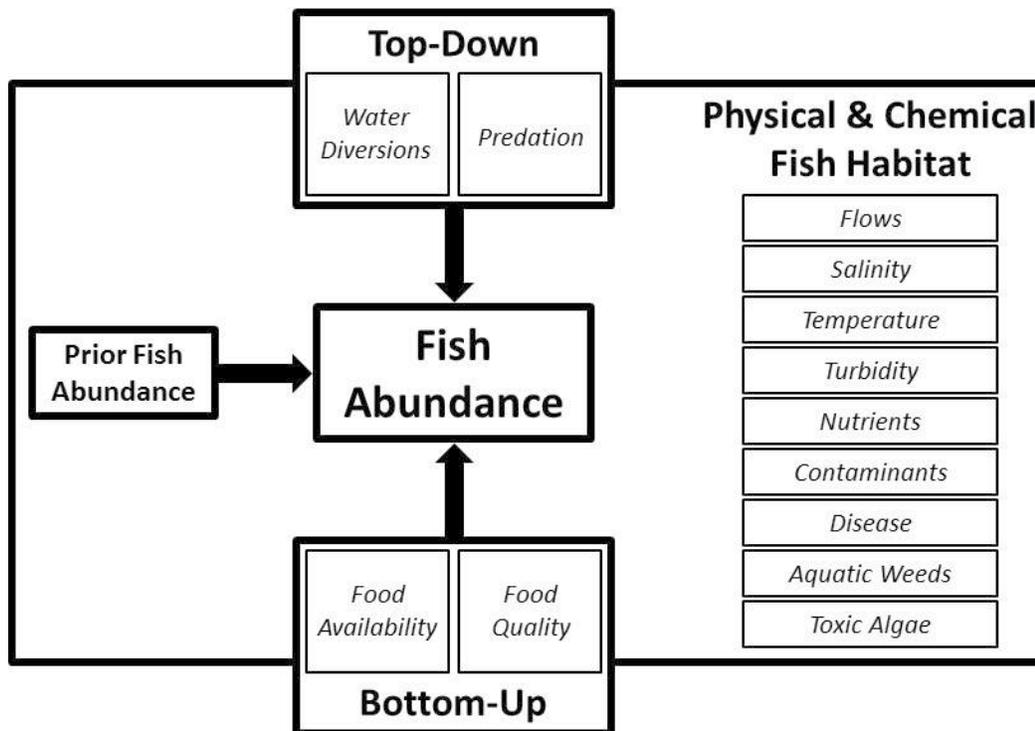

Recent Conceptual Models for the San Francisco Estuary

Over the last decade, two integrated sets of conceptual models have been developed for portions of the SFE. The first conceptual model set was developed by the Ecosystem Restoration Program (<http://www.dfg.ca.gov/ERP/>) to evaluate restoration actions in the Delta under the “Delta Regional Ecosystem Restoration Implementation Plan” (DRERIP; DiGennaro et al. 2012). DRERIP conceptual models were developed for ecological processes, habitats, specific species, and stressors. The DRERIP conceptual models were built around environmental drivers, their expected effects termed “outcomes,” and cause-and-effect relationships between the two shown as one-way arrows termed “linkages.” In the graphical depiction of the DRERIP conceptual models, different arrow widths, colors, and styles denote the importance, degree of understanding, and predictability, respectively, of the driver-linkage-outcome relationships, while symbols next to the arrows denote the direction and nature of the effect (positive, negative, or non-linear) (DiGennaro 2012, Opperman 2012). The DRERIP species conceptual models include “transition matrix” diagrams depicting how environmental drivers affect the probability of one life stage successfully transitioning to the next.

The second set of conceptual models was developed by the IEP as a comprehensive conceptual framework intended to guide investigations of the POD and to synthesize and communicate results (Sommer et al. 2007, Baxter et al. 2010). This framework includes a “basic” POD conceptual model about key drivers of change affecting pelagic fish and their habitat (Fig. 6), more narrowly focused “species-specific” conceptual models about drivers affecting the different life stages of each of the four POD fish species (e.g., Fig. 7), and a broader “ecological regime shift” conceptual model that placed the POD decline in a longer-term historical context (not shown; see Baxter et al. 2010). The basic POD conceptual model placed the four fish species in the center of interacting drivers affecting the quantity and quality of their habitat (Fig. 6), while the species-specific models identified key seasonal drivers in red, with proximal causes and effects in yellow (Fig. 7).

The National Research Council Committee on Sustainable Water and Environmental Management in the California Bay-Delta (NRC Committee) (NRC 2012) called the POD conceptual model framework “an important example of supporting science. This framework identifies and links, in the context of both ecosystem structure and functioning, the key stressors that help to explain the decline of pelagic organisms.” The NRC Committee further noted that the “drivers of change” identified in the POD conceptual models “are quantifiable” and “suitable for model evaluation” and that the:

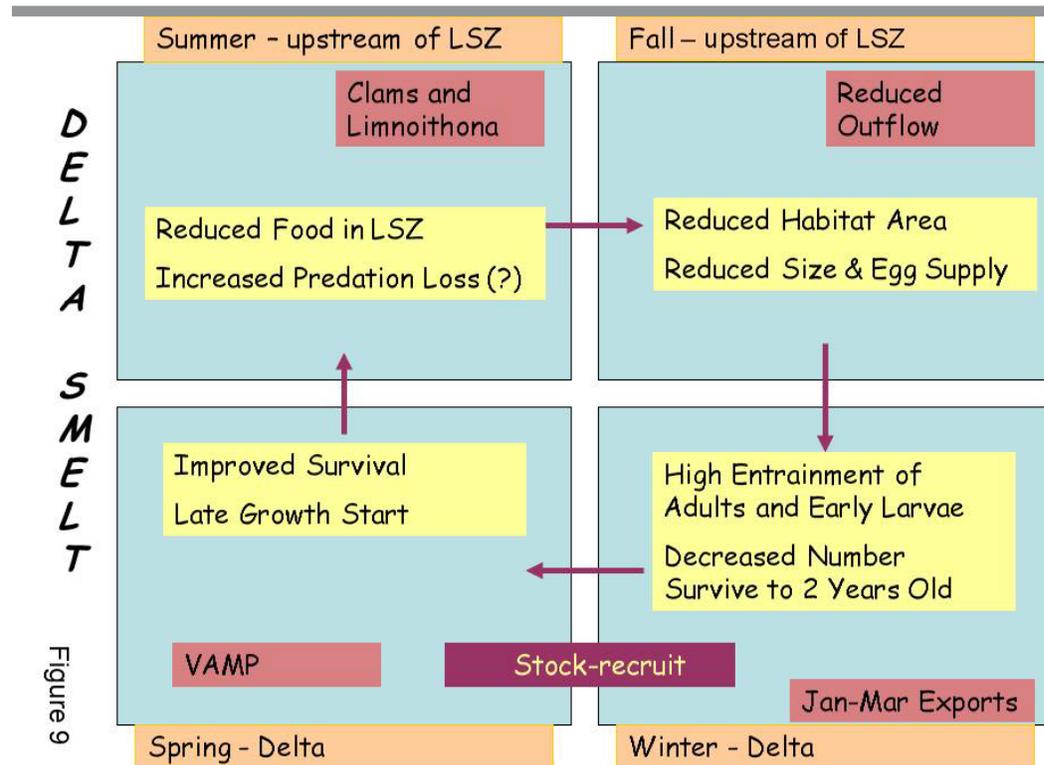

Figure 6. The basic conceptual model for the pelagic organism decline (Baxter et al. 2010).

“types of stressors identified are integrative, reflecting co-occurring physical, chemical, and biotic changes. They also apply to multiple structural (food web structure, biodiversity) and functional (food transfer changes, biogeochemical cycling) changes taking place in the Delta. The framework and associated detail are both comprehensive and useful in terms of linking these drivers to changes taking place at multiple levels of the food web. This type of conceptual approach will also be useful for examining other drivers and impacts of ecological change, including observed changes in fish community structure and production; specifically, how these changes are affected and influenced by changes in physico-chemical factors (e.g., salinity, temperature, turbidity, nutrients/contaminants) and at lower trophic levels (phytoplankton, invertebrate grazers, and prey)” (NRC 2012, p. 34-35).

Since the release of the 2012 NRC report, the POD conceptual model framework has been used as the basis for additional conceptual models developed to aid planning and quantifying the ecological effects of active adaptive management of Delta outflow to improve fall low salinity habitat for Delta Smelt and to guide the associated fall low salinity habitat (FLaSH) studies (Reclamation 2011, 2012). A more complete summary of the POD and FLASH conceptual models along with additional information about related conceptual and quantitative models in the SFE can be found in the initial FLASH report (Brown et al. 2014, see also <http://deltacouncil.ca.gov/science-program/fall-low-salinity-habitat-flash-studies-and-adaptive-management-plan-review-0>).

Figure 7. Species-specific conceptual model for Delta Smelt. This is one of four species-specific conceptual models developed as part of the conceptual framework for the pelagic organism decline (Baxter et al. 2010). The low salinity zone (LSZ) is defined as salinity 1-6. The Vernalis Adaptive Management Plan (VAMP) included reductions in spring exports with possible effects on Delta Smelt.

One important new feature of the conceptual model developed for the fall outflow adaptive management plan and the FLASH studies was the explicit consideration of interacting dynamic and relatively more stationary (geographically and temporally fixed) habitat components that was based on a conceptual model of environment-habitat-production linkages in tidal river estuaries developed by Peterson (2003). In the FLASH conceptual model, the interactions among dynamic and stationary habitat components determine the characteristics of Delta Smelt habitat in the fall and lead to varying Delta Smelt outcomes. In essence, the dynamic flow and salinity regimes of the SFE move water, particles, and organisms across the estuary's stationary topography, which has distinct physical features that modulate the dynamic habitat components. Together, these stationary and dynamic habitat components are hypothesized to control the survival, health, growth, fecundity, and, ultimately, the reproductive success of estuarine pelagic species, such as Delta Smelt. The interplay between stationary and dynamic habitat components also helps explain the distribution and movement of Delta Smelt across its range which cannot be understood – or managed – based on geography alone.

Numerous other conceptual and quantitative models have been developed for the SFE. Kimmerer (2004) summarized many of the earlier conceptual models. More recent conceptual model examples include those by Glibert (2012) and Glibert et al. (2011) as well as the five-tiered effects hierarchy by Miller et al. (2012). Recent examples of mathematical models of habitat use and population dynamics of Delta Smelt include models based on statistical approaches (e.g.,

Manly and Chotkowski 2006, Feyrer et al. 2007, Nobriga et al. 2008, Feyrer et al. 2010, Thomson et al. 2010, Mac Nally et al. 2010, Miller et al. 2012). There is also a rapidly developing body of life cycle models for Delta Smelt and other SFE fish species that use statistical and numerical simulation approaches (e.g. Blumberg et al., 2010, Maunder and Deriso 2011, Massoudieh et al. 2011, Rose et al. 2011, Rose et al. 2013a,b).

Chapter 3: Approach

This report is the result of a team effort by the IEP Management, Analysis, and Synthesis Team (MAST, often referred to as “we” in this report). Appendix A briefly describes the MAST and the report development process and schedule which included a public and independent expert peer review step that led to major revisions to the draft report.

General Approach

Our general approach in this report was to develop a new conceptual model framework for Delta Smelt and to use this framework to synthesize new scientific information and update and integrate existing conceptual models including the “basic” and “species-specific” POD conceptual models, the DRERIP “transition matrix” models, the tabular FLaSH conceptual model and the hierarchical conceptual model in Miller et al. (2012) described in Chapter 2.

The development of the new conceptual model framework was guided by the conceptual model literature (see Chapter 2) and by recommendations from the independent “FLaSH Panel” of national experts convened by the Delta Science Program. The FLaSH Panel recommended to:

“develop a schematic version of the [FLaSH] conceptual model that matches the revised, written version of the conceptual model in the draft 2012 FLaSH study report. The conceptual model in written and schematic form should continue to emphasize processes and their interactions over simple correlations, should ensure Delta Smelt vital rates remain central to thinking, and should be designed for routine use by scientists as an organizational tool and for testing hypotheses associated with the AMP [adaptive management plan]; it should be as complex as necessary to achieve these purposes. The conceptual model should also be able to encompass processes and interactions that extend before and after Fall Outflow Action periods, including areas both upstream and downstream of the LSZ” (FLaSH Panel 2012, page ii).

The conceptual modeling approach in this report is intended to provide a basis, not a substitute for the development or use of mathematical models. While mathematical models are outside of the scope of this report, we briefly discuss the promise and challenges of mathematical models for Delta Smelt, summarize some of the highlights of existing mathematical modeling efforts for Delta Smelt, and offer a brief description of two additional proposed mathematical modeling efforts — one qualitative and the other quantitative — we think are natural outgrowths of the information in this report (see Chapter 8). Development of a variety of flexible working tools to facilitate discussion of elements of the conceptual model is one intended outcome of the MAST effort. Even simple quantitative and qualitative models based on our revised conceptual model

will serve to further organize thinking and characterize weaknesses in current data collection and analysis efforts.

In this Chapter, we introduce the new conceptual model framework for Delta Smelt. This framework consists of a series of nested and tiered conceptual models: a general life cycle conceptual model and more detailed life stage transition conceptual models. It was developed following recommendations by the FLaSH Panel (FLaSH Panel 2012) and extensive reviews of a draft version of this report (see <http://www.water.ca.gov/iep/pod/mast.cfm> and Appendix A). In Chapter 4 we review and synthesize existing information about drivers, habitat attributes, and Delta Smelt responses with a focus on new information since 2010. We use the drivers in the basic POD conceptual model as the basis for this synthesis. This information is then used to populate the nested conceptual models in the new conceptual model framework with key drivers and their linkages to Delta Smelt responses. The fully populated nested conceptual models are presented in Chapter 5. Chapter 6 focuses on Delta Smelt life history and population dynamics and trends. Chapters 4 and 6 include some new analyses of long-term monitoring data, but are largely based on a review and synthesis of the existing published literature. In Chapter 7, we compare data pertaining to ecosystem drivers (drivers), habitat attributes (drivers or outcomes) and Delta Smelt responses (outcomes) in four recent years with moderate to wet hydrology: the two most recent wet years (2006 and 2011) and the two drier years immediately before them (2005 and 2010). The intent is to assess the utility of the conceptual model for formulating and testing hypotheses that expand the comparative FLaSH approach (Brown et al. 2014) that focused on the fall to a more comprehensive year-round investigation of why Delta Smelt abundance increased in the wet year of 2011, but failed to respond to wet conditions in 2006. In each of the sections in Chapter 7 covering a specific life stage, the hypotheses inherent in the conceptual model are stated and the reasoning for including each hypothesis is explained. Although we attempted to develop independent hypotheses, this was not always possible because many drivers were related and important habitat attributes were influenced by multiple drivers and their interactions, as shown in the conceptual model diagrams and explored in Chapter 4.

Key insights from Chapters 4–7 are summarized in Chapter 8. In Chapter 8, we also discuss limitations of the analytical approaches in this report. In Chapter 9, we describe additional data and analyses needed to test hypotheses that could not be conclusively tested with the available data and our simple comparative analysis approach. We also present some ongoing or possible next steps for future years, including some recommendations for future synthesis and mathematical lifecycle modeling efforts aimed at Delta Smelt and other species and for future adaptive management, including the fall outflow adaptive management and FLaSH studies effort.

Framework for the Delta Smelt Conceptual Model

The updated Delta Smelt conceptual model framework in this report integrates and modifies features of the “basic” and “species specific” POD conceptual models (Baxter et al 2010), the FLaSH conceptual model (Brown et al. 2014), the DRERIP “transition matrix” conceptual models (DiGennaro et al. 2012), and the hierarchical conceptual model in Miller et al. (2012). It consists of two nested and linked conceptual models of increasing specificity:

1. *A general life cycle conceptual model* for the four Delta Smelt life stages (adults, eggs and larvae, juveniles, and subadults) that includes stationary landscape attributes and dynamic environmental drivers, habitat attributes, and Delta Smelt responses; and

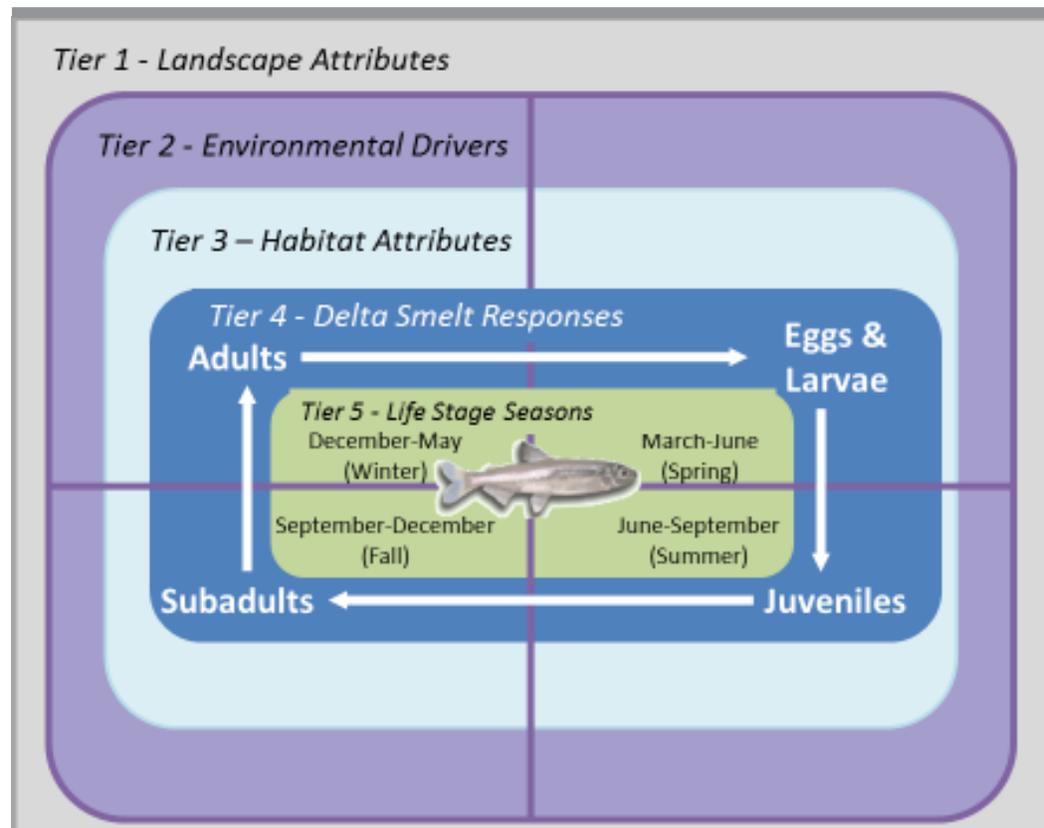

2. More detailed *life stage transition conceptual models* for each of the four Delta Smelt life stages that describe relationships between environmental drivers, key habitat attributes, and the population-level probability of successfully transitioning from one life stage to the next. This probability is dependent on the effects of environmental drivers and habitat attributes on the growth, survival, reproduction, and movements of Delta Smelt but data are currently inadequate to provide causal links for most of these processes individually.

General Life Cycle Conceptual Model

The updated general life cycle conceptual model for Delta Smelt (Fig. 8) follows the FLaSH Panels (2012) recommendation to “ensure Delta Smelt vital rates remain central to thinking” and is structurally similar to the basic POD conceptual model (Fig. 6). The general life cycle conceptual model is divided vertically and horizontally into four sections representing four Delta Smelt life stages from eggs and larvae to adults occurring in four “life stage seasons” indicated in the center of the diagram (Fig. 8; tier 5 box, green shading). This is similar to the four seasonal compartments of the species-specific conceptual model diagram in Baxter et al. (2010). Importantly, these life stage seasons are not exactly the same as calendar-based seasons. Instead, they have somewhat variable duration and overlapping months. This is because life stage transitions from eggs to adults are gradual and different life stages of Delta Smelt often overlap for a period of one to three months. Delta Smelt responses (Fig. 8; tier 4 box with dark blue shading) to important habitat attributes throughout their usually annual life cycle are placed within a box representing habitat attributes important to their growth and survival, which conveys the idea that biotic and abiotic habitat elements drive Delta Smelt responses (Peterson 2003; Fig. 8; tier 3 box with light blue shading). For each life stage season, there are a set of natural and anthropogenic environmental drivers associated with the estuarine environment (Fig. 8; tier 2 box with purple shading) that generate the habitat attributes important to Delta Smelt growth and survival. Surrounding the environmental drivers box is a fourth, outer box that represents the stationary (geographically and temporally fixed) landscape attributes of the estuarine ecosystem associated with its physical geometry and the orientation and connections of its component waterbodies (Fig. 8; tier 1 box with grey shading). In contrast to this outer box, the components and processes described in the inner boxes of this conceptual model are dynamic in space and time. Note that the fixed landscape attributes are considered fixed in the context of Delta Smelt population biology in any particular year rather than across longer time scales. The different spatial and temporal scales for each tier of the conceptual model are shown in Figure 9.

The tiered components of the general life cycle conceptual model for Delta Smelt can vary over a wide range of spatial and temporal scales (Fig. 9). Landscape attributes of the San Francisco Estuary (tier 1) encompass local to estuarine-wide features and change slowly over decades or longer periods. Environmental drivers (tier 2) that affect Delta Smelt habitat attributes vary and manifest over the broadest range of spatial and temporal scales, from local variations over tidal or daily cycles to long-term changes at the watershed or even larger geographic scales. Similar to environmental drivers, habitat attributes of Delta Smelt (tier 3) can be highly dynamic at small spatial and temporal scales or change gradually over many years, but they don’t extend beyond the geographic range of the species, which in the case of Delta Smelt is the SFE. Delta Smelt responses (tier 4) vary in response to changing habitat attributes within subregions of the estuary. In this small fish species with its maximum age of two years and extremely small geographic range, population-level responses can range from rapid (e.g., in response to toxic spills) to more

Figure 8. A new conceptual model for Delta Smelt showing Delta Smelt responses (dark blue box) to habitat attributes (light blue box), which are influenced by environmental drivers (purple box) in four “life stage seasons” (green box). Environmental drivers are influenced by landscape attributes (grey box).

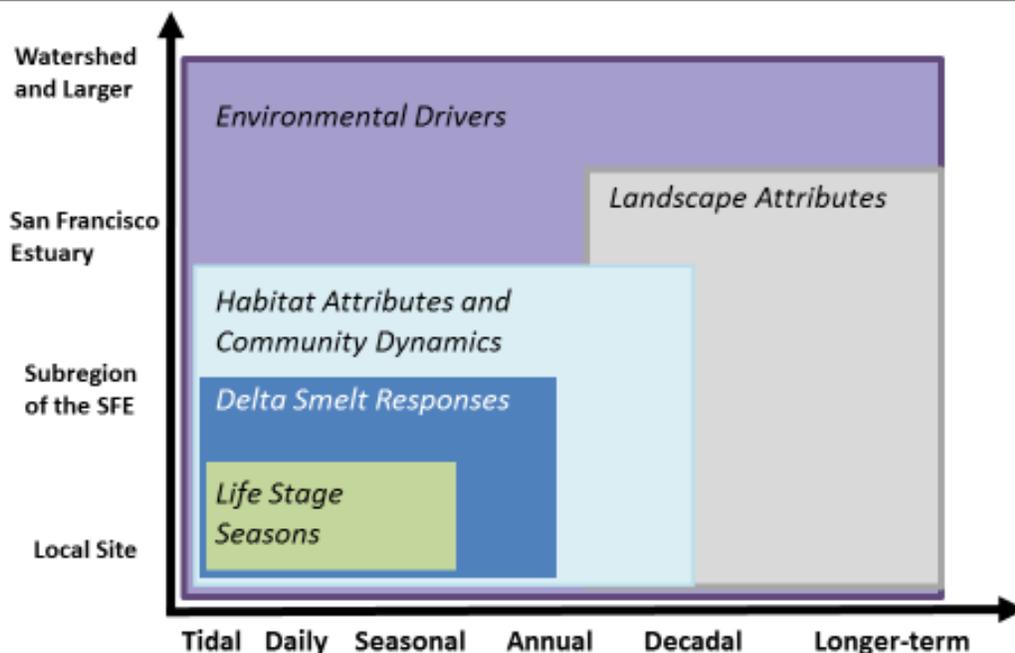

slowly over the course of one or more years. Life stage seasons (tier 5) occur over the course of a year in seasonally occupied areas of the estuary.

Similar to the POD and DRERIP conceptual models, the updated Delta Smelt life cycle conceptual model includes only those landscape attributes and environmental drivers with plausible mechanistic linkages to outcomes, which in this case are changes in habitat attributes and resulting Delta Smelt responses in the four life stage seasons. These mechanistic linkages are depicted as arrows in a series of four new conceptual models for each life stage season (Fig. 10). These life stage season conceptual models are nested components of the general life cycle conceptual model as shown in Fig. 8. They will be described in detail in Chapter 5.

Data Sources

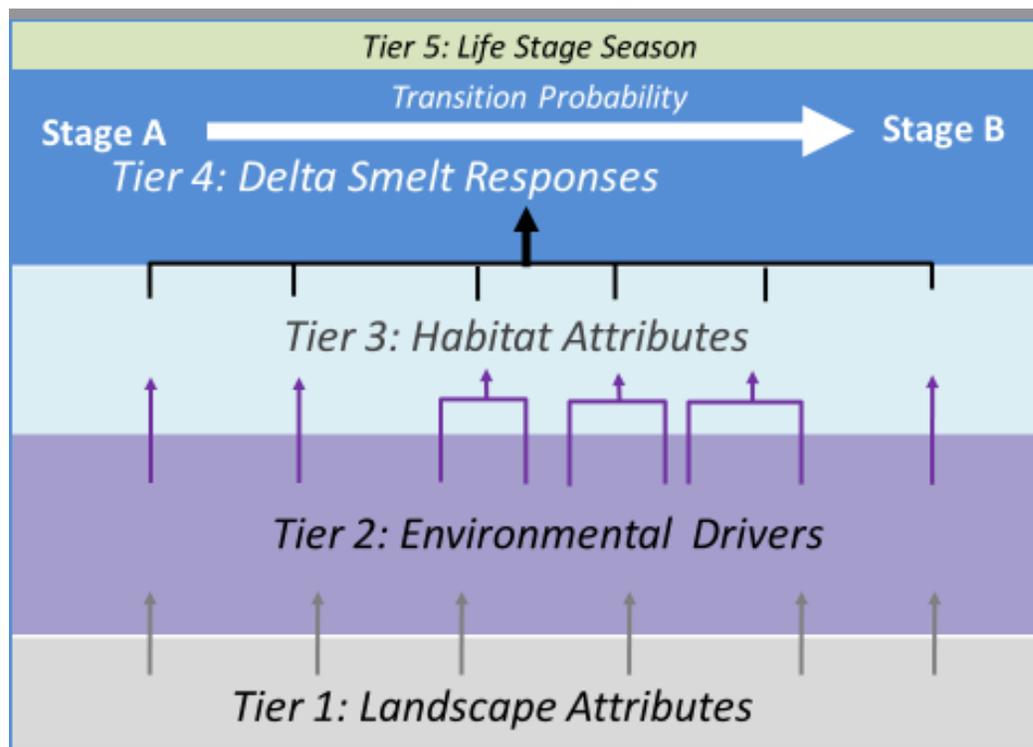

Our examination of environmental drivers in Chapter 4, Delta Smelt life history and population dynamics and trends in Chapter 6, and the evaluation of hypotheses about Delta Smelt responses to changing habitat attributes in Chapter 7 rely largely on results of previously published data and analyses, but in several cases we update these analyses with more recent data. We also include some additional analyses (described below). All these analyses depend largely on environmental monitoring data collected by IEP agencies during routine, long-term monitoring surveys

Figure 9. Spatial and temporal scales of the component tiers in the general life cycle conceptual model framework for Delta Smelt.

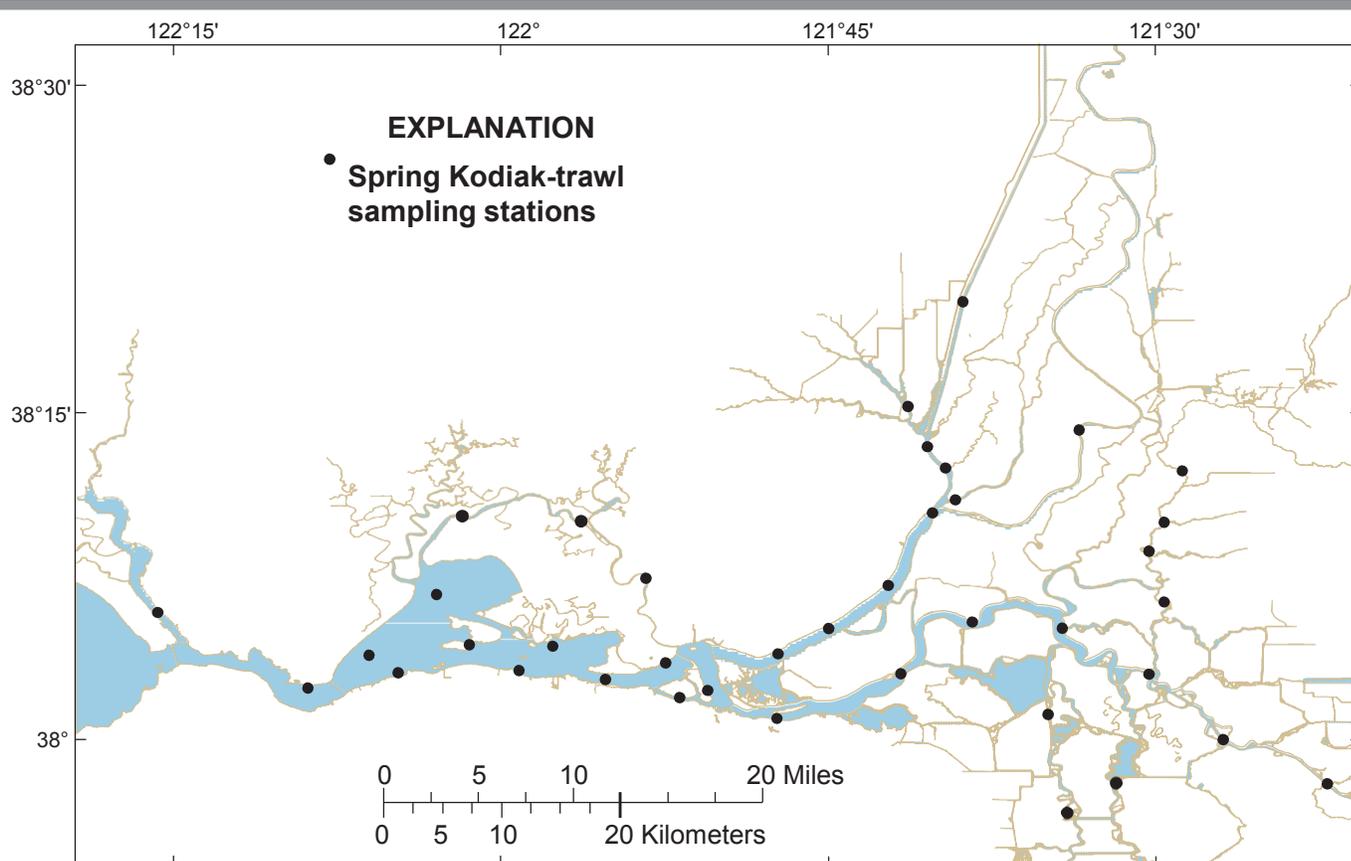

(<http://www.water.ca.gov/iep/products/data.cfm>). These surveys provide the long-term records and geographic coverage necessary and the data collected by these surveys are publicly available. Available data includes data on fish, invertebrates, phytoplankton, water quality variables, and flow. Use of these particular data sources does not reflect any preference for those data. Results from other ongoing research efforts were included as appropriate.

For the purposes of this report, we consider each stage, larvae through adults, of the Delta Smelt life cycle in the context of the monitoring programs that provide data on the Delta Smelt population. Delta Smelt eggs are not monitored and have in fact never been found in the wild. Monitoring surveys in the late winter and spring include the spring Kodiak trawl (SKT, Fig. 11), which samples maturing, spawning and post-spawning adults. The SKT is conducted monthly from January through May. Spring also includes the 20 mm survey (20 mm, Fig. 12), which samples larval and post-larval Delta Smelt and is conducted every two weeks from mid-March through mid-July. Summer includes the summer townet survey (TNS, Fig. 13); which samples juvenile fish and currently runs every two weeks from June through August. The Fall Midwater Trawl (FMWT, Fig. 14) survey samples subadult Delta Smelt monthly from September through mid-December. Each of these surveys samples fishes broadly within the upper SFE and generally covers the geographic habitat range used by Delta Smelt (Merz et al. 2011). Exceptions to complete coverage occur in some high outflow years when Delta Smelt can temporarily inhabit San Pablo Bay in association with decreased salinities caused by increased Delta outflows (Moyle 2002) and in other years when some adult fish move upstream of the geographic range of these surveys (probably to spawn) in the Yolo Bypass and Sacramento River (e.g., Feyrer et al. 2006, Merz et al. 2011). Also, FMWT and TNS sampling in the Cache Slough complex was instituted over several years starting in the 1990s for FMWT and 2000s for TNS. The current sampling locations have been in place since 2011. These exceptions to complete spatial coverage are believed to reflect small fractions of the population. Additional geographic coverage along

Figure 10. Framework for the Delta Smelt life stage season conceptual models.

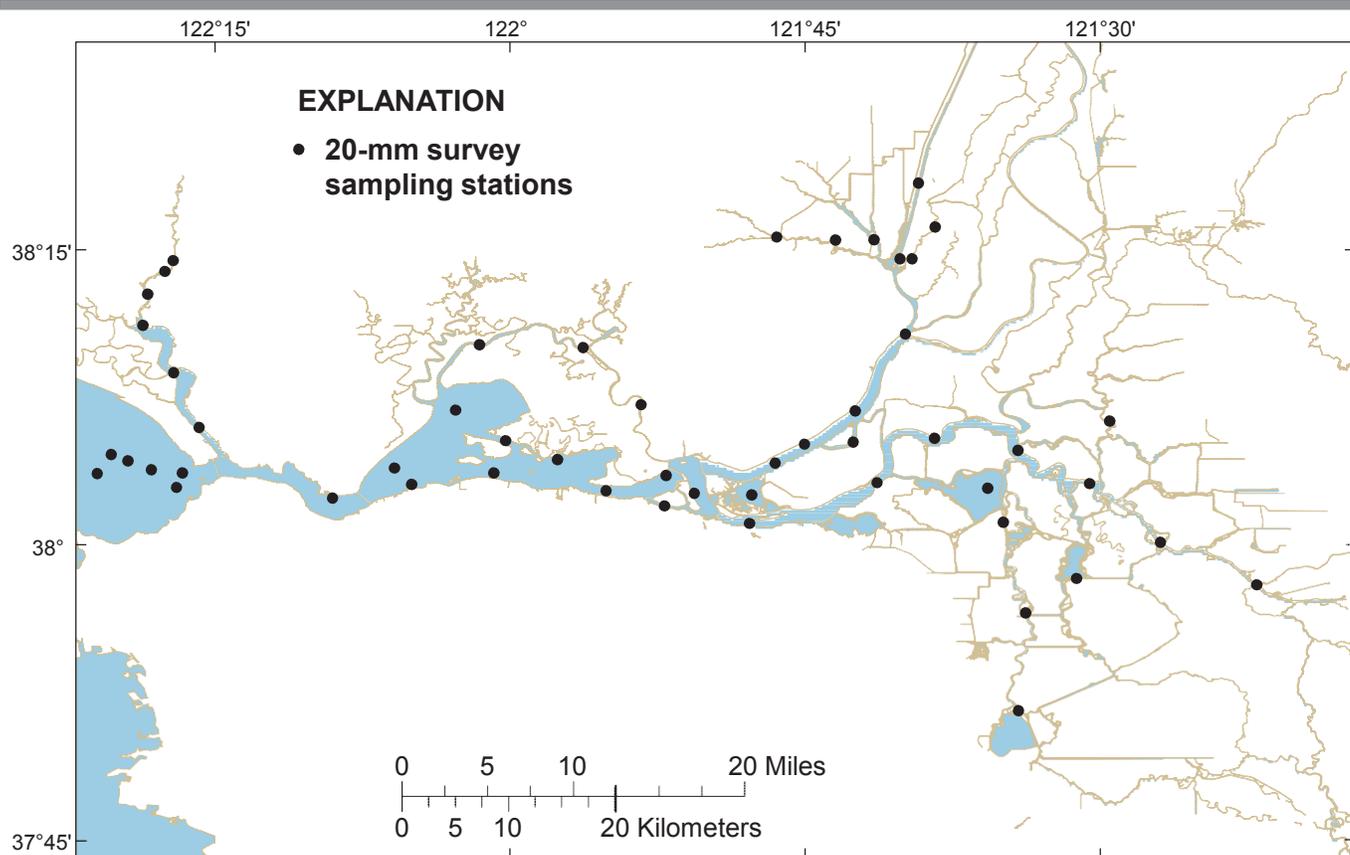

or outside of the margins of the other four monitoring surveys is provided by other IEP fish monitoring surveys such as the San Francisco Bay Study, trawling and seining conducted by the Delta Juvenile Fish Monitoring Program in the Sacramento River and the north Delta, as well as the fish salvage monitoring at the fish protection facilities associated with the SWP and CVP export pumps in the south Delta. All Delta Smelt life stages (larvae-adult) are also commonly collected from nearshore habitats and in shallow open water where trawls cannot be used effectively (e.g., Aasen 1999, Nobriga et al. 2005, Brown and May 2006); however, there are no data indicating these are preferred habitats, that these fish represent different populations (see Fisch et al. 2011), or that their abundance varies differently than data from the aforementioned trawl surveys would suggest.

Annual abundance indices for Delta Smelt life stages are calculated from the catch data provided by each of the four surveys (See Appendix B for details). Together, they provide a comprehensive account of long-term changes in the relative abundance of Delta Smelt (Fig. 3). The long series of abundance index records for the summer and fall have provided the basis for many data analyses and modeling studies (e.g., Jassby et al. 1995, Kimmerer 2002a,b, Bennett 2005, Manly and Chotkowski 2006, Thomson et al. 2010, MacNally et al. 2010, Maunder and Deriso 2011, Miller et al. 2012) and for regulatory actions (USFWS 2008). They have also been used to estimate absolute population abundance (Newman 2008). The Delta Smelt and other SFE fish abundance indices are generally considered useful indicators of the status and trends of the Delta Smelt population as well as of the status of other resident fishes in the SFE in general and serve as performance metrics for the success of management actions. All monitoring surveys have strengths and weaknesses, and the long-term fish monitoring programs in the SFE are no exception (Honey et al. 2004). In the case of Delta Smelt, strengths include reasonably good coverage of the geographic extent of Delta Smelt habitat and coverage of all life stages except

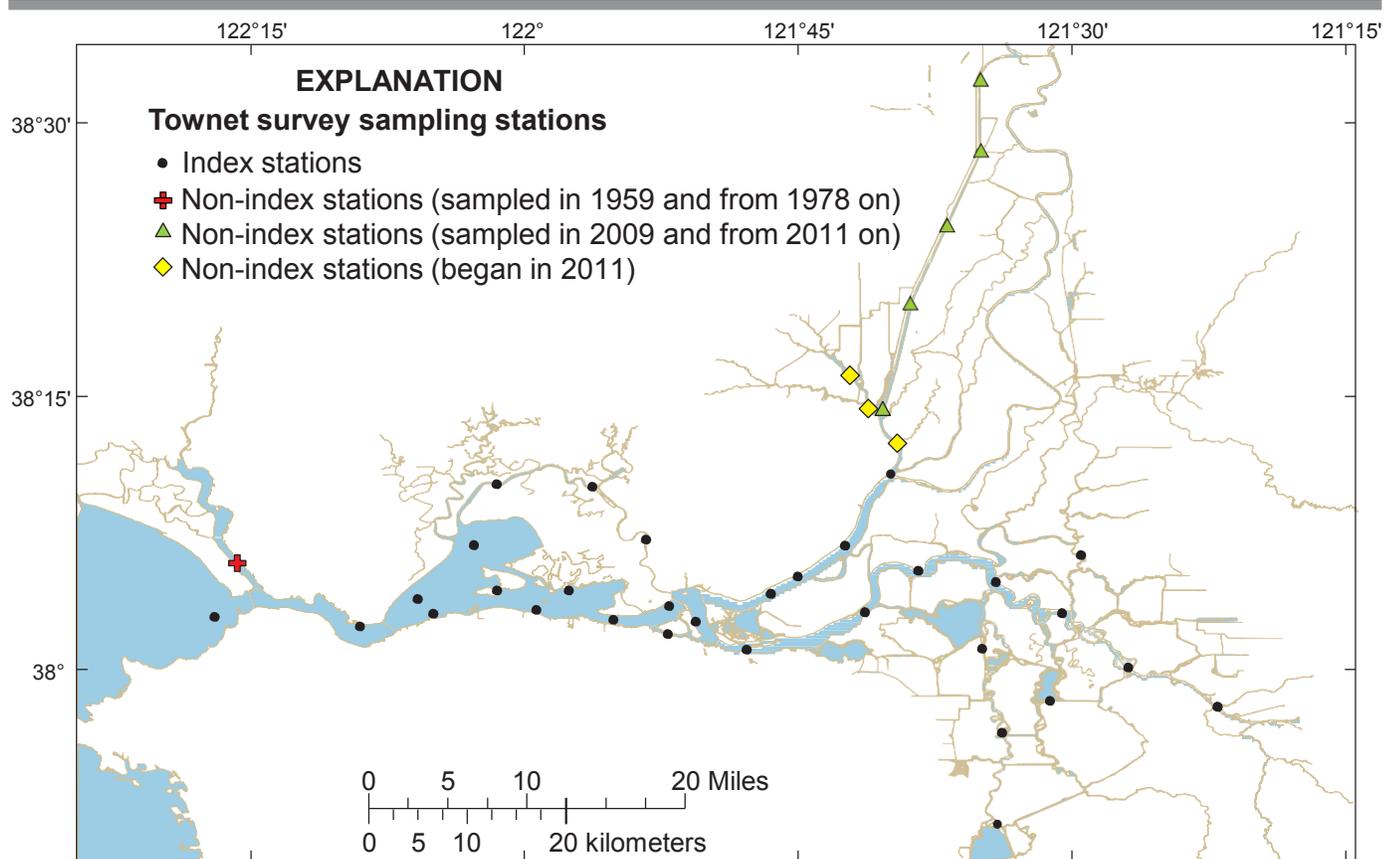

Figure 11. Map of Spring-Kodiak Trawl Survey sampling stations.

eggs (Gaines et al. 2006). They also include exceptionally long and consistent data records going back to 1959 in the case of the TNS, the oldest of the four surveys described here. There is a large amount of ancillary data (covariates), including data collected during the fish surveys, additional fish data from other monitoring surveys (Honey et al. 2004) as well as invertebrate, phytoplankton, water quality and hydrological data. Possible weaknesses include no measure of precision of abundance indices and imprecise estimates due to a high frequency of zero catches of Delta Smelt. These problems combine with survey design issues such as differences in Delta Smelt catchability with different nets and trawl regimes under changing environmental conditions, behavioral changes in distribution (Newman 2008) and the current low abundance of the species. For example, several studies have shown that Delta Smelt can exhibit lateral and vertical movements associated with tide and time of day (Bennett et al. 2002, Feyrer et al. 2013, Bennett and Burau 2014) but the overall frequency or effects of such local movements on abundance indices are unclear. Studies to further evaluate and address these issues are currently underway.

Two of the four fish monitoring surveys described here specifically target Delta Smelt; the other two do not. The SKT was designed and implemented specifically to improve detection of maturing adult Delta Smelt moving upstream in the winter and spring, particularly into the central and south Delta (Souza 2002). The 20 mm survey was designed and implemented specifically to capture late-stage larval Delta Smelt of about 20 mm in length; the SKT and 20 mm survey data help managers assess the risk of entrainment of these life stages by south Delta

Figure 12. Map of 20 mm Survey sampling stations.

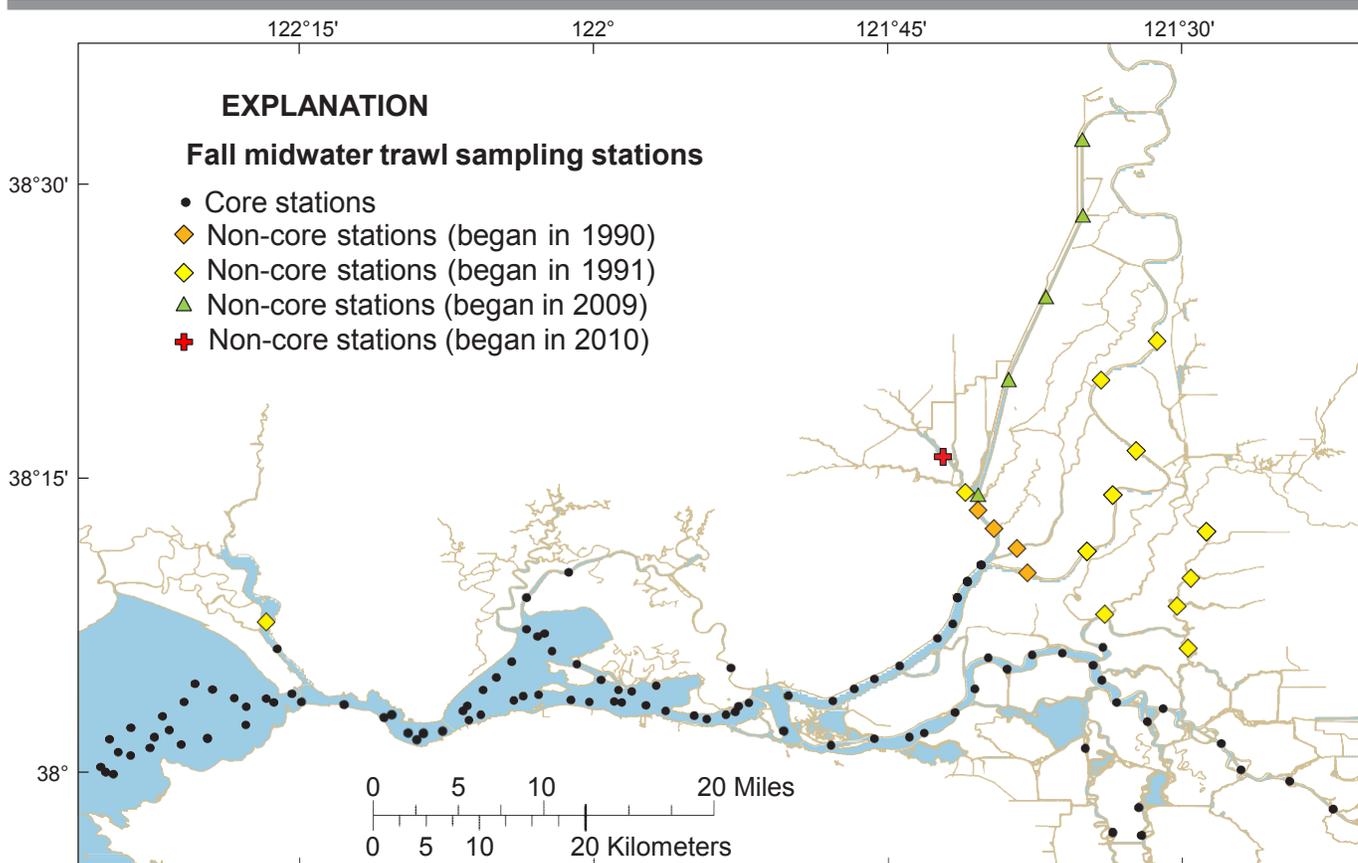

export pumps (Dege and Brown 2004). The TNS was designed to target small juvenile Striped Bass of about 17-50 mm fork length (the distance from the snout to the indentation of the tail fin) (Stevens 1977, Turner and Chadwick 1972); however, Delta Smelt tend to be of appropriate size for capture by the TNS net during the survey period. This occurs because Delta Smelt (see below) and Striped Bass spawning overlaps in time and growth of both are linked to water temperature, such that peak larval abundance occurs in April or May in most years. The TNS traditionally started and ended based on mean length of Striped Bass; however, young Delta Smelt attain sizes vulnerable to the TNS net during the same time period Striped Bass are vulnerable (Miller 2000). The survey ends when young Striped Bass surpassed 38 mm fork length (Miller 2000). Thus, regardless of the particular number of sampling surveys in a year or the index calculation method, Delta Smelt juveniles are generally vulnerable to the TNS whenever it samples. Similarly, the FMWT survey was designed to capture young-of-the-year Striped Bass, but in the 60-140 mm fork length size range (Stevens 1977). Although the survey and gear is generally effective for small pelagic fishes, the cod-end mesh (1.3 mm stretch mesh) on the net is large enough to allow some smaller sub-adult Delta Smelt to escape during the first couple survey months (see Newman 2008 for an approach to correct this effect). Even though the gear is not completely effective at retaining all sub-adult Delta Smelt, FMWT provides a reasonable relative measure of sub-adult abundance through time (Kimmerer and Nobriga 2005), albeit with low precision at the current low catch levels and given additional variation related to changes in growth, and thus changes in retention in the net from year to year. With the aforementioned caveats, we believe these surveys provide useful and valid relative abundance measures to examine the various life stage transition

Figure 13. Map of Summer Townet Survey sampling stations.

relationships described in this report as well as in many of the previously published studies cited in this report.

In addition to the annual abundance indices for Delta Smelt provided by the monitoring surveys described above, we also present annual indices of recruitment and survival. In this report, a survival index is simply the ratio of an abundance index for a particular life stage divided by the abundance index for a preceding life stage of the same Delta Smelt cohort. A recruitment index is the ratio of an abundance index for a particular life stage divided by an abundance index for a life stage of the preceding Delta Smelt year-class. These types of indices have been used in previous analyses (e.g. Miller et al. 2012), but it is important to note that they may compound the observation errors inherent in the annual abundance indices in complicated ways. This is likely more problematic for survival and recruitment indices that use the TNS and FMWT abundance indices because these surveys were not specifically designed to target Delta Smelt. It may be less problematic for the recruitment index calculated by dividing the 20 mm abundance index for larval and post-larval Delta Smelt by the preceding SKT abundance index for adult Delta Smelt because both surveys specifically target Delta Smelt. We use this recruitment index in some additional analyses included in this report. All other survival and recruitment indices are only used as a rough approximation and illustration of differences in recruitment and survival rates among different annual cohorts and life stages; they are not used for additional analyses.

Figure 14. Map of Fall Midwater Trawl Survey sampling stations.

Data Analysis

As noted previously, we review long-term trends in this report using published results, but in some cases include some additional analyses of long-term monitoring data (Chapters 4 and 7). These analyses are kept deliberately simple, for example, simple graphical explorations of time series, examinations of simple statistics such as medians and arithmetic means, and investigation of univariate relationships using simple correlation and least squares regression analyses. Such analyses are readily reproducible with the publicly available data described above. The purpose of presenting the results of these new analyses is to update previously published information with the most recent data. In many cases, the data presented in this report are summarized using boxplots. The center horizontal line in each box represents the median of the data. The upper and lower ends of the box represent the upper and lower quartiles of the data. These are also known as “hinges.” The “whiskers” are the lines extending above and below the box. The whiskers show the range of values falling within 1.5 times the inter-quartile distance from the nearest hinge. Values outside this range are shown as individual symbols. Asterisks denote values within 1.5 to 3.0 times the inter-quartile distance and circles denote values greater than 3.0 times the inter-quartile distance. Other types of plots are explicitly identified in the figure caption.

Some graphs and analyses refer specifically to the POD period. Analyses suggest the POD period started as early as 2002 or as late as 2004 (Thomson et al. 2010). We somewhat arbitrarily selected 2003-present as the POD period for this report. This period is not being recommended

as the baseline for management agencies to use when considering recovery of Delta Smelt. The time period simply reflects the consistently low level of Delta Smelt abundance in recent years and a useful baseline for identifying years with improved Delta Smelt abundance indices, which would indicate improved environmental conditions for Delta Smelt. Similarly, we also consider the 1982-2001 period between the two major step declines in Delta Smelt abundance identified by Thomson et al. (2010) separately in some graphs and analyses. Finally, some graphs and analyses refer to calendar years while others refer to water years. In California, a water year starts on October 1 and ends on September 30 of the next calendar year. California water year classifications are based on calculations of annual unimpaired runoff, which represents the natural water production of a river basin, unaltered by upstream diversions, storage, and export of water to or import of water from other basins.

In Chapter 7, we explore a series of hypothesized driver-outcome linkages using a comparative approach. The purpose is to demonstrate the utility of our conceptual model framework for generating hypotheses about the factors that may have contributed to the 2011 increase in Delta Smelt abundance. Specifically, we compare Delta Smelt responses to habitat conditions in four recent years with moderate to wet hydrology: the two most recent wet years (2006 and 2011) and the two drier years immediately before them (2005 and 2010). This comparative approach and data sources (described in Chapter 4) are deliberately similar to the comparative approach used in the FLaSH investigation (Brown et al. 2014). This approach allows us to place the results of the FLaSH investigation in a year-round, life cycle context and to more comprehensively evaluate factors that may have been responsible for the strong Delta Smelt abundance and survival response in 2011, including any possible relevant antecedent conditions from 2010. We attempt to draw comparisons with a similar set of data collected during 2005 and 2006. Our working assumption is that different Delta Smelt abundances in 2006 and 2011 should be attributable to differing environmental conditions, in some cases attributable to management actions, and subsequent ecological processes affecting the Delta Smelt population.

In Chapter 9 we briefly describe three examples of additional mathematical modeling approaches that can be used to further explore some of the linkages and interactions in our conceptual models and complement previously published and other ongoing mathematical modeling efforts for Delta Smelt. Importantly, results from the three modeling examples in Chapter 9 are included for illustrative purposes only; peer-reviewed publications of these analyses need to be completed before they can be used to draw firm conclusions.

