4. Throughout 2011, Delta Smelt may have benefitted from a combination of favorable habitat conditions: 1) adults and larvae benefitted from high winter 2010 and spring 2011 outflows which reduced entrainment risk and possibly improved other habitat conditions, prolonged cool spring water temperatures, and possibly good food availability in late spring; 2) juveniles benefitted from cool water temperatures in late spring and early summer as well as from relatively good food availability and low levels of harmful *Microcystis*; 3) subadults also benefitted from good food availability and from favorable habitat conditions in the large, westward low salinity zone.

Our hypothesis tests were carried out with the simple comparative approach used in the FLaSH investigations (Brown et al. 2014). Specifically, we compared differences in Delta Smelt responses and in individual habitat attributes during the two most recent wet years and the two years immediately preceding the two wet years. Using this approach allowed us to put the FLaSH results into a year-round context as recommended by the FLaSH Panel (FLaSH Panel 2012).

It also provided an opportunity to further assess the utility of this approach for evaluating the outcome of adaptive management actions such as the fall outflow action.

As with the FLaSH investigations (Brown et al. 2014), we restricted our analyses to simple comparisons among four recent years after the 2002 POD decline for several reasons including the following:

1. Using a comparative approach similar to that in the FLaSH investigation allowed us to place the results of the FLaSH investigation in a year-round, life cycle context as recommended by the FLaSH Panel (FLaSH Panel 2012).
2. This report is intended for a broad audience. Simple comparisons are easily replicated and understood by all.
3. More pertinent data is available for recent years than for earlier years. For example, adult Delta Smelt monitoring began in 2002 with abundance index values available starting in 2003.
4. The POD regime shift (Baxter et al. 2010) changed ecological relationships and the strong pre-POD signals would have likely overwhelmed more subtle, yet meaningful, signals in the period after the POD. For example, it appears that high larval recruitment may now be positively associated with wet hydrology, but that this may not have been the case before the onset of the POD.
5. Clear differences in habitat conditions among years might point to new or refined management strategies aimed at improving specific habitat conditions.
6. More complex modeling approaches take much more time and effort than was available to produce this report. A complex life cycle modeling effort is currently underway (see Chapter 9).

As noted above, our analytical approach yielded some interesting results, but it also raised more questions than it could answer. In many cases this was due to critical data and information gaps; these will be described in more detail in Chapter 9. It also illustrates, however, several limitations of our simple comparative approach as well as difficulties associated with posing and testing hypotheses about ecological phenomena in general. Examples of specific limitations and difficulties include the following:

1. Our hypotheses focused on individual habitat attributes and were tested with a series of separate univariate analyses even though we know that Delta Smelt are affected by multiple interacting habitat attributes. We did not conduct multivariate tests or examine the complex interactions that may have occurred when more than one hypothesis was true (or false), nor did we consider or rule out that a hypothesis may be true in some years and false in others.
2. Our simple comparisons of differences in individual habitat attributes among different years cannot conclusively establish whether these differences are indeed mechanistically linked to the observed differences in Delta Smelt dynamics. In addition, an absence of observed differences does not prove that there is really no effect because actual effects can be masked or counteracted by interactions with other causal factors that differ among years. For example predation in the South Delta may mask actual entrainment

effects and toxicity of anthropogenic contaminants may counteract the effects of abundant food in some years, but not in others.

3. Results contrary to our observations may simply indicate different outcomes in other years or that complex interactions among multiple habitat attributes (and corresponding hypotheses) contributed to the observed effects.
4. We restricted our analyses to observational data collected in a small number of moderately and very wet years during the POD period; including data from additional, more historical, and drier years may have provided more conclusive results.
5. Data available for our analyses were not necessarily collected to test hypotheses similar to the ones in this report; targeted data collections are needed in addition to routine status and trends monitoring.

Many of these difficulties and limitations were expected because hypothesis testing in an ecological context is nearly always problematic. For example, Quinn and Dunham (1983) warned that attempts to follow a strictly hypothetico-deductive scheme (Popper 1959, Platt 1964) to draw “strong inference” from a series of univariate tests aiming to falsify hypotheses about the ecological effects of individual causal factors often lead to inconclusive or even erroneous results. One reason for this is that by design, they generally do not consider non-additive interactions among causal factors. While we did not necessarily set out to strictly follow such a scheme, we nevertheless treated habitat attributes as largely independent from each other and formulated a series of distinct hypotheses about their univariate effects on Delta Smelt. But habitat attributes are not necessarily additive and habitat is indeed more than the “sum of its parts.” A more inductive, multivariate modeling approach with hypotheses about interactive effects and evaluations of the relative contributions of multiple interacting habitat attributes to these effects would have likely been more appropriate, but would have required analyses beyond the scope of this report.