Chapter 4: Environmental Drivers and Habitat Attributes

The general approach of this Chapter is to focus on how environmental drivers and interactions among them create habitat attributes of importance to Delta Smelt. Specifically, we review and synthesize existing information about drivers and habitat attributes and Delta Smelt responses to habitat attributes with a focus on new information since Baxter et al. (2010). We use the drivers and habitat attributes depicted in the basic POD conceptual model (Fig. 6) as the basis for this synthesis. We consider habitat attributes important when there are published studies suggesting ecological responses by Delta Smelt. Each section focuses on a habitat attribute that can be the outcome of one or more environmental drivers. Physical habitat attributes are presented first,

followed by biological habitat attributes. The order of presentation does not imply any kind of ranking of relative importance. For simplicity, we consider all habitat attributes discussed here as equally important because, as noted in Chapter 2, habitat arises from the combination of *all* physical and biological attributes affecting a species. We fully acknowledge that as Delta Smelt research proceeds and the system continues to change, additional habitat attributes may need to be added to the conceptual model, while others may be deemphasized or even deleted.

Each section starts with the general importance of a specific habitat attribute for estuarine biota followed by a brief discussion of its linkages with environmental drivers and its dynamics in space and time. Each habitat attribute is then placed in the context of Delta Smelt biology.

Water Temperature

Water temperature is fundamental to aquatic ecosystem health and function. It directly influences biological, physical, and chemical properties such as metabolic rates and life histories of aquatic organisms, dissolved oxygen levels, primary productivity, and cycling of nutrients and other chemicals (Vannote and Sweeney 1980, Poole and Berman 2001, Null et al. 2013). Water temperature is an important variable for ectothermic (“cold-blooded”) animals, including all fishes and invertebrates in the SFE. In the most extreme case, when water temperature exceeds the thermal tolerance of an organism, it will die. Temperatures within the thermal tolerance of an organism control the rate and efficiency of many physiological processes, including activity, digestion, growth, reproductive development, and reproductive output. We return to these processes after giving an overview of water temperature variability and its drivers in the Delta.

Long term temperature records from selected sites in the SFE show substantial seasonal and daily fluctuations in water temperature (Kimmerer 2004). While daily variations are evident and likely important to organisms, seasonal variations are much greater (Wagner et al. 2011). Median water surface temperatures across all stations monitored by the IEP Environmental Monitoring Program (EMP) (Fig. 15) from 1975-2012 range from 9 °C in January (minimum: 6 °C) to 22 °C in July (maximum: 28 °C). There are also clear regional variations in water temperature (Fig. 16). In July and August, the hottest summer months, water temperatures are usually highest at monitoring stations in the south Delta (average 23-26 °C, maximum 28 °C), lower at stations in the northern and western Delta (average 21-23 °C, maximum 25 °C) and lowest at stations in Suisun and San Pablo Bays (average 19-21 °C, maximum 24 °C). In January, the coldest winter month, average water temperatures are uniformly below 10 °C in the entire Delta, but above 10 °C in San Pablo Bay.

There is currently little evidence for increasing water temperatures in the Delta, although with climate change such increases are expected over the course of the century (Cloern et al. 2011, Wagner et al. 2011, Brown et al. 2013). In Spring (March-June) water temperature at IEP EMP water quality monitoring stations in the Delta increased during 1996–2005 by about 0.2 °C per year, but a similar trend was not apparent for the longer-term data record from 1975-2005 or for stations in Suisun Bay (Jassby 2008). These findings are similar to the results of Nobriga et al. (2008) who found no long-term (1970-2004) trends in temperature data collected during summer fish monitoring surveys in the Delta. Nobriga et al. (2008) also noted that the long-term (1970-2004) mean July water temperature at TNS fish monitoring stations in the southern region of the Delta is 24 °C, with current mid-summer temperatures often exceeding 25 °C. This agrees with average monthly EMP data from 1975-2012 which shows July and August water temperatures at

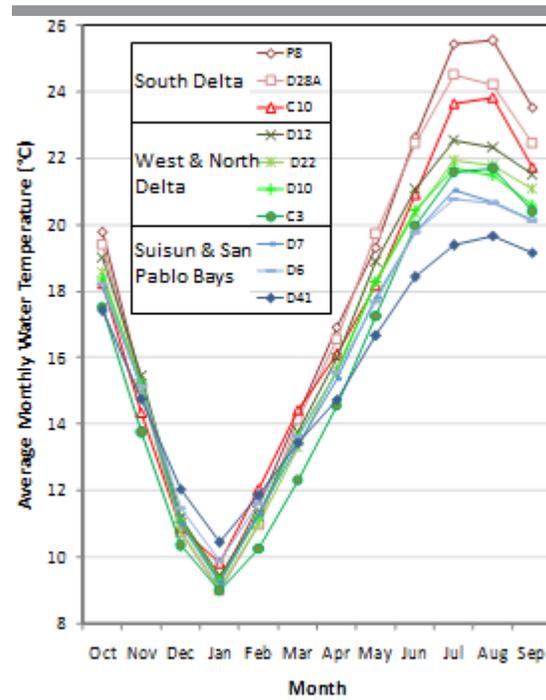

Figure 15. Map of active and historic IEP Environmental Monitoring Program (EMP) sampling stations.

a monitoring station located in Old River (station D28A) and in the San Joaquin River near the Port of Stockton (station P8) of more than 24 °C and 25 °C, respectively (Fig. 16).

In tidal systems, water temperature at a particular location is determined by the interaction between atmospheric forcing (e.g., air temperature and wind), tidal dispersion and riverine flows across the estuarine landscape (Monismith et al. 2009). In particular, estuarine water temperature is driven by heat exchange at the air–water interface and mediated by tidal and riverine flow dynamics and estuarine geomorphology (Enright et al. 2013). Wagner et al. (2011) found that regional weather patterns including air temperature and insolation (sunlight), are the primary drivers of water temperature variations in the SFE. Water flow and interaction with the stationary topography of the system also affects water temperature in the SFE, especially over shorter time scales and at smaller spatial scales. For example, Enright et al. (2013) showed that interaction

Figure 16. Average monthly water temperature for stations monitored by the Environmental Monitoring Program from 1975-2012.

of tides with tidal marsh topography can have a mediating effect on water temperature in tidal sloughs and on thermal variability at smaller spatial scales. Wagner et al. (2011) showed that high winter and spring flows can temporarily lower water temperatures. Greenberg et al. (2012) found that the present riparian vegetation on Delta levees lowers insolation by about 9% compared to a hypothetical situation without vegetation and suggested that riparian vegetation thus contributes to locally cooler water temperatures. This suggests that at least to some degree, water temperature can be managed locally and for short periods. Over larger scales, however, these types of locally mediated effects are overwhelmed by the effects of air temperature and insolation.

Air temperature and insolation in the SFE are correlated with each other (Wagner 2012) and vary strongly with

proximity to the Pacific Ocean because of the contrasting climate regimes prevailing in inland central California and the central California coast. While inland central California has a large annual air temperature range with hot, dry, sunny summers and cool, wet, and often foggy winters, the central California coast has a smaller annual air temperature range with cooler and often foggy summers and milder winters (Conomos et al. 1985). The SFE has a transitional climate with greater spatial and temporal variability in air temperature than either the coastal or the inland regions (Whipple et al. 2012). This is due to the interplay of the dynamic air masses from these regions across the stationary estuarine topography. In the summer, this interplay often results in strong afternoon winds from the ocean locally known as the “Delta breeze.” These onshore winds usually advance into the western and central Delta and, depending on the depth of the marine layer, often also into its marginal areas. In the Delta, these southwest to northeast winds can persist throughout the night and into the next morning and produce a marked decline in daily temperature. In the morning, this low is often followed by rapid warming once the winds subside and the high temperature inland air masses return to dominance (National Weather Service 2003). In the winter, ocean winds are weak and, during calm periods, cold air flows from the mountains into the estuary. This results in the formation of dense, overnight, near-surface fog locally known as “tule fog.” These calm and foggy periods are interrupted by winter storms. Many of these storms arrive from the south and southeast as “atmospheric rivers” that can often produce gale force winds and heavy rains lasting several days (Conomos et al. 1985, Dettinger and Ingram 2013).

The large variability in air temperature in the Delta is reflected by the larger annual variability in water temperature measured from 1998-2002 at continuous monitoring stations in the interior Delta compared to stations further upstream or downstream (Wagner et al. 2011). This high variability is also apparent in monthly water temperature data collected by the IEP Environmental

Monitoring Program since 1975 (Fig. 11). From 1975 to 2012, annual fluctuations in average monthly water temperature were greatest at stations in the south Delta (14-16 °C), smaller at stations in the northern and western Delta (12-13 °C), and lowest at stations in Suisun and San Pablo Bays (9-12 °C). Jassby (2008) reported that maximum daily air temperature could explain almost half the variability in maximum daily water temperature at the continuous monitoring station at Antioch during the summer months. The relationship between air and water temperature was also strong in all other months except January.

Wagner et al. (2011) and Wagner (2012) developed simple regression models for predicting water temperature at fixed temperature monitoring stations in the SFE using only air temperature and insolation on the day of interest and the water temperature from the previous day. Water temperature from the previous day accounts for both previous air temperature and the sources of water to the site, including advective flow from rivers or dispersive flow from more downstream reaches of the SFE. Each model had a different set of coefficients because of the differing influences of incoming river water or tidal exchange with San Francisco Bay. For stations with greater than 1 year of calibration data, model R^2 for daily average temperature exceeded 0.93, indicating that water temperature was highly predictable within the limits of the calibration data sets. High winter and spring flows were responsible for the largest divergences of the model outputs from measured temperatures.

The simple statistical models for water temperature developed by Wagner et al. (2011) and Wagner (2012) should be used with caution because they only predict temperature at the site of the recording instrument and do not explicitly account for mechanistic heat exchange. The analyses therefore do not incorporate the possible effect of site-specific features such as shading by riparian vegetation (Greenberg et al. 2012). Similarly, there are lateral and vertical variations in temperature on daily time scales (Wagner 2012) that could be important to organisms. For example, such variation might include substantial heterogeneity and formation of thermal refugia, which may be important to Delta Smelt.

In contrast to statistical modeling, which produces site-specific results, water temperature across regions is commonly modeled with computation-intensive deterministic simulation models. Such models use energy budgets to predict water temperature. Simple stochastic models are also possible. Like most statistical models, these stochastic models generally rely on the relationship between air and water temperature (Caissie 2006, Null et al. 2013). We are not aware that these types of models have been developed for the San Francisco Estuary.

Upper temperature limits for juvenile Delta Smelt survival are based on laboratory studies and corroborated by field data. Interpretation of the laboratory results is somewhat complicated as temperature tolerances can be affected by various factors including acclimation temperature, salinity, turbidity, and feeding status. Based on the critical thermal maximum, CT_{max} , juvenile Delta Smelt acclimated to 17 °C could not tolerate temperatures higher than 25.4 °C (Swanson et al. 2000). However, for juvenile Delta Smelt acclimated to 11.9, 15.7 and 19.7 °C, consistently higher CT_{max} were estimated (27.1, 28.2 and 28.9 °C, respectively; Komoroske et al. 2014), which corresponded closely to the maximum water temperatures recorded in the TNS and FMWT surveys. Swanson et al. (2000) used wild-caught fish, while Komoroske et al. (2014) used hatchery-reared fish, which may have contributed to the differences in results. Based on the TNS (Nobriga et al. 2008) and the 20 mm Survey (Sommer and Mejia 2013), most juvenile Delta Smelt were predicted to occur in field samples when water temperature was below 25 °C. In a multivariate autoregressive modeling analysis with 16 independent variables, MacNally et al. (2010) found that high summer (June – September) water temperature had a negative effect

on Delta Smelt subadult abundance in the fall. Water temperature was also one of several factors affecting Delta Smelt life stage dynamics in the state-space model of Maunder and Deriso (2011) and in an individual-based Delta Smelt life-cycle model (Rose et al. 2013a,b).

In addition to lethal effects, water temperature also has direct effects on the bioenergetics (interaction of metabolism and prey density) of Delta Smelt (Bennett et al. 2008) and it may affect their tolerance to other habitat attributes, such as toxicity (Brooks et al. 2012) and predation risk. Responses of different life stages of Delta Smelt to various temperature, salinity, and turbidity conditions are currently being further assessed as part of a larger UC Davis laboratory study about the “fundamental niche” of Delta Smelt (Komoroske et al. 2014, R. Connon et al., U.C. Davis, unpublished data).

The topic of bioenergetics is an important consideration in much of the remainder of this report, so we address it in more detail here. In general, the total metabolic rate of a fish will increase with temperature to an optimum temperature at which, given unlimited food, there is the maximum ability to grow and develop reproductive products (eggs or sperm) in addition to maintaining the basal metabolic rate required for survival, which also increases with temperature (Houde 1989, Hartman and Brandt 1995). As temperature increases beyond the optimum, metabolic rate continues to increase but physiological processes become less and less efficient and more energy is required just to meet the basal metabolic rate of the organism. Eventually, the metabolic rate begins to decline as temperatures approach the physiological limits of the organism and the basal metabolic rate can no longer be maintained.

At temperatures beyond the optimum, the ability to grow and mature becomes increasingly impaired. Long-term exposure to such stressful temperatures can eventually be lethal. In addition, resistance to disease and contaminants can also be affected (Brooks et al. 2012). The responses to contaminants can vary depending on the type of contaminant. For example, low temperatures can decrease the toxicity of organophosphate insecticides, but increase the toxicity of pyrethroid and organochlorine insecticides (Harwood et al. 2009), a characteristic that has been used in toxicity identification and evaluation (Weston and Lydy 2010). The previous discussion assumes unlimited food, which is unlikely to be the case for Delta Smelt or any organism in nature. Even at the optimum temperature, growth and reproductive development will depend on the quantity and quality (energy and nutrient content) of the food consumed. If the fish is unable to ingest enough food to meet its nutrient and energetic requirements, including the energy expended to capture and digest prey, it will starve, after first depleting any available energy stores (fat or muscle). Given an array of food items, fish will generally choose larger prey items. This is because the energy required to detect, chase, and capture multiple smaller prey that are equivalent in nutritional value to a single large prey item will, in many cases, exceed the energy required to capture the single prey item. Note that these same ideas apply to predatory fish that might consume Delta Smelt.

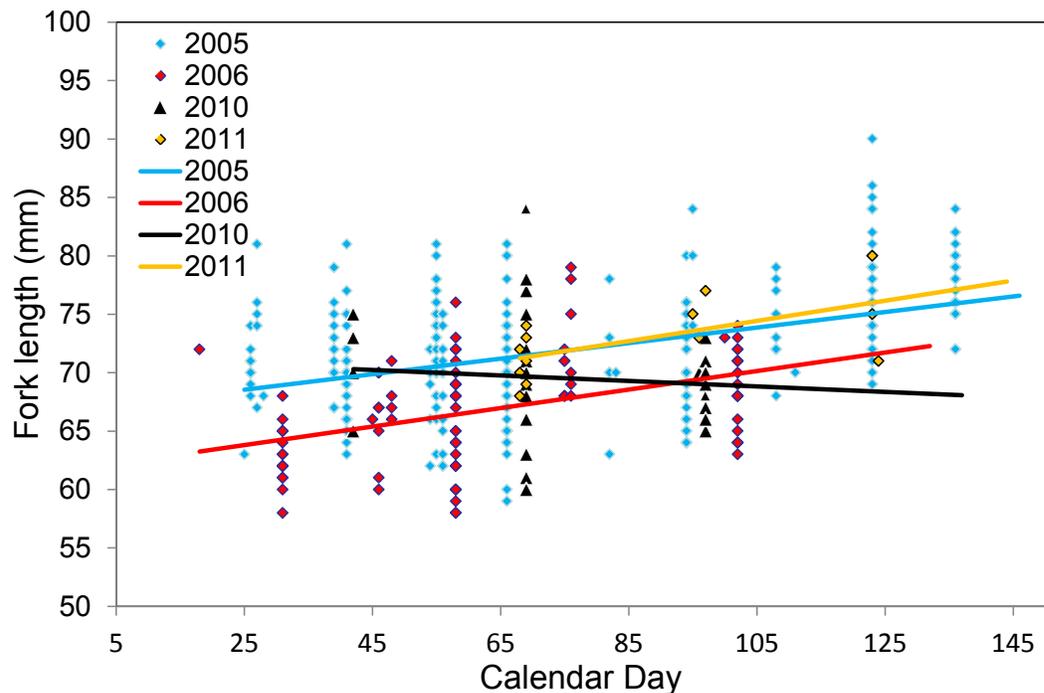

Water temperature is also thought to affect the number of eggs produced by female Delta Smelt. Egg production (i.e., fecundity) of the population is influenced not only by individual female size and number (Bennett 2005, DFW unpublished), but also by the duration of a temperature “spawning window” (Bennett 2005, Mac Nally et al. 2010), variously defined as: 15-20 °C by Bennett (2005); 7-15 °C by Wang (1986); and 12-15 °C by Baskerville-Bridges et al. (2004b). Bennett (2005) further stated that during cool springs this spawning window persists longer, allowing more cohorts to recruit. Given a sufficiently long spawning window, individual females may also repeat-spawn during the spawning season. This has been documented in culture (see Bennett 2005; J. Lindberg, U.C. Davis, personal communication 2013) and appears to occur

in the wild as well (L. Damon, CDFW, written communication 2012). Lindberg (U.C. Davis, personal communication 2013) observed that most females in culture spawned twice, some spawned three times and a very small number spawned four times. Each spawning was separated by a 4-5 week refractory period during February through June when water temperatures remained within the spawning window. Though laboratory conditions may not necessarily be representative of conditions in the wild, ripe females ready to release their second complete batch of eggs and developing a third batch have been detected in the wild during March and April (i.e., mid-season) suggesting that three spawns are possible (L. Damon, CDFW, written communication 2012). Thus, a longer spawning window would allow more females to repeat spawn adding both additional cohorts hatching under different conditions, and multiplying the fecundity of each repeat spawner (i.e., increasing the total fecundity of the individual), and thus, the total fecundity of the population. Moreover, in culture, individual females continued to grow through the spawning season and become more fecund with each batch of eggs (J. Lindberg, U.C. Davis, personal communication 2013). In the wild, the size of mature females generally increases month to month through the spawning season (Fig. 17), suggesting a potential increase in fecundity with each batch, but this has yet to be confirmed for wild fish. However, in culture, fish hatched later in the spawning season (mid-May to mid-June) grew up to be smaller-sized adults that started spawning later and had progeny with lower survival than the progeny of fish hatched earlier in the season (Lindberg et al. 2013). These observations are consistent with the reproductive patterns suggested for the wild Delta Smelt population (Bennett 2011). Overall, the effect of a prolonged spawning season on Delta Smelt population size and dynamics would seem to be positive; however, there is some uncertainty.

In the culture experiments reported by Bennett (2005), temperature strongly influenced hatching success of eggs. Specifically, Bennett (2005) reported that optimal hatching success and larval survival were estimated to occur at 15–17 °C based on studies conducted at 10, 15, and 20 °C. The data indicated that as incubation and early rearing temperatures increased, size at hatching and size at first feeding linearly decreased, possibly because basal metabolism of the developing embryo used more energy leaving less for growth. Fish that hatch relatively late in the season may experience high temperatures at a small size, which may reduce larval survival by several possible mechanisms. First, small size would limit the size of food items that the larvae could ingest because of smaller mouth size (see Nobriga 2002). Temperature may also affect food type and availability as discussed below. Second, small larvae are likely vulnerable to a larger range of predators for a longer period compared to larger larvae (e.g., “stage duration hypothesis;” Anderson 1988). Third, these fish could be potentially more vulnerable to transport toward the CVP and SWP export facilities, when Old and Middle River (OMR) flow restrictions are lifted. Restrictions are lifted when the 3-day mean water temperatures in Clifton Court Forebay (CCF) reach 25 °C or by the end of June.

As explained above, higher water temperatures increase energetic requirements and thus the food requirements of fish. To meet the increased need for food, it is possible that Delta Smelt spend more time foraging during the day. Since greater foraging time during the day increases visibility to predators, and those predators would also increase their foraging rates at higher temperatures, the encounter rate of predator and prey would likely increase at higher water temperatures. The net effect could be an increase in Delta Smelt predation risk (e.g., Walters and Juanes 1993). High temperatures can also decrease antipredator behavior, as described for Sacramento River Chinook Salmon (*Oncorhynchus tshawytscha*) (Marine and Cech 2004). In other words, the fish may make a behavioral choice to feed, grow, and become less vulnerable to predators as rapidly as possible, even though the short-term predation risk might increase. Water temperatures in the upper SFE are usually highest from June to September and decline rapidly between October and December

Figure 17. Individual female fork lengths by calendar day for mature female Delta Smelt collected in the Spring Kodiak Trawl Survey, January through May, 2005, 2006, 2010 and 2011. These data include both monthly distribution survey fish and directed survey fish. The directed survey (which targeted smelt spawning areas) was discontinued after January 2010.

(Fig. 16). The reported optimal culture temperatures for Delta Smelt larvae and late-larvae are 16.4 ± 0.25 °C (Komoroske et al 2014). Moreover, the chronic lethal thermal maximum for Delta Smelt varies by life stage (Komoroske et al. 2014). Juvenile and subadult Delta Smelt are observed in the field most commonly at temperature near or below 20 °C (Bennett et al. 2008, Nobriga et al. 2008), a temperature which is often exceeded beginning in May or June and continuing through September and more rarely in October (see Chapter 7). Thus, we suggest that the same tradeoffs between feeding and predation risk may persist through the warmer months and into early fall, but become less likely as the season progresses into late fall and winter. Note, however, that predation risk is also influenced by a complex suite of other factors such as turbidity, life stage, and proximity to predator habitat, so the level of risk to Delta Smelt can't be determined.

Another possible indirect effect of higher water temperatures is that they may promote harmful algal blooms (HAB) (Lehman et al. 2005), which may degrade Delta Smelt habitat quality in the summer and early fall (Baxter et al. 2010). In the Delta, Lehman et al. (2013) found that blooms of the harmful cyanobacteria (blue-green algae) *Microcystis aeruginosa* required a water temperature of at least 19 °C for initiation. Other drivers of HABs and the possible effects of HABs are discussed more fully in a separate section of this Chapter. The combination of large seasonal and regional water temperature variability in the SFE and substantial direct and indirect effects of water temperature for all life stages of Delta Smelt means that this variable should be considered one of the most important habitat attributes for Delta Smelt. Differences in water

temperature between regions or time periods may have important effects on the Delta Smelt population (Rose et al. 2013b).

Salinity and the Size and Location of the Low Salinity Zone

A dynamic salinity gradient from fresh water to salt water is one of the most characteristic features of an estuary (Kimmerer 2004). It originates from the mixing of fresh inland water with salty ocean water through tidal dispersion and gravitational circulation (Monismith et al. 2002). Many estuarine-dependent organisms occur in distinct salinity ranges (e.g., Kimmerer 2002a) and the extent and location of water with suitable salinities is thus an important habitat attribute for estuarine organisms. Over the time period of available monitoring data, there is no clear long-term trend in salinity levels and distributions in the estuary. Significant increases and decreases linked to changing flow patterns have been detected for various stations and months (e.g., Jassby et al. 1995, Enright and Culbertson 2009, Shellenbarger and Schoellhamer 2011, Cloern and Jassby 2012).

The brackish (oligohaline) “low salinity zone” (LSZ) is an important region for retention of organisms and particles and for nutrient cycling. In the SFE, the LSZ provides important habitat for numerous organisms including Delta Smelt (Turner and Chadwick 1972, Kimmerer 2004, Bennett 2005). In this report we define the LSZ as salinity 1-6; however, other salinity ranges have been used by others, such 0.5-6 (Kimmerer et al. 2013) or 0.5-5 (Jassby 2008).

In the SFE, the position of the LSZ is commonly expressed in terms of X2, which is the distance from the Golden Gate in km along the axis of the estuary to the salinity 2 isohaline measured near the bottom of the water column (Jassby et al. 1995). X2 represents the approximate center of the LSZ (Kimmerer et al. 2013).

X2 is an index of the physical response of the estuary to freshwater outflow from the Delta; it decreases with increasing outflow because increasing freshwater outflow prevents seawater from moving landward. The X2 index was developed two decades ago as an easily-measured, policy-relevant “habitat indicator.” Its ecological significance for multiple species and processes was established through statistical analyses of biological responses to seasonally or annually averaged X2 values (Jassby et al. 1995) and has since been reaffirmed in additional studies (e.g., Kimmerer et al. 2002a,b, 2009, 2013, Thomson et al. 2010, Mac Nally et al. 2010). There is, however, still much uncertainty regarding the causal mechanisms for the observed biological responses of biota to X2. As with all statistically derived functional relationships, biological responses to X2 do not necessarily reflect direct causal relationships and it is generally recognized that some of the causal mechanisms may not be directly linked to the size and location of the LSZ.

Most of the scientific and management attention has focused on the LSZ and X2 from late winter to early summer (hereafter “spring X2”) depending on the species of interest, but in recent years the LSZ and X2 during the fall months (“fall X2”) has also received considerable scientific and policy attention. Annual abundance indices of several estuarine fish and invertebrate species have a negative relationship with spring X2, meaning that abundance indices increase when X2 and the LSZ are more westward and Delta outflow is higher in the late winter and spring months (Jassby et al. 1995, Kimmerer 2002a, Kimmerer et al. 2009). Delta Smelt summer abundance indices have a significant relationship with prior fall X2 and fall abundance (USFWS 2008, Mount et al.

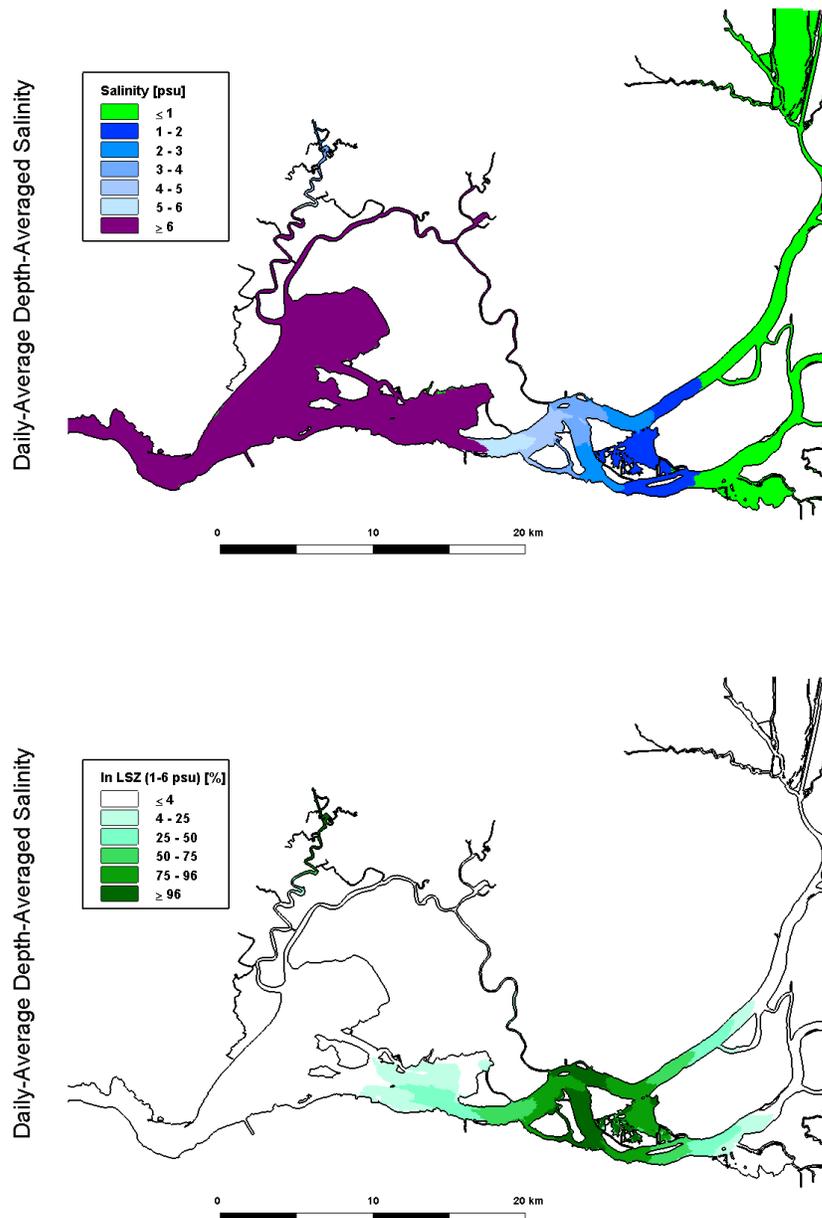

2013). Changes in spring and fall X2 have also been linked to long-term fish declines in the SFE (Thomson et al. 2010, Mac Nally et al. 2010).

The size and location of the LSZ are considered key factors determining the quantity and quality of low salinity rearing habitat available to Delta Smelt and other estuarine species. LSZ size and location are determined by the interaction of dynamic tidal and river flows with the stationary topography of the region (Reclamation 2011, 2012, Kimmerer et al. 2013). In a recent study, Kimmerer et al. (2013) used the three-dimensional hydrodynamic “UnTRIM” model which has an unstructured grid (Casulli and Zanolli 2002, 2005) to produce detailed maps of the distribution of salinity in the SFE under different outflow conditions. These maps (figure 2 in Kimmerer et al. 2013 and Fig. 18 and 19 in this report) show that under low outflow conditions typical of summer and fall months (outflow = $140 \text{ m}^3 \text{ s}^{-1}$, X2 = 85 km), the LSZ is in the western Delta confluence region, including the Sacramento and San Joaquin Rivers upstream of Chipps Island (Fig. 18), while under high outflow conditions typical of wet winter months (outflow = $1,440 \text{ m}^3 \text{ s}^{-1}$, X2 = 51 km), the LSZ is much further west in San Pablo Bay. At intermediate outflows (intermediate X2 = 74 km), it is located east of Carquinez Strait and covers Suisun Bay and parts of Suisun Marsh (Fig. 19).

Kimmerer et al. (2013) also examined the relationships between X2 and the area, average depth, and volume of the LSZ. They found that these relationships were bimodal, with the largest volumes and areas and shallowest depths at X2 values below 50 km when the LSZ is located in the large San Pablo Bay, and secondary peaks at X2 values between 60 and 75 km when the LSZ overlays the smaller Suisun Bay (Fig. 20). Area and volume were smallest and depth greatest when the LSZ was constricted in Carquinez Strait (X2~50-60 km) and in the confluence region of the Sacramento and San Joaquin Rivers (X2~80-85 km).

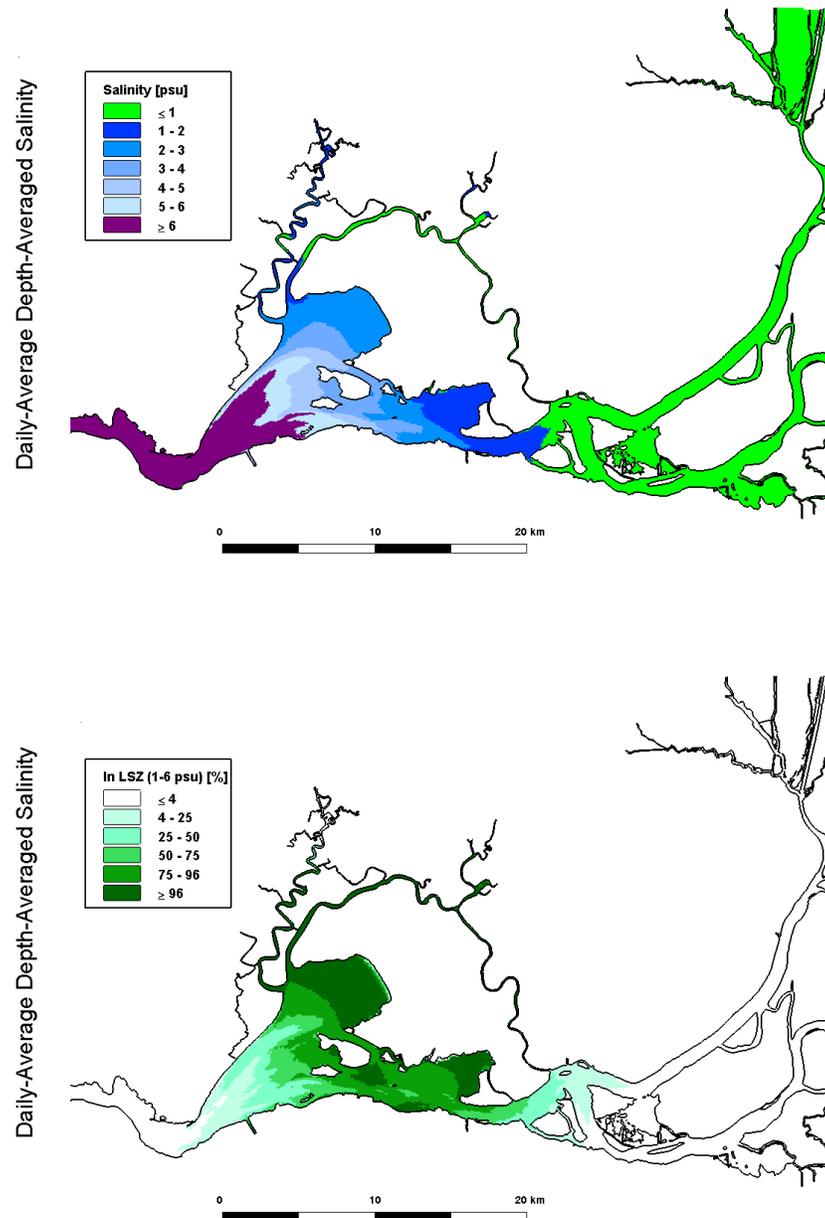

Paleosalinity investigations going back several thousand years indicate that the Delta has historically been largely fresh, while the Suisun region has alternated between brackish (oligohaline) and fresh (Ingram and Malamud-Roam 2013, Drexler et al. 2014). The LSZ and X2 likely moved according to predictable annual and interannual rhythms. Interannually, X2 was most variable in the higher-flow winter and spring months and least variable in the low-flow fall months. Seasonally X2 moved from the west in winter and spring to the east in summer and fall. CDWR (CDWR 2007) computes monthly “unimpaired” outflows which remove the effects of dam operations and water diversions. Annual X2 dynamics based on these unimpaired flows may give a sense of these historical fluctuations (Fig. 21). It is important to note, however, that unimpaired flows are not the same as historical “natural” flows because they do not take into account upstream water losses (e.g., consumption and evaporation) or physical water body alterations such as channelization, groundwater depletion, draining of wetlands, and disconnection of floodplains. The historical wetlands, floodplains, and groundwater basins would have naturally retained and released water (Whipple et al. 2012) and likely affected flows and the LSZ in different ways than today’s man-made reservoirs. Work is currently underway at UC Davis, the San Francisco Estuary Institute, and elsewhere to explore these issues, but results have not yet been published (W. Fleenor, U.C. Davis, personal communication). At this time, considerable uncertainty remains regarding the natural ranges in the timing and volume of the historical seasonal and interannual freshwater flows and how they caused the LSZ to spread out and contract across the estuary’s historical landscape. There is, however, little doubt that interannual variations in precipitation and hence river flows caused a high degree of interannual variability in the size and location of the low-salinity zone (Dettinger 2011).

Figure 18. Salinity distribution at low outflow. The upper panel shows the area of the low-salinity zone (4,262 hectares) at X2 = 85 km, when positioned mostly between Antioch and Pittsburg. Connections to Suisun Bay and Suisun Marsh are minimal. The lower panel shows the percentage of day that the low-salinity zone occupies different areas.

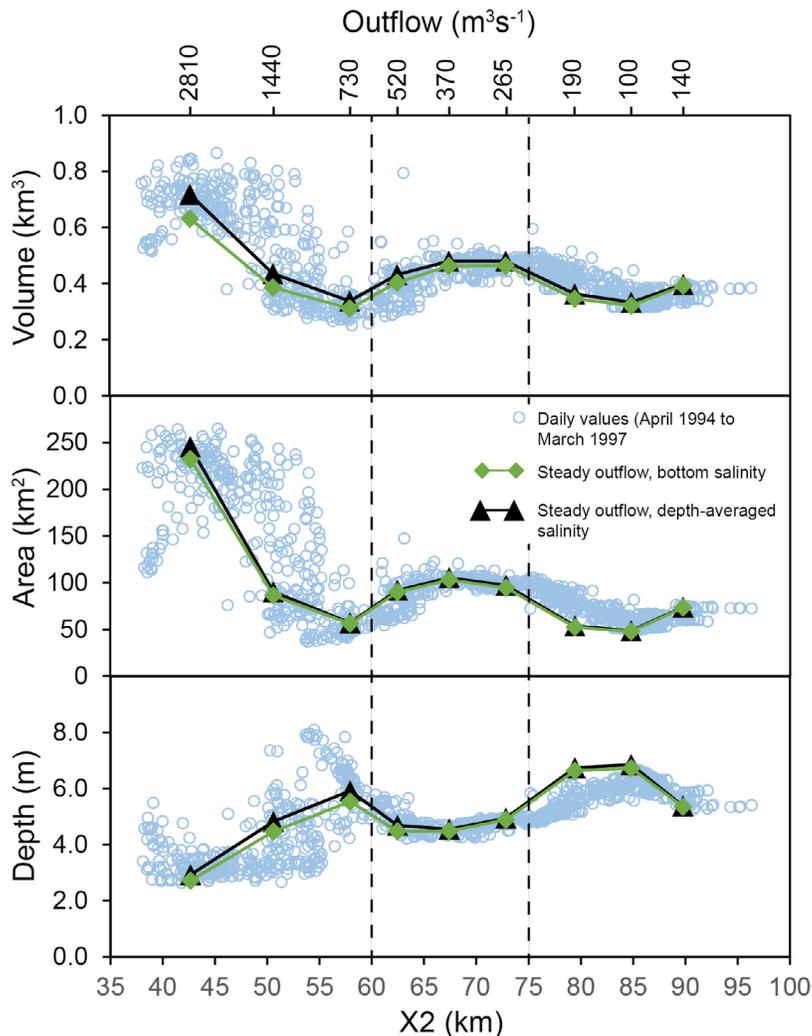

There is also no doubt that human water use and landscape alterations have changed flows into and out of the Delta and, consequently, salinity dynamics in the SFE, though changing precipitation patterns also play a role (Enright and Culberson 2009). Before the construction of today's major reservoirs, upstream water diversions coupled with the isolation of floodplains and wetlands, which had naturally stored runoff, from river channels by levees exacerbated salinity intrusions into the Delta in dry years. This was especially evident during the severe drought from

Figure 19. Salinity distribution at intermediate outflow. The upper panel shows the area of the low-salinity zone (9,140 hectares) at X2 = 74 km (at Chipps Island). The lower panel shows the percentage of day that the low-salinity zone occupies different areas.

1929 to 1934 when salinities of 2 were observed at Paintersville Bridge which is located on the Sacramento River at a distance of about 136 km from the Golden Gate (Mathew 1931). Operation of the large CVP and SWP reservoirs that were constructed after this drought has prevented such severe salinity intrusions since then and X2 has remained west of Rio Vista located on the Sacramento River 100 km upstream of the Golden Gate. Beginning with the salinity requirements in SWRCB water right decision D-1275 of 1967, salinity and the position of the LSZ have also

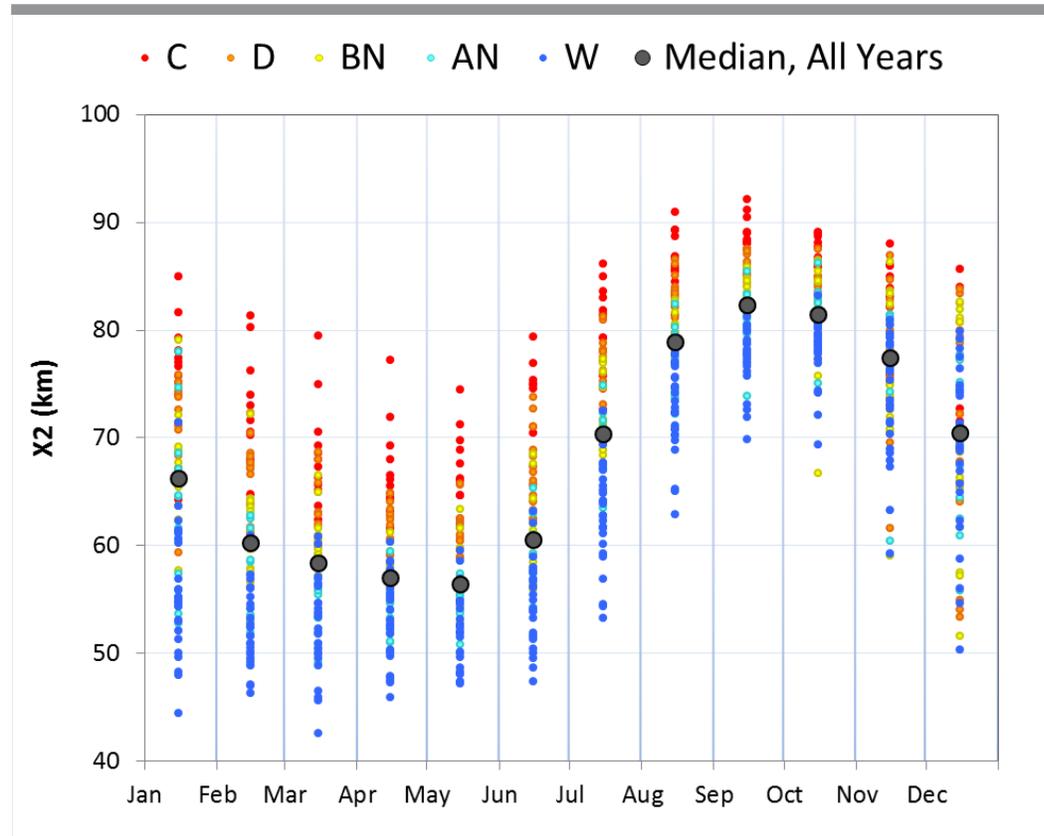

Figure 20. Modeled volume, area, and depth of the low salinity zone (salinity 0.5 to 6) at various values of X2 for 9 steady state values of outflow using bottom salinity (green diamonds) and depth-averaged salinity (black diamonds and for daily values based on variable values from April 1994 through March 1997 (blue circles) (modified from Kimmerer et al. 2013). The top axis gives the Delta outflow corresponding to the 9 steady state scenarios.

been increasingly regulated to protect “beneficial uses,” including habitat and fish protections (see Chapter 1).

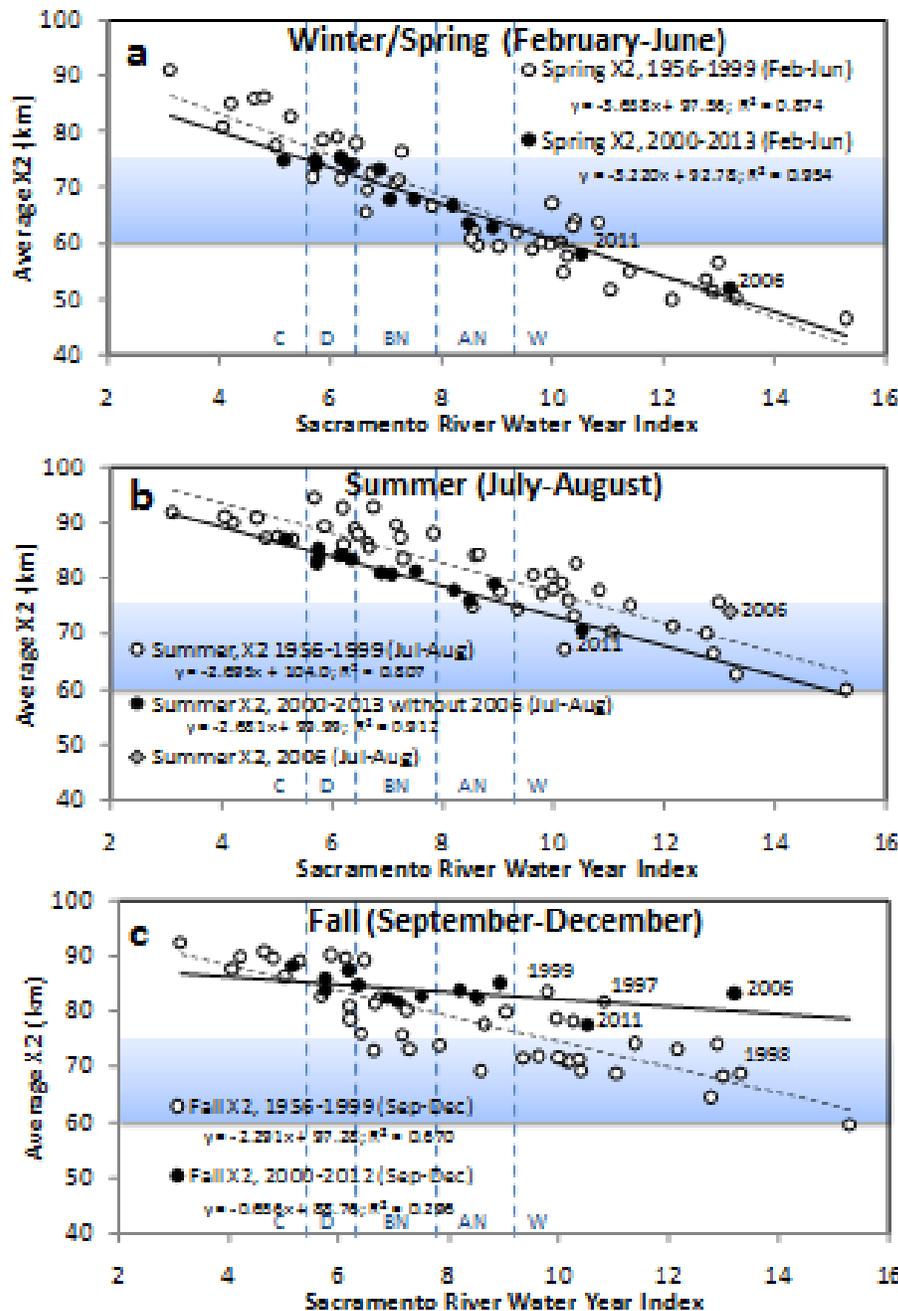

CVP and SWP water exports from the Delta began in the early 1950s with the completion of the CVP C.W. Bill Jones Pumping Plant (formerly known as the Tracy Pumping Plant) in 1951 and then increased with the completion of SWP’s Harvey O. Banks Pumping Plant in 1968. Long-term variability in the trend of Delta outflow has been reduced seasonally for the period 1921–2006, in part due to water project operations (Enright and Culberson 2009), but also due to overriding climate changes. Analyzing data from 1956–2010, Cloern and Jassby (2012) found significant increases in water exports from the Delta in all months of the year except May, but in the first half of the year, these increases in exports did not significantly affect Delta outflow. We

Figure 21. Plot of monthly X2 (km) values calculated from mean monthly unimpaired Delta outflows from 1921-2003. X2 values are categorized by water year type for the Sacramento Valley. Also shown are the median X2 values from 1921-2003 across all water year types (grey circles) C, red dots: critically dry; D, orange dots: dry; BN, yellow dots: below normal; AN, light blue dots: above normal; W, dark blue dots: wet. Water year type data from <http://cdec.water.ca.gov/cgi-progs/iodir/WSIHIST>. Unimpaired flow data from DWR 2007 (available at http://www.waterboards.ca.gov/waterrights/water_issues/programs/bay_delta/bay_delta_plan/water_quality_control_planning/docs/sjrf_sprinfo/dwr_2007a.pdf). X2 equation from Jassby et al. 2005.

show this by plotting the relationship between the Sacramento River Water Year Index, a measure of runoff, and average spring X2 (February-June) for two periods before (1956 to 1999) and after (2000-2013) the current flow and salinity requirements in SWRCB water right decision D-1641 became mandatory. The relationship appeared to remain essentially unchanged when the two time periods were compared (Fig. 22a). Cloern and Jassby (2012) further found that inflow to the Delta significantly increased in July and August, but these increases in inflow did not translate into significant increases in Delta outflow due to concurrent increases in exports during these months. Nevertheless, plots of recent data show that July and August outflows increased and the relationship between the Sacramento River Water Year Index and summer-time X2 (July-August) shifted downward in the years since the SWRCB water right decision 1641 went into effect in 2000 relative to previous years (Fig. 22b). The wet year 2006 did not fit this pattern because it had high summer X2 in spite of a high water year index. This means that with the exception of 2006, the LSZ has generally been located somewhat more westward in July and August since 2000 than from 1956 to 1999 under similar runoff conditions.

Figure 22. Plots of monthly X2 as a function of the Sacramento River Water Year Index (a measure of runoff) for the years 1956 to 1999 and 2000 to 2013 for: a, winter/spring; b, summer; and c, fall. The regression equation for each set of points is also shown. The index is calculated as: $0.4 * \text{Current April to July Runoff Forecast (in millions of acre feet, maf)} + 0.3 * \text{Current October to March Runoff in (maf)} + 0.3 * \text{Previous Water Year's Index (if the Previous Water Year's Index exceeds 10.0, then 10.0 is used)}$ (see <http://cdec.water.ca.gov/cgi-progs/iidir/WSIHIST> for further detail).

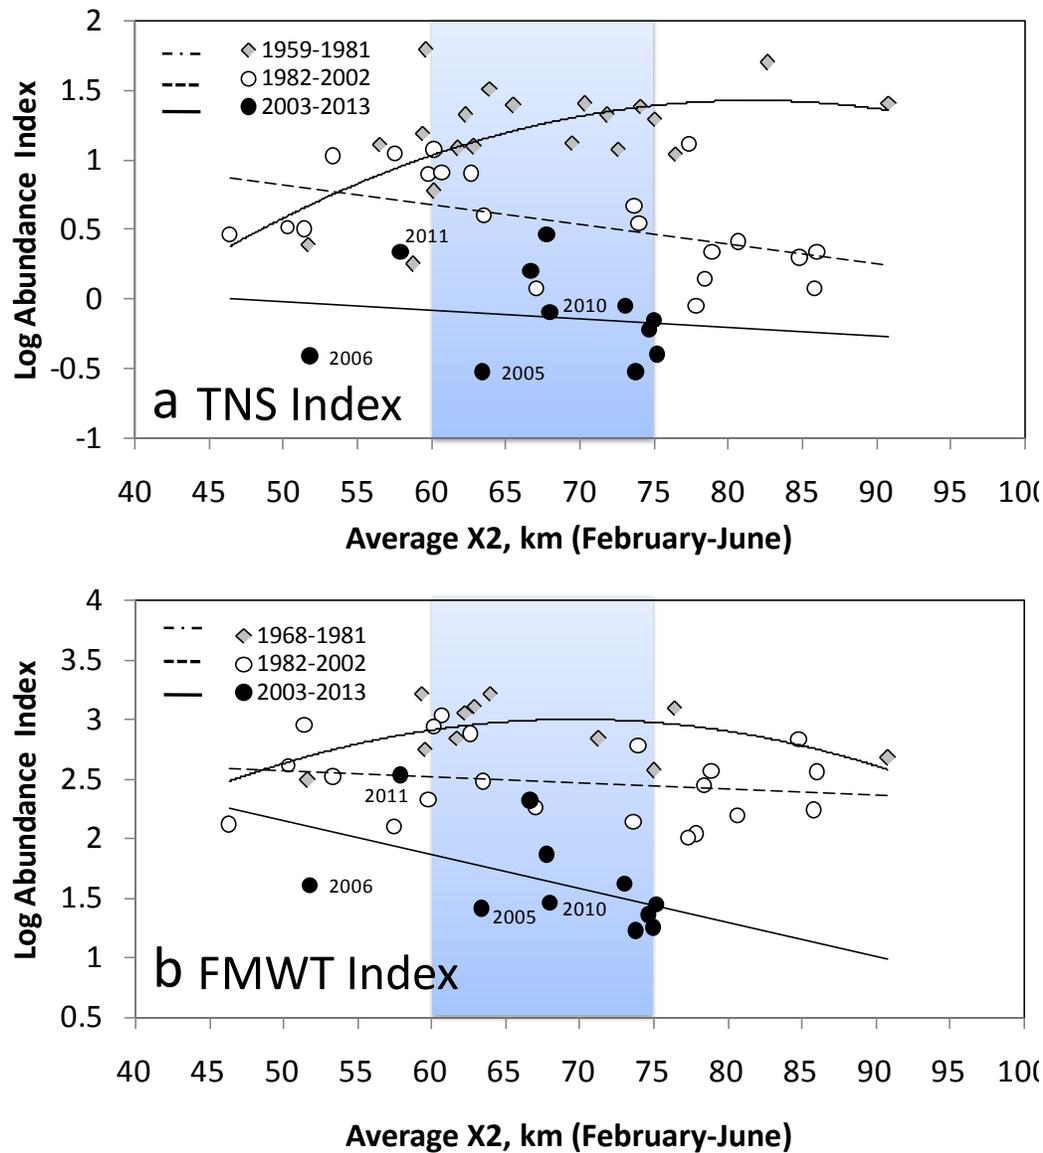

Cloern and Jassby (2012) also showed that significantly increasing exports combined with declining inflows led to significant declines in Delta outflow in each month from September to December. In plots of recent data, this led to a shallower slope of the relationship between the Sacramento River Water Year Index and fall X2 (September-December) and a more eastward LSZ location in the fall months of wetter years (below normal, above normal, and wet water year types) during 2000-2012 compared to 1956-1999, with the exception of two wet years at the end of the time series, 1997 and 1999, which fall on the 2000-2012 line (Fig. 16c, see also Feyrer et al. 2007, 2010). The areas with light blue shading in the three plots shown in Figure 16 show the range of X2 that places the LSZ over Suisun Bay and are associated with a high LSZ volume, area, and shallow LSZ depths (Kimmerer et al. 2013, Fig. 14). Fall X2 commonly fell into this range from 1956-1999 (in 18 of 44 years; Fig. 22c), but never after 2000. In 2011, the most recent wet year, fall X2 was lower than in the preceding wet years of 2006, 1997, and 1999, but still elevated relative to the majority of previous wet years. Overall, the changes in flows in the summer and fall months described by Cloern and Jassby (2012) have resulted in more muted seasonal and interannual variations in X2 and in the size and location of the LSZ in more recent years and possibly also relative to historical variability (Fig. 21).

Delta Smelt are found in the estuary at salinities up to 18 (Bennett 2005), but are most common in the in the LSZ (< 6) (Moyle et al. 1992, Sommer and Mejia 2013, Kimmerer et al. 2013). Sommer et al. (2011a) described Delta Smelt as a “diadromous species that is a seasonal reproductive migrant.” In the winter, adult Delta Smelt move upstream into fresh water for spawning. In the spring and summer, young Delta Smelt are transported or swim downstream into the LSZ (Dege and Brown 2004). Delta Smelt usually rear in low salinity habitat in the summer (Nobriga et al. 2008) and fall (Feyrer et al. 2007), although some Delta Smelt remain year-round in fresh water (Sommer et al. 2011a, Merz et al. 2011, Sommer and Mejia 2013).

The recruitment success of Longfin Smelt and age-0 Striped Bass increases linearly with more westward positions of the LSZ during spring (Jassby et al. 1995, Kimmerer 2002a). In contrast, the relationships of annual Delta Smelt indices with spring X2 are more complex because they have not been consistent over the period of record (Fig. 23). Jassby et al. (1995) found that from 1968-1991, the highest fall abundance indices for Delta Smelt coincided with intermediate values of average April-July X2 when the LSZ was positioned in Suisun Bay. Low fall abundances were, however, also observed at these intermediate X2 values. The analyses by Jassby et al. (1995) were later updated and augmented with an analysis of the relationship between Delta Smelt summer abundance and spring X2 (Kimmerer 2002a, Kimmerer et al. 2009).

We updated the analyses by Jassby et al. (1995) with more recent data and data from additional monitoring surveys to examine the hypothesis that during periods of relatively stable abundance (i.e. without step changes, Thomson et al. 2010), the abundance of different Delta Smelt life stages is related to spring outflow and the position of the LSZ as expressed by spring X2. To obtain spring X2, we first calculated mean monthly X2 values calculated from daily X2 values. We then averaged the mean monthly X2 values for February to June. This is different from the April-July period used by Jassby et al. (1995) for their Delta Smelt analyses, but similar to the spring X2 averaging period used by Kimmerer (2002a). Note that different averaging methods for calculating seasonal X2 values account for the small quantitative differences between results presented here and those of previously published analyses that used the same data, but this does not affect the overall patterns. We partitioned the data into the periods before, between, and after the 1981 and 2002 step declines in Delta Smelt abundance identified by Thomson et al. (2010). The 1981-1982 partition, but not the 2002-2003 partition, has been previously applied by Kimmerer (2002a) and Kimmerer et al. (2009).

Figure 23. Plots of the log transformed a) Delta Smelt Summer Townet Survey abundance index and b) Delta Smelt Fall Midwater Trawl Survey abundance index, in relation to monthly averaged daily X2 position from February to June. Lines are either simple linear least squares regression (lines) or quadratic regression (curves).

Kimmerer (2002a) and Kimmerer et al. (2009) found that the relationship between spring X2 and Delta Smelt juvenile abundance indices was positive before the step decline in Delta Smelt abundance that started in 1981 (Thomson et al. 2010), suggesting that historically, Delta Smelt population recruitment may have benefitted from lower outflows and a more upstream LSZ in the late winter and spring. In our analysis, we found that the relationship was perhaps more unimodal than linear (Table 1, Fig. 23a) because a model that included a quadratic spring X2 term explained more of the variation in the data than a linear model that did not, although the statistical significance of the linear model was slightly higher than that of the quadratic model because of the loss of a degree of freedom due to the additional quadratic term included in

the quadratic model. Similar to Kimmerer (2002a) and Kimmerer et al. (2009), we found that in the period after the 1981 step change and also in the period after the 2002 step change, the relationship of log-transformed summer abundance with spring X2 shifted downward and became more clearly negative than unimodal (Fig. 23a). The relationship remained statistically significant at the $P < 0.05$ level in the period after the 1981 step decline, but is no longer statistically significant after 2001. Similarly, the relationship is also not significant across the entire 52-year time series (Table 1).

Kimmerer et al. (2009) found a non-significant and essentially flat relationship between spring X2 and the entire log-transformed sub-adult abundance time series for Delta Smelt; this remains the case when data from the five most recent years is included in the analysis (Table 1). Similar to Jassby et al. (1995), we found a weakly unimodal relationship between spring X2 and log-transformed Delta Smelt subadult abundance indices before the first step change, but this relationship was not statistically significant at the $P < 0.05$ level (Table 1, Fig. 23b). Similar to juvenile abundance, the relationship of log-transformed subadult abundance with spring X2 shifted downward in the periods after each of the two step changes and became more negative than unimodal (Fig. 23b), but again these relationships were not statistically significant at the $P < 0.05$ level (Table 1).

Taken together, these findings are generally consistent with previous conclusions that moderate hydrological conditions in the late winter and spring and a large LSZ located in the Suisun region can be beneficial to Delta Smelt population abundance (Jassby et al. 1995). Historically, this may have been the case for several life stages. At present, however, juvenile and subadult Delta Smelt seem to barely respond to spring X2. As Jassby et al. (1995) point out, this does not mean that there is no longer an effect of spring X2 on juveniles and subadults; the spring X2 effect may just be masked or weakened by changes in other habitat attributes. The relationships between these life stages and spring X2 clearly underwent downward shifts after each step decline. These persistent downward shifts indicate that occasional years with beneficial spring X2 conditions continue to have a positive effect on Delta Smelt, but they are by themselves not enough to overcome the depressed abundance levels and recover the population.

The downward shifts and changes in shape of the spring X2-Delta Smelt abundance index relationships (Fig. 23) also illustrate the difficulties of determining and understanding functional responses of biota to dynamic physical habitat attributes in changing ecosystems; the species of interest, other habitat attributes, and their interactions may all change as much or more than the habitat attribute under consideration. Further, these changes may not always be gradual, but can take the form of sudden step changes that may be associated with system-wide regime shifts (Davis et al. 2010, Baxter et al. 2010, Cloern and Jassby 2012). Moreover, prior conditions and prior abundance may also influence outcomes. In Chapter 9 of this report we give a relatively simple example of additional multivariate analyses aimed at exploring the effects of hydrology and prior abundance on the abundance and recruitment of Delta Smelt larvae. More sophisticated multivariate life cycle modeling that greatly exceeds the scope of this report is needed to account for these simultaneous changes and interactive effects on all life stages.

Changes in the size, location, and dynamics of the LSZ likely also interact in complex ways with other changes, such as changes in sediment and nutrient loadings and resulting turbidity and nutrient dynamics and their effects on Delta Smelt and the food web. For example, LSZ position affects recruitment of the invasive clam *Potamocorbula amurensis*, which may in turn affect phytoplankton and zooplankton biomass, size, and production (Thompson 2005, Winder and Jassby 2011), and has likely affected fish-X2 relationships (Kimmerer et al. 2002a).

Table 1. Summary of relationships between log-transformed annual abundance indices for four Delta Smelt life stages (response variable) and spring X2 (February-June, see text): Survey: see description of monitoring surveys in Chapter 3; Regression: least squares linear or quadratic regression; n, number of observations (years); P, statistical significance level for the model; R², coefficient of determination; adjusted R², R² adjusted for the number of predictor terms in the regression model. Bold font indicates statistically significant relationships.

Ongoing studies coordinated by the IEP as part of the POD and FLASH studies focus on the processes that link physics, chemistry, and biology in the LSZ and its habitat value for Delta Smelt and other native and non-native species. Similar to Monismith et al. (2002), preliminary results indicate that the strength of physical mixing (lateral dispersion) in the LSZ changes with the volume of freshwater outflow, underscoring the importance of variable hydrodynamics on not just the location of the LSZ, but how ecological services (nutrient mixing, organism dispersal) are influenced by variable estuarine outflow (Monismith, U.C. Berkeley, personal communication).

Turbidity

In this report, turbidity is considered an environmental driver that interacts with other environmental drivers, resulting in habitat attributes that directly affect Delta Smelt responses, rather than a stand-alone habitat attribute. Clearly, studies have shown that distribution of Delta Smelt is correlated with turbidity (e.g., Feyrer et al. 2007, Nobriga et al. 2008, Grimaldo et al. 2009, Sommer and Mejia 2013). In the conceptual model we chose to incorporate turbidity as a modifier of several important linkages between environmental drivers and habitat attributes that are important to Delta Smelt, primarily food visibility for small larvae and predation risk for all life stages. If we had incorporated turbidity as a habitat attribute and, for example, predation risk

was discussed separately from turbidity, there would have been a great deal of overlapping text between the two sections because turbidity interacts with the presence of predators to determine predation risk. Our approach is not ideal but should reduce redundant text and contribute to clarity of presentation. Nonetheless, we recognize that turbidity by itself could reasonably be considered as a habitat attribute. For example, it is possible that Delta Smelt experience stress in low turbidity habitat, which would in turn affect survival (likely through predation) but also in other direct ways such as lower growth and reduced egg production. However, we do not have evidence at this point to support that hypothesis.

In addition to salinity gradients, estuaries often have turbidity gradients. Turbidity is an optical property of water, which is the loss of transparency due to scattering of light by suspended particles. Typically, the upper reaches of estuaries have areas with high levels of suspended particles known as “estuarine turbidity maxima.” In many estuaries, these areas are located in or near the low salinity zone and are associated with higher numbers and enhanced growth for larvae of some species (Sirois and Dodson 2000a, b, Shoji et al. 2005). In the SFE, turbidity is largely determined by the amount of suspended inorganic sediment in the water (Cloern 1987, Ganju et al. 2007, Schoellhamer et al. 2012), although organic components can also play a role (USGS 2008). Sediment particles are constantly deposited, eroded, and resuspended, and are transported into, within, and out of the estuary. The amount of sediment that is suspended in the water column depends on the available hydrodynamic energy, which determines transport capacity, and on the supply of erodible sediment in the estuary and suspended sediments from the watershed.

In the upper SFE there are two main physical processes controlling turbidity. Suspended sediment is transported from the tributary watersheds into the system during high flows associated with winter and spring storm runoff (Schoellhamer et al. 2012). The first large storm of the rainy season often carries the highest concentrations of suspended sediment. Some portion of the transported sediment moves through the system to San Pablo and San Francisco Bay and the remainder is stored within the system as bottom sediment. During the remainder of the year, turbidity is primarily caused by interactions of this stored sediment with other environmental drivers (Schoellhamer et al. 2012). Water moving with the tides can resuspend fine sediments because of turbulence resulting from interactions between the bottom and water moving at high tidal velocities. At a larger scale, irregularities in the bottom topography may define geographic regions of greater turbulence and greater turbidity. In the upper estuary, such regions occur at a large bathymetric sill between Carquinez Strait and Suisun Bay and at another location within Suisun Bay (Schoellhamer 2001). Sediments may also be resuspended by turbulence related to wind waves. This process is mainly limited to areas with fine sediments on relatively shallow shoals where wind wave turbulence reaches the bottom. This process is most important in the shallows of Suisun, Grizzly, and Honker Bays and Liberty Island (Ruhl and Schoellhamer 2004, Warner et al. 2004, Morgan-King and Schoellhamer 2013). Thus, turbidity at any particular location is the result of several environmental drivers, including hydrology (transport from the watershed) and weather (wind and precipitation) interacting with the physical configuration of the upper SFE. Further, annual variation in these factors may have important effects. For example, during a drought there is little transport of suspended sediment and the same wind patterns during the summer may result in less turbidity than would occur after a wet year because less sediment was stored as benthic sediment during the winter. There is also evidence of longer term changes in turbidity (Schoellhamer et al. 2011, Hestir et al. 2013), along with regional differences.

In addition to the inorganic component of turbidity, organic matter (e.g., phytoplankton) also contributes to both suspended solids and the sediment load on the bed that is re-suspended with

wind and wave action (McGann et al. 2013). In the SFE, phytoplankton concentration varies spatially, seasonally, and on an inter-annual scale (Cloern et al. 1985, Jassby 2008, Cloern and Jassby 2012), and is controlled by multiple factors, including benthic grazing, climate, river inflows (Jassby et al. 2002), and nutrient dynamics (Glibert et al. 2011, Parker et al. 2012, Dugdale et al. 2013), which in turn are likely to affect the organic component of turbidity. Phytoplankton dynamics are discussed in detail in the ‘Food and Feeding’ section (below), but it is important to note here that plankton concentration comprises part of the SFE turbidity and is significant as it relates to productivity at higher trophic levels.

Among the geographic regions of the upper SFE, the Suisun region is one of the most turbid, when the system is not being influenced by storm flows. This results from strong turbulent hydrodynamics in the Suisun region caused by strongly interacting tidal and riverine flows, bathymetric complexity, and high wind speeds, which create waves that resuspend erodible benthic sediment in the large and open shallow bays of the Suisun region. The North Delta, especially the large open expanse of Liberty Island (flooded since 1998) and the adjacent Cache Slough region are also relatively turbid. Recent evidence suggests that Liberty Island acts as a sediment sink in the winter and a sediment source for the surrounding Cache Slough complex in the summer (Morgan-King and Schoellhamer 2013).

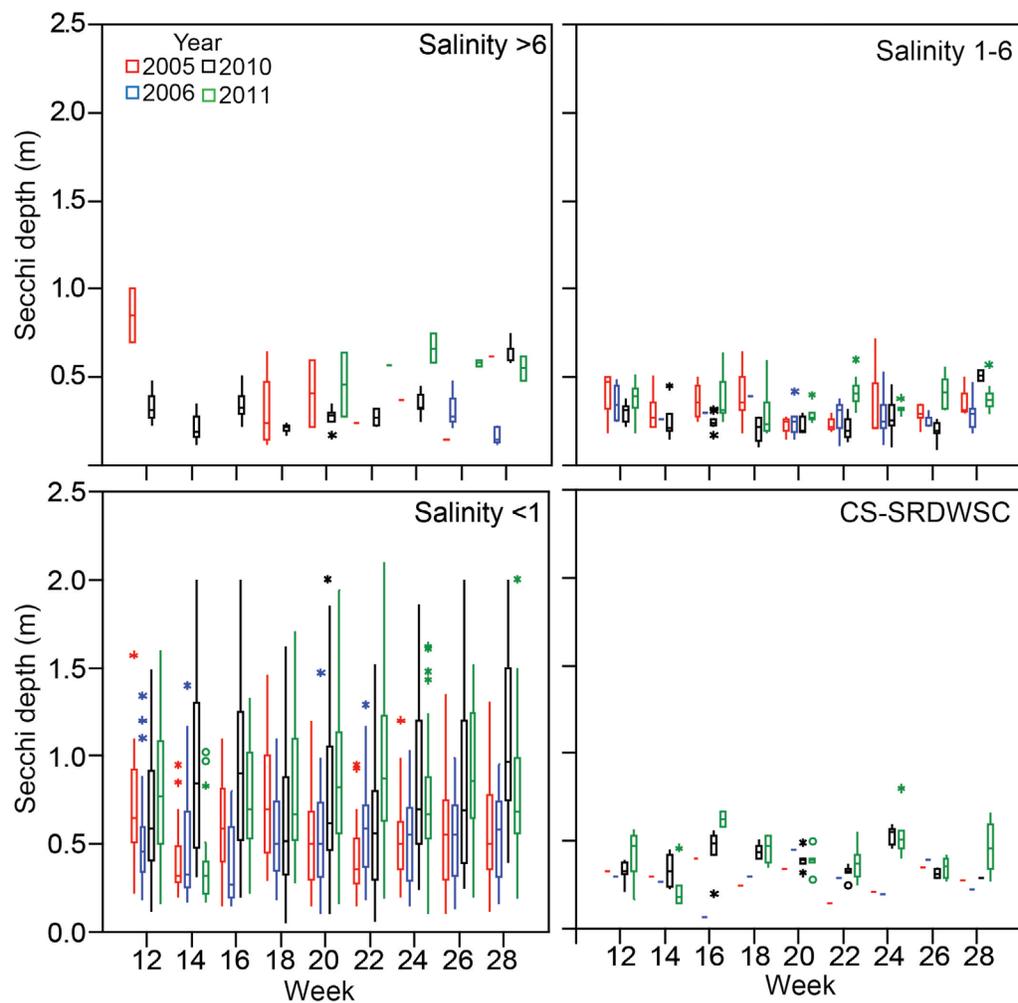

Turbidity is usually lower in the channels of the confluence of the Sacramento and San Joaquin Rivers compared to the Suisun region and North Delta region. Turbidity dynamics in the deep channels of the river confluence are driven more by riverine and tidal processes while high wind and associated sediment resuspension has little if any effect (Ruhl and Schoellhamer 2004). Turbidity is generally lowest in the south Delta (Nobriga et al. 2008). This may in part be due to sediment trapping by large, dense beds of *Egeria densa*, an invasive species of submerged aquatic vegetation (Hestir 2010). In winter/spring during the comparison years the highest Secchi disc depths (lowest turbidity) were found in the freshwater regions of the estuary (< 1 salinity), except for the Cache Slough region in the north Delta which was as turbid as the saltier regions of the estuary (Fig. 24).

There is strong evidence for an initial increase followed by a more recent long-term decline in sediment transport into the upper estuary, likely due to anthropogenic activities during the last century and a half (Schoellhamer et al. 2013, Wright and Schoellhamer 2004). Schoellhamer et al. (2013) presented a conceptual model of the effects of human activities on the sediment supplies in the SFE with four successive regimes:

1. The natural state.
2. Increasing sediment supplies due to mining, deforestation, agricultural expansion, etc.
3. Decreasing sediment supply due to sediment flushing during high flow events and sediment trapping behind dams and dikes.
4. A new altered state of low sediment supplies. The pulse of increased sediment inputs during and after the California gold rush and the more recent decline in these inputs is apparent in isotopic data from sediment cores taken in the estuary (Drexler et al. 2014).

The recent declines in sediment supplies have led to a long-term increase in water clarity in the upper Estuary (Jassby et al. 2002, Feyrer et al. 2007, Jassby 2008). Jassby et al. (2002) documented a 50% decrease in total suspended-solids concentration (TSS, a laboratory measurement of total suspended solids), approximated by suspended sediment concentration

Figure 24. Secchi depth data collected during the 20 mm Survey. Surveys are conducted biweekly March–July. See Chapter 3: Data Analyses for explanation of boxplots.

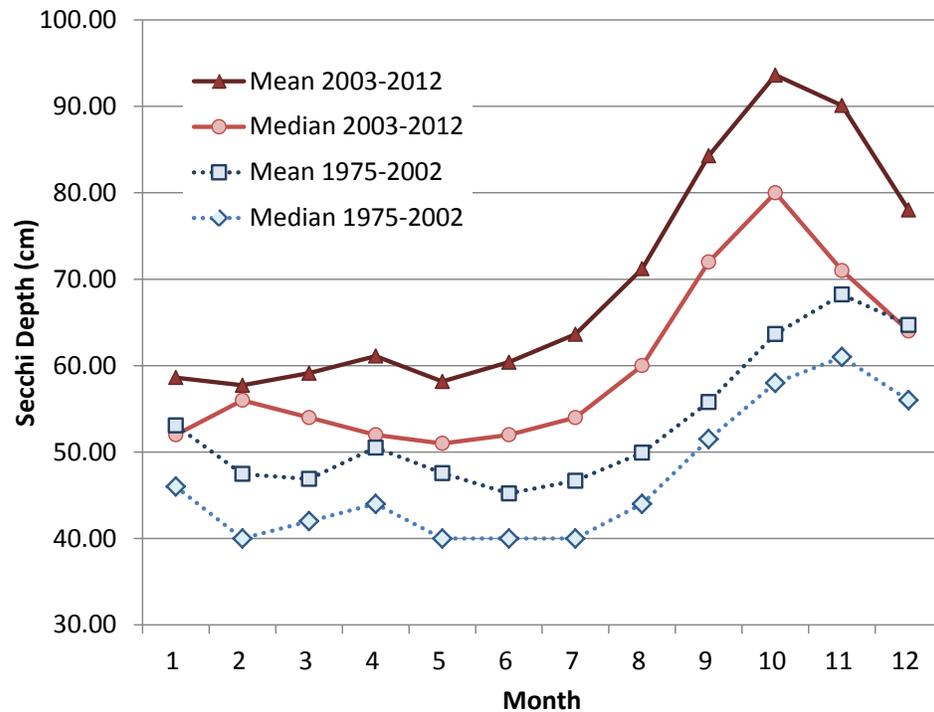

(SSC, an optical measurement done in the field for these data) in the Delta from 1975–1995. Jassby (2008) found that the downward trend continued in the decade after 1995, although at a slower pace than over the entire 1975–2005. From 1975–2005, there were significant declines in SSC of up to 6% per year at 8 of 10 Delta stations (Jassby 2008). Jassby et al. (2005) showed that TSS concentrations in the north Delta dropped sharply toward the end of the 1982–1983 El Niño–Southern Oscillation (ENSO) event, which was associated with extremely high outflows, and did not recover afterward. This step decrease after 1983 has been corroborated by further trend analyses of TSS (Hestir 2013). Following the El Niño event of 1997–1998, there was a 36% step decrease in SSC in San Francisco Bay as the threshold from transport to supply regulation was crossed as an anthropogenic erodible sediment pool was depleted (Schoellhamer 2011). Sediment trapping by dense beds of *Egeria densa* may be further reducing available sediment in the Delta (Hestir 2010). While other anthropogenic factors may have also contributed to long-term changes in turbidity (e.g., export operations; Arthur et al. 1996), quantitative analyses of the effects of these factors have not been conducted.

Before the step decline in SSC and the onset of the pelagic organism decline in the late 1990s and early 2000s (i.e. the “pre-POD” period), water transparency (roughly the opposite of turbidity) measured with a Secchi disc at all IEP EMP stations was usually highest in November and lowest in June (Fig. 25). From 2003-2012 (i.e. the “POD” period), average water transparency was not only higher (by an average of 16 cm Secchi depth) than in the previous period, but the annual dynamics also shifted forward by a month, to greatest transparency (i.e. lowest turbidity) in October and lowest transparency in May. The greatest differences in average water transparency between the pre-POD and POD periods occurred in September and October (28 and 30 cm difference between monthly averages, respectively) and the smallest differences in January-May (10 cm). While the EMP has collected turbidity data (nephelometric turbidity (NTU) measurements) since 1975, long-term fish monitoring surveys have traditionally collected Secchi disc data and only in recent years have incorporated turbidity. Therefore, Secchi disc data are presented in the majority of this report when relating Delta Smelt abundance to water clarity conditions.

Multiple field and modeling studies have established the association between elevated turbidity and the occurrence and abundance of Delta Smelt. The abundance of larval/postlarval Delta Smelt larvae was well explained by salinity and Secchi depth, a proxy for turbidity (Kimmerer et al. 2009). Sommer and Mejia (2013) and Nobriga et al. (2008) found that late-larval and juvenile Delta Smelt are strongly associated with turbid water, a pattern that continues through fall (Feyrer et al. 2007). Long term declines in turbidity may also be a key reason that juvenile Delta Smelt now rarely occur in the south Delta during summer (Nobriga et al. 2008). Thomson et al. (2010) found that turbidity (water clarity) was the only significant predictor variable that was shared by three of the four POD species; all other significant predictor variables were unique to each species. Grimaldo et al. (2009) found that the occurrence of adult Delta Smelt at the fish salvage facilities was linked, in part, with high turbidity associated with winter “first flush” events. Turbidity may also serve as a behavioral cue for small-scale (lateral and vertical movements in the water column) and larger-scale (migratory) Delta Smelt movements (Bennett and Burau 2014).

Delta Smelt are visual feeders, and feed primarily between dawn and dusk (Hobbs et al. 2006, Slater and Baxter 2014). As for all visual feeders, visual range and prey density determine feeding success of Delta Smelt. Visual range depends on size, contrast and mobility of the prey, retinal sensitivity and eye size of the visual feeder, and on the optical habitat attributes such as light scattering, absorption, and intensity (Aksnes and Giske 1993). Optical habitat attributes are affected by turbidity from suspended organic particles, such as algae and detritus, and inorganic particles, such as sand and silt. Somewhat counterintuitively, some level of turbidity appears important to the feeding success of larval Delta Smelt. Baskerville-Bridges et al. (2004a) conducted laboratory experiments in which alga densities (0, 0.5×10^6 cell/mL, and 2×10^6 cell/mL or 1, 3, and 11 NTU) and light levels (range tested: $0.01 \mu\text{moles/s} \times \text{m}^2$, $0.3 \mu\text{moles/s} \times \text{m}^2$, $1.9 \mu\text{moles/s} \times \text{m}^2$) were manipulated and first-feeding success of larval Delta Smelt was quantified. They found that maximum feeding response occurred at the highest alga concentrations and light levels tested. In a subsequent experiment, when algae were removed entirely, the feeding response was very low. The addition of algae or some other form of suspended particle is standard practice for successfully rearing Delta Smelt larvae in culture facilities (Mager et al. 2004, Baskerville-Bridges et al. 2005, Werner et al. 2010b, Lindberg et al. 2013). Presumably the suspended particles provide a background of stationary particles that helps the larvae detect moving prey. Sufficient turbidity also appears to be important to reduce overall environmental stress and increase survival of larval Delta Smelt (Lindberg et al. 2013). Thus, it seems likely that turbidity is important to the feeding success and survival of larval Delta

Figure 25. Average and median Secchi depth in cm from monthly sampling at IEP Environmental Monitoring Program stations. Data are shown for the time period up to the pelagic organism decline (1975-2002) and after the decline (2003-2012).

Smelt in the wild. Recent research on juvenile Delta Smelt, however, suggests that influence of turbidity on feeding success may vary across life stages and field conditions. Hasenbein et al. (2013) exposed juveniles to varying turbidities (5-250 NTU) and observed a negative relationship between turbidity and feeding rates, with a marked decline in feeding at 250 NTU. However, feeding rates were highest at 12 NTU and stable in the 12-120 NTU turbidity range, which is likely within the range experienced by juvenile Delta Smelt in typical summer conditions in the Delta. Turbidity values of 250 NTU are generally not observed during the summer; therefore, the typical summer turbidity range in the Delta likely does not limit juvenile feeding success.

In addition to its effects on feeding, turbidity may also reduce predation risk. Based on the general recognition that fish assemblages are often partitioned between turbid-water and clear-water assemblages (Rodríguez and Lewis 1997, Whitfield 1999, Quist et al. 2004), and that turbidity can influence the predation rate on turbid-adapted fishes (Rodríguez and Lewis 1997, Gregory and Levings 1998, Quist et al. 2004), it has generally been assumed that juvenile and adult Delta Smelt are closely associated with turbidity in order to minimize their risk of predation in their generally open-water habitat. There may also be complex interactions between feeding and predation risk that are mediated by turbidity. Recent laboratory work has shown that in light (as opposed to dark) conditions, the vertical distribution of larval Delta Smelt shifts upward in the water column when turbidity is increased from clear (< 2 NTU) to 24 NTU (L. Sullivan, San Francisco State University, unpublished data), suggesting that larval Delta Smelt may use turbidity to safely forage in surface waters that may be more food-rich. Interestingly, when a predator cue (water, after containing juvenile Striped Bass for 1 hr) is added to clear water, the distribution of larval Delta Smelt becomes bimodal, with increased densities near the surface and

closer to the bottom (L. Sullivan, San Francisco State University, unpublished data). Thus, while laboratory studies have demonstrated that larvae have improved feeding success at higher (but not too high, see above) turbidities, in natural settings, turbidity and predation risk may interact (e.g., Miner and Stein 1996) to affect Delta Smelt habitat choice and feeding success.

Turbidity may also be a migration cue for Delta Smelt. A recent field study investigated behavioral responses of Delta Smelt to winter “first flush” events in the Sacramento and San Joaquin Rivers near their confluence (W. Bennett, U.C. Davis, unpublished data). A first flush is defined as an increase in flow and turbidity associated with the onset of winter rain. This study found lateral turbidity gradients that changed with the tides and before and after first flush events and coincided with lateral Delta Smelt movements toward the channel during flood tides and toward the shoreline during ebb tides. The researchers concluded that this behavior likely facilitates maintaining channel position or moving upriver and cross-channel gradients in water turbidity may act as a behavioral cue. Feyrer et al. (2013) also found small-scale lateral and vertical gradients in turbidity in the lower Sacramento River just prior to a winter-time first flush event. In their study, turbidity and salinity were highest in the lower half of the water column and during flood tides and lowest during ebb tides in the center of the channel in the upper half of the water column. This coincided with observations of Delta Smelt which were more frequently caught throughout the water column during flood tides than during ebb tides when they were observed only in the lower half of the water column and sides of the channel. Feyrer et al. (2013) concluded that Delta Smelt may actively move in the water column by keying in on turbidity and salinity gradients or because of the physics underlying them.

Entrainment and Transport

The egg, larval, and juvenile stages of estuarine fishes and invertebrates along with small and weakly swimming adult stages are subject to involuntary transport (advection) by riverine and tidal flows. Entrainment is a specific case of involuntary transport. It refers to situations when altered flows misdirect and transport fish and other organisms in directions in which they would not normally travel or where they will encounter unfavorable conditions and increased risk of mortality. In this report, we use the term entrainment to specifically refer to the incidental removal of fishes and other organisms in water diverted from the estuary, primarily by CVP and SWP export pumping (Arthur et al. 1996, Grimaldo et al. 2009, Castillo et al. 2012).

Ultimately, watershed hydrology determines how much water can flow into and through the Delta; however, water flows into, within, and out of the Delta are manipulated in many ways. Water is: routed through and around artificial channels, gates, and barriers; stored in and released from reservoirs; discharged from agricultural and urban drains; and diverted with large and small pumps. Perhaps the greatest flow alterations in the Delta have taken place in Old and Middle Rivers (collectively referred to as “OMR”) in the central Delta (Fig. 2). Historically, these river channels were part of the tidal distributary channel network of the San Joaquin River (Whipple et al. 2012). Today, they are a central component of the CVP and SWP water conveyance system through the Delta. Water from the Sacramento River in the north now flows through the northern Delta (down Georgiana Slough, through Three-Mile Slough and around Sherman Island) and eastern Delta (via the artificial “Delta cross-channel” and down the forks of the Mokelumne River) to OMR in the central Delta, then to the SWP and CVP. The SWP and CVP pumps are capable of pumping water at rates sufficient to cause the loss of ebb tide flows and to cause negative net flows (the advective component of flow after removal of the diffusive tidal flow component) through OMR toward the pumps (see Grimaldo et al. 2009), thus greatly altering regional hydrodynamics and water quality (Monsen et al. 2007). Under these conditions, fish

and other aquatic species in the Delta may be transported toward the pumps (Arthur et al 1996, Brown et al. 1996, Moyle et al. 2010), may swim toward the pumps if they are behaviorally inclined to follow net flow (Grimaldo et al. 2009), or may move toward the pumps if they are employing tidal surfing behavior (Sommer et al. 2011).

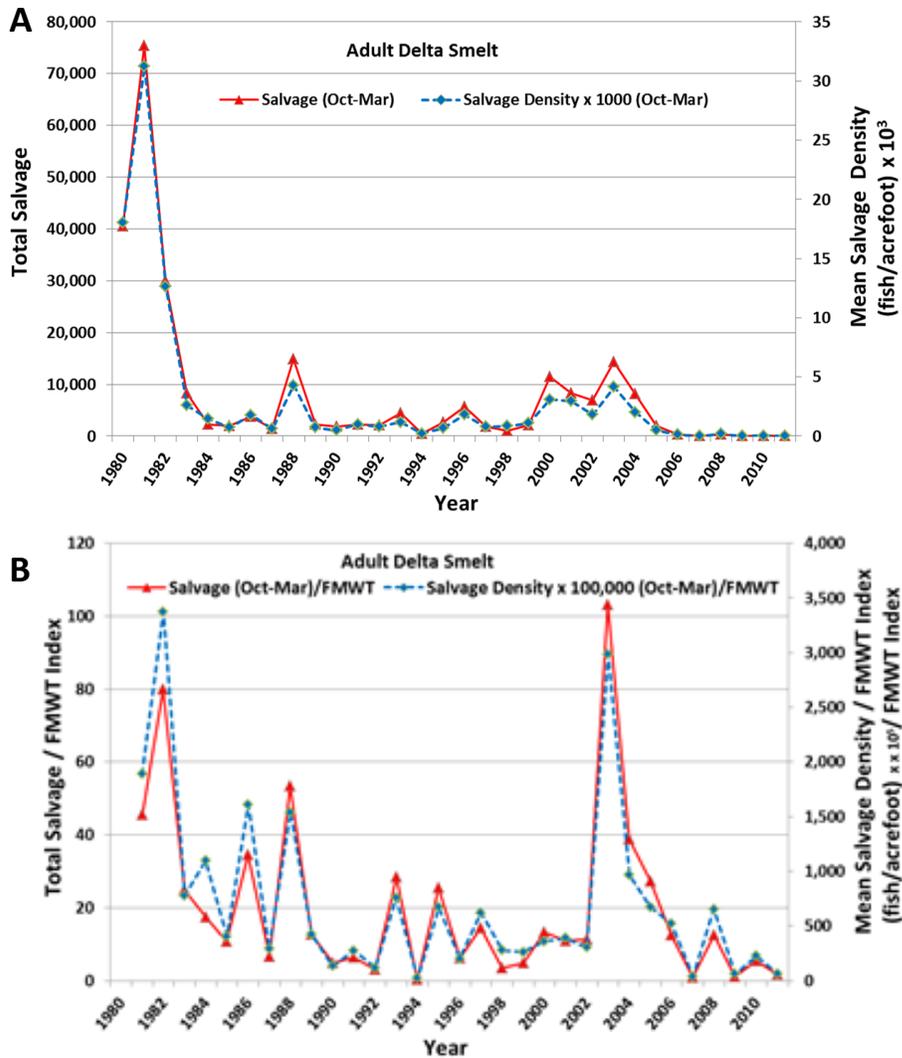

The SWP and CVP have large fish salvage facilities intended to reduce fish loss from the system due to entrainment - the State Skinner Fish Protective Facility (SFPP) and the federal Tracy Fish Collection Facility (TFCF). The SFPP and TFCF are located at the intakes to the State and federal export pumps on Old River in the southwestern Delta (Fig. 2). Both facilities have fish directing louvers and collecting screens that are used to capture and collect fish before they reach the pumps. The “salvaged” fish are then trucked to and released back into the western Delta. A variable fraction of these fish survive the capture, handling, trucking and release process (Miranda et al. 2010a,b, Aasen 2013, Afentoulis et al. 2013, Morinaka 2013a). The number of salvaged fish is monitored and reported as an index of SWP and CVP salvage and entrainment losses (Morinaka 2013b, more information and data available at <http://www.dfg.ca.gov/delta/apps/salvage/Default.aspx>). The SWP differs from the CVP in having a regulating reservoir, Clifton Court Forebay that temporarily stores water from Old River to improve operations of the SWP pumps. A change in the location of SWP water diversion from Italian Slough to Old River through CCF in 1969 may have led to a substantial increase in pre-screen losses at the SWP (Heubach ca. 1973, Kano 1990).

Fish have been salvaged since 1958 at the TFCF and since 1968 at SFPP, and the quality of the historical salvage data has improved over time. Delta Smelt salvage data is available since May 1979 for both the TFCF and SFPP (<ftp://ftp.delta.dfg.ca.gov/salvage/>). Juveniles less than 30 mm fork length are less efficiently captured in the salvage facilities (Kimmerer 2008, Morinaka 2013a) and Delta Smelt larvae less than 20 mm fork length have not been reported in the salvage data, although entrainment losses of Delta Smelt larvae have been calculated to be substantial under some circumstances (Kimmerer 2008). Development of a quantitative monitoring methodology for entrained Delta Smelt larvae at the CVP and SWP was recognized as necessary to refine triggers for protective actions (USFWS 2008). The current methodology for monitoring larval Delta Smelt at the TFCF and SFPP has provided presence-absence data since 2008 (Morinaka 2013b). Improved methods for sampling fish larvae have been reported at the TFCF (Reyes et al. 2012).

Despite these caveats salvage of Delta Smelt has been used as a rough index of entrainment losses. Delta Smelt salvage data since 1993 is considered more reliable than salvage data from earlier years. The difference in reliability is due to a change in count frequency from twice a day (0100 and 1300) from July 1978 to July 1992 to every two hours thereafter and an increased focus on proper identification of Delta Smelt following its State and federal listings as threatened (Morinaka 2013b).

Similar to the TNS and FMWT results for Delta Smelt, Delta Smelt salvage has declined dramatically since the beginning of this time series (Fig. 26). This is similar to trends for Chinook Salmon and Striped Bass salvage (not shown), but opposite to trends for Largemouth Bass and Bluegill (*Lepomis macrochirus*) salvage (Fig. 27), two species that may be benefiting from conditions resulting from an apparent ecological regime shift (Baxter et al. 2010). The ratio of Delta Smelt salvage divided by the previous year’s FMWT index has been used as a simple indicator of relative interannual entrainment losses. For adult (December-March) salvage, this ratio has been variable over time, but particularly high in the first three years of this time series (1980-1982, with 1982 being a wet year) and again during the beginning of a series of drought years in 1989 and in the fairly dry “POD” years 2003-2005 (Fig. 26). Current management

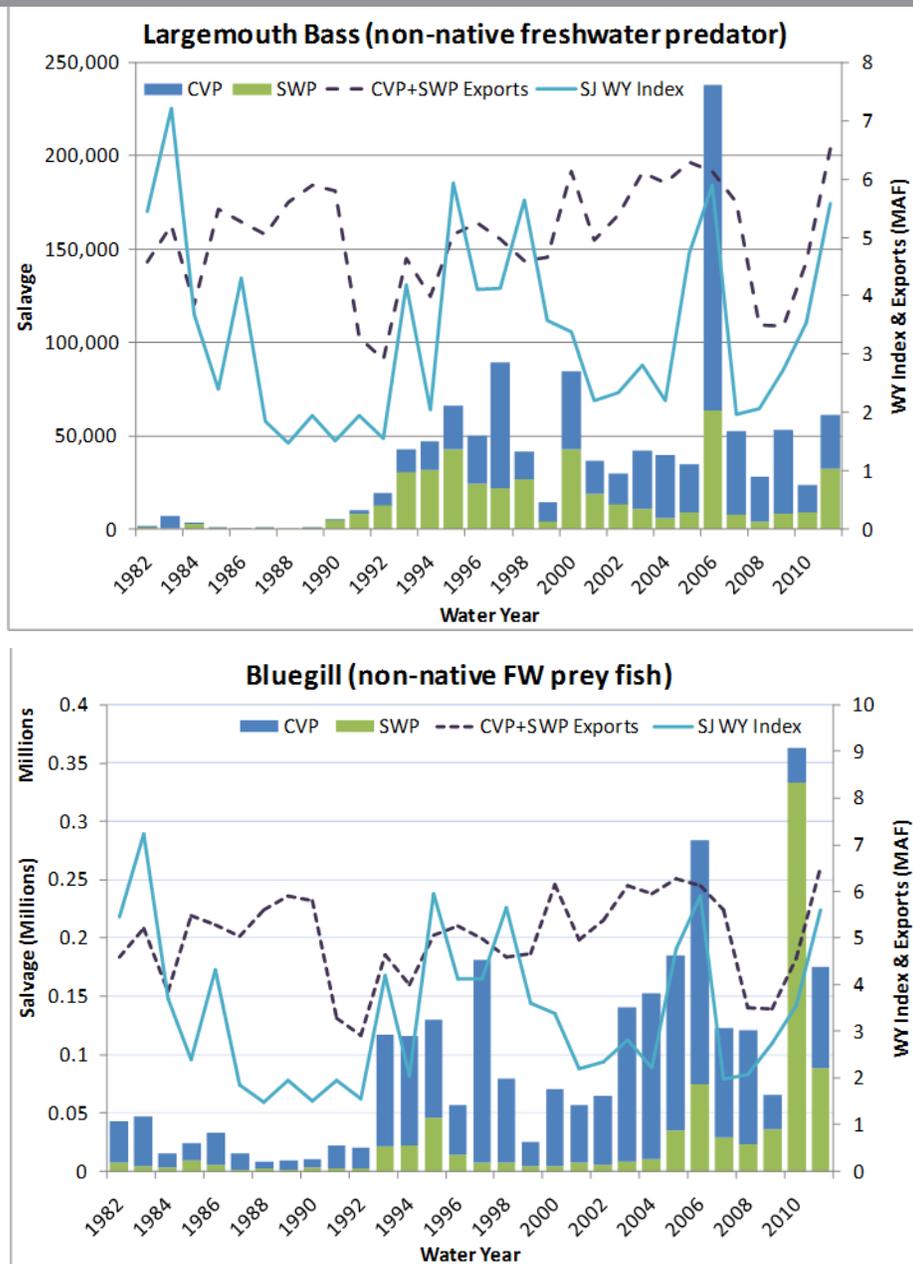

Figure 26. A: Total reported October-March salvage for adult Delta Smelt and the corresponding mean salvage density based on the total monthly salvage and water volume exported by CVP and SWP. **B:** Both salvage and salvage density standardized by the Fall Midwater Trawl (FMWT) index for the previous year.

provisions to protect Delta Smelt (USFWS 2008) are aimed at keeping this ratio at no more than the average during the period of 2006-2008.

Delta Smelt were salvaged nearly year-round in the beginning of this time series. Delta Smelt salvage since 2005 has occurred mostly from January through June, with substantial decline of May-June juvenile salvage since the mid 2000s (Fig. 28) and virtual disappearance of older juveniles from July-August salvage since the year 2000 (Fig. 29) and subadults since the early 1990s (Fig. 30). These patterns coincide with the near disappearance of Delta Smelt from the central and southern Delta in the summer (Nobriga et al 2008) and in the south Delta in the fall (Feyrer et al. 2007). Historically, adult and larval-juvenile (> 20 mm FL) Delta Smelt salvaged were not separately recorded and reported, but based on length measurements of a subset of salvaged fish, adults were predominantly salvaged between December and March or April

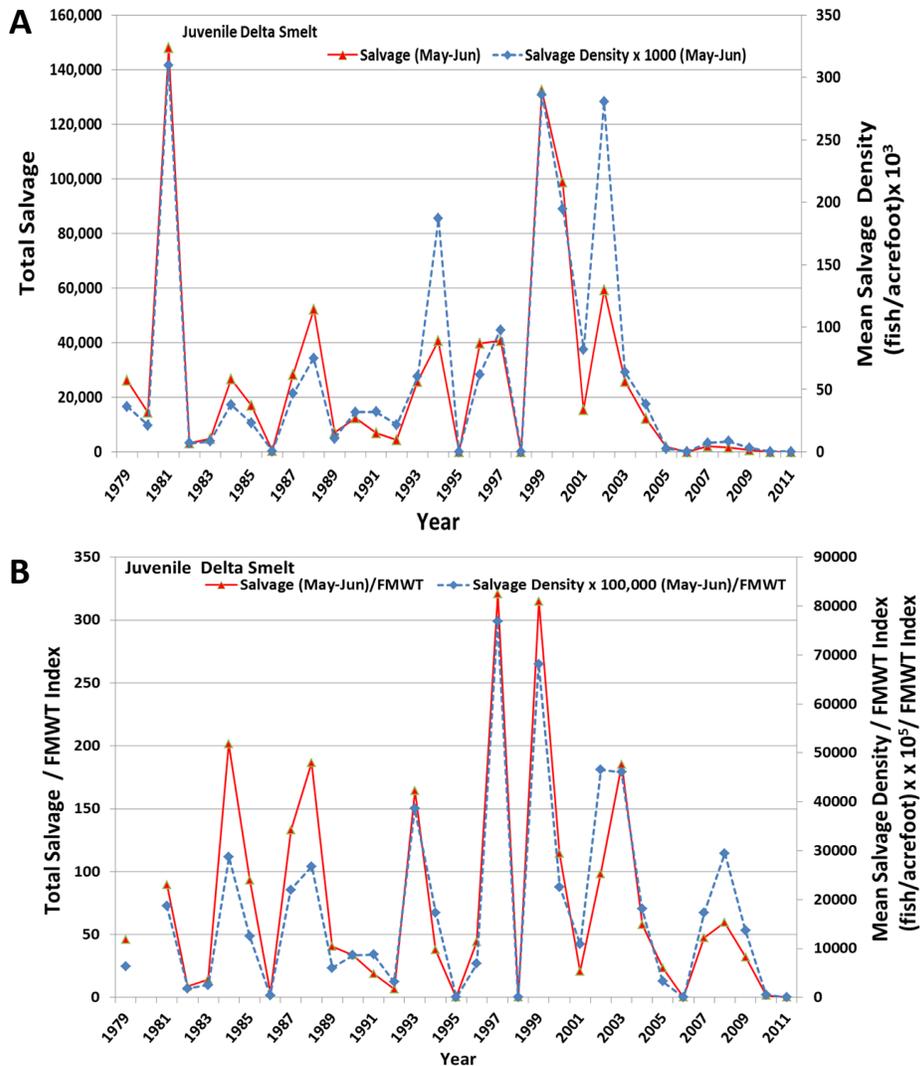

Figure 27. Annual time series of Largemouth Bass (top graph) and Bluegill (bottom graph) salvage at the CVP (blue bars) and SWP (green bars) fish protection facilities. Also shown are the annual San Joaquin Valley Water Year Index (SJWY Index) (blue line) and the combined annual (water year) SWP and CVP water export volume (purple line; MAF, million acre feet).

and most Delta Smelt larvae and juveniles were historically salvaged from April through July (Kimmerer 2008, Grimaldo et al. 2009).

Salvage data are routinely used to track and manage incidental take at the SWP and CVP and have been used to explore factors affecting entrainment and to estimate the effects of the SWP and CVP on Delta fishes. For example, Grimaldo et al. (2009) found that OMR flows and

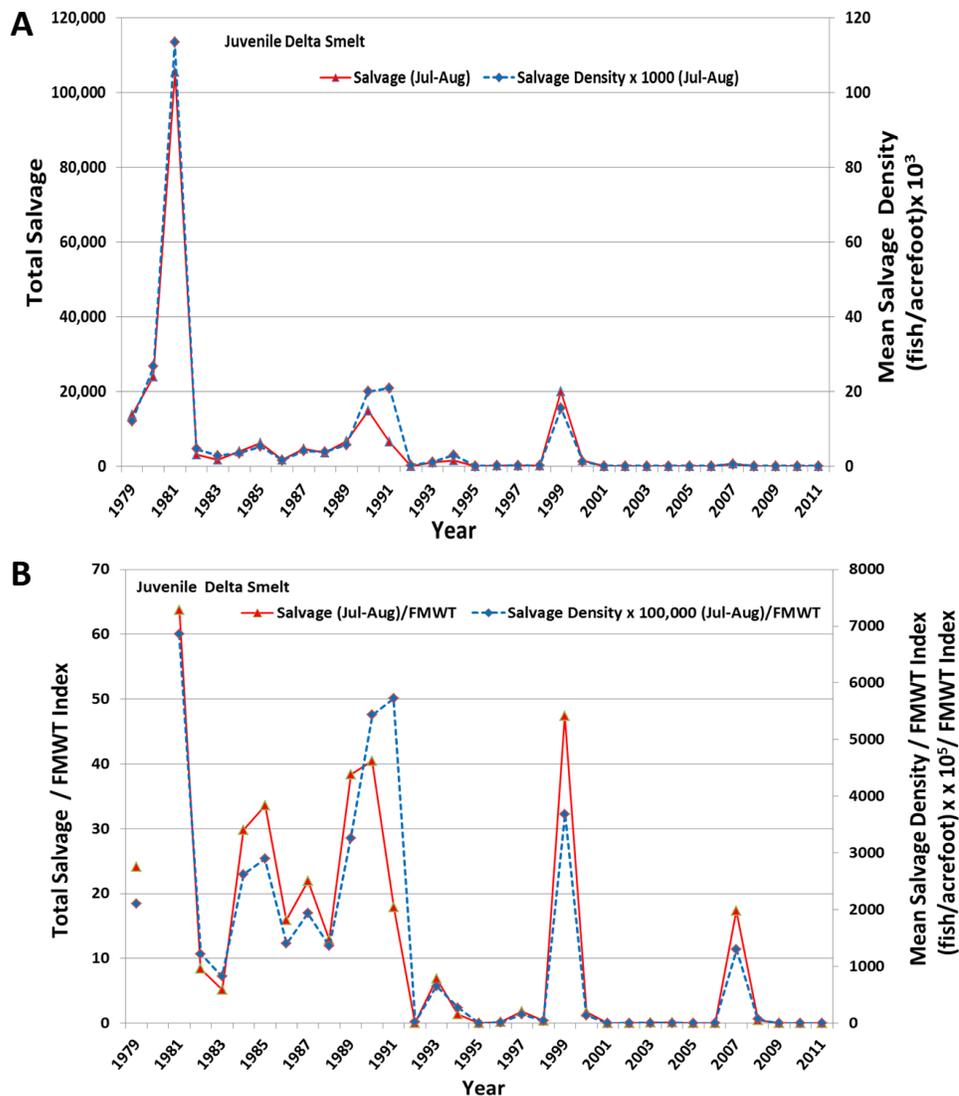

Figure 28. A: Total reported May-June salvage for juvenile Delta Smelt and the corresponding mean salvage density based on the total monthly salvage and water volume exported by CVP and SWP. **B:** Both salvage and salvage density standardized by the Fall Midwater Trawl (FMWT) index for the previous year.

turbidity account for much of the intra-annual variability in the salvage for juvenile and adult Delta Smelt.

It is important to remember, however, that salvage is only a very rough indicator of Delta Smelt entrainment. Based on mark-recapture experiments using cultured Delta Smelt, salvage was a very small fraction of total entrainment losses because of major pre-screen losses and low fish facility efficiency (Castillo et al. 2012). Experimental studies with cultured Chinook Salmon, Steelhead (*Oncorhynchus mykiss*), and Striped Bass have consistently shown that a large fraction (63% to 100%) of the entrained fish are not salvaged due to pre-screen losses and capture inefficiencies at the SWP fish facility (Brown et al. 1996, Gingras 1997, Clark et al. 2009). In addition, a mark-recapture test using field collected juvenile Chinook Salmon in CCF resulted in only 0.32% of the fish being salvaged (see Castillo et al. 2012). Pre-screen losses are generally

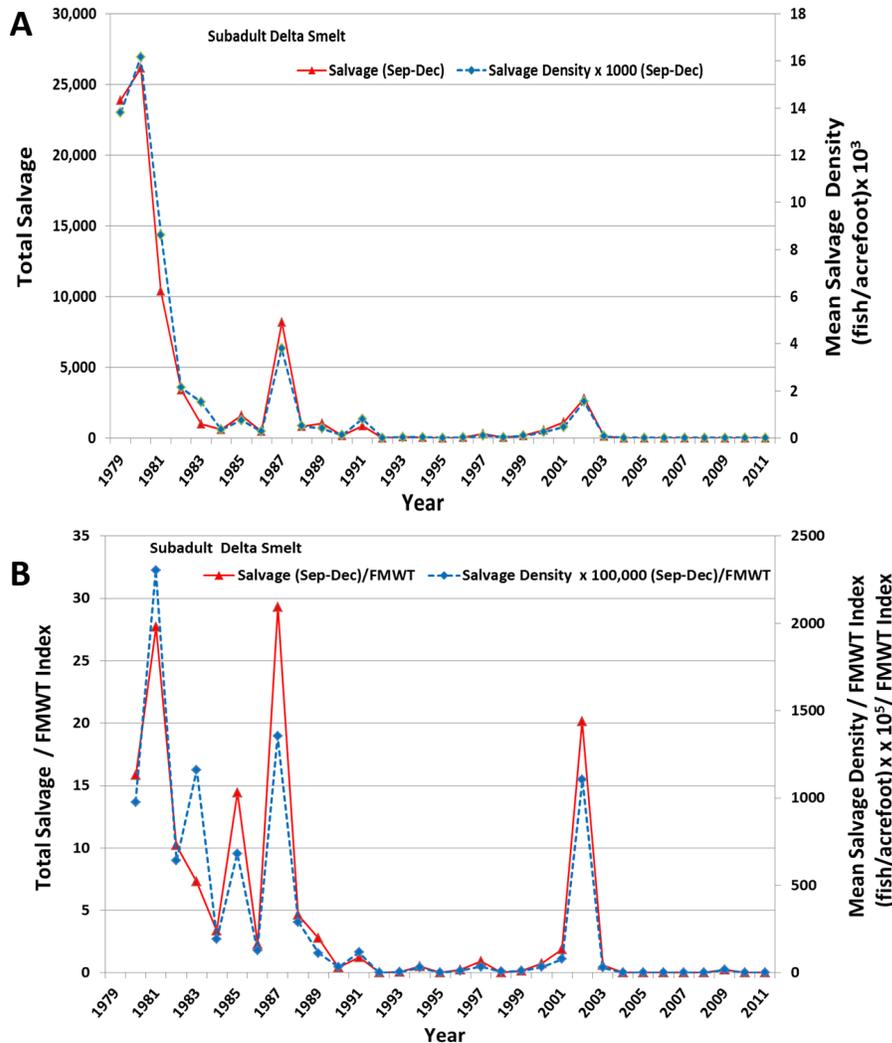

Figure 29. A: Total reported July-August salvage for juvenile Delta Smelt and the corresponding mean salvage density based on the total monthly salvage and water volume exported by CVP and SWP. **B:** Both salvage and salvage density standardized by the Fall Midwater Trawl (FMWT) index for the previous year.

attributed to increased predation and other unfavorable habitat conditions near the SWP and CVP pumps (e.g. Kano 1990, Brown et al. 1996, Gringas and McGee 1997, Clark et al. 2009, Castillo et al. 2012). For juvenile and adult Delta Smelt, Castillo et al. (2012) found that 94.3% to 100% of marked fish groups released into the SWP CCF were never salvaged and that salvage of marked fish decreased as the distance from the release site to SFPF increased and as residence time in CCF increased.

Large pre-screen losses of Delta Smelt in CCF are likely due to increased predation, especially when Delta Smelt spend a relatively long time in the reservoir in the presence of predators. MacWilliams and Gross (2013) used a particle tracking model to estimate residence time of passive particles, which can be considered surrogates for weakly swimming Delta Smelt. In 21-

Figure 30. A: Total reported July-August salvage for sub-adult Delta Smelt and the corresponding mean salvage density based on the total monthly salvage and water volume exported by CVP and SWP. **B:** Both salvage and salvage density standardized by the Fall Midwater Trawl (FMWT) index for the same year.

day simulations with the three-dimensional (3D) hydrodynamic model UnTRIM, MacWilliams and Gross (2013) found that the time particles spend in CCF varies greatly with wind and SWP operating conditions. They estimated transit times for passive particles (e.g., larval Delta Smelt) from the radial gates to the SFPF of 4.3 days under moderate export conditions (average daily SWP export rate of 2,351 cfs) and 9.1 days under low export conditions (689 cfs). The CVP does not have a regulating reservoir in the Delta and CVP pre-screen losses in the river channels leading to the TFCF are likely different from SWP pre-screen losses, but there are no studies quantifying these differences.

In general, Delta Smelt salvage increases with increasing net OMR flow reversal (i.e., more negative net OMR flows) and when turbidity exceeds 10-12 NTU (USFWS 2008, Grimaldo et al. 2009). Based on field and salvage data, Kimmerer (2008) calculated that from near 0% to 25% of larval-juvenile and 0% to 50% of the adult Delta Smelt population can be entrained at

the CVP and SWP annually, in years with periods of high exports. Although methods to calculate proportional loss estimates have since been debated (Kimmerer 2011, Miller 2011), a number of modeling efforts suggest that entrainment losses can adversely affect the Delta Smelt population (Kimmerer 2011, Maunder and Deriso 2011, Rose et al. 2013a, b).

High winter entrainment of Delta Smelt has been suspected as a contributing cause of both the early 1980s (Moyle et al. 1992) and the POD-era declines of Delta Smelt (Baxter et al. 2010). In addition to entraining Delta Smelt, water exports may likely also have indirect effects on Delta Smelt by contributing to adverse alterations of their habitat, for example, by changing Delta outflow and the size and location of the LSZ (see above) or by entraining food organisms (Jassby et al. 2002). The magnitude of these indirect effects of water exports on the Delta Smelt population has, however, not yet been quantified.

Delta Smelt are most vulnerable to entrainment when, as adults, they move from brackish water into fresh water, or as larvae, when they move from freshwater in the southern and central Delta into the brackish water of Suisun Bay. While some Delta Smelt live year-round in fresh water far from the CVP and SWP, most rear in the low-salinity regions of the estuary, also at a relatively safe distance from the SWP and CVP pumps. The timing, direction and geographic extent of the spawning movements of adult Delta Smelt affect their entrainment risk (Sweetnam 1999, Sommer et al. 2011a). Unlike the years prior to the 1990s, when high salvage of adult and juvenile Delta Smelt occurred at high, intermediate or low export levels, the risk of entrainment for fish that move into the central and south Delta is currently highest when net Delta outflow is at intermediate levels (~20,000 to 75,000 cfs) and OMR flow is more negative than -5000 cfs (USFWS 2008). In contrast, when adult Delta Smelt move upstream to the Sacramento River and into the Cache Slough region or do not move upstream at all, entrainment risk is appreciably lower. As explained later in this report, adult Delta Smelt may not move very far upstream during extreme wet years because the region of low salinity habitat becomes fresh and suitable for spawning (e.g., Suisun Bay or Napa River).

Transport mechanisms are most relevant to larval fishes, which have comparatively little ability to swim or otherwise affect their location. Dispersal from hatching areas to favorable nursery areas with sufficient food and low predation is generally considered one of the most important factors affecting the mortality of fish larvae (Hjort 1914, Hunter 1980, Anderson 1988, Leggett and Deblois 1994). Larvae of various smelt species exhibit diverse behaviors to reach and maintain favorable position within estuaries (Laprise and Dodson 1989, Bennett et al. 2002). Such nursery areas provide increased feeding success, growth rates and survival (Laprise and Dodson 1989, Sirois and Dodson 2000a, b, Peterson 2003, Hobbs et al. 2006). Until recently it was thought that larval Delta Smelt were transported from upstream hatching areas to downstream rearing areas, particularly the shallow productive waters of Suisun Bay (Moyle et al. 1992). Spring distributions of post-larval and small juvenile Delta Smelt support this view (Dege and Brown 2004). The distributions of these life stages were centered upstream of X2, but approached X2 as fish aged. These distributions could be displaced, and shifted up or down estuary with outflow and the shifting position of X2 (Dege and Brown 2004). More recent evidence suggests, however, that the timing and extent of downstream movement by young Delta Smelt is more variable than previously thought and that some may remain in upstream areas throughout the year (Sommer et al. 2011a, Contreras et al. 2011, Merz et al. 2011, Sommer and Mejia 2013).

Adult spawning site selection affects the potential importance of transport and entrainment to larvae. The risk of larval entrainment appears to increase with proximity to the south Delta export pumps (Kimmerer and Nobriga 2008). Larvae hatching in the San Joaquin River channel from

Big Break upstream to the city of Stockton and tidal channels south of these locations, can be affected by several interacting processes. Flows from the San Joaquin, Calaveras, Mokelumne and Cosumnes rivers act to cause net downstream flow, whereas export levels at the south Delta pumps act to reverse net flows in the lower San Joaquin River. High export rates can create negative flows past Jersey Point on the lower San Joaquin River (“Qwest,” see Dayflow documentation: <http://www.water.ca.gov/dayflow/output/Output.cfm>) and negative OMR flows (Fig. 31). Since the onset of the POD in 2002, positive average monthly OMR flows have only occurred in 9 months (6%) during the wettest years and average monthly Qwest flows were negative in just under half (49%) of all months (Fig. 31). Tidal conditions can also act in favor of downstream transport or entrainment depending upon whether the Delta is filling or draining in response to the fortnightly spring-neap cycle (Arthur et al. 1996). The combination of high export and low inflow can create very asymmetrical tides in OMR that covary with net negative flow resulting in stronger floods compared to ebbs, which may also contribute to fish entrainment.

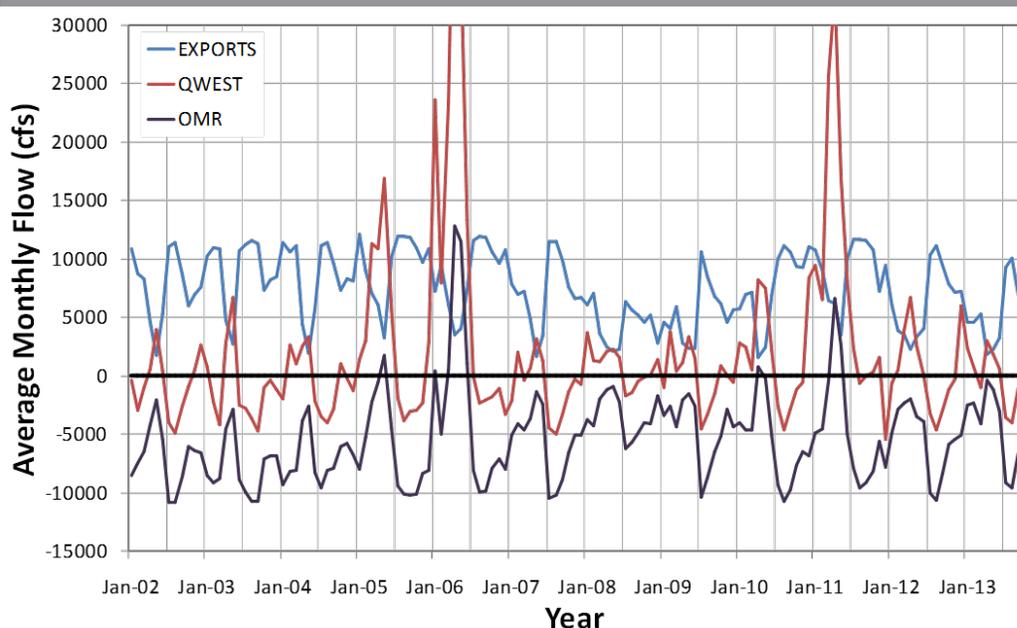

Predation Risk

Small planktivorous fishes, including osmerids, serve as prey for larger fishes, birds and mammals. As prey, they have the critically important trophic function of transferring energy to higher trophic levels. Consequently, they are often subjected to intense predation pressure (Gleason and Bengsten 1996, Jung and Houde 2004, Hallfredsson and Pedersen 2009). Prey fish populations compensate for high mortality through high reproductive rates, including strategies such as repeat spawning by individuals and rapid maturation (Winemiller and Rose 1992, Rose et al. 2001). Predation can be a dominant source of mortality for fish larvae, along with starvation and dispersion to inhospitable habitats (Hjort 1914, Hunter 1980, Anderson 1988, Leggett and Deblois 1994).

Since predation is a natural part of functional aquatic ecosystems, predators are likely not responsible for long-term declines in populations of prey fishes, such as Delta Smelt, without some additional sources of stress that disrupt the predator-prey relationship (Nobriga et al. 2013). Predation may become an issue when established predator-prey relationships are disrupted by habitat change or species invasions (Kitchell et al. 1994). As described in Chapter 1, the SFE has been extensively modified (Nichols et al. 1986, Cohen and Carlton 1998, Whipple et al. 2012, Cloern and Jassby 2012) so disrupted relationships between predators and prey are certainly plausible. For example, prey may be more susceptible to predation if they are weakened by disease, contaminants, poor water quality, or starvation. Similarly, the creation of more “ambush habitat” (e.g. structures, weed beds), declines in turbidity levels, or the introduction of a novel piscivore also may dramatically shift the existing predator-prey relationships (Ferrari et al. 2014). All of these changes have in fact taken place in the estuary, especially in the central and south Delta (Feyrer and Healey 2003, Nobriga et al. 2005, Brown and Michniuk 2007).

Virtually all fishes of appropriate size will feed on fish larvae when available and predation is theoretically maximal when larvae lengths are 10% of the length of the predator (Paradis et al. 1996). Presently, Mississippi Silverside (*Menidia audens*) is thought to be the most substantial predator of Delta Smelt larvae (Bennett and Moyle 1996, Bennett 2005, Baerwald et al. 2012). Juvenile and adult Delta Smelt have also been reported from the stomach contents of Striped Bass (Stevens 1963, Stevens 1966, Thomas 1967), White Catfish (*Ictalurus catus*) and Black Crappie (*Pomoxis nigromaculatus*) (Turner 1966a,b). Stevens (1963) reported “freshwater smelt” to be a very common component of Striped Bass stomach contents (nearly 100% frequency of occurrence in fifteen stomachs with food) on the Sacramento River near Paintersville Bridge

Figure 31. Flows in cubic feet per second for Qwest (positive values are seaward), Old and Middle River (OMR) (positive values are seaward), and total exports for years since the beginning of the pelagic organism decline (POD). Maximum monthly average Qwest values in 2006 and 2011 omitted to improve graph display, values are 50,086 cfs in April 2006, 35,477 in May 2006, and 32,884 cfs in April 2011 (Qwest and Export data are from 2013 Dayflow, OMR data are from USGS).

during March-April 1963. During 1963-1964, Stevens (1966) also evaluated seasonal variation in the diets of juvenile Striped Bass throughout the Delta; only age 2 and age 3 Striped Bass contained more than trace amounts of Delta Smelt. The highest reported predation on Delta Smelt was 8% of the age 2 Striped Bass diet by volume during the summer. Thomas (1967) reported on spatial variation in Striped Bass diet composition based on collections throughout the SFE and the Sacramento River above tidal influence. The field collections occurred from 1957-1961; data were collected on age 1 and older Striped Bass but data were only summarized as all ages combined. Delta Smelt accounted for 8% of the spring diet composition and about 16% of the summer diet composition in the Delta.

Several authors tested hypotheses about inverse correlations between estimates of adult and juvenile Striped Bass abundance and indices of Delta Smelt relative abundance or survival (Mac Nally et al. 2010, Thomson et al. 2010, Maunder and Deriso 2011, Miller et al. 2012, Nobriga et al. 2013). None of these statistical analyses has found evidence for the expected inverse correlation. Modeling studies indicate that Striped Bass predation rates on prey are affected by temperature and predator abundance (mostly the latter; Loboschewsky et al. 2012). However, the links between prey abundance and predator abundance vary from strong to non-existent, depending on the strength of their interaction in the food web (Essington and Hansson 2004). It is not currently known if changes in juvenile Striped Bass abundance correspond with changes in population-level or per capita Striped Bass predation rate on Delta Smelt (Nobriga et al. 2013).

Recent modeling efforts show that Delta Smelt declines are negatively associated with metrics assumed to reflect the abundance of predators in the estuary (Maunder and Deriso 2011, Miller

et al. 2012). These metrics are composites of the relative abundance of Mississippi Silverside, Largemouth Bass and other centrarchids; species that are potential predators of concern because of their increasing abundance (Fig. 27; Bennett and Moyle 1996, Brown and Michniuk 2007, Thomson et al. 2010), and because of inverse correlations between Largemouth Bass abundance and Delta Smelt abundance (Nobriga and Feyrer 2007, Thomson et al. 2010, Maunder and Deriso 2011). These correlations could represent predation on Delta Smelt by Largemouth Bass, or alternatively, the very different responses of the two species to changing habitat within the Delta (Moyle and Bennett 2008). Current data suggest that Largemouth Bass populations have expanded as the SAV *Egeria densa* has expanded and have come to dominate parts of the Delta (Brown and Michniuk 2007). *E. densa* and Largemouth Bass are particularly prevalent in the central and southern Delta (Brown and Michniuk 2007) and Largemouth Bass may contribute to the pre-screen losses of Delta Smelt entrained into the SWP and CVP export pumps (see above). Largemouth Bass will readily eat Delta Smelt when the opportunity exists (Ferrari et al. 2014). However, there is little evidence that Largemouth Bass are major consumers of Delta Smelt due to low spatial co-occurrence (Nobriga et al. 2005, Baxter et al. 2010; L. Conrad, California Department of Water Resources, unpublished data). Thus, the inverse correlations between these species may not be mechanistic. Rather, they may reflect adaptation to, and selection for, different environmental conditions.

As noted above, predation on fish larvae can also be an important source of mortality. Juvenile and small adult fishes of many species will consume fish larvae when they are available. Major predators of the eggs and larvae of nearshore coastal and pelagic estuarine forage fishes can include invertebrates (DeBlois and Leggett 1993) and numerous small fishes not typically thought of as “piscivorous” (Johnson and Dropkin 1992), including adults of their own species (Takasuka et al. 2003). Bennett and Moyle (1996) and Bennett (2005) noted this and specifically identified Mississippi Silversides (hereafter, Silversides) as potential predators on Delta Smelt larvae. These authors also documented increases in the Silverside population from the mid-1970s through 2002. Consumption of Delta Smelt larvae by Silversides in the Delta was recently verified using DNA techniques (Baerwald et al. 2012). Larval predation is discussed in more detail in the next Chapter.

Contaminants

Fish are particularly sensitive to alterations in the chemical composition of the natural aquatic environment, as these changes can have significant impacts on their behavioral and physiological systems (Radhaiah et al. 1987). Chemical alterations can be the result of natural processes, for example the changes in local water quality associated with tidal water movements or natural biogeochemical processes, or they can be caused by pollution from watershed- or land-based sources of nutrients, such as nitrogen compounds, and contaminants, such as pesticides, metals, and contaminants of emerging concerns (CECs). The movement of contaminants through aquatic ecosystems is complex and dynamic, and many contaminants are difficult to detect and expensive to monitor (Scholz et al. 2012).

Portions of the SFE are listed as “impaired” on California’s 303(d) list of Impaired Water Bodies due to metals, pesticides, legacy pollutants, and nutrients that exceed established water quality objectives (SWRCB 2010). In particular, the entire SFE has been listed as impaired due to pollution with metals, such as mercury and selenium, and pesticides such as chlorpyrifos, DDT (Dichlorodiphenyltrichloroethane), and diazinon. The entire Delta, but not the bays of the SFE, is also listed for observed toxicity to aquatic organisms. In addition, the Stockton Ship Channel

in the southeastern Delta is listed for enrichment with nutrients, organic compounds, and low dissolved oxygen levels; Old River in the south-central Delta is listed for elevated salinity (electrical conductivity; EC) and total dissolved solids (TDS). Delta Smelt are likely exposed to a variety of these contaminants throughout their life cycle; however, the frequency and magnitude of the effects of contaminants on Delta Smelt health and reproduction are not very well understood in the SFE (Johnson et al. 2010, Brooks et al. 2012). The following sections describe the potential effects of key contaminants on Delta Smelt.

Pesticides

Pesticides produce many physiological and biochemical changes in freshwater organisms through their influence on the activities of several enzymes (Khan and Law 2005). Specifically, pesticides can have an adverse effect on hormones or other chemical messengers important to the health of an individual. Previous work has shown that chronic exposure to low levels of pesticides may even have a more adverse effect on fish than a single acute exposure to high levels. Chronic exposures were associated with changes in behavior and physiology that could influence survival and reproduction of wild fish (Ewing 1999). Biochemical and physiological stresses induced by exposure to pesticides can result in metabolic disturbances, retardation of growth, as well as reduction in longevity and fecundity (Murty 1986).

Pesticides are among the key contaminants believed to have contributed to the Delta Smelt decline (Johnson et al. 2010, Brooks et al. 2012, NRC 2012). Because pesticide concentrations in surface water are typically highest during the winter and spring, pesticides are most likely to affect the adult and larval life stages; however, effects may occur during any life stage as pesticides are seasonally and geographically widespread (Kuivila and Hladik 2008). Kuivila and Moon (2004) found that peak densities of larval and juvenile Delta Smelt sometimes coincided in time and space with elevated concentrations of dissolved pesticides in the spring. These periods of co-occurrence lasted for up to 2–3 weeks. While concentrations of individual pesticides were lower than would be expected to cause acute mortality, little is known of the sublethal effects of pesticides on Delta Smelt. Although little evidence exists for acute effects of pesticides on fish or invertebrates, several studies have documented sublethal effects on fish health (Werner et al. 2008, Werner et al. 2010a, Werner et al. 2010b).

Herbicides and fungicides were among the most commonly detected classes of pesticides observed in water and sediment in the Delta and are also found in fish tissue (Orlando et al. 2013, Smalling et al. 2013). Herbicides are known to affect primary producers, while insecticides can affect invertebrate prey species (e.g., Brander et al. 2009, Weston et al. 2012), which could lead to contaminant-mediated food limitation for Delta Smelt. Fungicides have been found to cause endocrine disruption in fish, including reduced fecundity (Ankley et al. 2005). Recent work has shown that the insecticide esfenvalerate affects swimming behavior of exposed larval Delta Smelt (Connon et al. 2009). It was also found to alter the expression of genes involved in neuromuscular activity and immune response, detoxification, and growth and development (Connon et al. 2009). Additionally, insecticides are known to affect predator-prey relationships for fish, as well as lead to endocrine disruptions (Scholz et al. 2000, Junges et al. 2010, Relyea and Edwards 2010, Riar et al. 2013, Forsgren et al. 2013). Contamination of aquatic systems by pyrethroid insecticides was recently found to lead to genetic point mutations in the nontarget, aquatic amphipod *Hyalella azteca*, resulting in differences in pyrethroid sensitivity. Wild populations of *H. azteca* collected from areas with high sediment concentrations of pyrethroids exhibited remarkable resistance to pyrethroids compared to laboratory cultures and the observed

resistance was highly coupled to the presence of a genetic mutation. The LC50s (concentration that is lethal to 50% of the exposed population) of previously-exposed wild populations were up to two orders of magnitude greater than LC50s of laboratory cultures. Moreover, the presence of a genetic mutation was detected in 100% of *H. azteca* that survived exposure to high pyrethroid concentrations. The development of such resistance can result in costs to genetic and biological diversity, including reduced fitness, and may lead to impacts to the food web (Weston et al. 2013). The presence of such resistance and genetic mutations in Delta Smelt as a result of pyrethroids or other pesticide exposure has not been investigated

It is also important to note that environmental factors such as temperature and salinity affect pesticide toxicity in fish (Coats et al. 1989, Lavado et al. 2009). For that reason, seasonal variation in environmental factors may result in greater risk to certain life stages. The results above are for dissolved pesticides; pesticides may also be bound to sediments, representing another possible mechanism of exposure. Pesticides, such as pyrethroids and organochlorines, that strongly bind to sediment may be particularly important to the adult and larval life stage of Delta Smelt as these life stages occur during the winter and spring, when rain events (including the “first flush”) transport sediment and associated contaminants into the Delta; however, as the mechanisms that influence the desorption rates of pesticides are complex (e.g., temperature, contact time, pesticide) (e.g., Xu et al. 2008, Cornelissen et al. 1998), exposure rates for Delta Smelt life stages are likely multifaceted and difficult to predict.

Ammonia and Ammonium

Agricultural operations, wastewater treatment plant effluent, and other sources contribute to the accumulation of nutrients in the Delta. Nutrients, such as ammonium (a cation) and ammonia (its toxic, unionized form) are of particular concern in the Delta, as they can have significant negative effects on Delta Smelt and their habitat. Ammonium is increasingly converted into ammonia as pH rises. Delta Smelt spawning and larval nursery areas in the northern Delta are at particular risk to exposure to ammonia/um, mainly due to discharge by the Sacramento Regional Wastewater Treatment Plant (SRWTP) into the lower Sacramento River (Connon et al. 2011a). However, effects of nutrients such as ammonia/um are likely at all Delta Smelt life stages, as nutrients are discharged throughout the Delta year-round.

Recent work demonstrated that Delta Smelt exposed to ammonia exhibited membrane destabilization, which may lead to increased membrane permeability as well as increased susceptibility to synergistic effects of multi-contaminant exposures (Connon et al. 2011a, Hasenbein et al. 2013b); however, the concentrations of ammonia used in these studies were higher than the concentrations typically experienced by Delta Smelt in the wild. In other fish species, sublethal concentrations of ammonia/um have also led to histological effects such as gill lamellae fusions and deformities (Benli et al. 2008). Other work has also shown that neurological and muscular impacts of ammonia/um resulted in slowed escape response and subsequent mortality (McKenzie et al. 2008).

Metals and Other Elements of Concern

Historic mining sites, industrial and domestic wastewater discharges, and agricultural runoff are largely responsible for the presence of metals and other elements of concern in the Delta. Metals of particular importance in the Delta include copper and mercury; selenium is a trace element

of concern. Delta Smelt exposed to copper exhibited reduced swimming velocities and suffered digestive and neurological effects (Connon et al. 2011b). Other sublethal effects on fish caused by exposure to these elements include reduced fertility and growth, impaired neurological and endocrine functions, and skeletal deformities that affect swimming performance (Boening 2000, Chapman et al. 2010). These elements are often associated with sediment and may be particularly important to the adult and larval life stages, since sediment is transported with significant rain events, including the “first flush.”

Contaminants of Emerging Concern

Contaminants of emerging concern (CECs) such as pharmaceuticals, hormones, personal care products, and industrial chemicals are of increasing concern because they are widespread in the aquatic environment, biologically active, and are relatively unregulated (Kolpin et al. 2002, Pal et al. 2010). The California State Water Resources Control Board is currently investigating CECs in the Delta (<http://www.sccwrp.org/ResearchAreas/Contaminants/ContaminantsOfEmergingConcern/EcosystemsAdvisoryPanel.aspx>). CECs originate from many sources including industrial and domestic wastewater. They are responsible for a myriad of sublethal effects in fish including endocrine disruption, changes in gene transcription and protein expression, and morphological and behavioral changes (Brander 2013). Though the effects of CECs have been well studied in other fish species, the extent to which they influence Delta Smelt remains unclear.

Polycyclic Aromatic Hydrocarbons (PAHs) and Polychlorinated Biphenyls (PCBs)

The PAHs and PCBs found in the Delta are largely from urban and industrial sources. PAHs are formed during the incomplete burning of coal, oil, gas, garbage, and other organic substances. PCBs are synthetic organic chemicals that were used in many industrial and commercial applications. PCBs were banned in 1979, but continue to persist in the environment. PAHs and PCBs bind strongly to sediment and therefore are likely to be associated with the “first flush” and may be particularly important to the adult and larval life stages of Delta Smelt. Almost all sediments sampled in the Delta in 2006 contained PAHs (mean concentration of 0.3 parts per million in Suisun Bay) and PCBs (mean concentration of 0.8 parts per million in Suisun Bay) (SFEI 2007). Studies have found PAHs and PCBs in surface water, with concentrations in excess of established water quality objectives (Thomson et al. 2000, Oros et al. 2006). Both PCBs and PAHs can cause endocrine disruption in fish (Brar et al. 2010, Nicolas, 1999); however, specific impacts on Delta Smelt have not been documented.

Contaminant Mixtures

While the individual effects of the aforementioned contaminants can be severe, recent work has demonstrated that the interaction of the contaminants within mixtures can have both synergistic and antagonistic effects, exacerbating potential impacts on fish physiology (e.g., Jordan et al. 2012). There is increasing evidence that compounds in mixtures show adverse effects at concentrations at which no effects were observed for single toxicants (e.g., Baas et al. 2009, Silva et al. 2002, Walter et al. 2002). For example, recent work on Mississippi Silversides has demonstrated that contaminant mixtures resulted in endocrine disruptions such as varied

expression of mRNA levels for estrogen-responsive genes, reduced mean gonadal somatic indices (GSI), testicular necrosis, and biased sex ratios (Brander et al. 2013). Studies have also shown that mixtures can affect predator-prey interactions (Relyea and Edwards 2010) and cause liver abnormalities (Sacramento Splittail, *Pogonichthys macrolepidotus*; Greenfield et al. 2008). Other work on Striped Bass has demonstrated that contaminant mixtures can be maternally-transferred to fish eggs, resulting in larvae with impaired growth and abnormal brain and liver development (Ostrach et al. 2008).

Due to the unpredictability of their effects on organisms, the synergistic effects of contaminant mixtures have received a great deal of attention both within pharmacology and environmental sciences (Arnold et al. 1996, Ashby et al. 1997, Berenbaum 1989, Greco et al. 1995, Liang and Lichtenstein 1974). Currently, one of the greatest challenges in chemical mixture research is how to deal with the infinite number of combinations of chemicals and other stressors, as well as their interactive effects, on organisms (Baas et al. 2010). Additional challenges also exist trying to relate lab-based findings to wild populations for studies examining the effects of individual contaminants and contaminant mixtures on organisms using exposure concentrations that are environmentally representative. Therefore, while the potential for exposure to contaminant mixtures in all Delta Smelt life stages is highly probable, any specific effects of such interactions on Delta Smelt remain unknown.

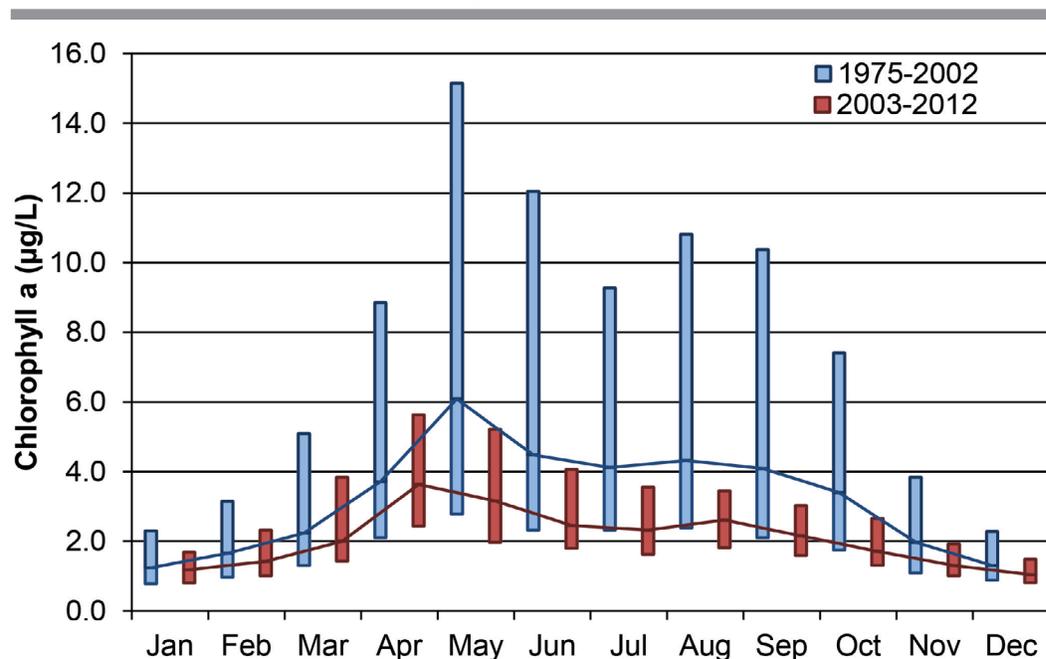

Food and Feeding

The presence of food is, obviously, a critical habitat attribute for any organism; however, the factors determining the quantity and quality of available food can be quite complex. In this section, we begin with a brief review of information about trophic processes in the upper SFE. We then discuss the available data on prey consumed by Delta Smelt. Finally, we provide a review of information on factors possibly affecting abundance and quality of food organisms.

Estuaries are commonly characterized as highly productive nursery areas for a suite of organisms. Productivity of estuarine ecosystems is often fueled by detritus-based food webs. In the SFE, much of the community metabolism in pelagic waters does result from microbial consumption of organic detritus. However, evidence suggests that metazoan production in pelagic waters is primarily driven by phytoplankton production (Sobczak et al. 2002, 2005, Mueller-Solger et al. 2002, 2006, Kimmerer et al. 2005). Protists (flagellates and ciliates) consume both microbial and phytoplankton prey (Murrell and Hollibaugh 1998, York et al. 2010) and are an additional important food source for many copepod species in the estuary (Rollwagen-Bollens and Penry 2003, Bouley and Kimmerer 2006, Gifford et al. 2007, McManus et al. 2008). However, the conversion of dissolved and particulate organic matter to microbial biomass and then to zooplankton is a relatively slow and inefficient process. Shifts in phytoplankton and microbial food resources for zooplankton might favor different zooplankton species. Moreover, phytoplankton production and biomass in the SFE is low compared to many other estuaries (e.g., Jassby et al. 2002, Kimmerer et al. 2005, Wilkerson et al. 2006, Cloern and Jassby 2012). The recognition that phytoplankton production might impose limits on pelagic fishes, such as Delta Smelt, through food availability has led to intense interest in factors affecting phytoplankton production and species composition and in management actions aimed at enhancing high-quality phytoplankton production. In addition, there is a major need to understand other trophic pathways given the observation that larger Delta Smelt periodically can take advantage of epibenthic prey (see below).

Phytoplankton biomass (measured as chlorophyll-*a*) has been routinely monitored in the estuary since the 1970s. The 1975-2012 median chlorophyll-*a* concentration across all IEP EMP stations is 2.8 $\mu\text{g/L}$ ($n = 13482$, interquartile range (IQR) = 5 $\mu\text{g/L}$). Seasonally, the highest chlorophyll-*a* concentrations tend to be observed in May and June and the lowest concentrations in December and January (Fig. 32). Regionally, monitoring stations in the South Delta/San Joaquin River usually have the highest chlorophyll-*a* concentrations. There has been a well-documented long-term decline in phytoplankton biomass (chlorophyll-*a*) and primary productivity (estimated from measurements of chlorophyll-*a* and of water column light utilization efficiency) to very low levels in the Suisun Bay region and the lower Delta (Jassby et al. 2002). Jassby et al. (2002) detected a 47% decline in June–November chlorophyll-*a* and a 36% decline in June–November primary production between the periods 1975–1985 and 1986–1995. Jassby (2008) updated the phytoplankton analysis to include the more recent data (1996–2005) from the Delta and Suisun Bay. Jassby (2008) confirmed a long-term decline in chlorophyll-*a* from 1975 to 2005 but also found that March–September chlorophyll-*a* had an increasing trend in the Delta from 1996 to 2005. Suisun Bay did not exhibit any trend during 1996–2005. A similar pattern was noted for primary production in the Delta. These chlorophyll-*a* patterns continued to hold through 2008 according to a more recent study by Winder and Jassby (2011). In the most recent decade (2003–2012), the median chlorophyll-*a* concentration across all IEP EMP stations was 2 $\mu\text{g/L}$ ($n = 2620$, IQR = 2 $\mu\text{g/L}$), compared to the 1975-2002 median chlorophyll-*a* concentration of 3 $\mu\text{g/L}$ ($n = 10862$, IQR = 6 $\mu\text{g/L}$) (Fig. 32). Most of the decrease was due to declines during May–October and especially the near-elimination of the formerly common “spring bloom” of phytoplankton in May (Fig. 32). In summary, phytoplankton biomass and production in the Delta and Suisun Bay seem to have reached a low point by the end of the 1987–1994 drought. While they recovered somewhat in the Delta, chlorophyll-*a* stayed consistently low in Suisun Bay through the POD years.

Figure 32. Interquartile ranges (boxes) and medians (lines) for chlorophyll-*a* measured monthly at all IEP EMP stations from 1975-2002 (blue) and 2003-2012 (red). Data from <http://www.water.ca.gov/bdma/>.

A major reason for the long-term phytoplankton reduction in the upper SFE after 1985 is benthic grazing by the invasive overbite clam (*Potamocorbula amurensis* also known as *Corbula amurensis*) (Alpine and Cloern 1992), which became abundant by the late 1980s (Kimmerer 2002). The overbite clam was first reported from San Francisco Estuary in 1986 and it was well established by 1987 (Carlton et al. 1990). Prior to the overbite clam invasion, the invasive Asiatic freshwater clam (*Corbicula fluminea*) (introduced in the 1940s) colonized Suisun Bay during high flow periods and the estuarine clam *Mya arenaria* (also known as *Macoma balthica*, an earlier introduction) colonized Suisun Bay during prolonged (> 14 month) low flow periods (Nichols et al. 1990). Thus, there were periods of relatively low clam grazing rates while one species was dying back and the other was colonizing, resulting in neither reaching high abundances. The *P. amurensis* invasion changed this formerly dynamic clam assemblage because *P. amurensis*, which is tolerant of a wide range of salinity, can maintain large, permanent populations in the brackish water regions of the estuary. *P. amurensis* biomass and grazing usually increase from spring to fall which contributes to the reduction in phytoplankton biomass from May to October relative to historical levels. In addition, the grazing influence of *P. amurensis* extends into the freshwater Delta beyond the clam's typical brackish salinity range, presumably due to tidal dispersion of phytoplankton-depleted water between regions of brackish water and fresh water (Kimmerer and Orsi 1996, Jassby et al. 2002).

Phytoplankton production in the SFE has been considered primarily light-limited because nutrient concentrations commonly exceed concentrations limiting primary production. According to some recent work, shifts in nutrient concentrations and ratios may, however, also contribute to the phytoplankton reduction and changes in algal species composition in the SFE. Nutrients may also play a larger role in regulating phytoplankton dynamics in the estuary as the estuary clears and light availability increases (see turbidity section above).

While phosphorus (total phosphorous and soluble reactive phosphorous) concentrations declined in the Delta and Suisun Bay region over the last few decades, nitrogen (total nitrogen and ammonium) concentrations increased. These changes have been attributed to the operation of the Sacramento Regional Wastewater Treatment Plant (SRWTP), a large secondary treatment facility that was completed in 1984 (VanNieuwenhuysen 2007, Jassby 2008). As stated previously, ammonia has two forms, un-ionized ammonia (NH_3) which is toxic to aquatic organisms and the ammonium ion (NH_4^+) which is considerably less toxic to animals and an important nutrient for plants and algae (Thurston et al. 1981). Ammonia exists in equilibrium between the two forms dependent primarily on the pH of the water, but also temperature, with increases in pH and temperature favoring the un-ionized form (Thurston et al. 1981). Dugdale et al. (2007) and Wilkerson et al. (2006) found that high ammonium concentrations prevented the formation of diatom blooms but stimulated flagellate blooms in the lower estuary. They propose that this occurs because diatoms preferentially utilize ammonium in their physiological processes even though it is used less efficiently and at high concentrations ammonium can prevent uptake of nitrate (Dugdale et al. 2007). Thus, diatom populations must consume available ammonium before nitrate, which supports higher growth rates, can be utilized or concentrations of ammonium need to be diluted. A recent independent review panel (Reed et al. 2014) found that there is good evidence for preferential uptake of ammonium and sequential uptake of first ammonium and then nitrate, but that a large amount of uncertainty remains regarding the growth rates on ammonium relative to nitrate and the role of ammonium in suppressing spring blooms.

Glibert (2012) analyzed long-term data (from 1975 or 1979 to 2006 depending on the variable considered) from the Delta and Suisun Bay and related changing forms and ratios of nutrients, particularly changes in ammonium, to declines in diatoms and increases in flagellates and

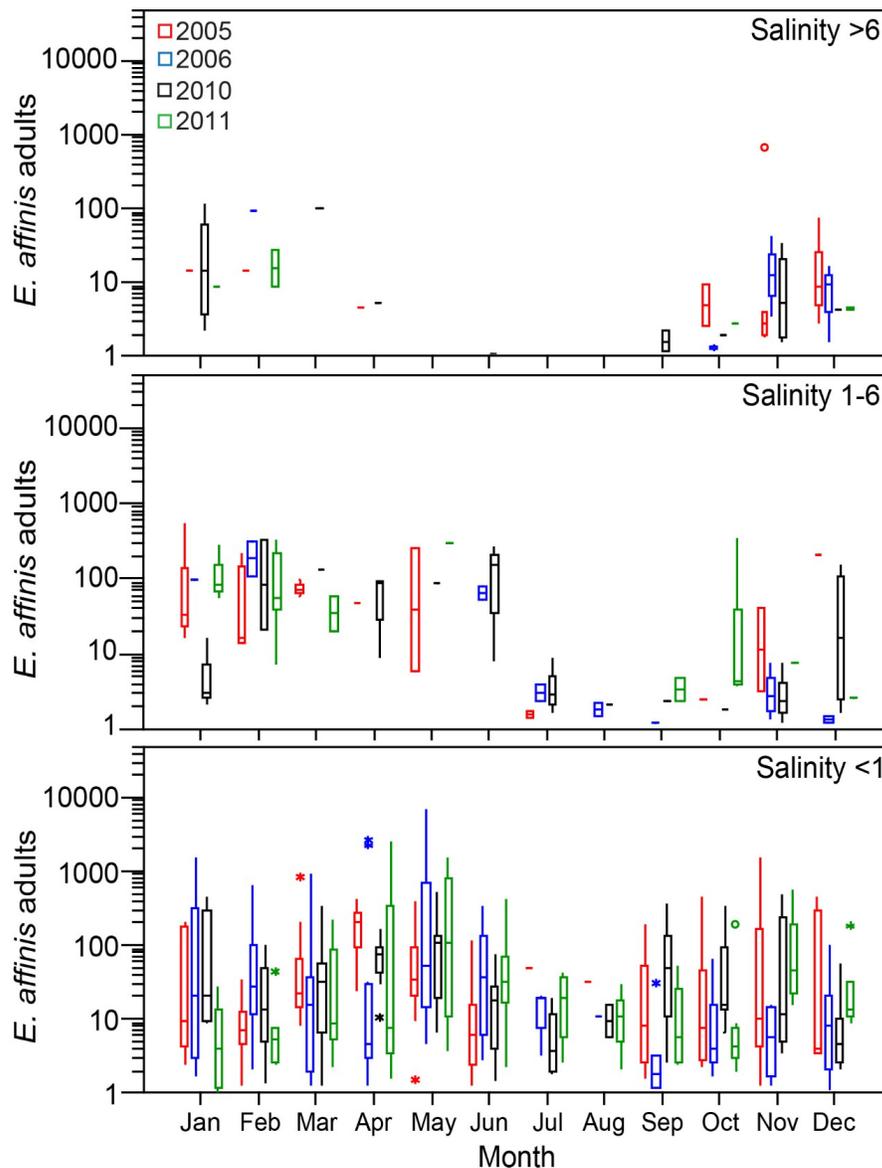

cyanobacteria. Similar shifts in species composition were noted by Brown (2009), with loss of diatom species, such as *Thalassiosira sp.*, an important food for calanoid copepods, including *Eurytemora affinis* and *Sinocalanus doerri* (Orsi 1995). More recently, Parker et al. (2012) found that the region where blooms are suppressed extends upstream into the Sacramento River to the SRWTP, the source of the majority of the ammonium in the river (Jassby 2008). Parker et al. (2012) found that at high ambient ammonium concentrations, river phytoplankton cannot efficiently take up any form of nitrogen including ammonium, leading to often extremely low biomass in the river. A study using multiple stable isotope tracers (Lehman et al. 2014) found that the cyanobacteria *M. aeruginosa* utilized ammonium, not nitrate, as the primary source of nitrogen in the central and western Delta. In 2009, the ammonia concentration in effluent from SRWTP was reduced by approximately 10%, due to changes in operation (K. Ohlinger, Sacramento Regional County Sanitation District, personal communication). In spring 2010 unusually strong spring diatom blooms were observed in Suisun Bay that co-occurred with low ammonia concentrations (Dugdale et al. 2013).

Jassby (2008) suggested the following comprehensive explanation for his observations. Phytoplankton production in the lower Delta is associated with flow and residence time; however, other factors introduce a substantial degree of interannual variability. Benthic grazing by *C. fluminea* is likely a major factor as grazing can exceed rates of primary production (Lucas et al. 2002, Lopez et al. 2006) and are abundant year round at some locations in the Delta (Fuller 2012). Current data are inadequate to estimate the overall magnitude of the grazing effect of *C. fluminea*. In Suisun Bay, benthic grazing by *P. amurensis* is a controlling factor that keeps phytoplankton at low levels. Thus, metazoan populations in Suisun Bay are dependent on importation of phytoplankton production from the upstream portions of the Delta. Upstream Delta phytoplankton can be lost via exports and within-Delta depletion; Cloern and Jassby (2012) reported phytoplankton losses equivalent to 30% of the primary production in the Delta. Ammonium concentrations and water clarity have increased; however, these two factors should have opposing effects on phytoplankton production. These factors likely also contribute to variability in the interannual pattern but the relative importance of each is unknown. The interactions among primary production, grazing, and transport time can be complex (Lucas et al. 2002, 2009a,b, Lucas and Thompson 2012).

The changes in phytoplankton production and invasion and establishment of the overbite clam *P. amurensis* were also accompanied by a series of major changes in consumers (Winder and Jassby 2011). Many of these changes likely negatively influenced pelagic fish production, including Delta Smelt. The quantity of food available to Delta Smelt is a function of several factors, including but not limited to seasonal trends in prey abundance and prey species specific salinity tolerances, which influence distribution (Kimmerer and Orsi 1996, Hennessy and Enderlein 2013). Seasonal peaks in abundance vary among calanoid copepods consumed as prey by Delta Smelt, *E. affinis* in April-May (Fig. 33), *P. forbesi* in July (Fig. 34), and *A. sinensis* in Sep-Oct (Fig. 35). Upstream, the calanoid copepod *S. doerrii* is most abundant May-June (Fig. 36). The seasonal trend in cladocerans (Fig. 37) and mysid (Fig. 38) prey are similar, being most abundant in summer.

From March through June, larval Delta Smelt rely heavily on first juvenile, then adult stages of the calanoid copepods *Eurytemora affinis* and *Pseudodiaptomus forbesi*, as well as cladocerans (Nobriga 2002, Hobbs et al. 2006, Slater and Baxter 2014), and *Sinocalanus doerrii* (Fig. 39). Nobriga (2002) found that Delta Smelt larvae expressed positive selection for *E. affinis* and *P. forbesi*, consuming these prey species in greater proportion than available in the environment. Such selection was not noted for other zooplankton prey. Regional differences in food use occur,

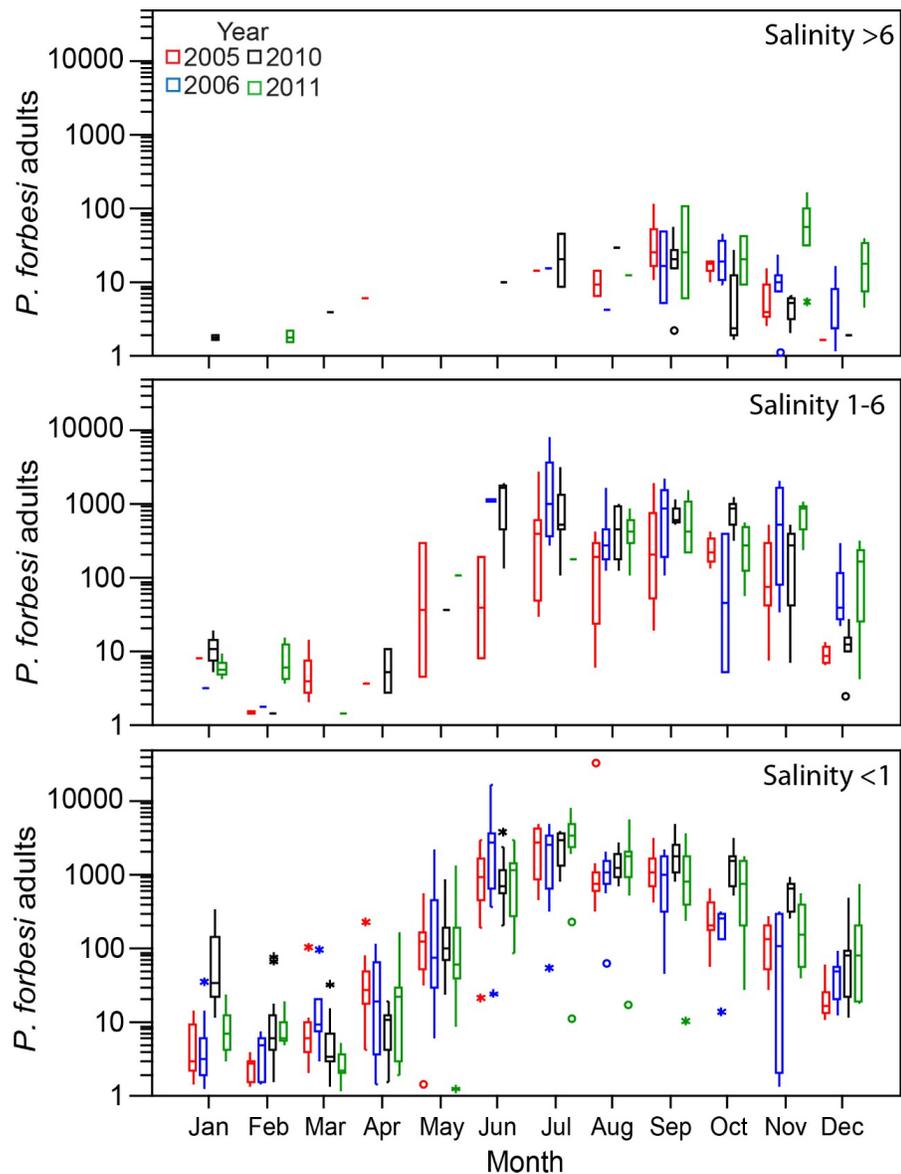

Figure 33. Density (number/m³) of adult *Eurytemora affinis* (*E. affinis*) by month for three salinity ranges. Each month 16 stations were sampled across all salinity ranges. with *E. affinis* and *P. forbesi* being major prey items downstream in the LSZ with a transition to *S. doerrii* and cyclopoid copepods as major prey items upstream into the Cache Slough-Sacramento River Deepwater Ship Channel (CS-SRDWSC) (Fig. 39).

Juvenile Delta Smelt (June-September) rely extensively on calanoid copepods such as *E. affinis* and *P. forbesi*, especially in freshwater (salinity < 1) and CS-SRDWSC but there is great variability among regions (figs. 40-43). Larger fish are also able to take advantage of mysids,

Figure 34. Density (number/m³) of adult *Pseudodiaptomus forbesi* (*P. forbesi*) by month for three salinity ranges. Each month 16 stations were sampled across all salinity ranges. cladocerans, and amphipods (Moyle et al. 1992, Lott 1998, Feyrer et al. 2003, Steven Slater, California Department of Fish and Wildlife, unpublished data) (Figs. 34-37). The presence of several epibenthic species in diets therefore indicates that food sources for this species are not confined to pelagic pathways. Such food sources may be especially important in regions of the estuary where there is extensive shoal habitat such as Liberty Island (Steven Slater, California Department of Fish and Wildlife, unpublished data).

See Chapter 3: Data Analyses for explanation of boxplots.

Subadult Delta Smelt (September through December) prey items are very similar to those of juvenile Delta Smelt but with increased variability in diet composition (Moyle et al. 1992, Lott 1998, Steven Slater, California Department of Fish and Wildlife, unpublished data) (Figs. 40-43) coinciding with the seasonal decline in pelagic zooplankton, such as *P. forbesi* (Fig. 34) and mysids (Fig. 38). Food habits of adult Delta Smelt during the winter and spring (January-May) have been less well documented (Moyle et al. 1992). In 2012, diet of adults in the LSZ and

< 1 ppt were found to include cyclopoid copepods, other than *Limnoithona* spp., with a mix of larger prey types, amphipods, cladocerans, cumaceans, and larval fish and in CS-SRDWSC the calanoid copepod *S. doerrii* continued to be a large portion of the diet (Steven Slater, California Department of Fish and Wildlife, unpublished data) (Fig. 44). Larval fish found in stomachs of Delta Smelt in the higher salinity areas were primarily Pacific Herring (*Clupea pallasii*), with

some Longfin Smelt, and Prickly Sculpin (*Cottus asper*) in the Sacramento River and CS-SRDWSC region; no Delta Smelt larvae were found in the stomachs of adults (Steven Slater, California Department of Fish and Wildlife, unpublished data).

The large proportion of benthic amphipods, cumaceans, and some cladocerans (*Camptocercus* spp.) in the diet is a notable change from Delta Smelt diet in the 1970s. Delta Smelt diets historically did include amphipods, notably *Corophium* spp. (Moyle et al. 1992), yet it was a small fraction of a mostly pelagic based diet. The considerable use of benthic invertebrates for food in recent years is believed to be in large part due to food limitation associated with the long-term decline and changes in composition of the pelagic food web (Slater and Baxter 2014). The quality of benthic invertebrates as food is not currently understood, but amphipods are lower in energy (calories per gram) than copepods (Cummins and Wuychek 1971, Davis 1993) and mysids (Davis 1993).

As noted previously, the changes in phytoplankton production and phytoplankton species abundances observed and the invasion of *P. amurensis* may have had important consequences for consumer species preyed upon by Delta Smelt. For example, there has been a decrease in mean zooplankton size (Winder and Jassby 2011) and a long-term decline in calanoid copepods, including a major step-decline in the abundance of the copepod *E. affinis*. These changes are possibly due to predation by the overbite clam (Kimmerer et al. 1994) or indirect effects of clam grazing on copepod food supply. Predation by *P. amurensis* may also have been important for other zooplankton species (Kimmerer 2008). Northern Anchovy *Engraulis mordax* abandoned the low salinity zone coincident with the *P. amurensis* invasion, presumably because the clam reduced planktonic food abundance to the point that occupation of the low-salinity waters was no longer energetically efficient for this marine fish (Kimmerer 2006). Similarly, Longfin Smelt *Spirinchus thaleichthys* shifted its distribution toward higher salinity in the early 1990s, also presumably because of reduced pelagic food in the upper estuary (Fish et al. 2009). There was also a decline in mysid shrimp (Winder and Jassby 2011), including a major step-decline in 1987–1988, likely due to competition with the overbite clam for phytoplankton (Orsi and Mecum 1996). Mysid shrimp had been an extremely important food item for larger fishes like Longfin Smelt and juvenile Striped Bass (Orsi and Mecum 1996), and may be consumed by larger Delta Smelt (Moyle et al. 1992). The decline in mysids was associated with substantial changes in the diet composition of these and other fishes, including Delta Smelt (Feyrer et al. 2003, Bryant and Arnold 2007). The population responses of Longfin Smelt and juvenile Striped Bass to winter–spring outflows changed after the *P. amurensis* invasion. Longfin Smelt relative abundance was lower per unit outflow after the overbite clam became established (Kimmerer 2002b). Age-0 Striped Bass relative abundance stopped responding to outflow altogether (Sommer et al. 2007). One hypothesis to explain these changes in fish population dynamics is that lower prey abundance reduced the system carrying capacity (Kimmerer et al. 2000, Sommer et al. 2007).

In addition to a long-term decline in calanoid copepods and mysids in the upper Estuary, there have been numerous copepod species introductions (Winder and Jassby 2011). *P. forbesi*, a calanoid copepod that was first observed in the estuary in the late 1980s, has replaced *E. affinis* as the most common Delta Smelt prey during the summer. It may have a competitive advantage over *E. affinis* due to its more selective feeding ability. Selective feeding may allow *P. forbesi* to utilize the remaining high-quality algae in the system while avoiding increasingly more prevalent low-quality and potentially toxic food items such as *M. aeruginosa* (Mueller-Solger et al. 2006, Ger et al. 2010a). After an initial rapid increase in abundance, *P. forbesi* declined somewhat in abundance from the early 1990s in the Suisun Bay and Suisun Marsh regions but maintained its abundance, with some variability, in the central and southern Delta (Winder and Jassby 2011).

Although substantial uncertainties about mechanisms remain, the decline of *P. forbesi* in the Suisun region may be related to increasing recruitment failure and mortality in this region due to competition and predation by *P. amurensis*, contaminant exposures, and entrainment of source populations in the Delta (Mueller-Solger et al. 2006, Winder and Jassby 2011, Durand 2010).

The abundance of a more recent invader, the cyclopoid copepod *Limnoithona tetraspina*, significantly increased in the Suisun Bay region beginning in the mid-1990s. It is now the most abundant copepod species in the Suisun Bay and confluence region of the estuary (Bouley and Kimmerer 2006, Winder and Jassby 2011). Gould and Kimmerer (2010) found that it grows slowly and has low fecundity. Based on these findings they concluded that the population success of *L. tetraspina* must be due to low mortality and that this small copepod may be able to avoid visual predation to which larger copepods are more susceptible. It has been hypothesized that *L. tetraspina* is an inferior food for pelagic fishes including Delta Smelt because of its small size, generally sedentary behavior, and ability to detect and avoid predators (Bouley and Kimmerer 2006, Gould and Kimmerer 2010). Nevertheless, this copepod has been found in the guts of Delta Smelt when *Limnoithona* spp. occurs at extremely high densities relative to other zooplankton (Slater and Baxter 2014). Recent experimental studies addressing this issue suggest that larval Delta Smelt will consume and grow on *L. tetraspina*, but growth is slower than with *P. forbesi* (Kimmerer et al. 2011). It remains unclear if consuming this small prey is energetically beneficial for Delta Smelt at all sizes or if there is a breakpoint above which larger Delta Smelt receive little benefit from such prey. *Acartiella sinensis*, a calanoid copepod species that invaded at the same time as *L. tetraspina*, also reached considerable densities in Suisun Bay and the western Delta over the last decade (Hennessy 2010), although its suitability as food for pelagic fish species remains unclear.

Preliminary information from studies on pelagic fish growth, condition, and histology provide additional evidence for food limitation in pelagic fishes in the estuary (IEP 2005). In 1999 and 2004, Delta Smelt growth was low from the Sacramento-San Joaquin confluence through Suisun Bay relative to other parts of the system. Delta Smelt collected in 2005 from the Sacramento-San Joaquin confluence and Suisun Bay also had high incidence of liver glycogen depletion, a possible indicator of food limitation (Bennett et al. 2008). As previously noted, warm water temperatures during the summer period may have exacerbated lack of food by raising the metabolic rate of Delta Smelt. Based on data for histopathology, date of birth from otoliths, and growth rates from otoliths of Delta Smelt in 2005, Bennett et al. (2008) proposed a novel strategy for Delta Smelt survival in 2005. Natural selection appeared to favor individuals with a specific set of characters, including relatively slow larval development, but faster than average juvenile growth in July. Water temperatures in July typically include the annual maximum (Fig. 16). The salinity field can also change rapidly as freshwater flow out of the Delta changes. Many of these fish surviving into the pre-adult stage had also hatched earlier in the spawning season (i.e., before May).

For many fishes, success at first feeding is believed to be critical to larval survival and a major cause of year-class variability (e.g., “critical period hypothesis,” Hjort 1914, Leggett and DeBlois 1994). In Rainbow Smelt *Osmerus mordax* a related smelt species, calculated larva mortality rates were related to feeding conditions at first feeding that varied on a predictable cycle of 15 days associated with tide and photoperiod (Sirois and Dodson 2000b). In feeding experiments, copepod evasion behavior affected capture by larval Striped Bass, and *E. affinis* was among the more easily captured species (Meng and Orsi 1991). There has been a long-term decline in calanoid copepods in the upper estuary, particularly in the Suisun Region (Winder and Jassby 2011), potentially reducing feeding success, growth and thereby survival. Currently, *E. affinis*

abundance peaks in spring (Hennessy 2010, 2011) coincident with hatching of Delta Smelt. *E. affinis* abundance has been negatively related to X2 since the overbite clam invasion (Kimmerer 2002b). When X2 is “high” outflow is low and *E. affinis* densities are low. These lines of evidence suggest that the first feeding conditions may improve in springs with higher outflow.

Changes in the quality and quantity of available prey may have contributed to the observed reduction in the mean size of Delta Smelt in fall since the early 1990s (Sweetnam 1999, Bennett 2005); however, mean size subsequently increased. The importance of food resources as a driver is supported by Kimmerer (2008), who showed that Delta Smelt survival from summer to fall is correlated with biomass of copepods in the low salinity zone, the central 50% of the summer Delta Smelt distribution. Other variations of this correlation were shown by Maunder and Deriso (2011) and Miller et al. (2012). Miller et al. (2012) have tested for an explicit influence of prey density during the fall. Miller et al. (2012) found a stronger correlation between Delta Smelt abundance during the fall and prey density during the fall than for prey density during the summer.

Harmful algal blooms

Periodic blooms of the toxic blue-green alga *Microcystis aeruginosa* during late summer, most commonly August and September are an emerging concern for Delta Smelt (Lehman et al. 2005, Lehman et al. 2013). Although this harmful algal bloom (HAB) typically occurs in the San Joaquin River away from the core summer distribution of Delta Smelt, some overlap is apparent during blooms and as cells and toxins are dispersed downstream after blooms (Baxter et al. 2010). Density rankings of *Microcystis* at TNS stations were highest in the south Delta, east Delta and lower San Joaquin River regions; yet *Microcystis* distribution may be expanding north over time (Morris 2013). Moreover, studies by Lehman et al. (2010) suggest that Delta Smelt likely are exposed to microcystins, which may degrade their habitat and perhaps affect the distribution of Delta Smelt (Baxter et al. 2010). For example, these HABs are known to be toxic to another native fish of the region, Sacramento Splittail (Acuña et al. 2012a) and the alien Threadfin Shad (Acuña et al. 2012b). Histopathology evidence from Lehman et al. (2010) suggested the health of two common fish in the estuary, Striped Bass, and Mississippi Silversides, was worse at locations where microcystin concentrations were elevated.

Indirect effects are also likely as *Microcystis* blooms are toxic to copepods that serve as the primary food resources of Delta Smelt (Ger et al. 2009, 2010a,b). Ger et al. (2009) determined toxicity of one form of microcystin (LR) to two species of calanoid copepods, *E. affinis* and *P. forbesi*, which are important as food to Delta Smelt. They found that, although the copepods tested were relatively sensitive to microcystin-LR compared to other types of zooplankton, ambient concentrations in the Delta were unlikely to be acutely toxic. However, chronic effects were not determined and Lehman et al. (2010) found that *Microcystis* may indeed contribute to changes in phytoplankton, zooplankton and fish populations in the Delta.

Factors that are thought to cause more intensive *Microcystis* blooms include warmer temperatures, lower flows, high nitrogen levels, and relatively clear water (Lehman et al. 2005, Baxter et al. 2010, Lehman et al. 2013, Morris 2013). These conditions occur during dry years in the SFE. Both *Microcystis* abundance and microcystin concentrations have been greater in recent years with dry year conditions (Lehman et al. 2013). These factors can also interact. For example, low flows can provide less dilution of ammonium from wastewater treatment plants (Jassby and Van Nieuwenhuysse 2005, Dugdale et al. 2012, Dugdale et al. 2013) and *Microcystis* can

readily utilize ammonium as a primary nitrogen source during blooms (Lehman et al. 2013). The intensity and duration of *Microcystis* blooms are expected to increase over the long-term, along with any negative impact on aquatic organisms, due to increased frequency of drought conditions associated with climate change (Lehman et al. 2013).

Chapter 5: Updated Conceptual Models for Delta Smelt

In this Chapter we transfer the information on drivers and Delta Smelt responses reviewed and presented in Chapter 4 into the conceptual model framework established in Chapter 3. The Delta Smelt general life cycle conceptual model recognizes the pervasive, year-round importance of the tier 1 landscape attributes and the seasonal importance of the various tier 2 environmental drivers and tier 3 habitat attributes to the tier 4 life stage transitions of Delta Smelt in the four tier 5 “transition seasons” (Fig. 45). Some habitat attributes – food, toxicity, and predation – affect life stage transitions in all seasons, while other habitat attributes – temperature, entrainment and transport, size and location of the low salinity zone, and harmful algal blooms – affect some life stage transition more than others. Clearly, adequate food must be available at all life stages for Delta Smelt to survive. Toxicity is included during all seasons because we know that contaminants of various types are present throughout the year; however, little is known about the direct or indirect effects of contaminants at ambient concentrations on individual Delta Smelt or the population as a whole. Predation is included in all seasons because we recognize that predation is likely the ultimate cause of mortality for most individual fish; however, responses of Delta Smelt to other habitat attributes and environmental drivers such as food availability and turbidity can modify predation risk.

The mechanistic linkages between landscape attributes, environmental drivers, habitat attributes and Delta Smelt responses in the four life stage seasons are depicted as one-way arrows in four new “life stage transition” conceptual models (Figs. 46-49). As mentioned in Chapter 3, the life stage transition conceptual models are nested components of the general life cycle conceptual model (Fig. 8). Each life stage transition conceptual model (Figs. 46-49) includes the habitat attributes hypothesized to affect the transition of Delta Smelt from one life-stage to the next. Hypotheses selected for detailed consideration in Chapter 7 are indicated by “H” in the diagrams. The models also show the landscape attributes and environmental drivers. While the models include many linkages among individual landscape attributes, environmental drivers, and habitat attributes, they do not include linkages between individual habitat attributes and the specific biological processes (growth, survival, reproduction) underlying the life stage transitions. The primary reason for this simplification is that the available data are generally inadequate to fully describe and differentiate among specific functional relationships and mathematical modeling that could help estimate them is beyond the scope of this report. Instead, the combined effects of all habitat attributes on the life stage transition probability are depicted by one upward arrow in each life stage transition conceptual model. This does not imply, however, that all habitat attributes have an equal role in determining life stage transition probability and population success or that the role of each habitat attribute remains constant from year to year.

In the remainder of this Chapter we briefly describe the linkages and associated hypotheses depicted in each of the life stage transition conceptual model diagrams (figs. 46-49). These

Figure 45. Delta Smelt general life cycle conceptual model.

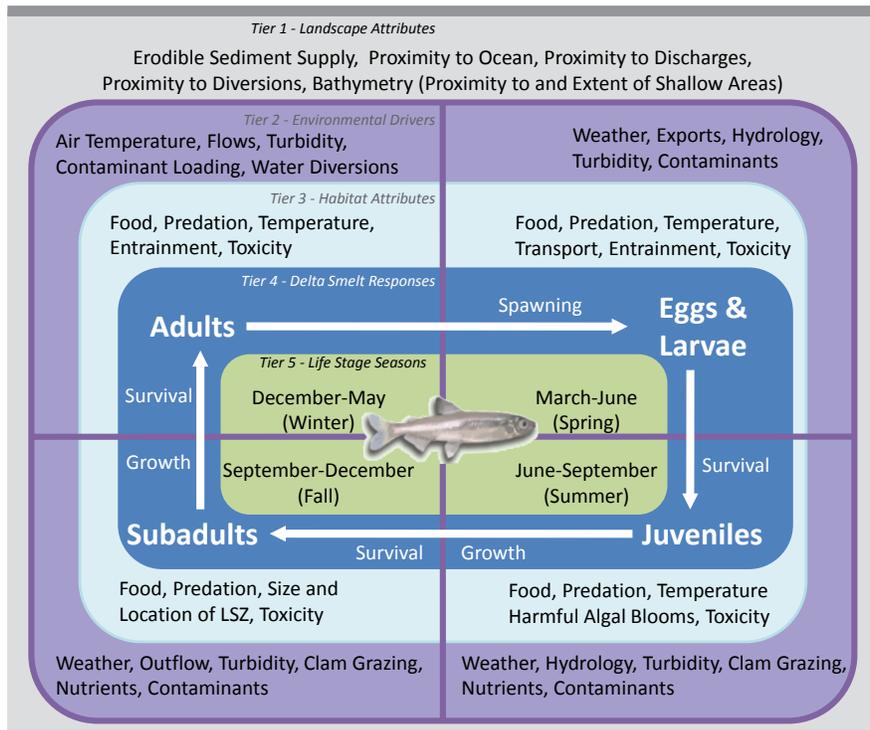

Figure 46. Conceptual model of drivers affecting the transition from Delta Smelt adults to larvae. Hypotheses addressed in Chapter 7 are indicated by the “H-number” combinations.

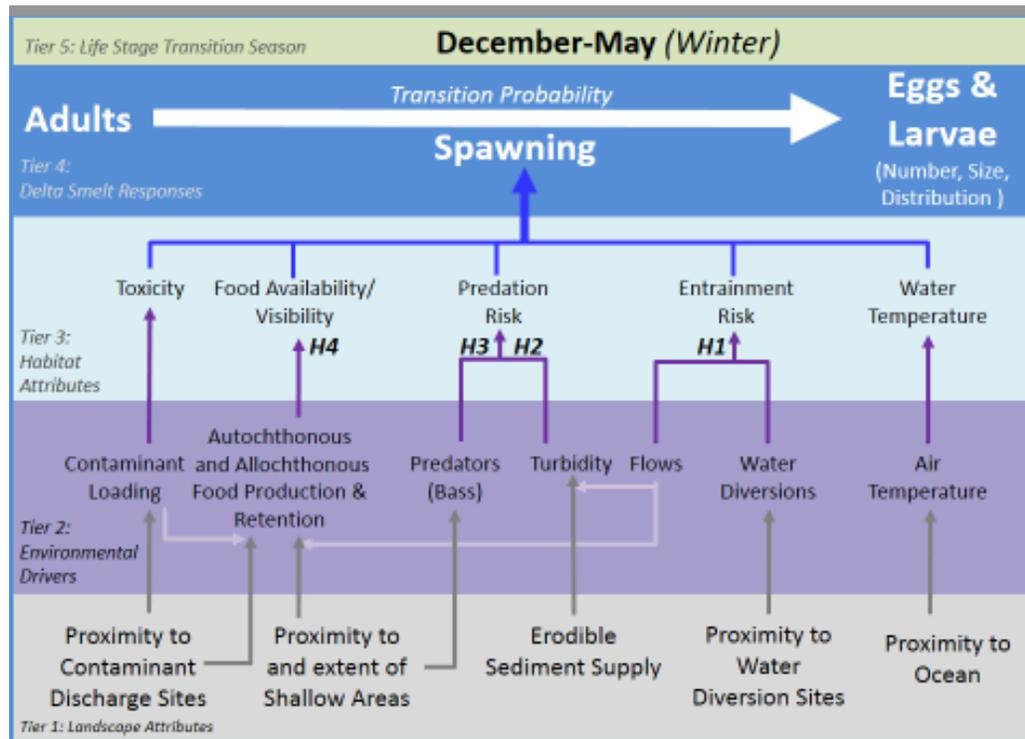

Figure 47. Conceptual model of drivers affecting the transition from Delta Smelt larvae to juveniles. Hypotheses addressed in Chapter 7 are indicated by the “H-number” combinations.

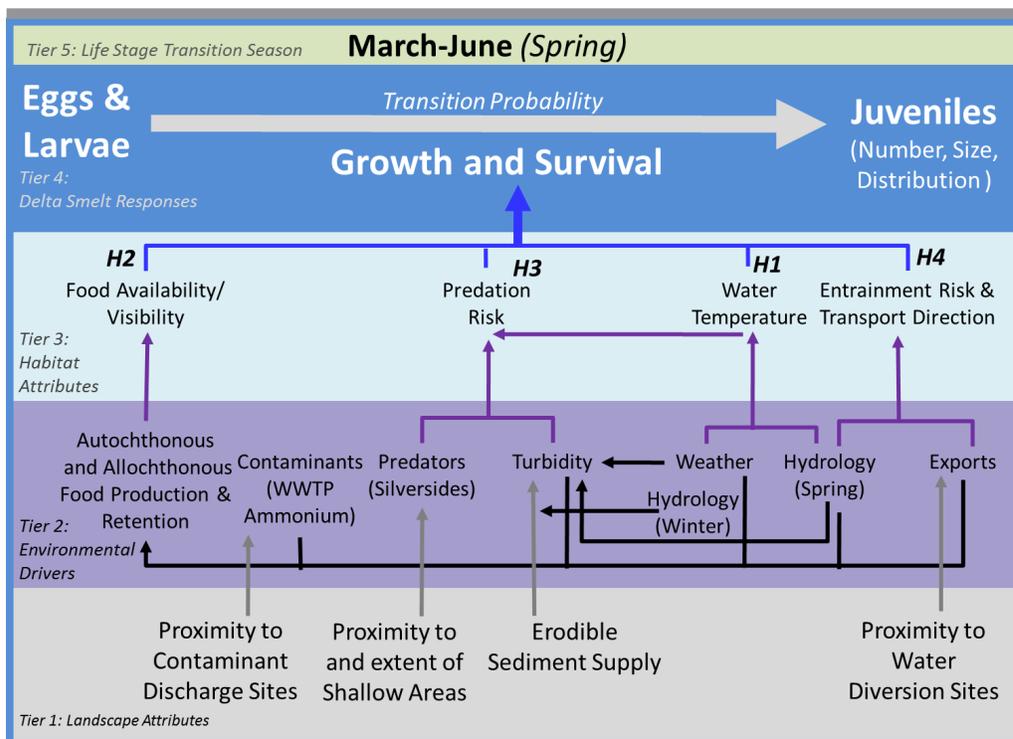

Figure 48. Conceptual model of drivers affecting the transition from Delta Smelt juveniles to subadults. Hypotheses addressed in Chapter 7 are indicated by the “H-number” combinations.

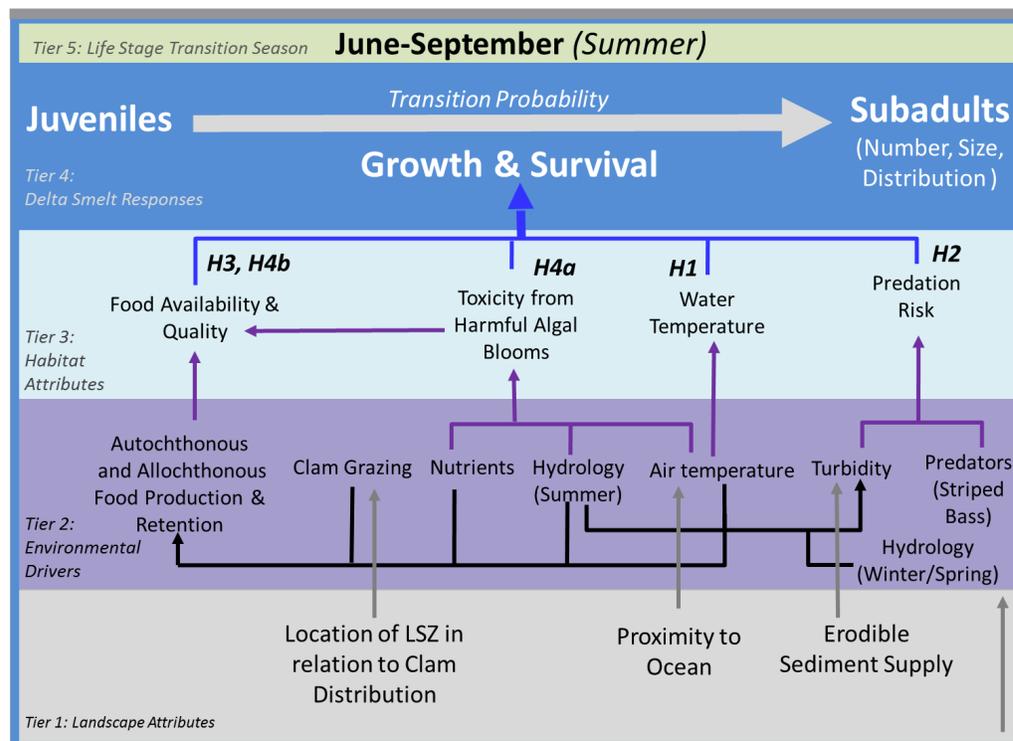

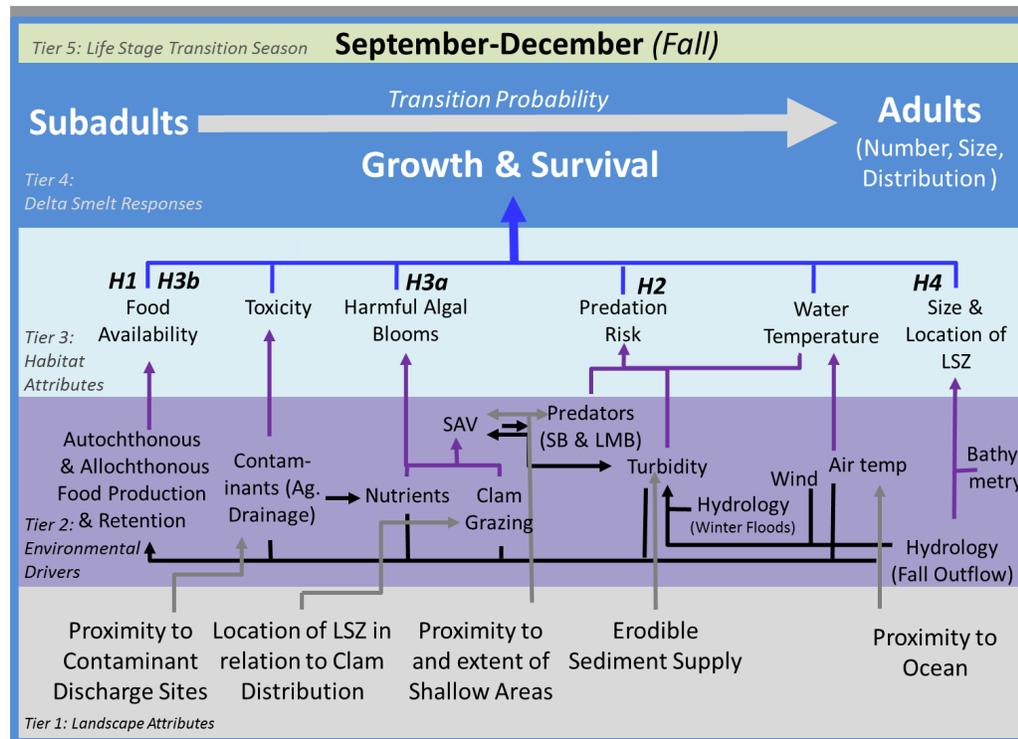

Figure 49. Conceptual model of drivers affecting the transition from Delta Smelt subadults to adults. Hypotheses addressed in Chapter 7 are indicated by the “H-number” combinations.

hypotheses are stated and addressed in more detail in Chapter 7. All hypotheses focus on the life stage that is transitioning to (i.e. occurs prior to) the next life stage, for example, adults but not eggs and larvae, larvae and post-larvae but not juveniles, and so on. That said, it is important to remember that all life stages overlap and all transitions except for the transitions from adults to eggs and from eggs to freshly hatched larvae are gradual, not abrupt, and delineations of life stages are somewhat arbitrary (see Chapter 3).

The life stage conceptual model for the transition of adult Delta Smelt to eggs and larvae (Fig. 46) includes 5 habitat attributes. Because of the lack of information about specific contaminant effects on Delta Smelt noted above, there are no specific hypotheses regarding the effects of contaminants and possible direct or indirect toxicity on Delta Smelt, but based on the information discussed in Chapter 4, the model does recognize that effects on Delta Smelt or its food supply may be occurring. Food availability and visibility are hypothesized to be important with respect to providing nutrition that allows Delta Smelt to grow into healthy, large adults that can produce a large numbers of high quality eggs as well as multiple clutches of eggs over the spawning season. The availability of food is considered dependent on both food production and the availability of such food to the fish. There are two hypotheses related to predation risk. The first is that turbidity, created by the interaction of high winter and spring flows with the erodible sediment supply in the watershed and within the Delta, influences the vulnerability of Delta Smelt to predators that co-occur with them. The second is that Delta Smelt behaviors that bring Delta Smelt close to channel edges may increase their vulnerability to Largemouth Bass, which generally occupy nearshore and vegetated habitats such as SAV beds. Entrainment risk in this life stage transition conceptual model is focused on adults. Entrainment of adults would reduce the reproductive

potential of the population. Entrainment risk depends on the distribution of the adult Delta Smelt in relation to water diversions, and the magnitudes of water diversions and flows. Delta water temperature determines the beginning and duration of the spawning season (hereafter “spawning window”).

The life stage conceptual model for the transition of Delta Smelt eggs and larvae to juveniles includes 4 habitat attributes (Fig. 47). Food production and availability is important for the survival of larvae to juveniles. Food quantity is dependent on multiple interacting factors. Turbidity is important for early feeding by delta smelt larvae. Predation risk focuses on predation of Mississippi Silversides on Delta Smelt larvae because of recent evidence that such predation occurs. Predation risk is hypothesized to depend on co-occurrence of the two species, with Mississippi Silverside generally being associated with shallower waters, turbidity, which decreases the effectiveness of predators, and water temperature, which affects energy requirements of predators (hunger level). In addition to its effect on predator bioenergetics, water temperature is hypothesized to affect the length of the spawning season (spawning window). If food availability is sufficient, then a longer spawning window may allow the adult population to produce multiple clutches of eggs, resulting in more young. This hypothesis could arguably be included in the previous life stage transition conceptual model, but considering it here allows for consideration of predation on larvae in the context of the time period over which larvae are being produced. Larvae are also at risk of entrainment or transport to unfavorable areas. The magnitude of this risk is hypothesized to depend on an interaction of spring hydrology and water exports. As indicated by numerous arrows, winter and spring hydrology affect Delta Smelt spawning and larval rearing habitat in many ways. We thus also include a more general hypothesis about the hydrological effects on Delta Smelt larval abundance and recruitment.

The life stage conceptual model for the transition of Delta Smelt juveniles to subadults includes 4 habitat attributes (Fig. 48). In addition, there is a stand-alone hypothesis dealing with population dynamics. Juvenile growth and survival is hypothesized to depend on availability and quantity of food. Food production during this summer period is hypothesized to involve complex interactions of clam grazing, nutrients, hydrology and harmful algal blooms. The probability of observing a harmful algal bloom is hypothesized to be a function of the same factors but with temperature playing an important role. Harmful algal blooms may also affect Delta Smelt directly through production of toxic microcystins. Summer water temperatures are hypothesized to have a very direct effect on juvenile Delta Smelt with water temperatures hypothesized to reach stressful levels, affecting their bioenergetics and the area of suitable habitat. The transition probability hypothesis is that at the currently small population sizes, survival from juvenile to subadult is density independent, meaning independent of the number of individuals present (see Chapter 6 for details).

The life stage conceptual model for the transition of Delta Smelt subadults to adults includes 6 habitat attributes (Fig. 49). As for the previous conceptual model, there is a stand-alone hypothesis dealing with population dynamics. As in the previous conceptual model, growth and survival are hypothesized to depend on food availability and food production and availability depends on interactions of a variety of landscape attributes and environmental drivers. Toxicity is recognized as potentially important but no specific hypotheses have been tested. Harmful algal blooms may still be present with hypothesized direct effects on Delta Smelt subadults and indirect effects on their food. Predation risk on subadult Delta Smelt is hypothesized to depend on co-occurrence of Delta Smelt with the two most likely predators, Largemouth Bass and Striped Bass. Largemouth Bass occurrence is linked with that of SAV and the vulnerability of prey to both predators is affected by turbidity and bioenergetics. Water temperature is mainly

hypothesized to have an effect through bioenergetics because water temperature becomes less stressful than in the summer. In this conceptual model the size and location of the LSZ is considered both a landscape attribute and a habitat attribute. In the earlier conceptual models, the LSZ was mainly viewed as a landscape attribute that interacted with other landscape attributes and environmental drivers to create habitat attributes. In this conceptual model the size and position of the LSZ is hypothesized to have certain characteristics that directly determine habitat quantity and quality for Delta Smelt. The transition probability hypothesis is that at the currently small population sizes, survival from subadult to adult is density independent, meaning independent of the number of individuals present (see Chapter 6 for details).

Chapter 6: Delta Smelt Population Biology

This Chapter consists of two main parts. In the first part, we introduce general concepts in population biology that are utilized in the following sections of this Chapter and to generally describe Delta Smelt population dynamics. Explaining these concepts and population trends now is intended to reduce repetitive text in the remaining sections and to reduce possible confusion for readers unfamiliar with the concepts. The concepts are discussed specifically in the context of Delta Smelt.

In the second part of this Chapter, we review information about the life history and population trends of each Delta Smelt life stage represented in our conceptual models, starting with adults. While we describe trends over the entire available time series for each life stage, we pay particular attention to differences in Delta Smelt abundance and life stage transitions between the two most recent wet years, 2006 and 2011. Our working assumption is that these differences should be attributable to differing habitat conditions and, in some cases, management actions. Differences in habitat conditions between these two years will be further explored in Chapter 7.

Population Biology

Recruitment is the addition of new individuals to a population through reproduction or immigration. In fisheries science, the term recruitment was first used by Ricker (1954) to describe the addition of fish of a new generation to a fish population, in other words, the number of young surviving to a particular age or life stage. We use the term recruitment to refer to production of larvae, juveniles, subadults, or adults by adults of the previous generation. Relationships between numbers of spawning fish or other measures of potential spawning stock (e.g., numbers of subadult or mature prespawning fish) and the numbers of fish of a given age or life stage in the subsequent generation are known as stock-recruitment relationships.

Stock-recruitment relationships have been described for many species and are a central part of the management of commercially and recreationally fished species (Myers et al. 1995, Touzeau and Gouze 1998). Different forms of stock-recruitment relationships are possible, including density-independent, density-dependent, and density-vague types. The density-independent type occurs when the current size of the population has little or no effect on the number of recruits (except possibly when stock size is extremely low). This type of population growth is rare in fish

populations and occurs when environmental factors largely determine the survival and number of recruits (e.g., the Longfin Smelt outflow abundance relationship; see Myers 1998). Density dependence occurs when the current population size affects survival and abundance of recruits and thus population growth. In such populations, within the lower range of stock size, the number of recruits is strongly and positively related to stock size. At some point as stock size increases, competition for food (or some other limiting factor) between the adult population and recruits affects survival and abundance of recruits; cannibalism is another means by which recruitment can be affected by stock size. Thus, the growth and survival of the recruit population strongly depends on the density of the stock population. In reality it's difficult to determine which type of response is occurring (e.g., Myers and Barrowman 1996). Moreover, a predominantly annual fish, such as Delta Smelt, is predicted to conform poorly to models that assume density-dependent recruitment (Winemiller 2005), which appears to be the case (e.g., Rose et al. 2013).

The idea of density dependence is related to the idea of carrying capacity. The carrying capacity of an ecosystem is the number of individuals of all species that can be supported by the available resources. In reality it can be very difficult to apply this idea to a single species in an ecosystem because of the complex relationships among species and the seasonal, annual, and other changes in resource availability. The density vague type of population growth refers to situations where there is not a statistically demonstrable stock-recruitment relationship observable in available data.

In density-dependent stock-recruitment relationships, the factors causing the density dependence can operate at various points in the life cycle of the new generation. For some species, the concept of density dependence is separated into two concepts. In this formulation, density-dependent stock recruitment is limited to the direct effects of the adult stock on recruitment of the next generation, as described above. For example, if a large spawning stock has a limited spawning area, as in the case of salmonids, then successive waves of female spawners are known to re-excavate previous nests while building their own, substantially increasing mortality of the eggs. Density dependence could also occur at the larval or juvenile stage if adults are predatory and feed on young, or if adults are in direct competition for food or space with young. The second concept of density-dependent survival is often inextricably linked to density-dependent stock-recruit relationships because the mechanisms causing declines in recruits at high stock levels are unknown. In density-dependent survival, the abundance of young affects their own survival.

In the case of Delta Smelt, density dependent survival could occur if many of the larvae starved because of insufficient food supplies due to competition with other Delta Smelt larvae, or other species. Because many Delta Smelt die after their first spawning, density-dependent survival is certainly the dominant mechanism for the species and for the remainder of this report the direct effects of adults on survival of eggs and larvae are assumed to be minimal. If resources were sufficient for larvae and juvenile fish to survive in large numbers, the surviving subadults might overwhelm food sources (i.e., surpass carrying capacity), resulting in low survival and poor reproductive output. Thus, it is important to understand species ecology and survival between life stages to understand how density dependence is affecting a population. This is particularly important for fishes in estuaries where environmental factors can create large variation in habitat size and food web productivity from season to season and year to year, thus affecting carrying capacity and the potential for density-dependent survival.

Density-independence is more straightforward. In this case, the population is controlled by factors unrelated to the density of the population. For example, high water temperatures will affect individual fish, whether the population is large or small. In reality, populations can be

affected by both density-dependent and density-independent factors at different times. This interaction is the basis for the idea of compensatory density dependence. In this formulation, a population is governed by density independent factors when population size is small. As the population increases and approaches the carrying capacity, density-dependent factors become important and the population growth rate declines. Fluctuations in carrying capacity, as noted above, are an added complication. Again, it is essential to understand the ecology of the species and survival between life stages to understand the relative importance of density dependent and density independent factors.

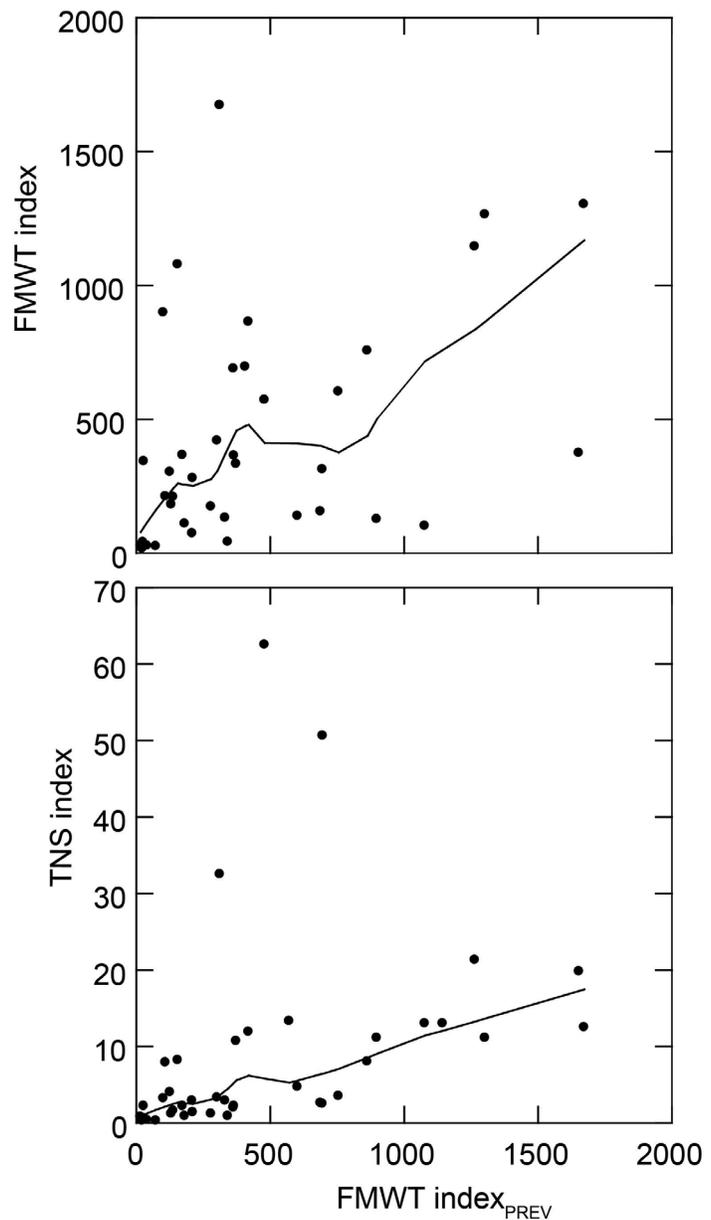

Unfortunately, Delta Smelt were never of sufficient interest as a commercial or recreational species to warrant development of stock-recruitment models until they were listed. Data now used to develop stock-recruitment models for Delta Smelt started becoming available after the initiation of fisheries studies and monitoring surveys in the late 1950s (TNS initiated 1959; FMWT initiated 1967) in association with the planning and operation of the CVP and SWP. These IEP fish monitoring surveys were designed to produce relative abundance indices or catch-per-unit-effort (CPUE, e.g., number per trawl) that could be used to monitor trends in abundance over time. More recently, annual abundance indices based on these surveys have also been incorporated into stock-recruit relationships (e.g., Moyle et al. 1992, Sweetnam and Stevens 1993, Miller 2000, Bennett 2005, Maunder and Deriso 2011). Neither of these early IEP fish monitoring surveys (TNS, FMWT) were specifically designed to monitor Delta Smelt, but instead targeted primarily the commercially and recreationally more important Striped Bass. As researchers began using TNS and FMWT indices for Delta Smelt analyses, they began investigating how the indices performed and means to improve them (see Wadsworth and Sommer 1996, Miller 2000, Newman 2008). This work is ongoing and also includes similar investigations for the newer SKT (initiated in 2002) and 20 mm survey (initiated in 1995) monitoring surveys.

The two stock-recruitment relations based on the longest data records include the relationship of the FMWT abundance index with the FMWT abundance index in the previous year and the relationship of the TNS abundance index with the FMWT abundance index in the previous year (Fig. 50). Because of the large changes that have occurred in the Delta ecosystem, including the invasion by *P. amurensis* and the POD, these plots can be difficult to interpret because carrying capacity is assumed to have changed (Bennett 2005, Kimmerer et al. 2000, Sommer et al. 2007). It does appear that there is much more variability associated with the FMWT relationship compared to the TNS relationship. This might indicate variable survival between the juvenile and subadult life stage.

In any form of a stock-recruitment model, there is a point at which low adult stock will result in low juvenile abundance and subsequent low recruitment to future adult stocks. This can occur even under favorable environmental conditions while the stock “rebuilds” itself. From a stock-recruitment perspective, the recent low abundance of Delta Smelt is of particular concern. Since about 2002, the current population is smaller than at any time previously in the record, with the exception of the 2011 year class. This strong year class suggests that Delta Smelt have yet to reach low levels where the stock will need years to rebuild, at least to pre-POD levels (Fig. 3).

In addition to their use in exploring stock-recruitment relationships, ratios of annual Delta Smelt abundance indices can also be used to obtain rough estimates of relative annual recruitment and survival rates (figs. 51 and 52). As for the stock-recruitment relationships these recruitment and survival indices should be interpreted with caution given the large changes that have taken place in the Delta and the absence of estimates of variability for the indices. The main utility of these

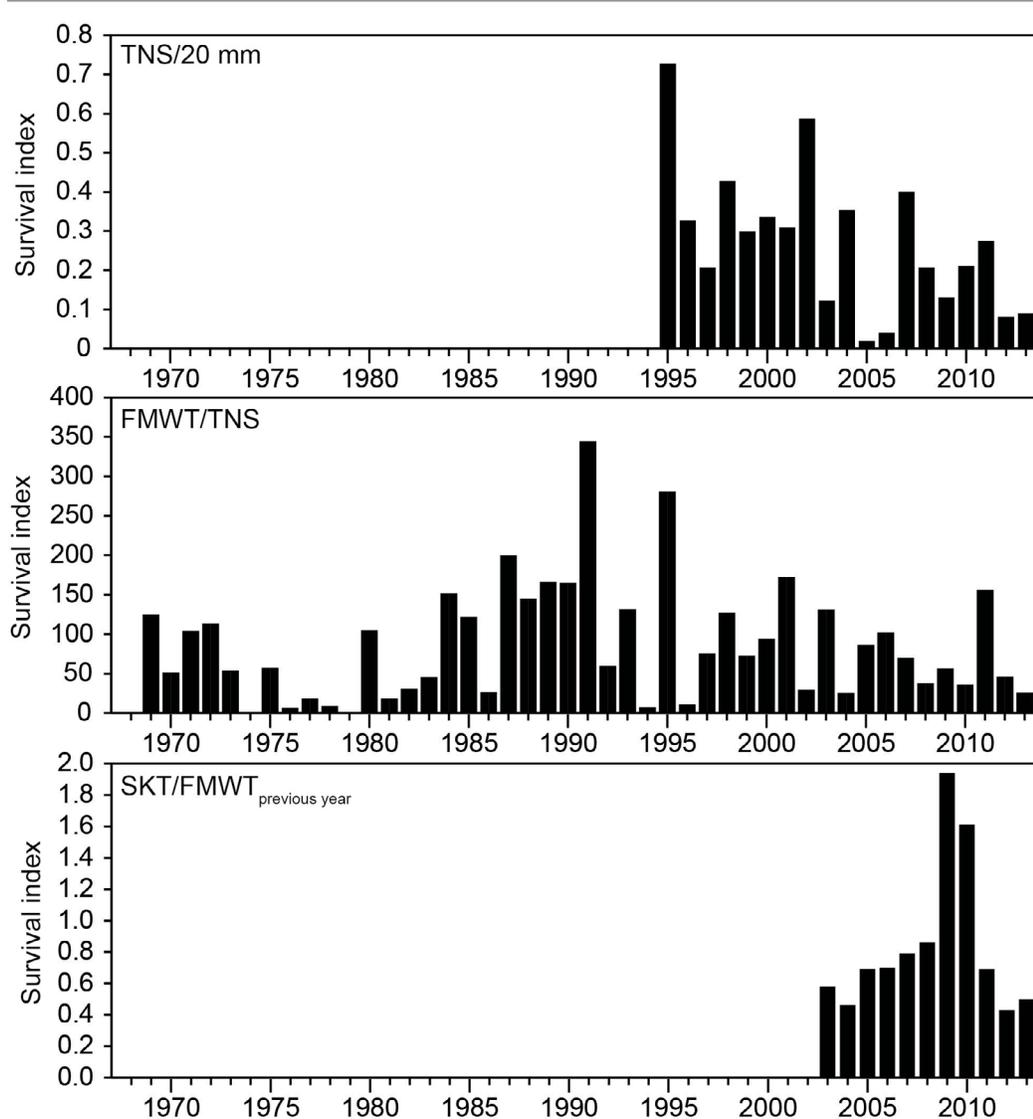

Figure 50. Scatterplots and LOWESS splines depicting the relationship of the Fall Midwater Trawl index of Delta Smelt relative abundance (FMWT) (1968-2012) and Summer Towntnet Survey (TNS) (1969-2012) with the FMWT in the previous year.

indices is identifying years with relatively high or low survival for a specific life stage transition or life stage transitions with differences in annual variability.

Here, we use the ratios of abundance indices for different life stages of the same generation as indices of survival (survival indices, Fig. 51) and the ratios of current to preceding year abundance indices as indices of recruitment (recruitment indices, Fig. 52). For the density-independent case, recruitment rate is independent of the size of the adult population. The number

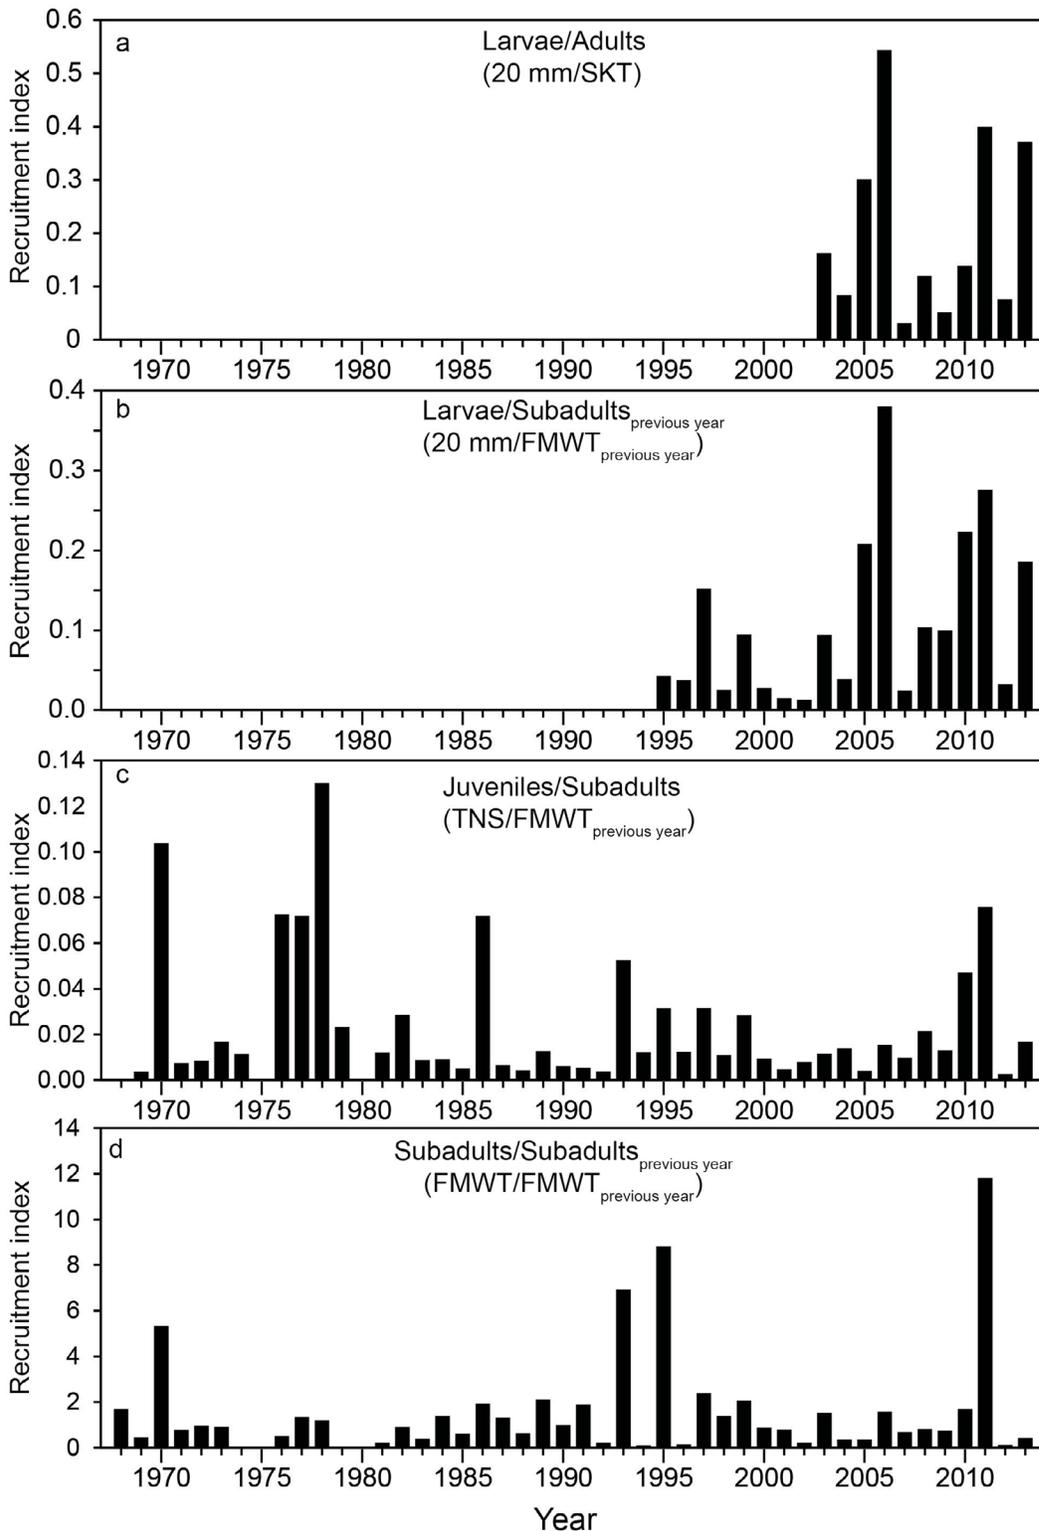

Figure 51. Stage to stage survival indices based on data from Summer Townet Survey (TNS), Fall Midwater Trawl (FMWT), and Spring Kodiak Trawl (SKT).

of recruits produced is the product of recruitment rate and the size of the adult population. For this report, we assume that the estimates have sufficiently low and comparable uncertainty to provide worthwhile interpretations, as long as caution is exercised. It is also important to remember that abundance, survival, and recruitment index values are only meaningful in a relative, not in an absolute sense.

The annual stage to stage survival indices from larvae to juveniles, subadults, and adults are shown in Figure 51. The relative recruitment rates from adults and subadults in one year to larvae, juveniles, and subadults the next year are shown in Figure 52. We recognize that a life cycle model with environmental covariates is needed to fully assess the combined effects of stock-recruitment and stage-to-stage survival indices on Delta Smelt population dynamics. Nevertheless, examination of the recruitment and survival index data sets reveal several interesting patterns for the POD period (2003-2013).

Figure 52. Delta Smelt recruitment indices based on the annual adult, larval, juvenile, and subadult abundance indices provided by the Spring Kodiak Trawl (SKT, adults), 20 mm Survey (20 mm, larvae), Summer Townet Survey (TNS, juveniles), and Fall Midwater Trawl (FMWT, subadults).

First, interannual variability in these stock and survival indices declines from larval recruitment (coefficient of variation (CV): 92%), to subsequent larvae to juvenile survival (CV: 67%), juvenile to subadult survival (CV: 43%), to subadult to adult survival (CV: 38%). This result is consistent with expected highly dynamic patterns of recruitment and survival for an annual opportunistic species such as Delta Smelt. The pattern of reduced variability in survival for larger fish suggests that older fish may no longer be vulnerable to some forms of mortality affecting earlier life stages either because a factor is no longer important when larger fish are present (e.g., effect of summer high water temperatures on juveniles) or that larger fish escape some forms of mortality (e.g., larger fish are no longer eaten by the large variety of predators able to consume larvae).

Second, the patterns of adult and larval abundance (Fig. 3) and adult to larvae recruitment (Fig. 52a) suggest: (1) even a small adult Delta Smelt stock can produce a large number of larvae under the right habitat conditions; but (2) larval recruitment is not a good predictor of juvenile survival and subsequent adult stock size. In other words, good larval recruitment sets the stage for population recovery, but good survival through subsequent life stage transitions is needed to realize its potential.

Third, there are clear contrasts in Delta Smelt responses between the two wet years 2006 and 2011 (the years of particular interest in this report) (Figs. 51 and 52). Since the initiation of the SKT survey for adult Delta Smelt in 2002 (indices calculated beginning in 2003), the recruitment of larvae from adults was greatest in the two wet years 2006 and 2011 (Fig. 52a) compared to the other, drier years in the time series, but in 2006 very strong adult to larvae recruitment was followed by very poor larvae to juvenile survival in the summer (Fig. 51a) and only average survival in the fall (Fig. 51b) and winter (Fig. 51c). This led to low abundance of the subsequent life stages of the 2006 cohort. Survival from larvae to juveniles and subadults was much better in 2011 and, along with good recruitment, led to the highest juvenile and adult abundance indices since the onset of the POD (Fig. 3). In other words, good recruitment set the stage for population recovery in both recent wet years, but a substantial abundance increase was realized only in 2011. Unfortunately the 2011 abundance increase was short-lived; it was immediately followed by poor recruitment and survival in 2012 and abundance indices for the 2012 and 2013 cohorts were once again at the low levels typical for the POD period (Fig. 3). Several consecutive years of good recruitment and survival are likely needed for a more sustained increase of the Delta Smelt population abundance to pre-POD abundance levels. Population declines such as the decline experienced by Delta Smelt do not only reduce the number of individuals, but can also reduce the genetic diversity present in the population. While the 2011-2012 data suggest that recovery of Delta Smelt abundance can still be fairly rapid via high larval recruitment followed by good survival (Figs. 51 and 52) recovery of genetic diversity is a much slower process which is an important conservation concern (Fisch et al. 2011).

Small Delta Smelt population size affects the effective population size (N_e), a measure of the genetic properties of a population and the abundance at which significant genetic diversity is lost due to inbreeding (Falconer and Mackay 1996, Schwartz et al. 2007, Antao et al. 2010). In many species N_e may be orders of magnitude smaller than the census population size (N) and low N_e/N ratios indicate the population may be in danger of losing genetic variability, potentially resulting in reduced adaptability, population persistence, and productivity (Hauser et al. 2002). For Delta Smelt, Fisch et al. (2011) detected a genetic bottleneck in each of four sampling years (2003, 2005, 2007 and 2009) and observed a significant decline in effective population size between sampling years 2003 and 2007 (Fisch et al. 2011). The genetic signal of the decline in N_e is corroborated by the observed abundance index declines and support the hypothesis that decreases

in N_e and allelic richness have likely occurred over the last few decades (Fisch et al. 2011). Genetic changes within the Delta Smelt population deserve continued evaluation with respect to changes in population size.

In addition, Delta Smelt recruitment and the fecundity of adult Delta Smelt likely vary substantially from year to year (Rose et al. 2013b). Delta Smelt fecundity is a function of female size (Bennett 2005, Lindberg et al. 2013). The mean size of adult Delta Smelt declined in the early 1990s (Sweetnam 1999), possibly due to changes in the food web (see Chapter 4), but substantially recovered in the late 2000s. Another possible reason is that in some recent years, there may have been selection for smaller, late-spawned larvae as a result of export pumping schedules (Bennett 2011). For example, Bennett (2011) proposed that high export pumping in late winter may have resulted in high entrainment mortality of offspring from larger, fitter, early spawning females, which produced larger, fitter offspring (Bennett 2011). Further, Bennett et al. (2008) and Bennett (2011) posited that curtailment of export pumping in mid-April related to the Vernalis Adaptive Management Program (VAMP), allowed for greater survival of later-spawned, smaller larvae. The major concern is that these smaller later-spawned larvae have less opportunity to grow to large adult size, especially when food is scarce. If correct, the combined effects of export pumping and food supply on Delta Smelt growth and size could have a nonlinear impact on overall fecundity and population success. This is corroborated by the results from individual-based modeling which showed that growth in fall-winter and the subsequent number of eggs produced per adult were the most important factor determining the success of the next generation (Rose et al. 2013b). Moreover, repeated losses of early-spawned larvae could potentially have a negative effect on expression of this important phenotype and result in eventual loss of genetic variability in the population, and contribute to the genetic bottlenecks reported by Fisch et al. (2011).

Given the unprecedented low abundance of Delta Smelt since 2002 (Fig. 3, summer and fall), serious consideration should be given to evaluation of Allee effects. Allee effects occur when reproductive output per fish declines at low population levels (Berec et al. 2006). In other words, below a certain threshold the individuals in a population can no longer reproduce rapidly enough to replace themselves and the population, exhibiting inverse density dependence, spirals to extinction. For Delta Smelt, possible mechanisms for Allee effects include processes directly related to reproduction and genetic fitness such as difficulty finding mates, genetic drift, and inbreeding (Gascoigne et al. 2009), although none of these effects have been documented yet in Delta Smelt (Fisch et al. 2011). Other mechanisms related to survival such as increased vulnerability to predation (Gascoigne and Lipcius 2004) are also possible. While theoretical work suggests that Allee effects might be common in nature, empirical evidence for Allee effects in natural populations of fishes remains relatively sparse (Myers et al. 1995, Liermann and Hillborn 1997), possibly because they are often masked by measurement errors (Gregory et al. 2010). Recent meta-analytical work by Keith and Hutchings (2012) suggests that Allee effects in marine fish species might be more common than previously thought. But even in the absence of “true” Allee mechanisms, small population size (Hutchings 2013) can produce an emergent Allee effect and prevent recovery of collapsed fish populations even when threats are reduced (Kuparinen et al. 2012). This may be one of the reasons why recovery of many collapsed fish populations remains slow despite large reductions in fishing (Pauly et al. 1998, Hutchings et al. 2010). This finding challenges the traditional fisheries management view that depleted populations will grow and recover rapidly when fishing pressure is relaxed (Hilborn and Walters 1992). In addition, the interactive effects of multiple Allee effects may have important implications for species conservation, but have not yet been well explored in ecology (Berec et al. 2006).

Compensatory density dependence predicts that a fish's population growth or survival rates can increase when abundance is low and decrease if abundance increases beyond a carrying capacity (Rose et al. 2001). If compensatory density dependence occurred in 2011, Delta Smelt survival would be expected to increase as long as the carrying capacity of the environment was not exceeded. Therefore, the sudden increase in subadult abundance in 2011 is consistent with the higher survival predicted by compensatory density dependence at low population abundance coupled with widespread availability of good habitat conditions throughout the year. Among the remaining comparison years, both 2005 and 2006 show evidence of compensatory recruitment to larvae (Fig. 52a). Adult abundance was moderately high in 2005, but low in 2006 and 2010 (Fig. 3). As predicted by compensatory density dependence processes, the recruitment index to larvae was higher in 2006 than in 2005. However, low adult abundance in 2010 did not give way to a similarly high recruitment index (Fig. 52a). In addition, the relatively high recruitment index in 2006 did not result in a higher larval abundance index compared to 2005 (Fig. 3). These inconsistencies, combined with a small number of comparison years, prevent any firm conclusion regarding compensatory recruitment or survival.

Similarly, if compensatory density-dependent survival was important we might expect larva to juvenile survival to be lower when larva production per adult was higher assuming similar adult populations. This was not the case for 2006, 2010, and 2011, which had relatively similar values for the SKT abundance index (figs. 3). In 2006, larval survival was low with high larval production per adult, and 2010 and 2011 had very similar larval survivals with similar adult abundances. Finally, in 2011, the highest population of juveniles led to the highest population of subadults and adults (2012 SKT), which argues against compensatory density-dependent survival. These comparisons argue against strict compensatory density dependence operating within the POD years. It seems more likely that population dynamics are driven by density independent relationships with factors such as summer water temperatures and resource availability (fluctuations in carrying capacity); however, the evidence is not conclusive. In particular, we do not understand how carrying capacity fluctuates over seasons and years or how other factors, such as predation, affect carrying capacity (Walters and Juanes 1993; Walters and Korman 1999).

Adults

Life History

The Delta Smelt is generally considered a diadromous seasonal reproductive migrant, and in the winter, many adult Delta Smelt move upstream into fresh water for spawning (Moyle et al. 1992, Bennett 2005, Sommer et al. 2011). These movements may be a specific change in behavior in response to one or more environmental cues, for example, to the rapid and often dramatic environmental changes during winter first flush periods (Sommer et al. 2011, Bennett and Burau 2014). Focused, fixed-station sampling in the winters of 2009-10 and 2010-11 revealed higher catch of Delta Smelt at higher turbidity levels, as well as an asymmetry in probability of catch with respect to tidal phase; catch was highest in the channels during flood tide, but highest near the shoreline during ebb tides (Bennett and Burau 2014). This change in horizontal channel position with respect to tidal direction has recently been confirmed by a second study in the fall of 2012 that used the "SmeltCam," an underwater video camera attached to the cod-end of the FMWT net to detect Delta Smelt (Feyrer et al. 2013). This study demonstrated that during flood tides, Delta Smelt were relatively abundant throughout the water column, but less abundant during ebb tides, and found only in the lower portion of the water column and closer

to shorelines. This asymmetry in catch supports the idea of a “tidal surfing” behavior during migration that may minimize energetic costs of upstream movement and allow Delta Smelt to follow favorable conditions with respect to turbidity and salinity (Feyrer et al. 2013). Variations of this behavior would allow fish to maintain position in the channel (stay on the edge during flood or ebb tide) or move downstream (move into the channel on ebb tide).

It is also possible that Delta Smelt movements do not represent a change in behavior; rather, fish are simply expanding their foraging or refuge distribution to habitat upstream when it becomes turbid or otherwise more suitable during and after the first flush period (Murphy and Hamilton 2013). The specific mechanism for the seasonal change in distribution, however, may be more a matter of terminology than of ecological relevance for a fish with as small a home range as Delta Smelt. Here, we acknowledge the existence of both possibilities, but will use the term “spawning migration” to simply refer to a directed movement upstream or downstream occurring prior to and during the spawning season. Using this definition, this seasonal change counts as a migration since it represents a relatively predictable and substantial change in distribution that has adaptive value including potential spawning, foraging and refuge functions (Lucas and Bara 2001).

The Delta Smelt spawning migration from their low-salinity rearing habitat into freshwater usually occurs between late December and late February, typically during first flush periods when inflow and turbidity increase on the Sacramento and San Joaquin Rivers (Grimaldo et al. 2009, Sommer et al. 2011a). Increased catches of Delta Smelt in the Delta Juvenile Fish Monitoring Program’s Chipps Island Trawl Survey and at the south Delta salvage facilities are unimodal in most years and occur within a couple of weeks of first flush events, suggesting that adult Delta Smelt are responding to environmental changes and migrating rapidly upstream once the first flush occurs (Grimaldo et al. 2009, Sommer et al. 2011a). However, spawning migrations are not always upstream. During occasional periods of very high river flows that spread freshwater habitat throughout much of the estuary, some Delta Smelt “migrate downstream” from rearing habitats in Suisun Bay and the Delta to freshwater spawning habitats as far west as the Napa River (Hobbs et al. 2007). Also under high flow conditions, it is possible that some Delta Smelt may not migrate in any direction; if their brackish-water rearing habitat becomes fresh, they can presumably spawn in suitable areas nearby. In addition, there is a small subset of the population that appears to remain in the Cache Slough complex year around; these fish presumably stay in the region for spawning (Sommer et al. 2011).

Osmerids generally spawn in shallow waters (Moulton 1974, Murawski et al. 1980, Hirose and Kawaguchi 1998, Martin and Swiderski 2001, Bennett 2005). It is believed that Delta Smelt spawn over sandy substrates in shallow areas based on the observation that first hatch larvae are collected in high concentrations in areas near expansive sandy shoals (Bennett 2005, L. Grimaldo, U.S. Bureau of Reclamation, unpublished data); confirmation of this hypothesis has not been verified through egg collections or observations of spawning adults, except in mesocosm studies (J. Lindberg, U.C. Davis, unpublished data). Pilot studies to identify egg deposition areas have been conducted by the IEP but these efforts were unsuccessful; it is unknown whether it was due to the method used, locations selected, or because of the low probability of detecting eggs from a relatively rare species.

The Delta Smelt is an opportunistic strategist (Nobriga et al. 2005). Opportunistic strategists are characterized by their short life spans, but high intrinsic rates of population increase driven by rapid maturation and repeat spawns over a protracted spawning season (Winemiller and Rose 1992). The importance of per capita fecundity to the success of the Delta Smelt population was recently highlighted in an individual-based modeling study (Rose et al. 2013a,b). In culture,

Delta Smelt can spawn up to four times per year depending on water temperature (J. Lindberg, U.C. Davis, unpublished data). Recent evidence indicates that Delta Smelt can spawn multiple times in the wild if water temperatures stay cool in the later winter and early spring (Wang 2007, L. Damon, CDFW, written comm. 2013). The ability of Delta Smelt to spawn multiple times in the wild could substantially increase per capita fecundity over previous estimates for individuals of a specific size. It could also be a contributing factor to the large interannual variability in adult to larvae recruitment (Fig. 52a).

Population Trends

Adult Delta Smelt are monitored by the Spring Kodiak Trawl (SKT) survey which was initiated by CDFW (then CDFG) in 2002 and runs from January to May each year (Honey et al 2004). An indexing method was recently developed by CDFW for the SKT survey, allowing for year to year comparisons as well as comparisons with the abundance indices for other life stages (Fig. 3). The SKT index time series used in this report comprises 11 annual indices, from 2003 to 2013; no index is available for 2002. Each index represents the abundance of adult fish hatched in the previous calendar year that survive to spawn at the beginning of the next calendar year. The highest SKT index on record occurred in 2012 (147), as a result of the high 2011 abundance of younger fish, and the lowest in 2006 (18). Of the four comparison years, 2005 had the highest SKT index (51), followed by 2010 (27) and 2011 (20) and then 2006 (18). While the SKT index was thus lower in the two wet years than in the two drier years, the SKT index increased substantially in each of the years following the two wet years; however it increased only 2-fold from 2006 to 2007 while it increased 7-fold from 2011 to 2012 (Fig. 3). It is also possible that the SKT is less effective during very high flow events. Delta outflow at times exceeded 200,000 cfs in winter 2011 and 300,000 cfs in winter 2006. These high flow events might have contributed to the low SKT indices in these two wet years, if Delta Smelt remained near shore to avoid displacement or moved into San Pablo Bay with the LSZ. In both cases they would be outside of SKT sampling range. Further evaluations are needed, however, to investigate and quantify this hypothesized effect.

The annual adult Delta Smelt abundance indices track the annual abundance indices of subadults calculated from the previous years' FMWT survey closely (Fig. 53; see also Kimmerer 2008). The relationship is particularly strong at higher fall abundance indices (FMWT index > 50), with more variability at lower abundance indices. Before the POD decline in 2002, all Delta Smelt FMWT indices were greater than 50 (Fig. 3). Thus, the FMWT might provide a useful surrogate for estimating long-term abundance trends in the adult Delta Smelt population prior to the initiation of the SKT survey in 2002, but great caution is warranted with the approach because this hindcasting would rest on only four data points with high leverage (2003-2005, 2012) and assume stable subadult to adult survival relationships and habitat conditions, neither of which is likely true. Moreover, the Kodiak trawl more efficiently captures Delta Smelt than the FMWT net. The SKT survey was set up to target Delta Smelt, while the FMWT survey was designed to monitor young Striped Bass, which tend to be larger than Delta Smelt during fall; however, there is no reason to expect the difference in capture efficiency to affect the relationship, unless such differences were a function of population size (i.e., efficiency was different above and below FMWT = 50). The utility of the FMWT as a descriptor of long-term adult population trends in the absence of long-term data from the SKT will benefit from ongoing IEP efforts to quantitatively estimate the efficiency of the FMWT and to compare efficiencies of different trawling gear and protocols. While survival from subadults in the fall (FMWT) to adults in the winter and spring (SKT) (Fig. 53) has been more stable than adult to larvae recruitment and survival between other

life stages (Figs. 51 and 52), it nevertheless shows some variability, especially when abundance is low. These data suggest that at least in the POD decade, adult numbers appear largely driven by juvenile abundance and the influence of changes in winter-time habitat attributes is less important and relatively stable from year to year.

The number of adult spawners affects population dynamics through production of eggs. Potential reproductive output is proportional to the number of adult female spawners, the clutch size for females of a specific size, and the number of egg clutches produced by each female. Although egg production in the wild has not yet been documented, we can evaluate the relationship of the SKT adult population index to the 20 mm Survey abundance index (Fig. 54). This relationship does not appear to be strong during the POD period (linear regression, $P > 0.05$). This suggests that egg production or subsequent hatching of eggs and survival of larvae and thus overall recruitment of larvae from the previous generation's adults is affected by other factors than adult population size. Hypotheses about the effects of habitat attributes in our conceptual model on adult growth and fecundity and recruitment of young are explored in Chapter 7.

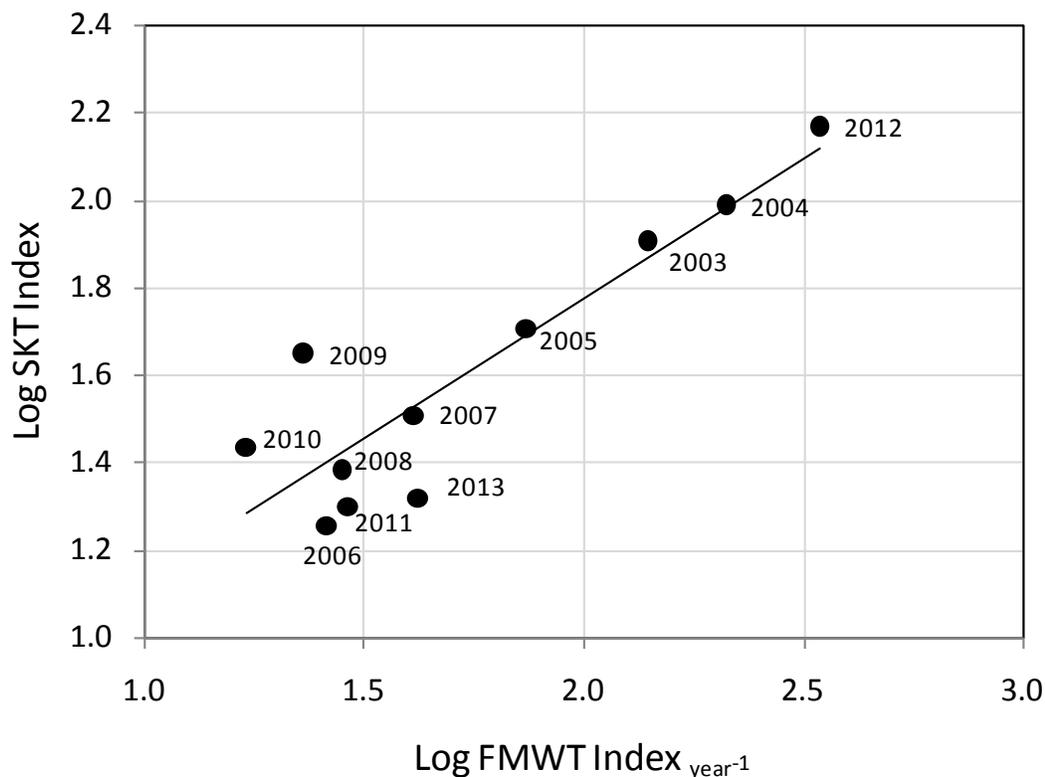

Clutch sizes of fish collected in the SKT were not measured, but annual fork lengths of Delta Smelt collected in the SKT did not vary greatly (Fig. 55). It does not appear that clutch size should have varied much in the POD years, including the four comparison years 2005-6 and 2010-11, with 2003 as the exception where the median length was greater than 70 mm standard length (Fig. 55). For Delta Smelt, which are now considered seasonal indeterminate spawners (i.e., they spawn multiple times), total reproductive output of an individual female should vary with: 1) size at the onset of the spawning window because batch fecundity is a function of size (Bennett 2005, CDFW unpublished data), 2) length of the spawning window, which is the number of days with suitable water temperatures for spawning (see larvae section below) and determines the number of batches possible; and 3) growth during the spawning window, which can potentially improve batch fecundity over time (see larval section below). Obviously, reproductive output will be higher in years when adult females are larger, abundances are higher, and the spawning window is prolonged such that multiple clutches are produced. Note that maximum reproductive output of the adult population at the beginning of spawning is not often realized due to mortality arising from density-dependent (e.g., food limitation or predation) or density-independent (e.g., entrainment, contaminants) mechanisms. According to Bennett (2011), larvae from bigger, early-spawning females may be disproportionately lost to CVP and SWP entrainment. In this report, we consider years when there are bigger females and/or a higher spawning stock size to be better in terms of reproductive potential than years when adult female size and spawning stock are smaller.

Larvae

Life History

Adult Delta Smelt, through their selection of spawning sites and spawn timing, largely determine the early rearing habitat and environmental conditions encountered by larvae. Given the Delta Smelt's annual life cycle, small size at maturity, relatively low fecundity, and small egg size compared to other fishes, life history theory suggests that parental care, here limited to selection of spawning sites and spawn timing, should be an important factor in reproductive success (Winemiller and Rose 1992). Since eggs have not been detected routinely in the wild, spawning and early rearing habitat locations are inferred from collection of ripe adults and early stage

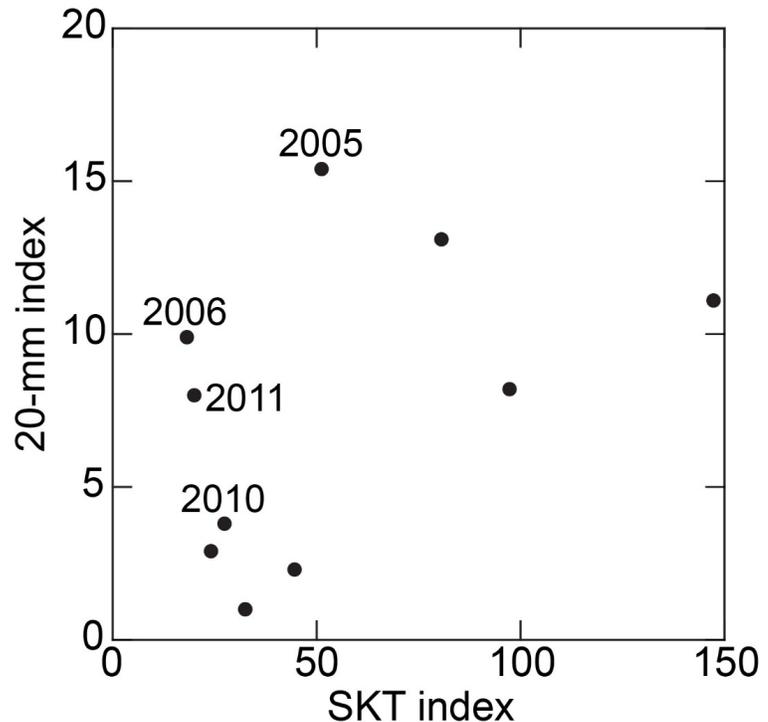

Figure 53. Relationship of annual indices of Delta Smelt abundance from the Spring Kodiak Trawl (SKT) and Fall Widwater Trawl (FMWT) from the previous year. Year labels correspond to the year of the SKT. The linear regression with all index values log-transformed to address non-normal distributions in the raw data is: $\text{Log SKT Index} = 0.4997 + 0.6381(\text{Log FMWT Index Year}^{-1})$, $n = 11$, $p < 0.001$, $R^2 = 0.79$.

larvae, which occur from the Delta margins through eastern Suisun Bay (see: <http://www.dfg.ca.gov/delta/projects.asp?ProjectID=SKT>; Wang 1986, 1991, 2007). In culture, Delta Smelt begin spawning as water temperatures increase to 10-12 °C, at which time individual females accompanied by several males select appropriate water velocities and release gametes close to the substrate from dusk to dawn (Baskerville-Bridges et al. 2004b). In lab experiments, females deposited significantly more eggs on sand and gravel substrates as compared to other substrates offered for egg deposition (J. Lindberg, U.C. Davis, unpublished data). Based on periodicity in egg deposition in culture, Bennett (2005) proposed that spawning likely coincides with peak tidal currents (i.e., spring tides), which would result in hatching near neap tides. Such a strategy would limit the initial tidal dispersal of larvae.

In culture, larvae hatch after an 11-13 day incubation period at 14.8-16.0 °C and begin a short period of buoyancy (or positive phototaxis; Baskerville-Bridges et al. 2004b) prior to slowly settling to the bottom (Mager et al. 2004). After this buoyant period, Mager et al. (2004) found that larvae were demersal unless actively swimming to feed, which occurred only during daylight hours. Exogenous feeding begins at 5-6 days post-hatch as the last of the yolk sac is absorbed; the lipid globule is absorbed at 10 days (Mager et al. 2004) providing some nutritional reserve if feeding conditions are poor. Larvae probably remain somewhat bottom oriented until swim

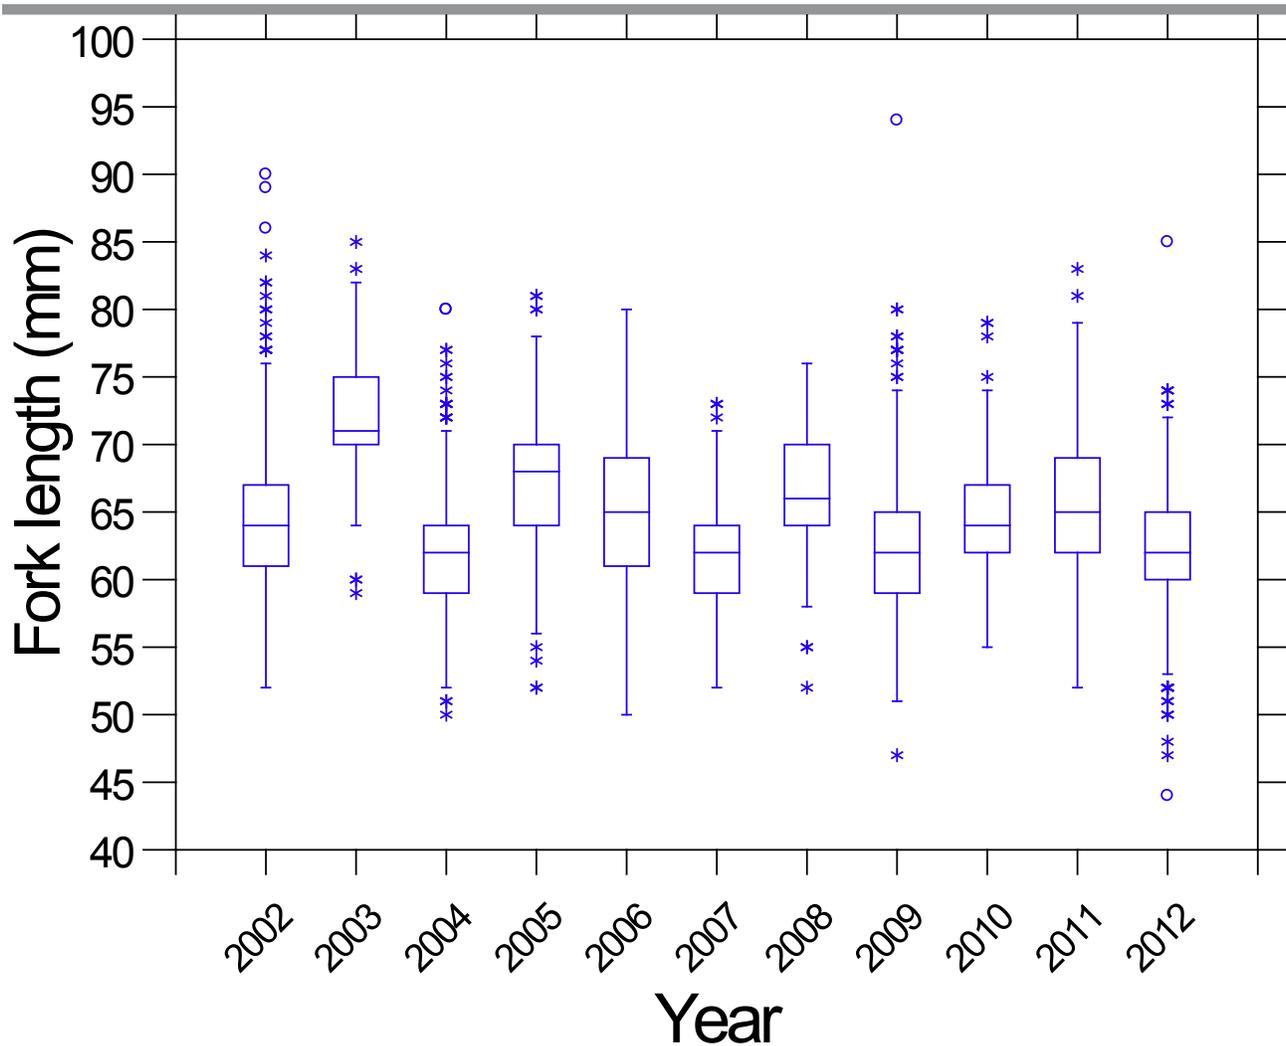

Figure 54. Plot of the Spring Kodiak Trawl (SKT) adult abundance index against the 20 mm Survey larval abundance index 2003-2012. The comparison years of 2005, 2006, 2010, and 2011 are labeled.

bladder and fin development are complete at about 65 days of age and about 20 mm TL (Mager et al. 2004, Baskerville-Bridges et al. 2004b), at which time they can fully control their buoyancy and efficiently use tidal and river currents to migrate. The center of distribution for Delta Smelt larvae and young juveniles is generally downstream of the spawning habitat, but upstream of and varying in association with X2 during spring (Dege and Brown 2004).

Early larval stages of Delta Smelt (4-15 mm) tended to be poorly collected by gear previously used in historical SFE egg and larval surveys (Striped Bass Egg and Larva Survey; sled-mounted 500 micron mesh net with 0.38 m² mouth area), but with growth and development greater proportions of the population become vulnerable. This observation led to a sampling gear change in the mid-1990s from the historical egg and larval gear to new gear targeting more vulnerable post-larvae and early juvenile Delta Smelt (i.e., 20 mm Survey). The improved catch and distribution information resulting from this change has since proven valuable to the management of Delta Smelt, and the 20 mm Survey results are now considered essential information (USFWS 2008). In the mid-2000s, an abundance index was developed from 20 mm data (Gleason and Adib-Samii 2007) that has since been used to index abundance trends of larvae in spring (e.g., Hieb et al. 2005, Contreras et al. 2011). We use 20 mm Survey abundance indices as one Delta Smelt end-point to evaluate the support for our hypotheses concerning the environmental drivers and habitat attributes responsible for abundance and survival of larvae.

Figure 55. Median fork length (mm) of Delta Smelt collected in January and February by the Spring Kodiak Trawl by year, 2002-2012. See Chapter 3: Data Analyses for explanation of boxplots.

Population Trends

The highest larval abundance indices on record occurred in the late 1990s, shortly after the initiation of the 20 mm survey in 1995. The lowest larval abundances were observed in 2007-2010 (Fig. 3). In 2011, larval abundance improved substantially from the recent minimum in 2007, and achieved levels comparable to those earlier in the 2000s (Fig. 3). Although 2011 larval abundance compared favorably to that of 2010, it remained below levels of 2005 and 2006. Thus, the modest larva abundance in 2011 did not appear sufficient to explain the high FMWT index observed in 2011 (Fig. 3). As explained above, larval abundance does not track the abundance of the parent generation very well (Fig. 54). In contrast, subsequent life stages of the same cohort track larval abundance and abundance relationships of larvae (log 20 mm index) with juveniles (log TNS index) and subadults (log FMWT index) in the same year are statistically significant (Fig. 56). However, the linear regression based on the FMWT explains less variance than the linear regression based on the TNS suggesting more variability in the abundance of the older life stages. This suggests that factors affecting juvenile mortality rates also play an important role in eventual recruitment.

Juveniles

Life History

During summer, juvenile Delta Smelt primarily rear in the west Delta, Suisun Bay, and Cache Slough complex (Moyle 2002, Bennett 2005, Merz et al. 2011, Sommer and Mejia 2013). As in late spring and fall, the center of distribution of the fish occurs in the low salinity zone, with the exception of the Cache Slough complex. The degree to which the fish use particular geographic areas depends on salinity, temperature, and turbidity (Nobriga et al. 2008); other factors that may affect their summer distribution include *Microcystis* distribution, and possibly prey density, bathymetric features, or other water quality constituents. As noted previously, Delta Smelt used to be common in the central and south Delta during the summer months, but this is no longer the case (Nobriga et al. 2008).

Population Trends

Relative abundance of juvenile Delta Smelt is presently indexed by the Summer Towntnet Survey (TNS). The survey was not designed specifically to measure Delta Smelt abundance and catches are low (Honey et al. 2004). Nonetheless, patterns in the annual abundance index provide a useful basic measure of population trends.

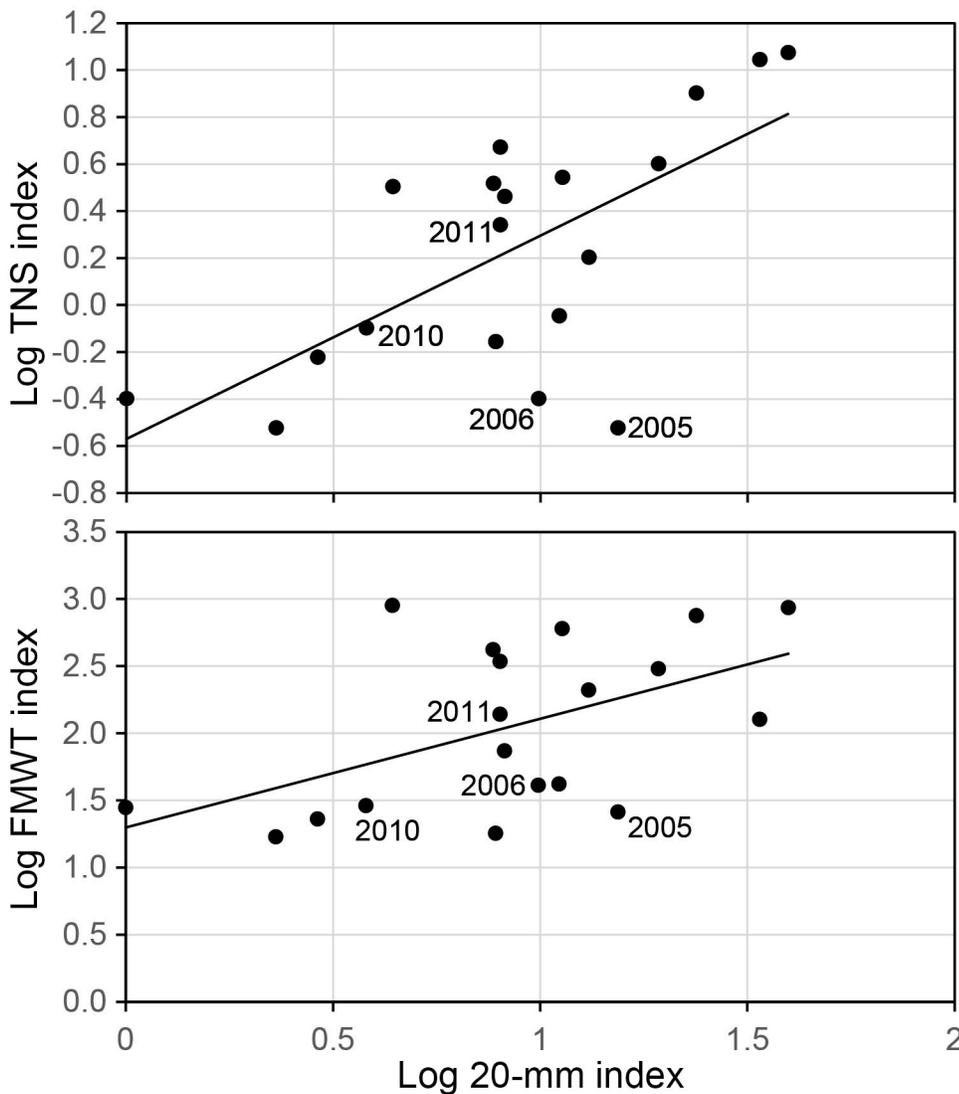

The TNS index rebounded substantially in 2011, but declined to a value consistent with low recent year indices in 2012 (Fig. 3). This pattern of persistently low abundance is consistent with the POD, which began over a decade ago (Sommer et al. 2007, Thomson et al. 2010). During the last decade, TNS abundance indices were especially low from 2005-2009 (Fig. 3). The onset of the 2005-2009 period of low juvenile abundance was characterized by extremely low larvae to juvenile survival in 2005 and 2006 (Fig. 51). Larval survival to juveniles recovered somewhat in the following years, but TNS indices stayed low (Fig. 3). Historically (e.g., early 1970s), high levels of Delta Smelt abundance during summer apparently allowed density dependent effects to occur between summer and fall in some years; this conclusion was still supported after the species declined in the early 1980s, but the apparent carrying capacity was lower (Bennett 2005). The available trawl data suggest that this trend of declining carrying capacity has continued as suggested by the very low Fall Midwater Trawl indices produced by a range of juvenile TNS abundance levels, during the POD years (Fig. 57).

Subadults

Life History

During fall, subadult Delta Smelt primarily rear in the western Delta, Suisun Bay, and Cache Slough complex (Moyle 2002, Bennett 2005, Sommer and Mejia 2013). The center of distribution is in the low-salinity zone (Sommer et al. 2011), with the exception of the Cache Slough complex. The degree to which the fish use particular geographic areas depends on salinity and turbidity (Feyrer et al. 2007). Other factors that may affect their distribution during the fall include *Microcystis* distribution and water temperature in the early fall (September-October), and possibly prey density.

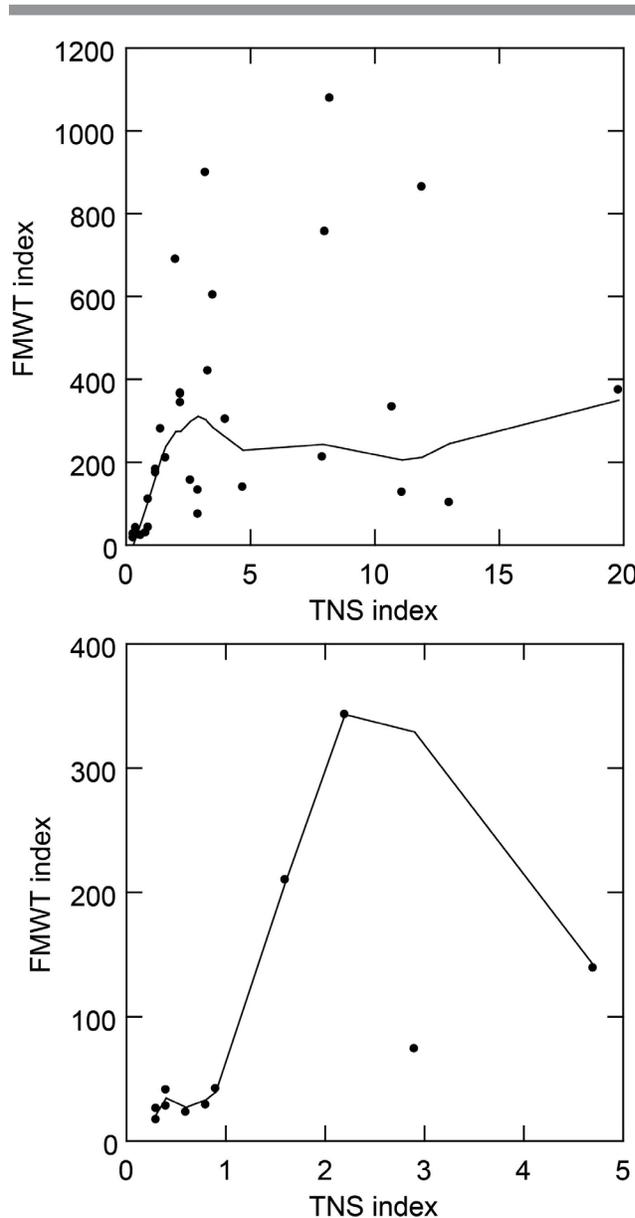

Figure 56. Relationship of annual index of Delta Smelt abundance from the 20 mm survey (20 mm) with the annual indices from the summer tonet survey (TNS) and fall midwater trawl survey (FMWT). Year labels correspond to the comparison years of interest. The linear regressions with all index values log-transformed to address non-normal distributions in the raw data are: $\text{Log 20 mm index} = 0.57 + 0.87(\text{Log TNS index})$, $n = 19$, $p < 0.05$, $R^2 = 0.44$ and $\text{Log 20 mm index} = 1.30 + 0.81(\text{Log FMWT index})$, $n = 19$, $p < 0.05$, $R^2 = 0.27$.

Population Trends

Population trends for subadult Delta Smelt are presently indexed by the FMWT. Like the TNS, the FMWT was not designed specifically to measure Delta Smelt relative abundance and catches are low (Honey et al. 2004, Newman 2008). The data are nonetheless a useful basic measure of population trends, except perhaps at very low abundance (i.e., FMWT index values less than about 50; Fig. 53). However, the general agreement between the FMWT and subsequent Spring Kodiak Trawl (SKT) sampling (Fig. 53), suggests that FMWT results are a reasonable indicator

Figure 57. Plots of fall midwater trawl (FMWT) abundance index as a function of summer townet survey (TNS) abundance index for 1982-2013 and 2003-2013. Note the very different scales for both axes. Lines are LOWESS smooths.

of general trends in abundance of adult Delta Smelt.

The FMWT index rebounded substantially in 2011, but declined to a value consistent with low recent-year indices in 2012 (Fig. 3). During the last decade, FMWT indices were especially low from 2005-2010 (Fig. 3). After the rebound in 2011, the index went back to a lower level similar to the 2005-2010 period. Since 2003, the juvenile to subadult survival index was lowest in 2004. During the four comparison years, the juvenile to subadult survival index was lowest in 2010, but relatively high in the other three years and highest in 2011 (Fig. 51).

Historically, high levels of Delta Smelt abundance during summer apparently resulted in density-dependent mortality between summer and fall in some years (Bennett 2005). This conclusion was still supported after the species declined in the early 1980s, but the apparent carrying capacity, meaning the magnitude of the FMWT index relative to the TNS index, was lower (Fig. 57). The available FMWT data suggest that these trends of density-dependent mortality during the summer-fall and declining carrying capacity have continued (Fig. 57). The close correlation of the FMWT and SKT (Fig. 53) indicates that the

factors likely affecting survival of Delta Smelt to the adult spawning population operate earlier in the life cycle (i.e., between the egg and subadult life stages). Additional mortality certainly occurs between the FMWT and SKT but the lack of variability around the regression line suggests there is not a lot of variability in the rate of that mortality. Thus, the relative annual spawning stock appears to be largely determined by fall of the birth year.

Chapter 7: Using the Conceptual Model—Why did Delta Smelt abundance increase in 2011?

In this Chapter, we further explore Delta Smelt responses and habitat attributes as depicted in the driver and life stage transition conceptual model diagrams presented in Chapter 5. The purpose is to demonstrate the utility of our conceptual model framework for generating hypotheses about the factors that may have contributed to the 2011 increase in Delta Smelt abundance. For each life stage transition, we explore a series of hypothesized linkages among ecosystem drivers, habitat attributes, and Delta Smelt responses. We evaluate these hypotheses by comparing habitat conditions and Delta Smelt responses in the wet year 2011 to those in the prior wet year 2006 and in the drier years 2005 and 2010.

In this Chapter we briefly describe the comparative approach and the hydrological conditions during the four years that are the focus of our comparisons. We then state and explore each hypothesis for the adult, larval, juvenile, and subadult life stages of Delta Smelt using data sources described in Chapter 3. Key points from these evaluations, as well as previous report Chapters, along with benefits and limitations of the comparative approach are summarized and discussed in Chapter 8. In several cases, we lacked suitable data or other necessary information to evaluate our hypotheses; these data and information gaps are described in Chapter 9. Chapter 9 also includes a brief review of some of the more complex mathematical analyses used in recent peer-reviewed publications, such approaches currently being used by others, and three examples of additional mathematical modeling approaches that can be used to further explore some of the linkages and interactions in our conceptual model and complement previously published and other ongoing mathematical modeling efforts for Delta Smelt.

Comparative Approach

The comparative approach used for evaluating the hypotheses stated in this Chapter is similar to the approach taken in the FLaSH investigation (Brown et al. 2014, see also <http://deltacouncil.ca.gov/science-program/fall-low-salinity-habitat-flash-studies-and-adaptive-management-plan-review-0>). This allowed us to place the results of the FLaSH investigation in a year-round, life cycle context as recommended by the FLaSH Panel (FLaSH Panel 2012). Specifically, we compared data from the two most recent wet years, 2006 and 2011, and the two years that immediately preceded them, 2005 and 2010. To conduct our comparisons, we determined how Delta Smelt responses or habitat attributes would be expected to respond in the different years and then compared the expected response to the observed response. If the expected and observed responses were similar, the hypothesis was considered to be supported.

Moderate to wet hydrological conditions tend to benefit many estuarine organisms, including Delta Smelt (Sommer et al. 2007). But low recruitment or low survival at any point in the predominantly annual Delta Smelt life cycle can lead to low abundance even in a wet year. Identifying the reason(s) for low abundance in a wet year may give important insights into key habitat attributes and environmental drivers that could be managed in a way that would improve the likelihood of abundance increases in all wet years.

The two wettest years after the onset of the POD were 2006 and 2011 (Fig. 58). Delta Smelt abundance increased substantially in 2011, but not in 2006 (Fig. 3). The failure of the Delta Smelt population to increase in the wet year 2006 and the increase of Delta Smelt in the wet year 2011 provides an opportunity to compare and contrast habitat attributes in these two years and possibly identify new options for management actions. As stated in Chapter 3, our working assumption is that different Delta Smelt abundances in 2006 and 2011 should be attributable to differing environmental conditions, in some cases attributable to management actions, and subsequent ecological processes influencing the Delta Smelt population.

Preceding habitat conditions may have important implications for the response of a population to the environmental conditions present during a wet year; therefore, we also consider data from 2005 and 2010. Further, we also consider adult and larval abundance in 2012 following the wet year of 2011. We did not include any years predating the POD period in this analysis. This was done to prevent the possibly more subtle, but management-relevant, environmental changes occurring during the POD period from being overwhelmed by effects of the strong POD step changes in the early 2000s as well as similarly strong changes that occurred before the POD (e.g., after the invasion of the clam *Potamocorbula amurensis*).

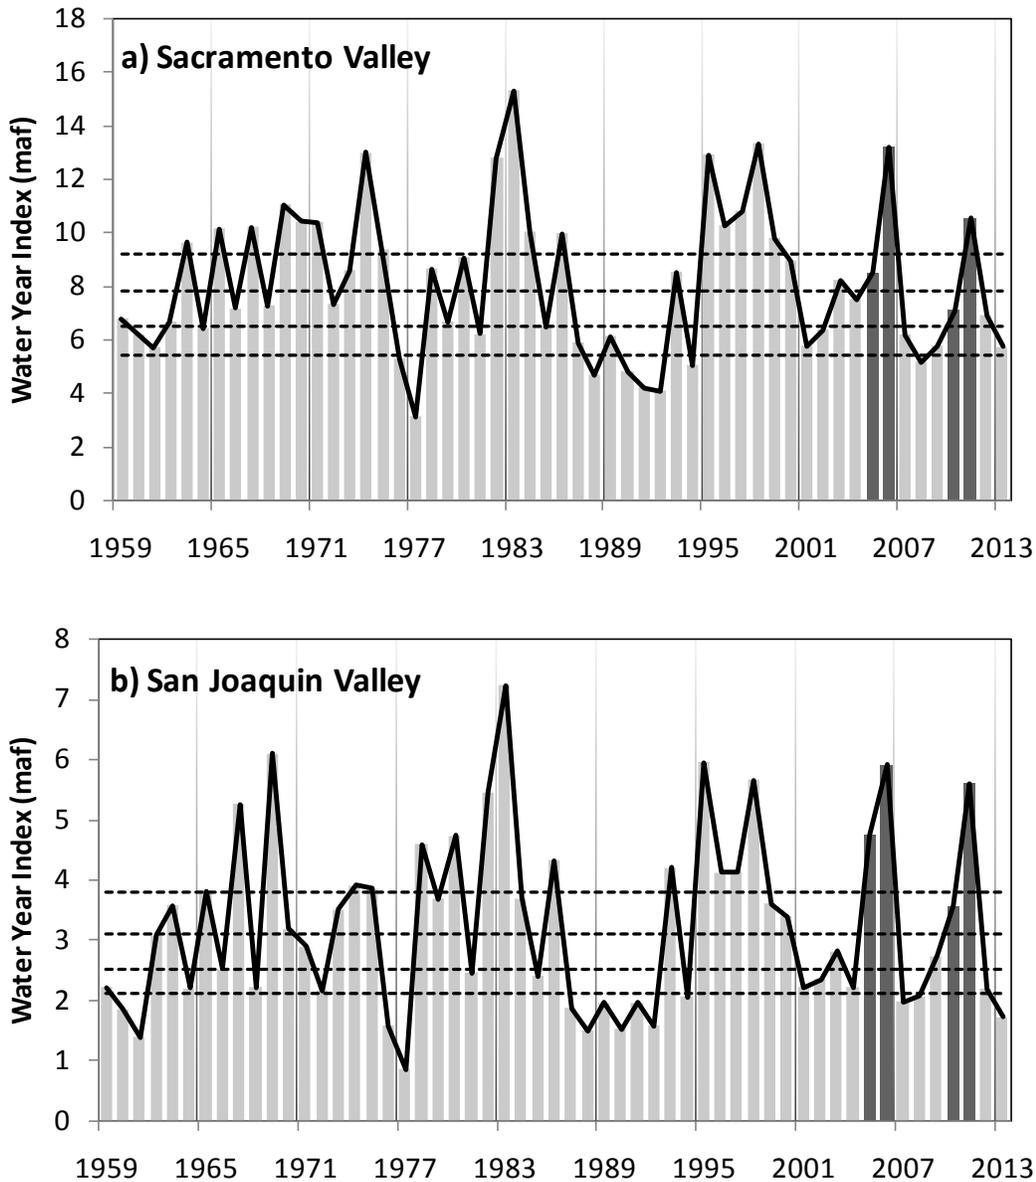

For the purpose of this report, we call 2005, 2006, 2010, and 2011 our “study years.” We use “year” rather loosely because the Delta Smelt life cycle does not follow the calendar year. As already explained, life stages can overlap and can be observed during different months in different years. Mature adults of a cohort produced in one year are generally not observed until the following year. Similarly, the life cycle does not strictly follow the water year type. We do our best to explain these mismatches when they occur and keep the presentation focused on the life cycle and the conceptual models.

Note that we do not examine the complex interactions that may occur when more than one hypothesis is true (or false), nor do we rule out that a hypothesis may be true in some years and false in others. Therefore, it is important to recognize that data contrary to a hypothesis may indicate that the habitat attribute was not controlling in the selected years, or that complex interactions among multiple habitat attributes (and corresponding hypotheses) contributed to the observed effects. Addressing such complexities is more appropriate for quantitative models as discussed in Chapter 9.

Hydrological Conditions

According to annual water year indices and classifications for overall hydrological conditions in the Sacramento and San Joaquin Valleys that provide the freshwater inflow into the Delta, 2005, 2006 and 2011 were the wettest years of the POD period (Fig. 58, see also <http://cdec.water.ca.gov/cgi-progs/iodir/WSIHIST>). In the San Joaquin Valley, 2010 was the fourth wettest year of this period. In the Sacramento Valley, 2003 and 2004 were wetter than 2010. Specifically, water year 2010 was classified as “below normal” in the Sacramento Valley and “above normal” in the San Joaquin Valley and 2011 was classified as wet in both areas, according to the water year index classifications. Water year 2005 was classified as “above normal” in the Sacramento Valley and “wet” in the San Joaquin Valley and 2006 was classified as wet in both areas. (Fig. 58). Water year 2012 was classified as “below normal” in the Sacramento Valley and “dry” in the San Joaquin Valley.

Figure 58. Annual water year indices for the a) Sacramento and b) San Joaquin Valleys since the initiation of the Summer Towntnet Survey in 1959. Horizontal dashed lines: threshold levels for water year type classifications as wet (W), above normal (AN), below normal (BN), dry (D) and critically dry (C). Darker grey bars indicate the four study years (2005, 2006, 2010, 2011) examined in Chapter 7 of this report. (Data are from <http://cdec.water.ca.gov/cgi-progs/iodir/WSIHIST>).

The overall wet hydrological conditions in the Sacramento and San Joaquin Valleys in 2005-6 and 2010-11 resulted in relatively prolonged periods of high Delta inflow and outflow and low X2 values in the winter and spring months of the four study years (Fig. 59). In the first half of the year, 2006 had the highest outflow and lowest X2 values followed by 2011, 2005, and 2010. In the second half of 2011, outflow was higher and X2 values were lower than in the second half of 2006 and of all other years during the POD period. In spite of having the lowest spring X2, 2006

had the highest fall X2 (September to October) of all study years, followed by 2005, 2010, and 2011 (Fig. 60).

The overall high flows during these four years allowed for periods of very high fresh water exports from the Delta (Fig. 59). This led to record high volumes of fresh water exported in water year 2011 (6.7 maf) and in water year 2005 (6.5 maf) and a somewhat lower export volume in water year 2006 (6.3 maf). The total water export volume was substantially lower in water year 2010 (4.8 maf) because 2010 immediately followed a three-year drought and the below normal hydrological conditions in the Sacramento Valley (Fig. 58) were not sufficient to rapidly replenish reservoirs and allow for greater exports.

Hypotheses

Individual hypotheses are indicated in the life stage transition conceptual model diagrams next to the arrows depicting each hypothesized linkage or outcome (figs. 46-49). While all linkages are considered important, we only developed hypotheses for selected linkages. We developed hypotheses for linkages with sufficient data for quantitative assessments and where there is disagreement or uncertainty regarding the outcome resulting from a driver. We also developed hypotheses for linkages considered important but where we found critical information was missing; thus, highlighting topics where new work is needed. For each of these hypotheses, we then considered the available data to examine whether the Delta Smelt response expected under the hypothesis was consistent with the observed trends in habitat attributes or population dynamics. While we would have liked to test hypotheses about the linkages between habitat attributes and the specific life stage transition processes shown in the life stage transition conceptual model diagrams, the available data often only allowed us to test “lower tier” hypotheses about the linkages between ecosystem drivers and habitat attributes.

Note that we have not examined the complex interactions that may have occurred when more than one hypothesis was true (or false), nor have we ruled out that a hypothesis may be true in some years and false in others. Therefore, it is important to recognize that data contrary to a hypothesis may indicate that the habitat attribute was not controlling in the selected years, or that complex interactions among multiple habitat attributes (and corresponding hypotheses) contributed to the observed effects. Addressing such complexities is likely more appropriate for quantitative models as discussed in Chapter 9. Our overall objective in this Chapter is to provide a demonstration of how the conceptual model can be used to generate and test hypotheses and highlight data gaps while addressing a specific topic of management interest—the increased Delta Smelt abundance index in 2011.

Adult Hypotheses

Hypothesis 1: Hydrology and water exports interact to influence entrainment risk for adult Delta Smelt.

As discussed earlier, we do not currently have a reliable measure of actual entrainment of fishes by the SWP and CVP export pumps. We also do not have actual population abundance estimates for Delta Smelt. As discussed by Kimmerer (2008, 2011) and Miller (2011), it is thus difficult to estimate proportional population losses due to entrainment. We consider the published

Figure 59. Net daily flows in cubic feet per second for a) Delta inflow from all tributaries, b) Delta outflow into Suisun Bay, and d) total freshwater exports from the Delta. Also shown are daily values for c) X2 (see Chapter 4 for explanation). Flow data are from Dayflow (<http://www.water.ca.gov/dayflow/>). X2 values are calculated from daily Delta outflow with the equation in Jassby et al. (1995.)

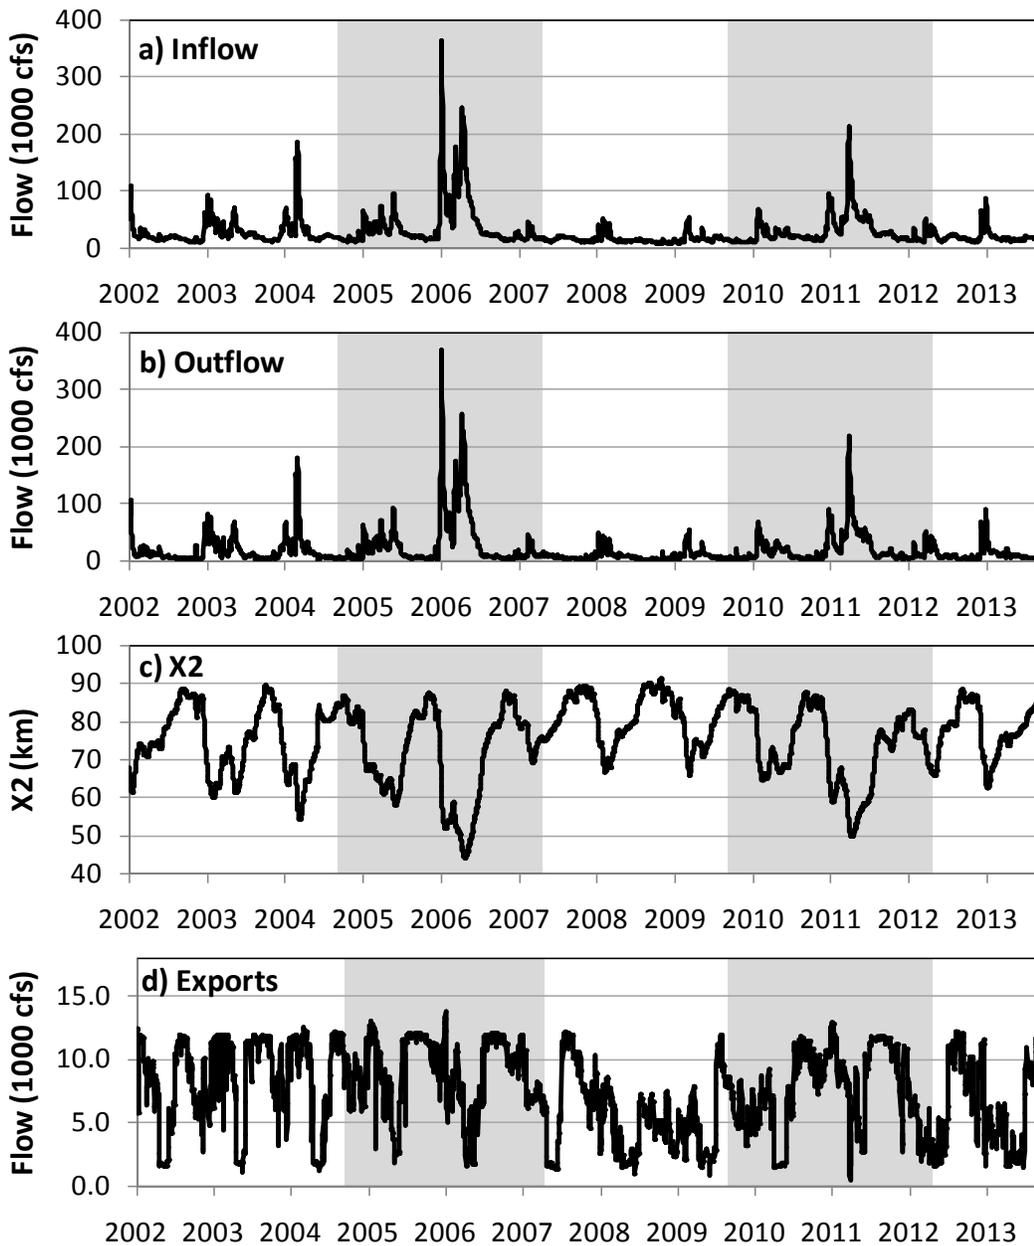

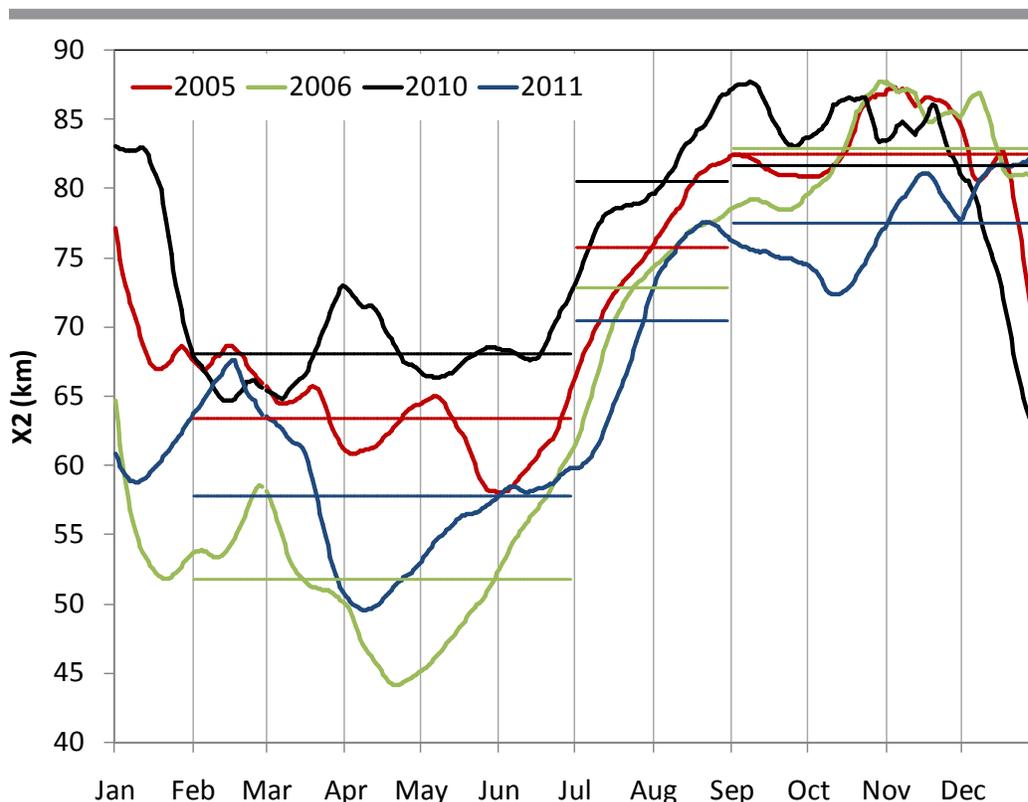

Figure 60. Daily X2 values in January to December for each of the four study years. Seasonal X2 averages are indicated by horizontal lines for spring X2 (February to June), summer X2 (July and August), and fall X2 (September to December). See Fig. 15 for seasonal X2 in other years.

proportional loss estimates for adult Delta Smelt entrainment losses for the two years for which they are available (2005 and 2006; Kimmerer 2008). However, we otherwise restrict our analysis – and this hypothesis – to an assessment of entrainment risk based on salvage and OMR flow data. Note that high entrainment risk for an individual fish does not automatically lead to a high proportion of the population lost to entrainment mortality. For example, in wetter years when large numbers of fish are present but most of the population is distributed farther away from the pumps, a large number of fish can be entrained but only a small percentage of the entire population.

Adult (December-March) Delta Smelt salvage was highest in 2005 followed by 2006 and 2010 and lowest in 2011 (Fig. 61). In 2005, most salvage occurred in January, while in the other three years it occurred in February and March (Fig. 62). Overall, adult Delta Smelt salvage in the four comparison years was on the very low end of the historical time series starting in 1980 (Fig. 26). On the other hand, the ratio of adult salvage divided by the previous year's FMWT index was high in 2005 (6th highest on record since 1979), but much lower in 2006 and 2010, and lowest in 2011 (Fig. 26).

Low salvage levels in these years and especially in 2010 and 2011 were not particularly surprising due to the low FMWT levels of the POD years along with more active management of OMR flows for Delta Smelt and salmonid protection after 2008 in accordance with the USFWS (2008) and NMFS (2009) BioOps. For management purposes, the onset of increased

adult Delta Smelt entrainment risk is inferred from distributional patterns of Delta Smelt detected by the SKT survey, Delta Smelt salvage and, more recently, consideration of Delta conditions, including turbidity patterns. Since 2009, net OMR flows during periods of increased adult Delta Smelt entrainment risk are now always less negative than they were in years prior to the BioOps. Prior to 2008, net OMR flows often reached -8,000 to -10,000 cfs (see Fig. 31, Kimmerer 2008, Grimaldo et al. 2009), when outflow was low. An exception to these strongly negative flows occurred during April-May export curtailments associated with the Vernalis Adaptive Management Program (VAMP, 2000-2012). These curtailments were especially pronounced in the first half of the VAMP period (2000-2005). During the four comparison years, winter (December-March) net OMR flows were least negative in 2006 followed by 2011 and 2010 with the most negative net OMR flows in 2005 (Fig. 63). High inflows particularly from the San Joaquin River during 2005, 2006 and 2011 moderated effects of negative OMR flows, while export pumping generally remained high. In 2010 at the end of a three-year drought, there was little water in storage to provide for Delta exports prior to the first substantial inflows in mid-January. Subsequently, export levels had to be curtailed to achieve the desired OMR flows. Average winter-time net flows past Jersey Point on the San Joaquin River were positive in all four study years and greatest in 2006 followed by 2011, 2005, and 2010 (Fig. 63).

Kimmerer (2008) used salvage, OMR flows, and fish survey data to estimate proportional population losses due to entrainment for the years 1995-2006. The years 2005 and 2006 represent some of the lower loss estimates in the years examined by Kimmerer (2008); mean population losses reached up to 22% of the adult population in some years when OMR flows were more negative than -5000 cfs (Kimmerer 2008). Even if Kimmerer's estimation method provides a potential overestimate of loss (Miller 2011), proportional losses of the adult population were less than 10% in the two years that coincide with our comparison years (2005 \approx 3% , 2006 \approx 9%; from Fig. 12 in Kimmerer 2008). These types of proportional loss estimates are not available for

Figure 61. Annual adult (December-March) Delta Smelt salvage at the CVP (blue bars) and SWP (green bars) fish protection facilities for 2005-2012.

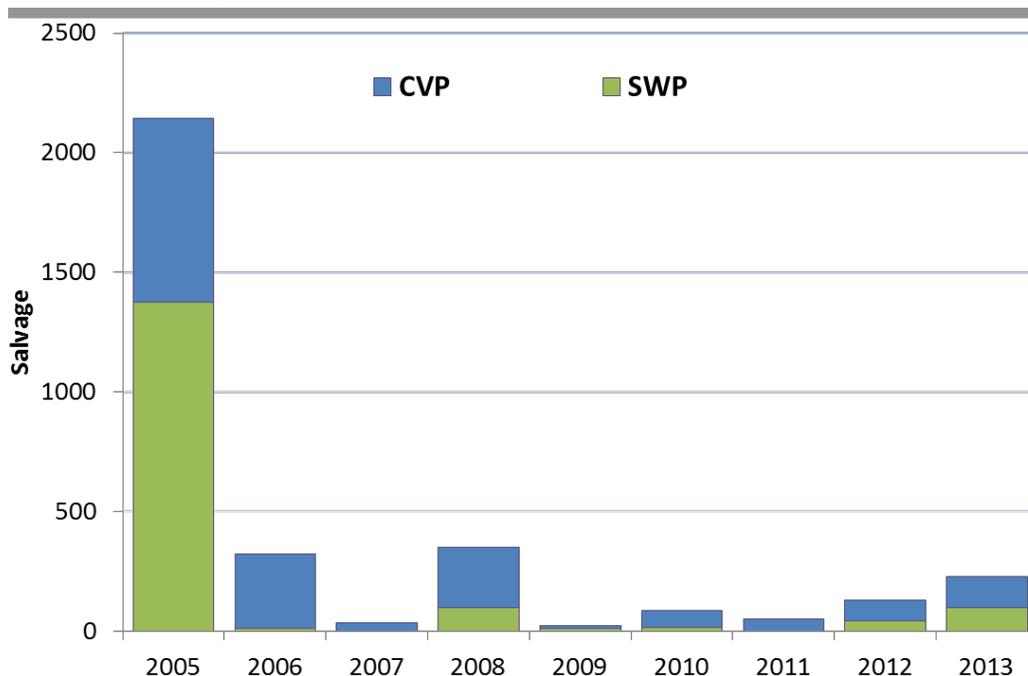

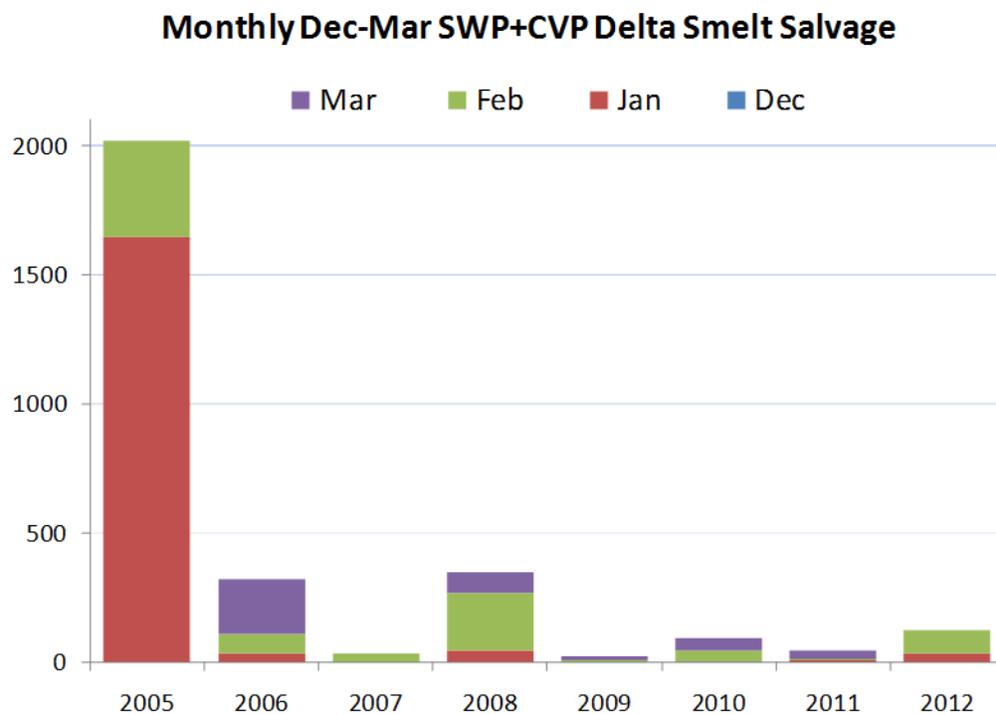

Figure 62. Annual combined adult (December-March) Delta Smelt salvage at the CVP and SWP fish protection facilities by month for 2005-2012.

2010 and 2011, but would likely be even smaller than for 2005 due to less negative OMR flows and fish distributions away from the CVP and SWP pumps. Salvage was also lower in these two years than in 2005 and 2006.

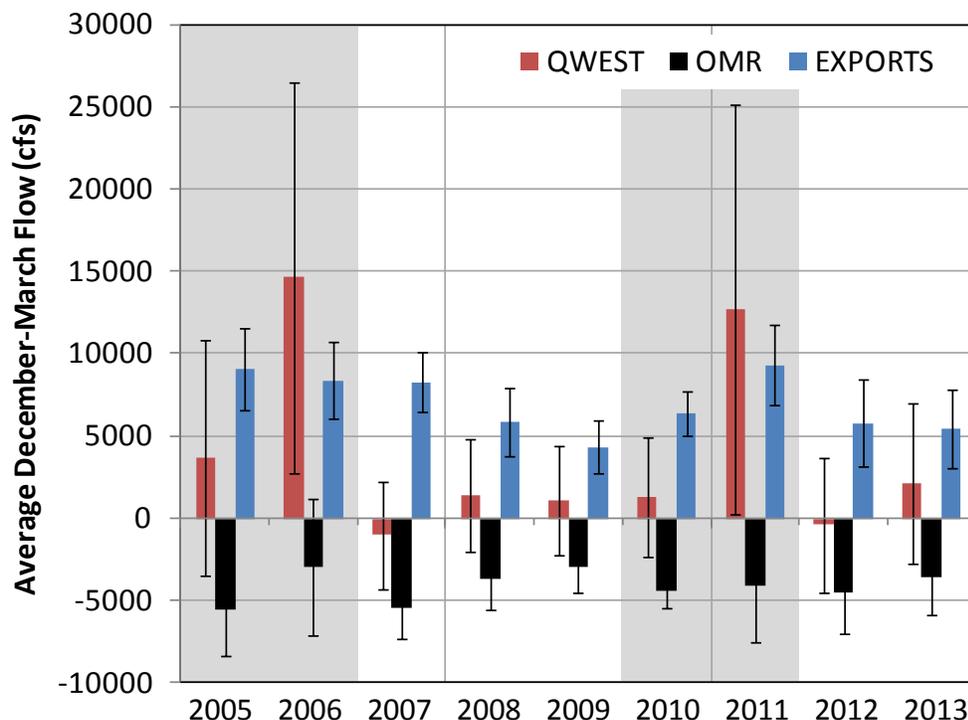

In summary, we conclude that hydrology and water exports do interact to influence entrainment risk for adult Delta Smelt and that adult Delta Smelt entrainment risk during the four comparison years was perhaps higher in 2005 than in the other years, but was low relative to historical levels in all four years.

Hypothesis 2: Hydrology interacting with turbidity affects predation risk for adult Delta Smelt.

At present, we do not have information about differences in actual predation mortality between the comparison years. As with entrainment, we thus limit this hypothesis and our analysis to to a general discussion of predation risk. Fully characterizing predation risk is exceptionally complicated, making it difficult to generate simple hypotheses that describe associated losses of all life stages of Delta Smelt. We thus limit our hypotheses about predation risk to a few factors for each life stage. For adults, we consider hydrology and turbidity as well as overlap with predators (next hypothesis).

Because Delta Smelt migrate during higher flow conditions when the water is generally turbid, it is assumed that losses to visual predators are lower or at least not substantially higher during the migration period than during other periods. First flush studies led by the USGS and UC Davis

Figure 63. Annual average daily net flows for December through March in cubic feet per second (cfs) in Old and Middle River (OMR), past Jersey Point on the lower San Joaquin River (QWEST) and total exports in millions of acre feet (MAF), 2005-2013. Error bars are 1 standard deviation.

suggest that Delta Smelt aggregate in the water column away from channel edges during daytime flood tides during upstream migration events (Bennett and Burau 2014), but it is not known if Striped Bass or Sacramento Pikeminnow *Ptychocheilus grandis*, the most likely predators of Delta Smelt in the water column, can detect and exploit these aggregations.

In the winters of 2005, 2006, 2010, and 2011 the highest Secchi depths (lowest turbidity) were found in the freshwater regions of the estuary (< 1 salinity), except for the Cache Slough region in the north Delta which was as turbid as the saltier regions of the estuary (Fig. 64). Winter-time Secchi depths in the freshwater region recorded during the SKT surveys (Fig. 64) were often higher (water clearer) than the average Secchi depths across all IEP EMP monitoring sites during these months since 2003 (about 60 cm) and especially when compared to pre-POD winter Secchi depths (around 50 cm on average) recorded by the EMP (Fig. 25). Winter-time Secchi depths in the other salinity regions were generally lower (water more turbid) than the EMP Secchi depth averages for the POD years and more similar to historical averages. In all four comparison years, predation risk associated with turbidity levels was thus likely not different from the historical risk in the more saline regions and the Cache Slough complex, but possibly higher in the freshwater regions, except for the Cache Slough region.

The salinity region differences were much more pronounced than the interannual differences between the four comparison years. Based on these data, it is not clear that higher flows in 2006 and 2011 contributed to higher turbidity in the winter months. The exception might be near the end of the Delta Smelt spawning season in early April when Secchi depths in the freshwater

region were often substantially lower in the two wetter years 2006 and 2011 than in the two drier years 2005 and 2010 (Fig. 64). This will be discussed further in the report section about larval Delta Smelt. For adults, we conclude that interannual differences in turbidity between the wetter and drier of the four comparison years did not likely contribute substantially to reduced predation risk and increased survival in the two wetter years.

Hypothesis 3: Predator distribution affects predation risk of adult Delta Smelt

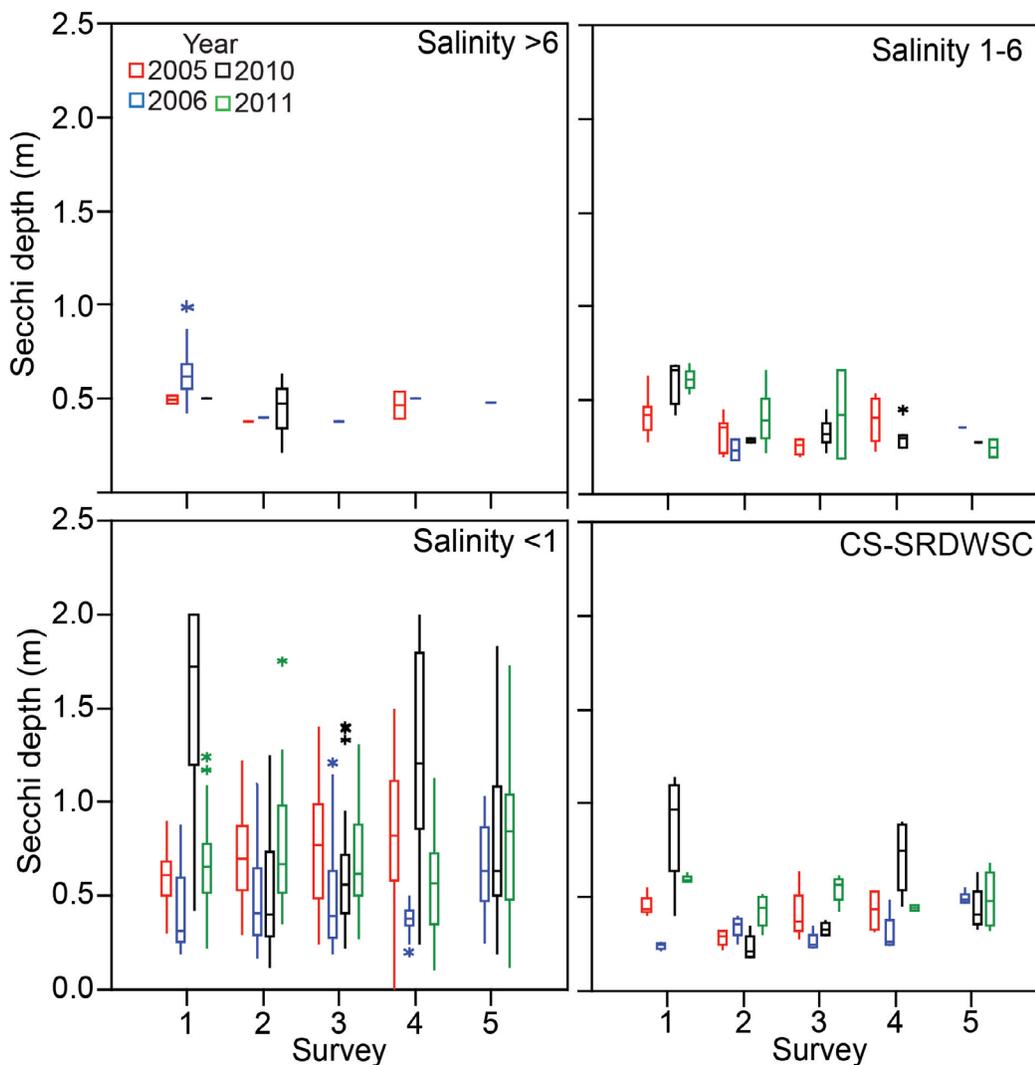

Spatial and temporal overlap with predators is a likely factor contributing to predation risk for all life stages. At present, we do not have information about how predator distribution varied between our comparison years but it is recognized that adult Delta Smelt could be vulnerable to predation if the distributions of predators and Delta Smelt populations overlapped. As already mentioned, Striped Bass and Sacramento Pikeminnow are the most likely open-water predators of adult Delta Smelt. If Delta Smelt utilize littoral habitats to a greater extent than presently assumed, then increased overlap with the distributions of Largemouth Bass and other centrarchid populations is possible. Results of field studies (Feyrer et al. 2013, Bennett and Burau 2014), described for Adult Hypothesis 2, found that adult Delta Smelt did move nearshore on a tidal basis to avoid displacement or move upstream during the “first flush.” Such movements would increase proximity to shoreline predators like Largemouth Bass, albeit during periods of increased turbidity when such visual predators would be at a disadvantage. Clearly, Hypothesis 2 and Hypothesis 3 are closely linked because predation risk is a function of predator presence and prey vulnerability. More information about predator presence is needed to evaluate this aspect of predation risk.

Hypothesis 4: Variability in prey availability during winter and spring affects growth and fecundity (eggs per clutch and number of clutches) of female Delta Smelt.

The hypothesis is that increased food availability leads to not only increased adult survivorship, but also growth, which in turn increases reproductive output (number of eggs per female increases with size; Bennett 2005). In addition, with cooler temperatures and lower metabolic rates, sufficient food resources during winter can contribute to energetically demanding multiple spawning events (three spawns possible in wild fish; L. Damon, CDFW, written communication 2012).

For adult females, the ability to meet the bioenergetic demands of reproductive development with sufficient food consumption may be particularly important for fish that spawn multiple times in a year. Preliminary findings from January through April 2012 indicated that adult Delta Smelt are indeed consuming large prey items, such as amphipods, mysids, and larval fish during their spawning period (Fig. 44) with feeding incidence near 98% for the period (Table 2). For this report, we cannot address whether food limitation is a relevant factor during the late winter-spring spawning period because we do not have sufficient data about adult Delta Smelt feeding, but we hypothesize that it may be a critical issue for spawners that need energy for multiple egg clutches. Evidence in support of this hypothesis comes from the modeling simulation experiment by Rose et al. (2013b) who found that food availability along with water temperature affected fall and winter growth and egg production prior to spawning and ultimately population success.

Figure 64. Secchi depth data collected during the Spring Kodiak Trawl Survey. Surveys are conducted monthly January-May. See Chapter 3: Data Analyses for explanation of boxplots.

Based on trajectories in adult fork lengths, it appears that adult growth may have been somewhat higher in 2005 and 2011 than in 2006 and 2010, although differences were not pronounced (Fig. 17) and as noted in Chapter 6, annual fork lengths of Delta Smelt collected in the SKT were similar in the four study years (Fig. 55). From these data we infer that environmental conditions were generally good, supporting both continued growth in length and maturation of eggs, except perhaps in 2010. In 2011, only 13 mature females were collected, so growth estimates are uncertain. In general, the number of mature females collected each year reflected year-class strength as measured by the SKT (Fig. 3), except in 2011 when only 13 ripe or ripening females were collected. Adults may use more energy for egg production than for continued somatic growth, but we do not have data on clutch sizes to evaluate this for the four study years.

Data on prey availability for current IEP sampling locations is also limited. Adult Delta Smelt diet is varied (Fig. 44) and includes pelagic and demersal invertebrates, as well as larval fish. Current mesozooplankton (copepod and cladoceran) and mysid sampling by the EMP

Table 2. Percent of age-1 Delta Smelt captured during the Spring Kodiak Trawl Survey with food present in the stomach collected January through May 2012 for three salinity regions and the freshwater Cache Slough-Sacramento River Deepwater Ship Channel (CS-SRDWSC).

		Month						
YEAR	REGION	JAN	FEB	MAR	APR	MAY	GRAND TOTAL	
2012	> 6	100%	100%				100%	
	1 - 6	100%	100%	100%	100%	0%	99%	
	< 1	100%	93%	100%	90%	89%	94%	
	CS-SRDWSC	100%	100%	100%	96%	100%	99%	
GRAND TOTAL	100%	99%	100%	95%	90%	98%		

Zooplankton Study and invertebrate sampling by the EMP Benthic Monitoring Study does not sample the full geographic range occupied by adult Delta Smelt, including Cache Slough and the Sacramento River Deep Water Ship Channel. In addition, epibenthic cumaceans and amphipods consumed by Delta Smelt might not be effectively sampled with current methods (substrate grabs using a Ponar dredge), which are more suited to sampling organisms in or attached to the substrate. Amphipods found in stomachs of adult Delta Smelt collected January 2012-May 2012 (Fig. 44) were 95% *Corophium* spp., and of those, 90% were juveniles ranging 0.8 to 1.3 mm in body length. These amphipods are believed to be mostly juvenile *Americorophium spinicorne* and *A. stimpsoni*, which as adults are tube building amphipods (Hazel and Kelley 1966). Dirt, substrate debris, and tube pieces were not found in Delta Smelt stomachs with the amphipods, so it is possible these juveniles amphipods are epibenthic or pelagic prior to settling and building tubes. Size distribution of amphipods collected by the DWR EMP Benthic Monitoring Study is not currently available. The IEP Smelt Larva Survey does collect larval fish data during winter (January-March) over a wide section of the estuary, but comparisons with larval fish consumption by adult Delta Smelt are limited because this survey is still new; it was initiated in 2009.

Data were insufficient to conclusively test the hypothesis that variability in prey availability affects growth and fecundity of adult Delta Smelt. More data are needed on growth, clutch number and size, and prey availability.

Larval Hypotheses

Hypothesis 1: Delta Smelt larvae numbers are positively affected by increased duration of the temperature spawning window

To evaluate this hypothesis, we developed two water temperature measures. The first is the number of days in the temperature spawning window as indexed by mean daily water temperatures at Rio Vista between 12 and 20 °C. This temperature range was selected as representing a reasonable balance between the various temperature ranges observed in laboratory

and field studies (Wang 1986, Baskerville-Bridges et al. 2004b, Bennett 2005) and reviewed in earlier sections of this report. Presumably, a longer duration spawning window would result in more repeat spawning for individual females and greater total fecundity. The second water temperature measure is the number of days in the optimal temperature for egg survival to hatch. We referred to Fig. 10a in Bennett (2005) and selected the temperature range of 12-17 °C as optimal for egg survival. As explained in previous sections, adult abundance, based on SKT sampling, peaked in 2012 as the 2011 year-class of Delta Smelt reached maturity (Fig. 3). In contrast, the spawning stock (i.e., 2011 SKT) that produced the 2011 year-class ranked second lowest to 2006 (Fig. 3, Adults). Despite this low level, the 2011 spawning stock produced the highest adult abundance observed to date in 2012. This suggests that adult stock size has not limited subsequent adult recruitment from rebounding to levels comparable to those of immediate pre-POD years (see Fig. 3, Subadult). As mentioned in Chapter 6, this suggests that even a severely depleted adult stock can still produce a substantial number of larvae and a rebound in the Delta Smelt population, albeit with potentially lower genetic variability than before (Fisch et al. 2011). It also suggests that factors acting on the survival of larval, juvenile and later stages have a substantial effect on recruitment of adults, because relatively low larval abundance in 2011, was associated with the high 2012 adult abundance (Fig. 3).

As mentioned in the adult section, mature adult female Delta Smelt appeared to grow throughout the spawning seasons of the years compared, except 2010 (Fig. 17). We used water temperatures at the Rio Vista Bridge as a surrogate for temperatures experienced by spawning Delta Smelt (Fig. 65) and calculated the duration of the spawning window and of optimal temperatures to hatch. We calculated each as the number of days between the date of first achieving the lower temperature and the date of first achieving the upper temperature. The onset of the spawning window occurred earliest in 2010, followed by 2005 and 2011 (Fig. 65; Table 3). The spawning window occurred latest in 2006 (Fig. 65; Table 3). The spawning window was broad in both 2005 and 2010 at 128-129 days, intermediate in 2011 at 113 days (20 °C not achieved until July 4, not shown), and was shortest in 2006 at 85 days (Fig. 65; Table 3). Assuming that female Delta Smelt undergo a 35-day refractory period, based on a 4-5 week refractory period (J. Lindberg, U.C. Davis, personal communication, 2013) between each spawning, even in 2006 three spawning events were possible, assuming fish were mature and ready to spawn at the initiation of the spawning window. In all other years, four spawning events were possible, so this measure does not discriminate among years well. The duration of optimal hatch temperature was also lowest in 2006, but other durations ranked differently across years than did spawning window duration (Table 3).

The data for the four study years do not provide conclusive support for the hypothesis that the duration of the spawning window or duration of optimal hatching temperature affected larval production. Relatively high larval abundance in 2005 was consistent with a long spawning window and moderate duration of optimal hatch temperatures (129 days and 68 days, respectively; not shown). However, 2006 with the shortest spawning window (85 days) and shortest optimal hatch duration among the 4 study years also had relatively good larva abundance (Fig. 3). In contrast, larval abundance was low in 2010 although the spawning window and optimal hatch duration were both relatively long. Other factors likely contributed to poor larval abundance in 2010, because ripening and ripe females were not detected after early April 2010 and female growth through the winter was poor (Fig. 17). Finally, both the spawning window and optimal hatch duration were fairly long in 2011 as compared to 2006, so slightly lower larval production in 2011 is inconsistent with these durations. This hypothesis was not supported.

Figure 65. Mean daily temperatures (°C) at Rio Vista from February 1 through June 30, 2005, 2006, 2010, 2011. The green lines enclose the spawning window, which represents temperatures at which successful spawning is expected to occur.

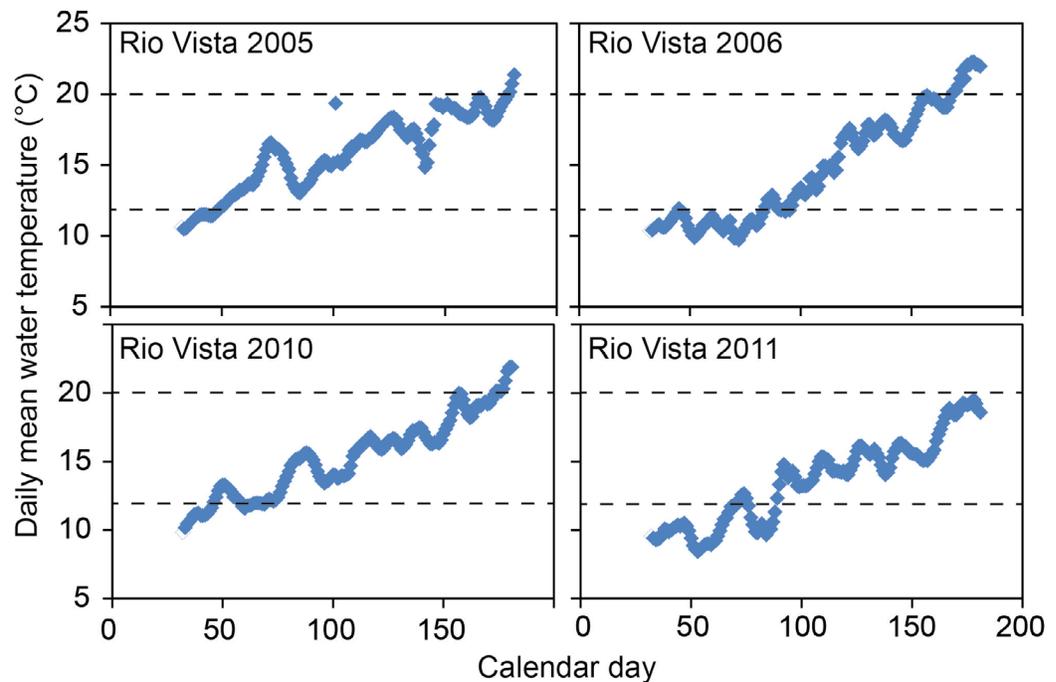

Table 3. Delta Smelt spawning window (12 to 20 °C inclusive) and optimal hatching period (12 to 17 °C inclusive) for 2005, 2006, 2010, and 2011, defined as number of days of water temperatures, based on mean daily water temperatures measured at Rio Vista. Data are calendar day when water temperature achieved 12, 17, and 20 °C and the duration (days) between those calendar days. The upper limit in 2011 was not reached until July 4, outside the spring season.

Year	Day 12 °C Achieved	Day 17 °C Achieved	Day 20 °C Surpassed	Duration 12-20	Duration 12-17	Duration 17-20
2005	50	118	179	129	68	61
2006	84	120	169	85	36	49
2010	46	136	174	128	90	38
2011	72	163	185	113	91	22

Hypothesis 2: Increased food availability results in increased larval abundance and survival.

This hypothesis focuses on seasonal changes in phytoplankton biomass and the zooplankton community and resulting changes in abundances of food items most often consumed by Delta Smelt larvae. Phytoplankton biomass data (chlorophyll-*a*) collected at 10 stations by the IEP

EMP show that the highest spring biomass levels were observed in May of 2010 and 2011 (Fig. 66). Median biomass levels were lower in April and May of 2005 and 2006 than in April and May of 2010 and 2011. This suggests that more food was available for zooplankton growth in the spring of 2010 and 2011 than in 2005 and 2006. In all four years, however, chlorophyll concentrations were lower than 10 ug/L at almost all stations, suggesting that zooplankton may have generally been food limited in these years (see Chapter 4). Nevertheless, greater phytoplankton biomass in late spring of 2010 and 2011 may have contributed to overall greater food availability and better survival of late larvae and early juveniles in these years.

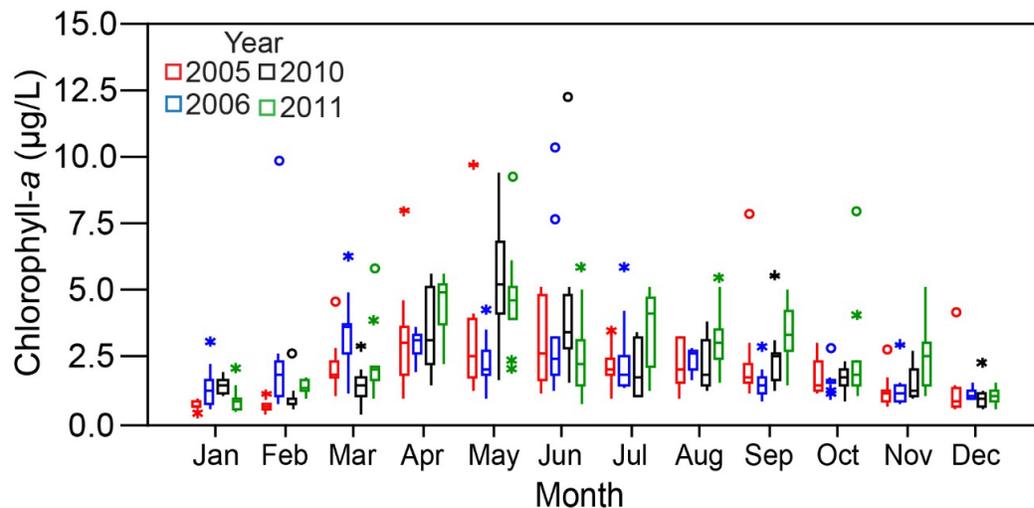

Juvenile and adult calanoid copepods, particularly *E. affinis* and *P. forbesi*, comprise most of the larval diet through June (Nobriga 2002, Slater and Baxter 2014). *E. affinis* is moderately abundant only during winter and spring and rare in summer and fall, whereas *P. forbesi* is abundant only in summer and fall (Durand 2010, Hennessy 2010, 2011, Winder and Jassby 2011). It is not clear whether the seasonal decline in abundance of *E. affinis* is related to temperature, potential competitive interactions with *P. forbesi*, differences between the species in vulnerability to consumption by *P. amurensis* (Miller and Stillman 2013), or a combination of such factors. The transition between high abundances of the two species, may create a seasonal “food gap” during late spring or early summer. This food gap has been hypothesized to be an important period for Delta Smelt larval survival (Bennett 2005, Miller et al. 2012).

To assess whether a gap in prey availability existed between periods of high abundance of *E. affinis* and *P. forbesi*, we evaluated abundance patterns in 20 mm Survey copepod data for stations with and without Delta Smelt. The food gap hypothesis was only weakly supported by the data. The density of *E. affinis* (in the presence of Delta Smelt larvae) typically reached 100 m³ by week 16 (Figs. 67 and 68). Assuming 100 m³ as a baseline density for *E. affinis*, this baseline was generally maintained until about week 22, when they declined at about the same time that *P. forbesi* densities increased to 100 m³ (Figs. 67 and 68). After combining the densities of both *E. affinis* and *P. forbesi* and tracking them through time, we detected a gap in food during week 22 (late May – early June) of 2005 (Fig. 67), which is inconsistent with 2005 exhibiting the highest larva abundance among our comparison years (Fig. 3). Such density gaps were not observed in the other three comparison years (Figs. 67 and 68), which exhibited lower abundance than 2005 (Fig. 3). Survival of larvae to juveniles was very low in 2005, but was also low in 2006 (Fig. 51) with no evidence for a food gap in 2006. Survival of larvae to juveniles was relatively high in 2010 and 2011 (Fig. 51). This analysis does not support the hypothesis that differences in zooplankton availability affected larval abundance and survival in the four study years, but higher phytoplankton biomass in April and May of 2010 and 2011 could have contributed to overall greater food availability and better survival of late larvae and early juveniles in these years.

Hypothesis 3: Distributional overlap of Mississippi Silverside with Delta Smelt and high abundance of Mississippi Silverside increases predation risk/rate on larval Delta Smelt, whereas, increased turbidity, decreases predation risk/rate on larval Delta Smelt.

Silversides are ubiquitous within the Delta (Brown and May 2006) and have long been proposed (Bennett 1995) and more recently confirmed as a predator of Delta Smelt larvae (Baerwald et al. 2012). We do not have estimates of predation losses to Silversides during the four study years and thus focus on assessing predation risk by evaluating fish distributions, predator and prey sizes, and prey growth, which is related to temperature.

Figure 66. Trends in chlorophyll-a concentrations ($\mu\text{g/L}$) in samples collected by the IEP Environmental Monitoring Program during each the four study years (2005, 2006, 2010, and 2011). Sample site locations shown in figure 15. See Chapter 3: Data Analyses for explanation of boxplots.

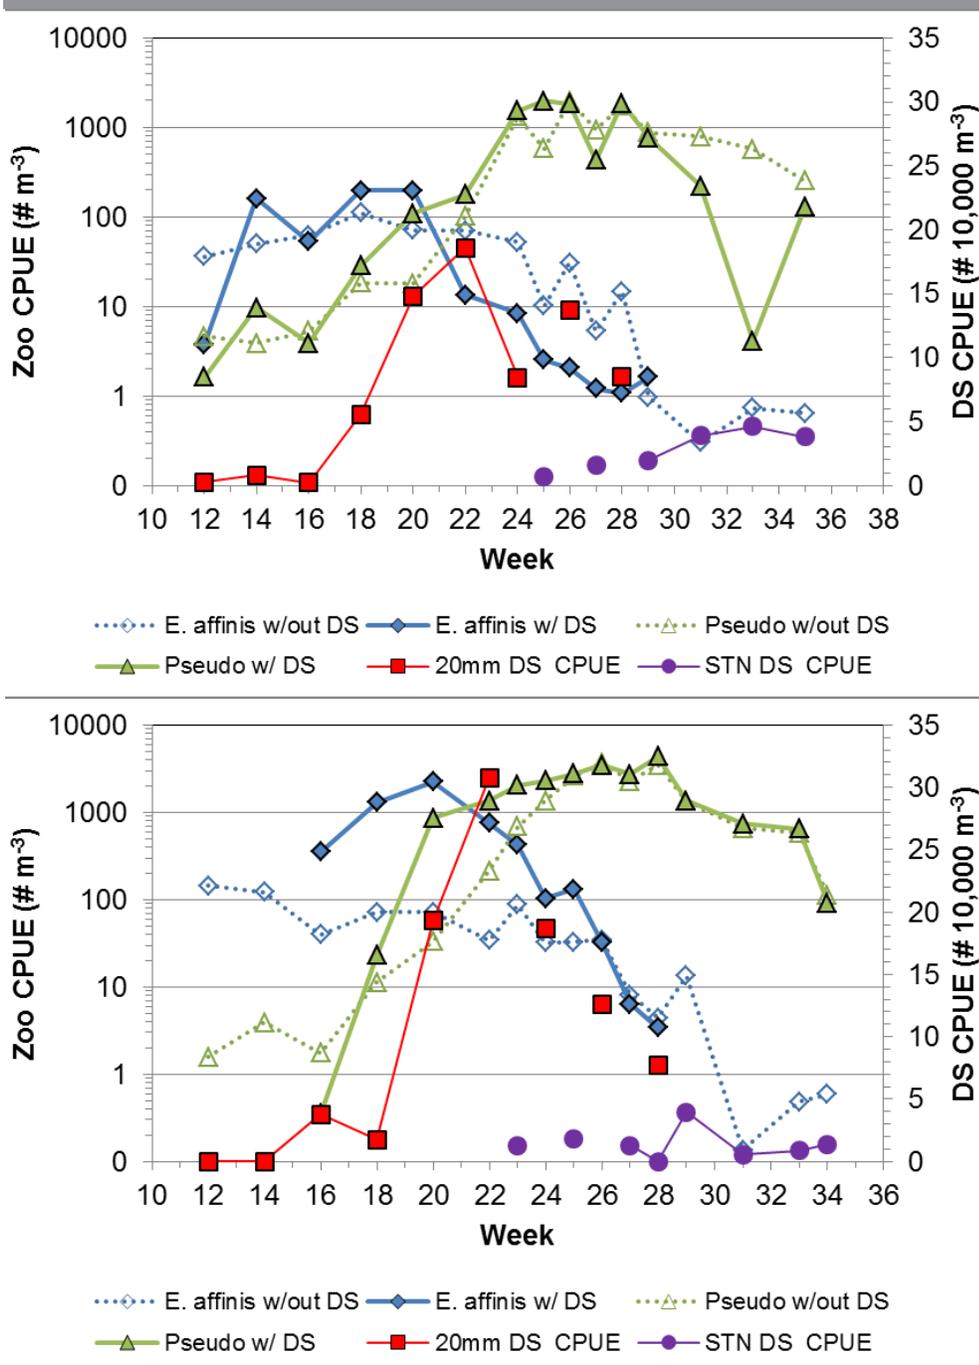

Silversides large enough to consume fish larvae are present in the Delta during spring and are likely to prey upon Delta Smelt larvae. Silverside habitat has been characterized as open water shoals and shoreline (Brown and May 2006, Grimaldo et al. 2012); however, the species also occurs in low density in deep open water primarily in summer (Grimaldo et al. 2012). Catches in the SKT confirm silverside presence in open water in spring as well, though catches tended to be low. However, SKT sampling does not occur at night when offshore Silverside densities may be higher, if foraging patterns follow those observed in Clear Lake, California (see Wurtsbaugh and Li 1985). Compared to the open embayments, SKT Silverside catches were higher in channels such as Montezuma Slough, Cache Slough, the San Joaquin River, and especially the Sacramento Deepwater Ship Channel (Table 4). This Silverside distribution matched higher March through May regional catches of Delta Smelt larvae (Table 4, see http://www.dfg.ca.gov/delta/data/20mm/CPUE_map.asp), except that larvae catches in Suisun Bay and the lower Sacramento River were occasionally high and Silversides catches were usually low. Delta Smelt larvae were found in significantly higher densities in offshore-open water habitats (Grimaldo et al. 2004), which corresponds to the habitat where Silversides consuming Delta Smelt larvae were captured (Baerwald et al. 2012). As discussed above, the relatively large-sized silversides present in the Spring Kodiak Trawl indicates some offshore movement and overlap of predator-sized foraging silversides with Delta Smelt larval habitat.

The frequency and magnitude of Silverside catches by the Spring Kodiak Trawl increased as Secchi depths approached and dropped below 50 cm (Fig. 69), suggesting that Silversides may venture offshore more frequently and in higher numbers in turbid water. This might also represent a displacement effect resulting from high flows, but high catches were most common in Montezuma Slough and the Sacramento Deepwater Ship Channel (Table 4) where displacement by flow should not have been a factor.

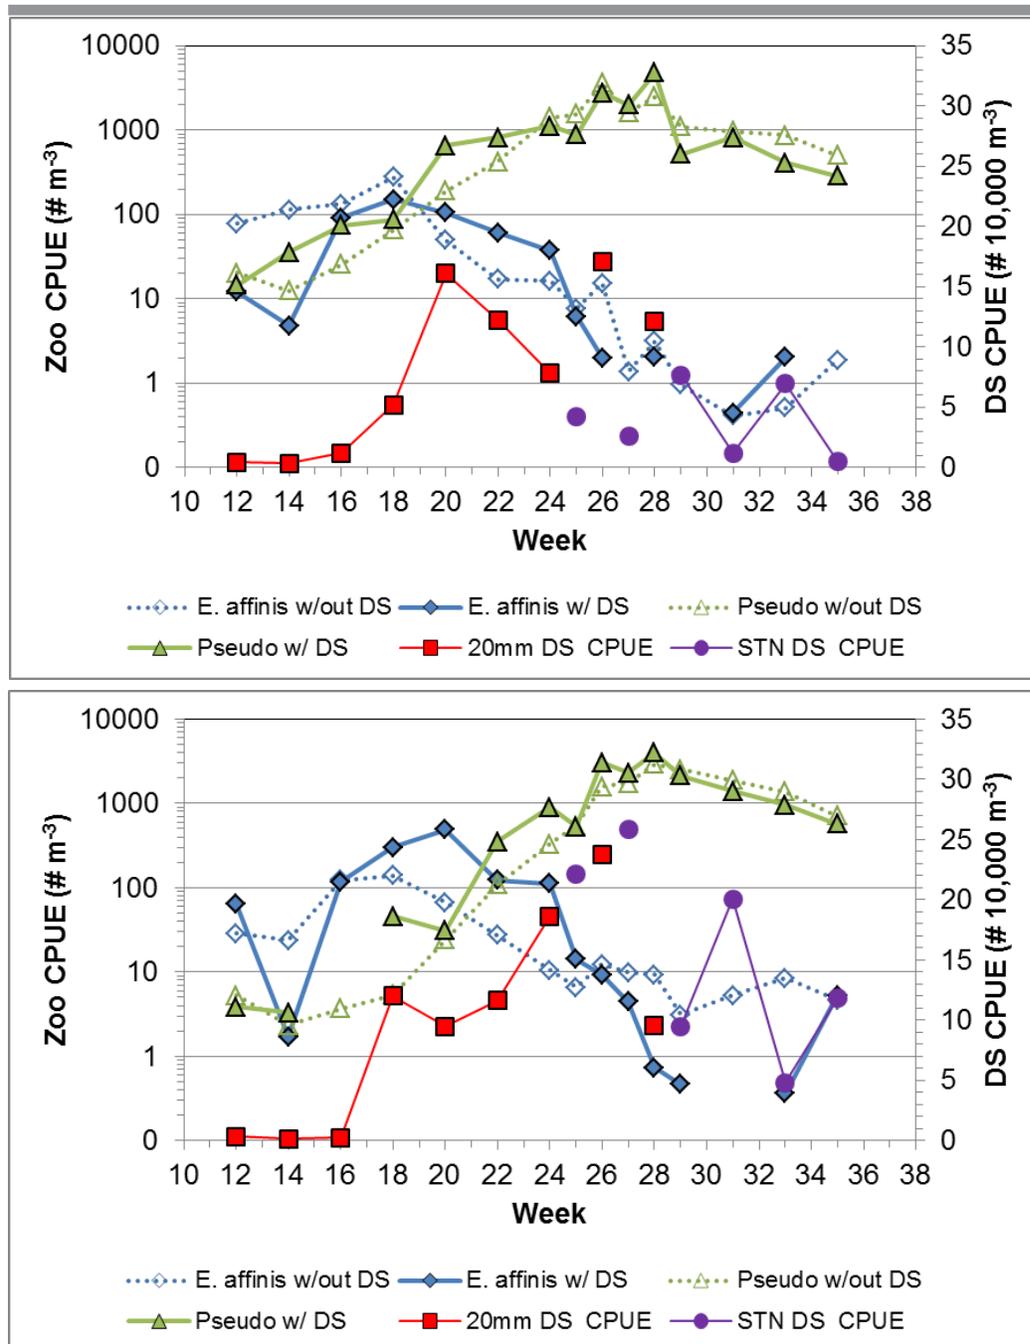

The hypothesis is somewhat supported in that: 1) Silversides are captured in Spring Kodiak Trawl in March and April (Fig. 70), when early stage Delta Smelt larvae are common; 2) Silverside

Figure 67. Catch per unit effort (CPUE) of adult *Eurytemora affinis* and *Pseudodiaptomus forbesi* (Zoo; number individuals/m³ sampled) and Delta Smelt (DS; number individuals/10,000 m³ sampled) by calendar week from mesozooplankton sampling and Delta Smelt catch by the 20 mm and Summer Towntet surveys, 2005 (top) and 2006 (bottom)

catches offshore increase with increased turbidity (i.e., declining Secchi depth; Fig. 69), and 3) there is regional overlap in Cache Slough and the Sacramento Deepwater Ship Channel, and some in Montezuma Slough (cf. Table 4 and http://www.dfg.ca.gov/delta/data/20mm/CPUE_

Figure 68. Catch per unit effort (CPUE) of adult *Eurytemora affinis* and *Pseudodiaptomus forbesi* (Zoo; number individuals/m³ sampled) and Delta Smelt (DS; number individuals/10,000 m³ sampled) by calendar week from mesozooplankton sampling and Delta Smelt catch by the 20 mm and Summer Townet surveys, 2010 (top) and 2011 (bottom).

map.asp), known larval rearing regions. It is also possible the nighttime offshore foraging by silversides is a more common strategy (Wurtsbaugh and Li 1985), but one that goes undetected by current sampling. Silverside catch per trawl (Table 4) indicates low offshore densities and the same turbidity that facilitates offshore movement may also inhibit predation effectiveness.

Table 4. Mississippi Silverside catch by region (monthly sample number in parentheses) and year by the Spring Kodiak Trawl Survey sampling monthly March through May (months when Delta Smelt larvae are present), 2005, 2006, 2010 and 2011; distribution survey data only. Annual sampling effort summarized consisted of 3 surveys and 37 stations. Tow volume varied substantially, but averaged 6,300 m³ per tow for the 4 years.

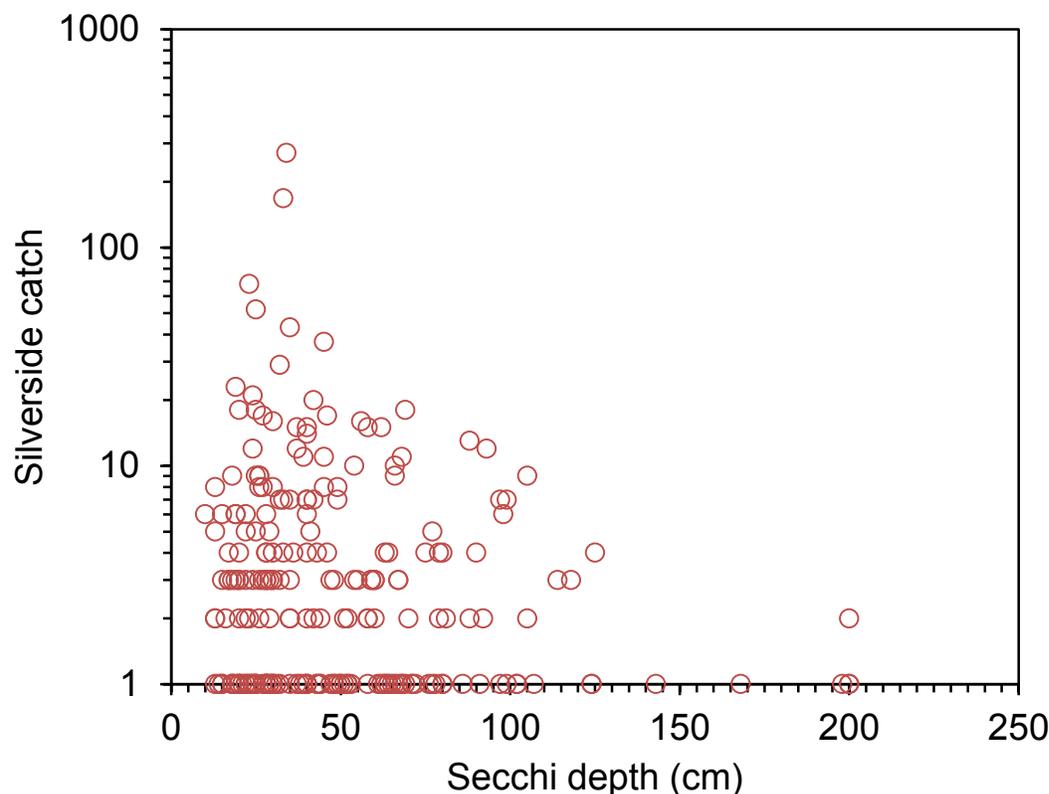

Region	2005	2006	2010	2011	Total Catch	Total Catch per Trawl
SUISUN BAY (N=10)	1	1	2	1	5	0.04
MONTEZUMA SL (N=3)	51	4	17	22	94	2.61
LOWER SACRAMENTO R (N=4)	10	1	1	3	15	0.31
CACHE SL (N=3)	9	2	4	2	17	0.47
SAC DEEPWATER SHIP CHANNEL (N=1)	14	20	45	22	101	8.42
SAN JOAQUIN R (N=8)	39	9	11	14	73	0.76
MOKLEMNE R. (N=5)	1	1	1	8	11	0.18
SOUTH DELTA (N=3)	1	0	1	1	3	0.08
ANNUAL TOTAL FOR REGIONS	126	38	82	73	319	

Overall, the conclusion regarding the effects of species distributions and abundances on predation risk is unclear. If there is an effect, it is most likely to occur in smaller channels, such as Montezuma Slough and those in the Cache Slough and the Sacramento Deepwater Ship Channel where Silversides are present in high numbers along the shoreline and larval Delta Smelt occur offshore.

Hypothesis 4: Hydrology and water exports interact with one another to influence direction of transport and risk of entrainment for larval Delta Smelt.

As for adults, we do not have proportional entrainment estimates for all four study years, so the entrainment portion of this hypothesis cannot be directly evaluated. Also, larvae (< 20 mm fork length) entrained in the State and federal water export systems are generally not quantified. To test this hypothesis we use data for the distribution and density of larvae (\geq 20 mm fork length)

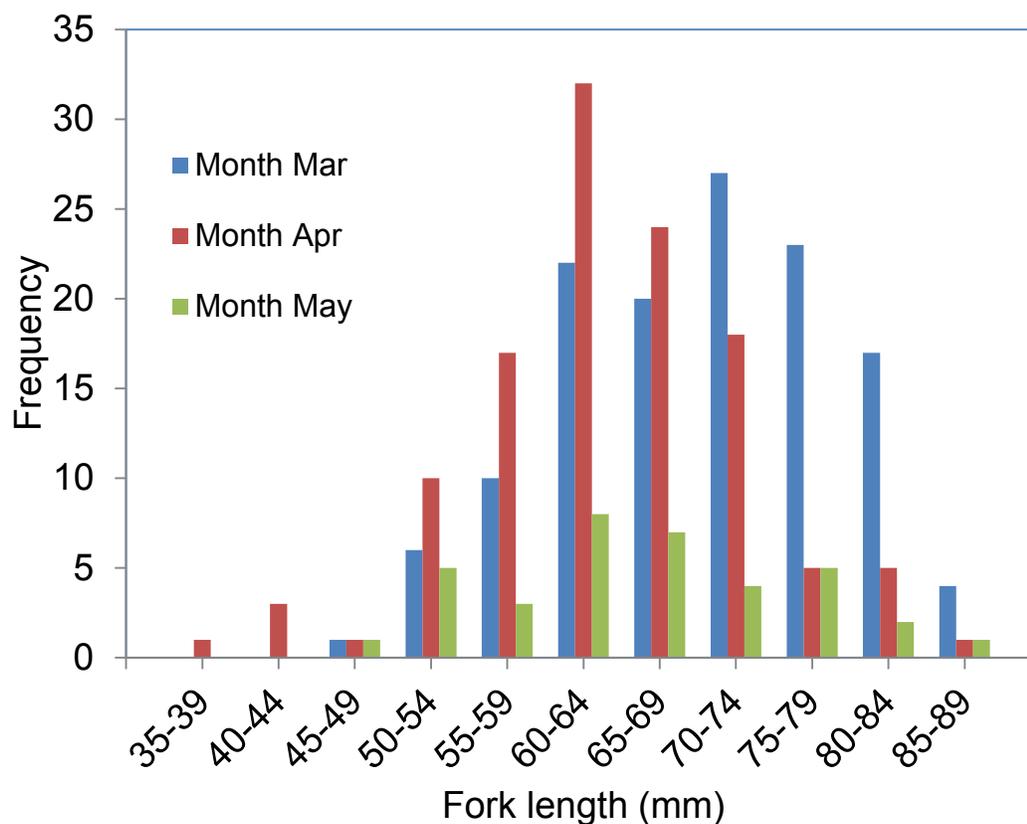

Figure 69. Scatter plot of Mississippi Silverside catch plotted on Secchi depth (cm) at location of capture from the Spring Kodiak Trawl Survey, 2005, 2006, 2010 and 2011.

in the central and south Delta and estimates of channel flows to infer risk of entrainment. Among the study years only 2005 larval entrainment was estimated by Kimmerer (2008), and loss to the population was relatively low. However, Delta Smelt density and distribution in the central and south Delta were greater in 2005 than in the three other study years (Table 5). This simple analysis suggests that in our 4-year comparison, entrainment risk for larval Delta Smelt may have been highest in 2005. Hardly any larval Delta Smelt were caught in this region in the two wet years, 2006 and 2011.

As for adults, we also used OMR flows (Fig. 31) to assess larval entrainment risk. Mean March through May OMR flows were positive during the two wet years 2006 and 2011 (8,221 cfs and 3,560 cfs respectively) and negative during the two dry years 2005 and 2010 (-417 cfs and -1,302 cfs, respectively). These OMR values suggest little if any risk during 2006 and 2011, and at most moderate risk in 2005 and 2010. Grimaldo et al. (2009) found that juvenile salvage was a function of abundance in the 20 mm Survey (positive) and OMR flows (negative). Looking more closely at various net daily flows from March to June of 2005, we find that OMR flows were moderately negative (i.e., toward the export pumps) only in March, and were zero to weakly positive in April and May, except for a brief period in mid-April (Fig. 31); also in 2005, Qwest was strongly positive from late March through early June, promoting downstream transport in the San Joaquin River, and exports were low from late April through late May (Fig. 31). The other dry year, 2010 exhibited a similar pattern, but lower inflows resulted in the magnitude of exports more directly influencing OMR flows (Fig. 31), and leading to moderately negative OMR flows

Figure 70. Monthly length frequency of Mississippi Silversides captured by the Spring Kodiak Trawl during distribution sampling March – May in the Sacramento River and Cache Slough sampling stations only, 2002-2012. The months and geographic range were selected to overlap with that of Delta Smelt larvae as they hatch and begin to grow.

in March and again in June, but only weakly negative flows in April and most of May coincident with positive Qwest. In the high outflow years 2006 and 2011, few larvae were detected in the central or south Delta (Table 5) and Qwest flows were strongly positive from March through at least early June, while OMR flows were near zero or weakly negative in March and positive to strongly positive by April and continuing to early June of both years (Fig. 31). Thus, for our comparison years, it appears that the available data generally support our hypothesis, but entrainment of larvae was unlikely to be an important factor during either wet year and was probably not a substantial factor in either dry year.

Table 5. Mean monthly catch of Delta Smelt per 10,000 m³ by station for stations in the south and central Delta for the 20 mm Survey, 2005, 2006, 2010, 2011. Non-zero values are bolded.

Juvenile Hypotheses

Hypothesis 1: High water temperatures reduce juvenile Delta Smelt growth and survival through lethal and sublethal (bioenergetic stress; reduced distribution) effects.

High water temperatures have a strong effect on juvenile Delta Smelt survival (Swanson et al. 2000, Komoroske et al. 2014). In addition to the obvious potential for lethal effects, temperature can have sub-lethal effects such as reduced habitat area, higher food requirements, increased susceptibility to disease and contaminants, and increased predation. The potential for increased prey requirements and increased predation is described below for other hypotheses.

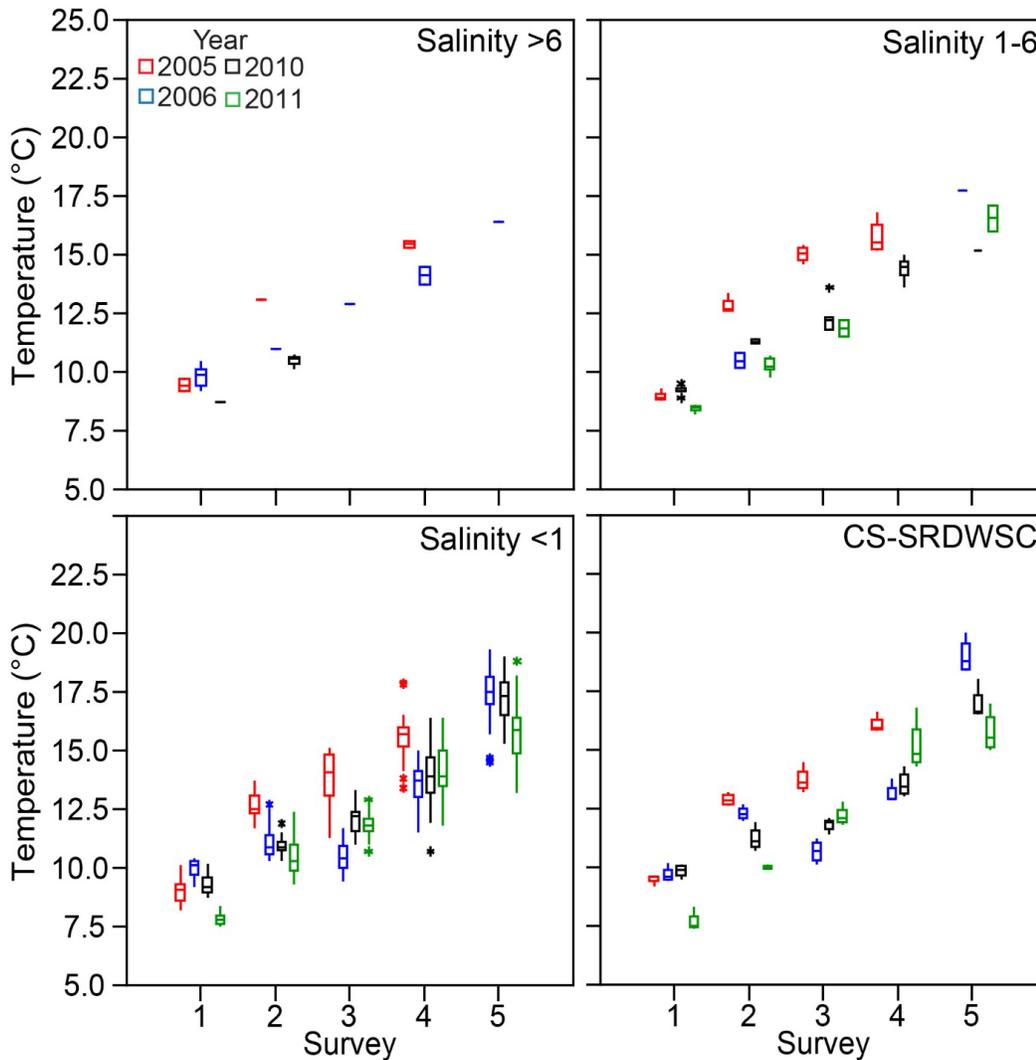

As noted in the adult section, spring water temperature was generally coolest in 2006 and 2011, but warmed up more rapidly toward the end of spring 2006 (May) than in spring 2011. Spring water temperature was overall warmest in 2005 (Fig. 71). Following the high late-spring water temperatures in 2005 and 2006, summer temperatures in 2005 and 2006 tended to be higher than in 2010 and 2011 during July and August (e.g. TNS surveys 3-5; Fig. 72). Temperatures during surveys 4 and 5 may have been particularly important as they exceeded lethal levels in freshwater at some sites, suggesting the potential for mortality. Note that this does not mean that temperatures were universally cooler in 2010 and 2011 than in 2005 and 2006; for example the region around Cache Slough had relatively high temperatures in August 2011. Larval to juvenile survival (ratio of TNS index to 20 mm index) was highest in 2011 followed by 2010, 2006, and 2005, suggesting that the cooler late spring and summer temperatures in 2011 and 2010 may have been beneficial for Delta Smelt. However, juvenile to subadult survival (ratio of FMWT index to TNS index) was highest in 2011 and lowest in 2010 (Fig. 51). While relatively high water temperature in late spring and early to mid summer of 2005 and 2006 may thus have contributed to low survival of late-stage larvae and early juveniles, water temperature may have been less important to survival in the late summer and early fall. Overall, the results of this analysis of temperature and survival data support our hypothesis that high water temperatures reduce juvenile Delta Smelt growth and survival.

At this point, our data and analyses are inadequate to address temperature effects on juvenile Delta Smelt growth. Although there are some data for Delta Smelt growth during several of the target years, it is difficult to separate the relative effects of improved bioenergetics (see below) versus simple ontogenetic changes in fish size. Juvenile fish growth rates are typically not constant and change with size (“allometric effects;” Fuiman 1983). Specifically, daily growth rates (e.g., mm/day) are often faster for smaller fish and slower for older fish. Hence, cooler years may delay Delta Smelt transitions from faster to slower growth phases, yielding a relatively fast measured growth rate at a specific point in time (e.g., September) because at that specific time the fish are still relatively young and still on the “steepest” part of an idealized growth curve.

Hypothesis 2. Distribution and abundance of Striped Bass, temperature, and turbidity influence predation risk/rate on juvenile Delta Smelt

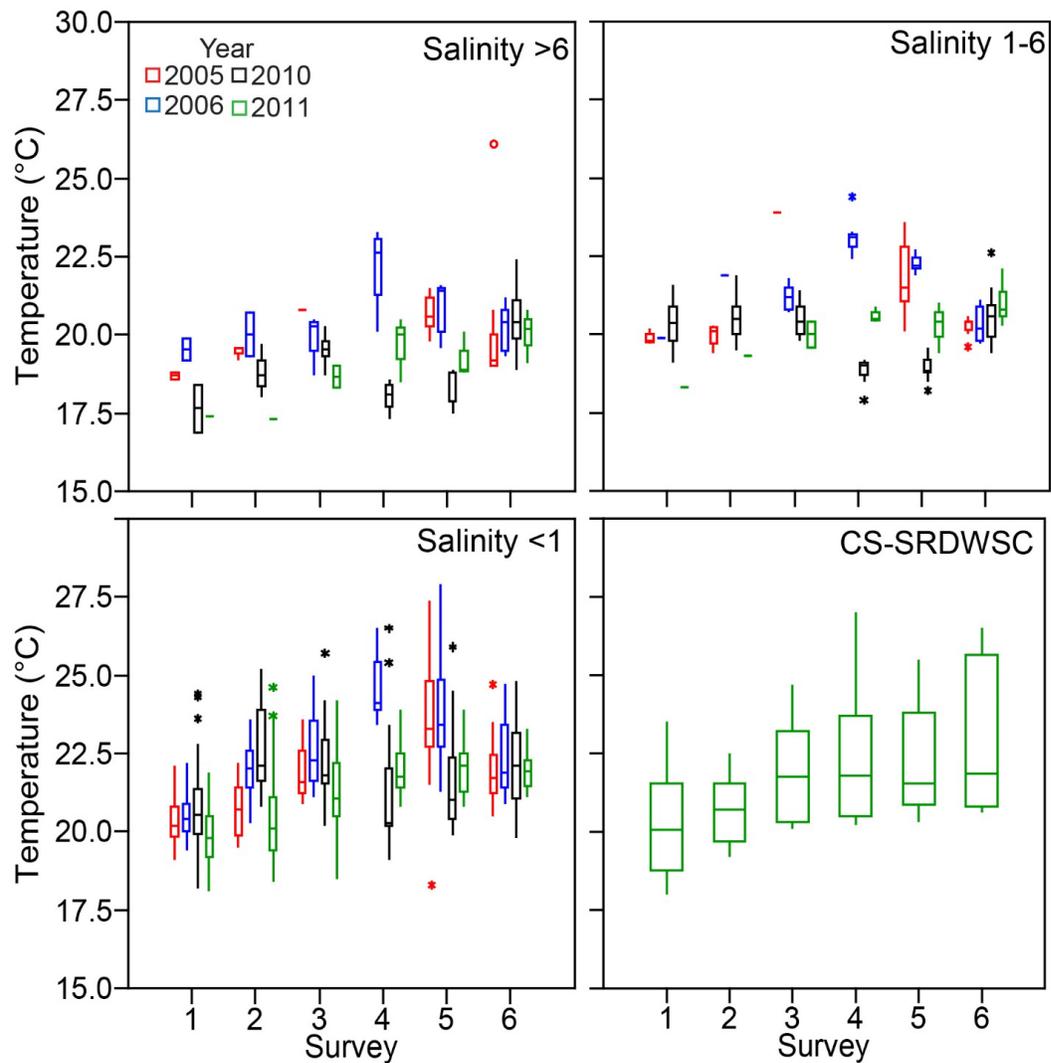

We hypothesize that subadult (age 1-3) Striped Bass are the major predator on juvenile Delta Smelt and that losses are likely affected by temperature and turbidity patterns. However, other factors likely affect predation risk (e.g., other predators such as centrarchids) and several factors

Figure 71. Water surface temperature data collected during the Spring Kodiak Trawl Survey for three salinity regions and the Cache Slough-Sacramento River Deepwater Ship Channel (CS-SRDWSC). Surveys are conducted monthly January-May. See Chapter 3: Data Analyses for explanation of boxplots.

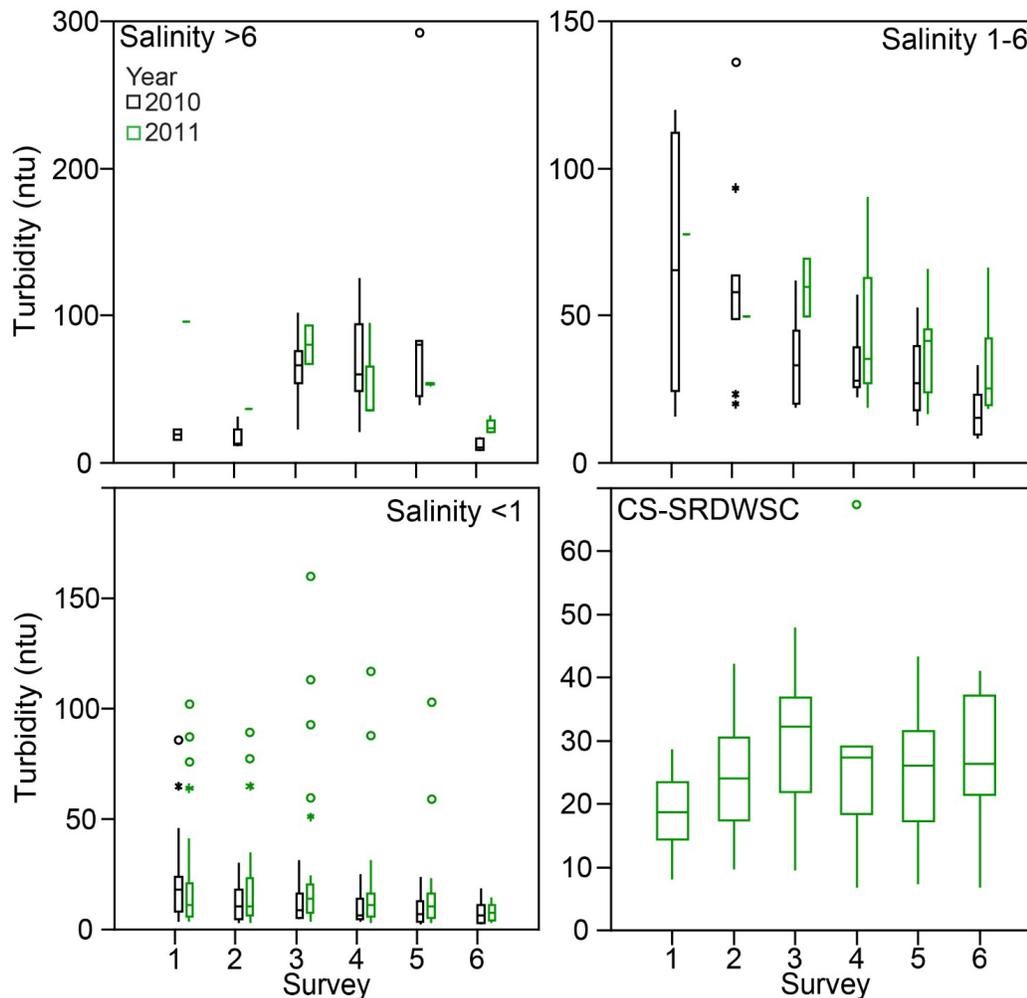

may interact. As noted above for temperature and below for food, high temperatures and low prey density likely lead to bioenergetics problems and increased foraging activity, which might reduce predator avoidance behavior (e.g., Marine and Cech 2004) in Delta Smelt. These effects may be compounded by low turbidity, which makes Delta Smelt more visible to predators in their habitat. Although higher Striped Bass abundance could theoretically result in greater consumption of prey including Delta Smelt (Lobschefsky et al. 2012), changes in habitat variables for both species such as food, temperature, and turbidity mean that predation rates on Delta Smelt periodically may be independent of predator abundance. Although there has been substantial progress in modeling (Lobschefsky et al. 2012, Nobriga et al. 2013) and genetic methods (Baerwald et al. 2012), there is not yet a standardized way to assess the effects of predation on Delta Smelt. Moreover, there are no effective surveys to assess age 1-3 Striped Bass abundance or distribution. Therefore, we are unable to directly evaluate this hypothesis. Lacking this information, we can

Figure 72. Water temperature data collected during the Summer Towntnet Survey for three salinity regions and the Cache Slough-Sacramento River Deepwater Ship Channel (CS-SRDWSC). Surveys are conducted biweekly June-August. See Chapter 3: Data Analyses for explanation of boxplots.

at least examine turbidity and temperature patterns for the four years. Temperature responses were described for Hypothesis 2. In general, summer 2005 and 2006 temperatures were relatively higher than 2010 and 2011 during key summer months (e.g. TNS surveys 3-5; Fig. 72). We expect that cooler temperatures in 2010 and 2011 may have contributed to reduced predation on Delta Smelt. Turbidity data are limited to 2010 and 2011 (Fig. 73). There were no consistent differences between the two years. Secchi depth data did not suggest major differences among the 4 years except at salinities > 6 when 2005-2006 had higher values in some months (Fig. 74).

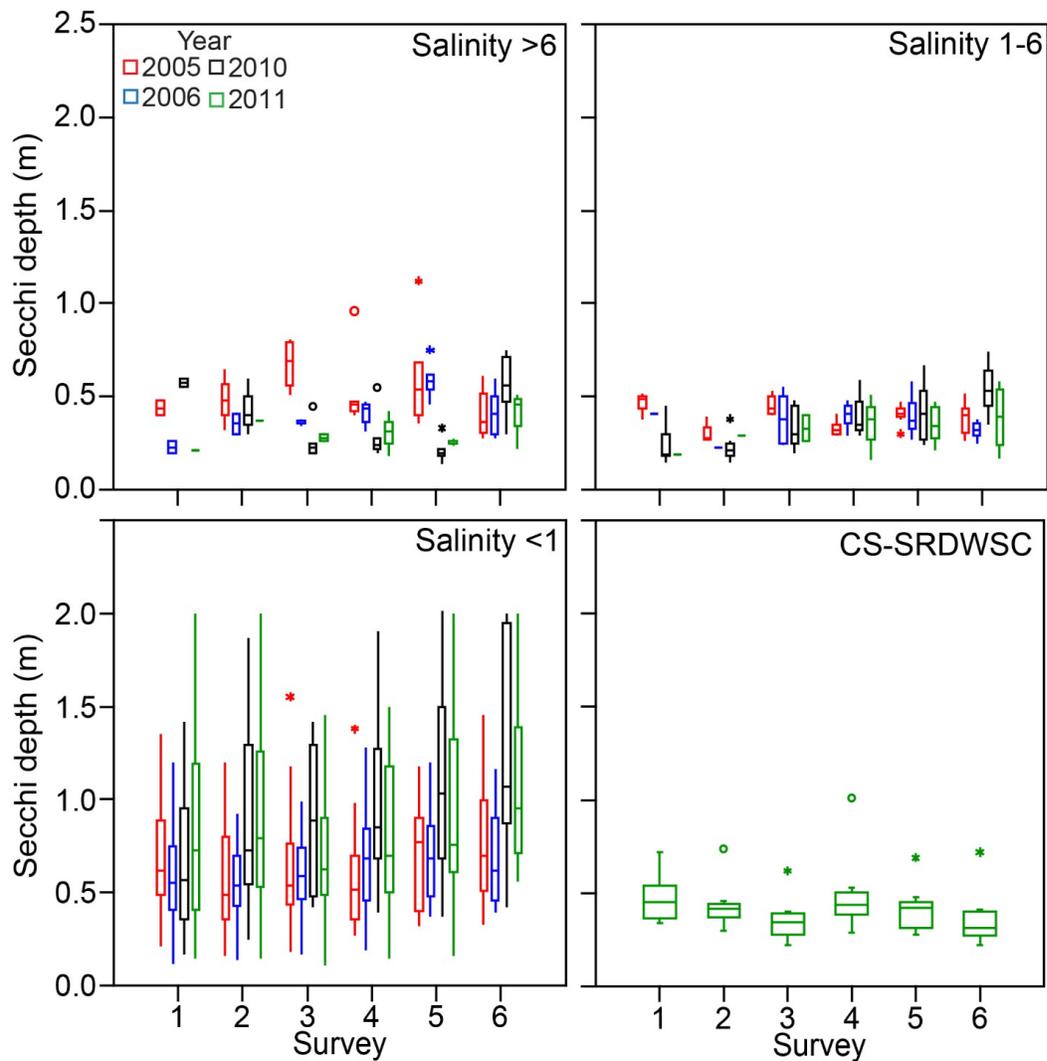

Figure 73. Turbidity data collected during the Summer Townet Survey. Surveys are conducted biweekly June-August. Note different scales among salinity regions. See Chapter 3: Data Analyses for explanation of boxplots.

Hypothesis 3. Juvenile Delta Smelt growth and survival is affected by food availability.

As for Hypothesis 1, we are currently unable to evaluate the growth data because water temperature affects development time, and because growth curves are complicated by allometric effects. The general conceptual model is that higher food abundance results in faster growth rates and larger, healthier fish. In addition, larger, healthier Delta Smelt are presumably less vulnerable to predators because of increased size making them difficult for smaller predators to capture and consume. In general, the median abundance of some of the key prey for juvenile Delta Smelt such as calanoid copepods is highest in summer months (Fig. 75), when juvenile Delta Smelt are present; however, the range of observed densities is broad in all months. As noted previously, Kimmerer (2008) found that Delta Smelt survival from summer to fall was positively associated with calanoid copepod biomass in the low salinity zone.

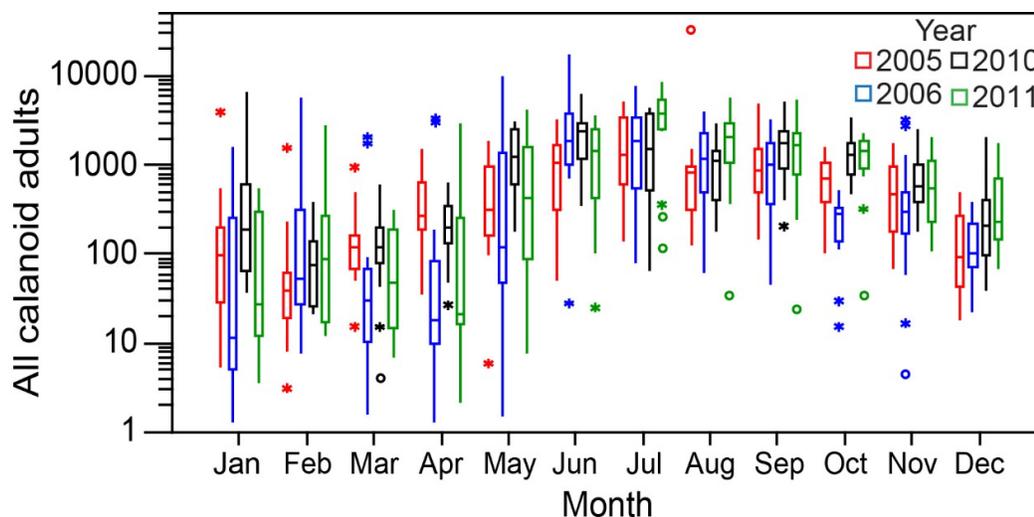

Figure 74. Secchi depth data collected during the Summer Townet Survey. Surveys are conducted biweekly June-August. See Chapter 3: Data Analyses for explanation of boxplots.

Interpretation of the field data is complicated because there are no long-term IEP EMP study stations located in some of the core habitats for Delta Smelt, for example, Cache Slough and the Sacramento River Deep Water Ship Channel. Moreover, densities of calanoid copepods vary among regions based on differing habitat (temperature and salinity) requirements of each species (Fig. 76).

Summer-time phytoplankton data (chlorophyll-*a*) suggest that the base of the food web was most enhanced in July and August 2011 and relatively depleted in 2005 (Fig. 66). There is some evidence that these changes may have affected zooplankton abundance. For example, summer densities of calanoid copepods in the LSZ and <1 ppt regions also tended to be highest in 2011 as compared to the other years (Fig. 76). This pattern generally held when individual taxa are considered including two of the most important food sources for Delta Smelt, *Eurytemora affinis* (Fig. 33) and *Pseudodiaptomus forbesi* (Fig. 34).

Figure 75. Trends in calanoid copepods (number/m³ for all taxa combined) collected by the IEP Environmental Monitoring Program (EMP) during each the four study years (2005, 2006, 2010, and 2011).

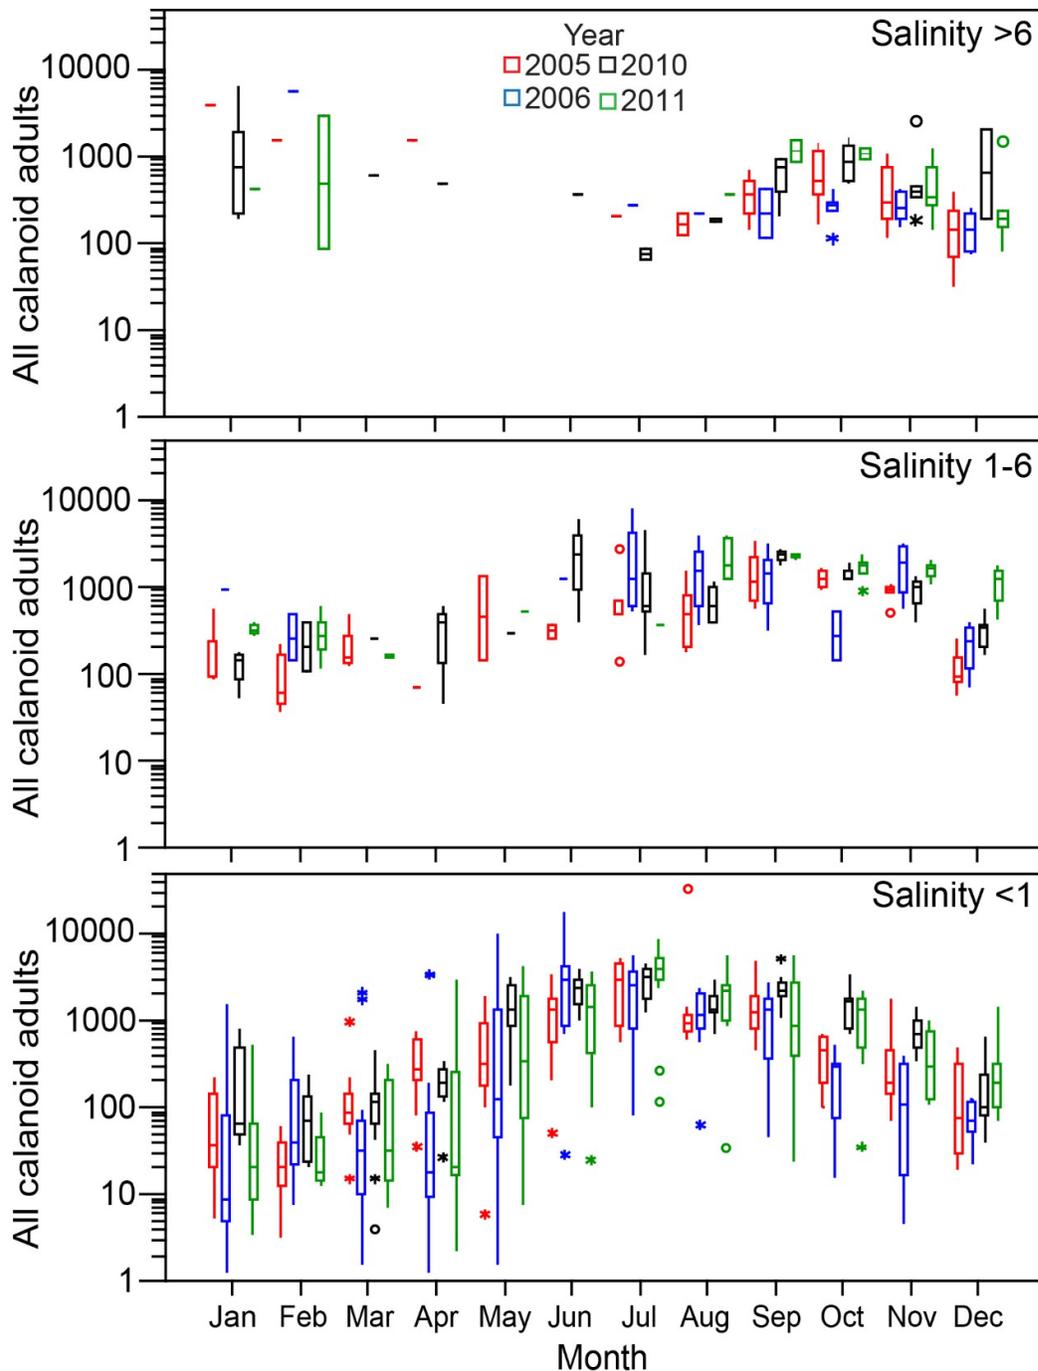

As mentioned above (Hypothesis 1), juvenile to subadult survival was highest in 2011 followed by 2006 and 2005 and lowest in 2010 (Fig. 51). If food availability was the primary habitat attribute driving juvenile survival, our expectation was that summer prey abundance would have been higher in 2011 than 2010. Figure 69 suggests that while differences were not very pronounced, prey levels were indeed somewhat higher in July and August of 2011 than 2010. Calanoid copepod levels varied across the different salinity ranges, but generally followed the same pattern (Fig. 76). In addition, calanoid copepod densities in June and August were higher in 2006 than in 2005 (Fig. 75), which may have contributed to higher juvenile to subadult survival in 2006 compared to 2005 (Fig. 51).

Fish bioenergetics are affected by both food and temperature. As mentioned above, both summer 2010 and 2011 had relatively cool temperatures as compared to 2005 and 2006, which may have affected bioenergetics. In addition, recent studies (S. Slater, CDFW, unpublished data) indicate that Delta Smelt consumption was not just limited to calanoid copepods, so our assessment does not reflect the full dietary range.

In conclusion, our analyses provide some support for the hypothesis that juvenile Delta Smelt growth and survival is affected by food availability; greater food availability may have contributed to greater juvenile survival in 2011 and 2006 compared to 2010 and 2005. However, differences in prey availability among years were not very pronounced and our analyses were limited to calanoid copepods; other species may also be important prey items for Delta Smelt.

Figure 76. Trends in calanoid copepods (number/m³ for all types combined) collected by the IEP Environmental Monitoring Program (EMP) in three salinity ranges (> 6 ppt; 1-6 ppt; < 1 ppt) during each the four study years (2005, 2006, 2010, and 2011). See Chapter 3: Data Analyses for explanation of boxplots.

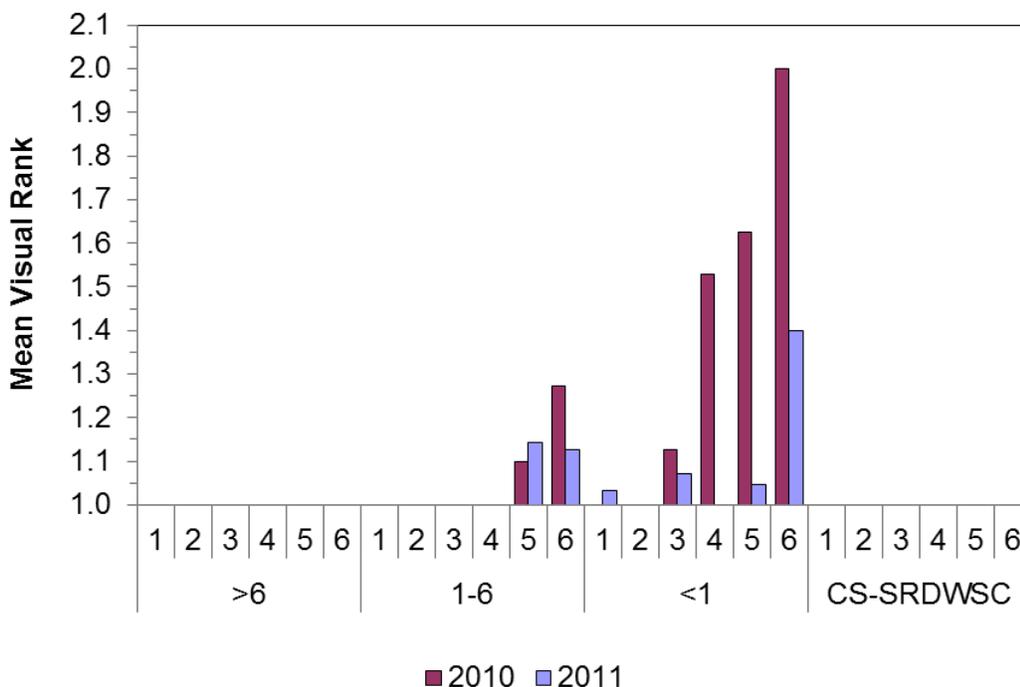

Hypothesis 4. Juvenile Delta Smelt survival and growth is reduced by harmful algal blooms (HAB) because of direct (habitat quality and toxic effects) and indirect (food quality and quantity) effects.

The appearance of late-summer HAB, especially *Microcystis*, is thought to be another component of the decline in habitat quality for Delta Smelt (Baxter et al. 2010, Lehman et al. 2010). Direct effects may include toxicity to Delta Smelt and a reduced area of suitable habitat. There also may be indirect effects on food quantity and quality, particularly with respect to their zooplankton prey (Ger et al. 2009, 2010a,b, Lehman et al. 2010).

The growth responses of Delta Smelt during the four target years are still unclear (see below), but there is evidence that Delta Smelt juvenile to subadult survival was highest in 2011 and lowest in 2010 (Fig. 51). If HABs have a negative effect on survival, we would expect that lower *Microcystis* (or other HAB) abundance would be associated with higher survival in 2011. This seems to have been the case for 2010 and 2011. Densities of *Microcystis* near the water surface were qualitatively assessed (visually ranked) at all TNS stations in these years. In agreement with our expectation, observed levels were low during the TNS in 2011 as compared to 2010 across a range of salinities (Fig. 77).

Unfortunately, we do not have data about other HAB species and more quantitative estimates, nor is similar data available for 2005 and 2006. In general, our expectation is that 2006

Figure 77. Summer Townet Survey mean visual rank of *Microcystis* spp. (ranks 1-5 possible; 1 = absent) observed at all stations during biweekly surveys (1-6) in various salinity regions (> 6, 1-6, and < 1 ppt) and in the CS-SRDWSC during June through August 2010 and 2011. Observations were not made in Cache Slough-Sacramento River Deepwater Ship Channel (CS-SRDWSC) during 2010.

Microcystis levels would have been relatively low as a result of higher flow levels that discourage blooms (Lehman et al. 2005). Based on the available qualitative data for 2010 and 2011, this analysis supports the hypothesis that juvenile Delta Smelt survival and growth is better when *Microcystis* does not bloom as intensely, but more data is needed to more conclusively assess this relationship.

Subadult Hypotheses

Hypothesis 1. Subadult Delta Smelt abundance, growth, and survival is affected by food availability.

Similar to juveniles, the general conceptual model is that higher food abundance results in faster growth rates and subsequently, lower predation loss and greater survival (e.g., Houde 1987, Sogard 1997, Takasuka et al. 2003); however the opposite situation in which the fastest growing fishes are most vulnerable to predators has also been observed in at least one east coast estuary (Gleason and Bengston 1996). Fall abundance of Delta Smelt was highest in 2011 followed by 2006, 2010, and 2005 (Fig. 3) while survival of subadults to adults was highest in 2010 followed by 2006 and equal in 2011 and 2005 (Fig. 45). In spite of the lower subadult survival in 2011, the relatively large number of subadults in 2011 gave rise to the highest adult abundance on record in 2012.

In general, fall calanoid copepod abundance and cladocera abundance were higher in 2011 in freshwater and the low-salinity zone compared to the other years, particularly 2005 and 2006 (Fig. 71). However, these data are highly variable, so this conclusion does not apply to each region in every month. With that caveat, the data generally support the hypothesis that food availability affects Delta Smelt abundance and survival; on average, prey density was higher for subadult Delta Smelt in 2011. This may have contributed to the high FMWT abundance index in 2011, although it did not contribute to an equally high survival to adults relative to the other three years. Nevertheless, it seems likely that the relatively good food availability in 2011 also contributed to the high number of adults in 2012. As noted above, we are currently unable to evaluate whether Delta Smelt grew faster in 2011 because water temperature affects spawning and hatch dates, which complicates the interpretation of growth rates.

Hypothesis 2. Distribution and abundance of Striped Bass, temperature, and turbidity influence predation risk/rate on subadult Delta Smelt

As already described for other life stages, predation risk is exceptionally complicated, making it difficult to generate simple hypotheses that describe associated losses of Delta Smelt. The data are not currently available to test this hypothesis (Nobriga et al. 2013). Thus, no firm conclusion can be made.

Hypothesis 3. Subadult Delta Smelt abundance, survival and growth are reduced by harmful algal blooms (HAB) because of direct (habitat quality and toxic effects) and indirect (food quality and quantity) effects.

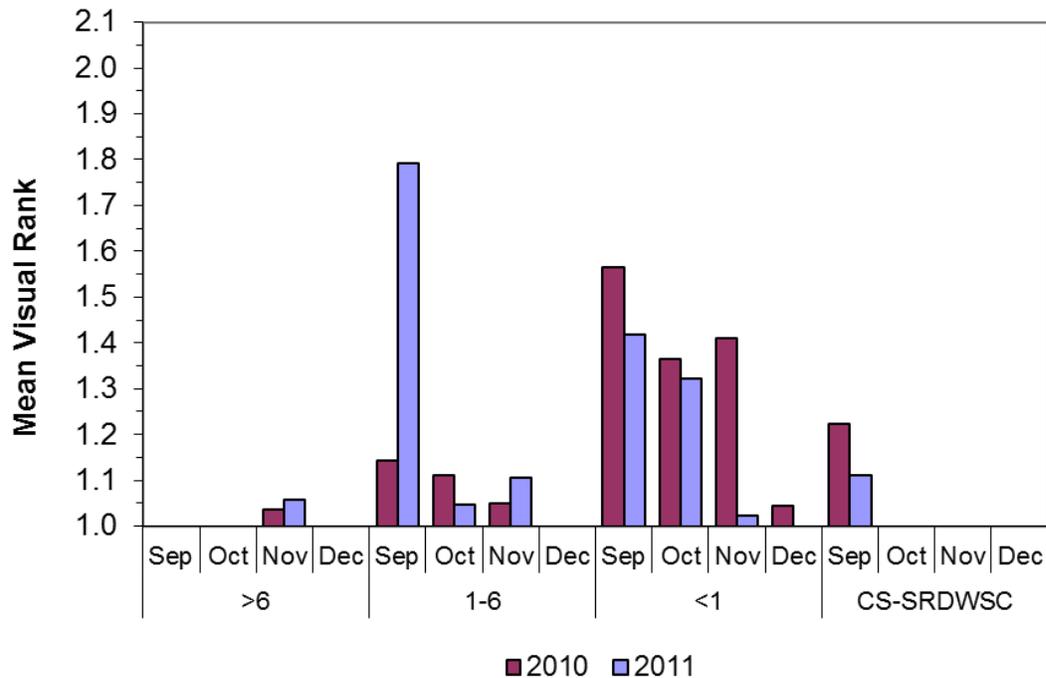

The appearance of late-summer harmful algal blooms (HAB), especially *Microcystis*, is thought to be another detriment to habitat quality for Delta Smelt (Baxter et al. 2010, Lehman et al. 2010). Direct effects may include toxicity to Delta Smelt and a reduced distribution if the fish try to limit their overlap with the bloom. There also may be indirect effects on food quantity and quality, particularly with respect to their zooplankton prey (Ger et al. 2009; 2010a,b, Lehman et al. 2010).

The growth responses of Delta Smelt during the four target years are still unclear (see above), but there is evidence that summer juvenile to subadult survival was highest in 2011, while juvenile survival to adults was highest in 2010 (Fig. 45). Our expectation is therefore that HAB were less prevalent in the summer of 2011 compared to 2010, but more prevalent in fall 2011. As already described for juveniles, the hypothesis that summer *Microcystis* bloom would be less intense in 2011 compared to 2010 was generally supported (Fig. 77). In fall, *Microcystis* levels were also overall lower in 2011 than in 2010, except in September 2011 when a high level of *Microcystis* was observed in the LSZ (Fig. 78). This may be an indication that the higher outflow in September-October 2011 displaced *Microcystis* produced in the Delta seaward into the LSZ. The comparatively high 2011 Delta Smelt FMWT index that coincided with this shift in *Microcystis* distribution is not consistent with the hypothesis; however, the occurrence of fairly high levels of *Microcystis* in the LSZ in 2011 may help explain the lower subadult to adult survival in 2011 compared to 2010. It is also important to remember that the visual survey results presented here are only qualitative and do not necessarily reflect the potential for differences in actual toxicity among years. Overall, these results are inconclusive, although they may provide limited support for the hypothesis that high *Microcystis* levels may have a negative effect on subadult to adult survival; this may help explain the lower subadult survival in 2011 compared to 2010.

Hypothesis 4. Subadult Delta Smelt abundance, survival and growth are affected by the size and position of the low salinity zone during fall.

We do not address this hypothesis in detail because it is the subject of an adaptive management experiment (FLaSH) described earlier (Reclamation 2011, 2012; see also Brown et al. 2014, <http://deltacouncil.ca.gov/science-program/fall-low-salinity-habitat-flash-studies-and-adaptive-management-plan-review-0>). According to the FLASH conceptual model, conditions are supposed to be favorable for Delta Smelt when fall X2 is approximately 74 km or less, unfavorable when X2 is approximately 85 km or greater, and intermediate in between (Reclamation 2011, 2012). Surface area for the LSZ at X2s of 74 km and 85 km were predicted to be 4000 and 9000 hectares, respectively (Reclamation 2011, 2012). The data generally supported the idea that lower X2 and greater area of the LSZ would support more subadult Delta Smelt (Table 6). The greatest LSZ area and lowest X2 occurred in September and October 2011 and were associated with a high FMWT index which was followed by the highest SKT index on record, although survival from subadults to adults was actually lower in 2011 than in 2010 and 2006. There was little separation between the other years on the basis of X2, LSZ area, or FMWT index (Table 6). The position and area of the LSZ is a key factor determining the quantity and quality of low salinity rearing habitat available to Delta Smelt and other estuarine species (see Chapter 4 for more detail

Figure 78. Fall Midwater Trawl mean visual rank of *Microcystis* spp. (ranks 1-5 possible; 1 = absent) observed at all stations during monthly surveys in various salinity regions (> 6, 1-6, and < 1 ppt) and in the CS-SRDWSC during September through December 2010 and 2011.

and Chapter 8 for additional analysis results). In addition, the complex hydrodynamics produced during higher outflows may alter the lateral mixing environment of the Estuary (especially in shallower areas like Suisun Bay) in ways that improve the quality of Delta Smelt habitat in general (Monismith, personal communication). The limited amount of available data provides some evidence in support of this hypothesis, but additional years of data and investigations are needed.

Chapter 8: Conclusions

As with all reports focusing on conceptual models, this report is intended as a working document, not as the final word on Delta Smelt ecology, because our knowledge will continue to increase. We intend the conceptual model to be used as a framework and tool to further improve our understanding of Delta Smelt ecology and to explore and test management options for improving conditions for the Delta Smelt population. In essence, the updated conceptual model represents a synthesis of our current thinking on the factors affecting vital rates of the Delta Smelt population. We fully expect a wide range of opinion about the relevance of the conceptual models presented here and about the degree of certainty regarding many of its component dynamics and linkages. We have clearly acknowledged that we lack information on many important factors and processes that likely affect Delta Smelt, such as predation and toxicity and their functional relationships

Table 6. Mean and standard deviation (SD) for X2, surface area of low salinity zone (M. McWilliams, Delta Modeling Associates, unpublished data), and values of the Fall Midwater Trawl index (FMWT) for abundance of subadult Delta Smelt.

	X2 (km)		Surface area LSZ (hectares)		FMWT index
YEAR	MEAN	SD	MEAN	SD	
2005	83	2	4889	252	26
2006	82	3	4978	320	41
2010	85	2	4635	226	29
2011	75	1	8366	133	343

with survival and growth. The conceptual model incorporates many hypotheses that should be tested via new research, modeling, and ongoing analysis and synthesis of new and previously collected data. This is how science advances.

Conceptual models are increasingly used as tools to develop questions or hypotheses about specific mechanisms through which stressors or other environmental factors drive ecological outcomes. Conceptual models can be used as a basis for communication among managers and scientists to plan research activities and assess outcomes of management actions (Ogden et al. 2005). Because of their broad utility, conceptual models are viewed as a critical element of adaptive management programs (Thom 2000). In the SFE, conceptual models have become common and even required as the community moves toward adaptive management and collaborative science. A primary outcome of conceptual models is the identification of key areas of uncertainty due to lack of information, or areas of disagreement due to different interpretations of the available data and information. Careful examination of these areas often identifies critical data and information gaps, which if filled, would allow a more robust evaluation of the major hypotheses derived from conceptual models. In this way, conceptual models can guide the research community to the topics critical for understanding Delta Smelt biology and formulating effective management actions.

The development of our conceptual model, based on assessment of recent information, identified some key points about conceptual models that are worth highlighting, including the following:

1. Nested and linked conceptual models of increasing specificity provide a useful framework for capturing the dynamics of ecosystem drivers and habitat attributes over a large range of temporal and spatial scales and for providing a comprehensive picture about their effects.
2. Our knowledge about Delta Smelt and the SFE is constantly growing and conceptual models about them have to be regularly updated and revised to properly reflect this knowledge.
3. Construction of our conceptual model and the formulation and evaluation of hypotheses greatly benefitted from the large amount of high-quality ecological data and information available about Delta Smelt and the SFE. The most critical data about Delta Smelt dynamics came from four long-term IEP fish monitoring surveys. Other monitoring

and studies provided key data and information about habitat attributes and ecosystem drivers.

4. Our conceptual model is also useful for identifying important data and information gaps. More data and information is especially needed about predation risk and toxicity, two potentially important attributes of Delta Smelt habitat.

Conceptual models are meant to be useful tools for scientists, managers, and others. But just how useful are the new conceptual models in this report? To find out, we used them to generate and test hypotheses and highlight data gaps while addressing a specific topic of high management interest—the increased Delta Smelt abundance index in 2011.

We found that our conceptual model allowed us to formulate a variety of testable hypotheses about individual components and the linkages among them. Our hypotheses and the analyses we conducted to test them had some clear limitations (discussed below), but highlighted some key points about Delta Smelt and their habitat. In many respects, the points about Delta Smelt seem self-evident from basic biology and earlier conceptual models, but they warrant reinforcement because they are crucial to understanding Delta Smelt and to developing and assessing habitat management actions. Key points about Delta Smelt include the following:

1. Environmental conditions occurring in all four seasons contribute to year-class strength of Delta Smelt - “it takes a year to make a mature Delta Smelt.”
2. Survival and recruitment are affected by many factors that interact in complex ways and the importance of these factors and interactions varies from season to season and year to year.
3. Recovery of Delta Smelt depends on better than average larval production (recruitment) and survival in all seasons. The number of eggs and larvae sets an upper limit for the production of mature adults. Low survival between any two life stages can substantially reduce the actual production of mature adults. Success of Delta Smelt in 2011 was related to a high level of larval production (recruitment) followed by moderate to high stage-to-stage survival over the entire year. In contrast, the high level of larval production (recruitment) in 2006 was followed by very low survival from larvae to juveniles which led to low abundance of mature adults.