We give some examples of multivariate approaches in Chapter 9, but note that even with the most sophisticated modeling techniques, ecological responses to management manipulations and other changes of the SFE have been notoriously difficult to assess and interpret. Reasons for this persistent difficulty include limited opportunities for experimental control, multiple interacting causal factors, multiple ecological response pathways, and changing environmental conditions due to species invasions, species declines, and the many physical and chemical changes and management manipulations described in this report. In other words, the signal to noise ratio of management actions to environmental variation tends to be low in the SFE because of its size and complexity. The fact that Delta Smelt is now a rare species adds another considerable difficulty. Together, these difficulties are part of the reason why adaptive management actions such as those described in the ongoing Fall Outflow Adaptive Management Plan (Reclamation 2011, 2012) and the now concluded Vernalis Adaptive Management Plan (VAMP, San Joaquin River Group Authority 2013) are planned for a minimum of 10 years, allowing accumulation of data, development of appropriate interpretation of these data, and comparison of observations across as broad a range of conditions as is possible given a 10-year time frame. But even after such a relatively long period of manipulation and observation, questions will likely remain about how some factors interact to affect Delta Smelt abundance.

In summary, we conclude that our new conceptual models can be used successfully to derive testable hypotheses about Delta Smelt responses to changing habitat conditions. Our hypotheses

and the analyses we conducted to test them highlighted some key points as well as critical data gaps and the challenges associated with formulating and testing hypotheses in complex ecological contexts. The key points about Delta Smelt and their habitat generally agree with basic biological principles and earlier conceptual models, but warrant reinforcement because they are crucial to understanding Delta Smelt and to developing and assessing habitat management actions. Other results are less conclusive because of data limitations and the shortcomings of our largely univariate hypotheses and simple comparative analysis approach. Next steps should include addressing critical data gaps, modeling that more fully considers the effects of interacting factors on Delta Smelt, and applications of the information in this report in support of management actions. Examples of such efforts are provided in Chapter 9.

Chapter 9: Recommendations for Future Work and Management Applications

The conceptual model in this report can be viewed as a collection of hypotheses. These hypotheses are not limited to the hypotheses posed in Chapter 7 of this report; essentially, each component and linkage in the conceptual models can give rise to meaningful questions and hypotheses by itself or together with other components and linkages. This is one of the main functions of conceptual models.

Some of the hypotheses that can be derived from our conceptual model have already been addressed in the published research reviewed in Chapter 4 of this report. These results provide the knowledge base used to construct our conceptual model as well as previous conceptual models. They also provide the knowledge base for current Delta Smelt management efforts. The results and conclusions in this report add to this knowledge, but they also emphasize the need for additional monitoring, focused studies, and/or additional analysis and synthesis of existing data. These are the information gaps that can be used to guide future research activities to enhance our understanding of how factors interact to control Delta Smelt abundance.

Filling these information gaps is critically important for improving management strategies for Delta Smelt and for constantly adapting them to expected and unexpected future changes. It is clear that ecological changes due to continued growth of California's human population, climate change, new species invasions, and other natural and anthropogenic factors will increase the challenges associated with Delta Smelt management. Moreover, as discussed in the previous Chapter, we will likely never be able to correctly detect or predict all effects of management actions and other changes in an ecosystem as complex and constantly changing as the San Francisco estuary. Science and management have to go hand in hand to constantly identify, implement, evaluate, and refine the best management options for this ever-changing system. In this Chapter, we provide examples of next steps in three major areas where additional work is needed: 1) filling critical data and information gaps; 2) mathematical modeling; and 3) applications to support adaptive management actions. We conclude this report with recommendations for future analysis and synthesis efforts.

Critical Data and Information Gaps

A short list of the most critical data and information gaps identified by the updated conceptual model is given below. It is important to note that this is not an exhaustive list of the potentially productive research questions that could be addressed for Delta Smelt. Instead, these are primary research topics that emerge as major data and information gaps in multiple places within the updated conceptual model. This indicates that additional monitoring and research on these topics may be particularly urgently needed and filling these gaps would provide immediately useful results. The list of critical data and information gaps is organized around the environmental drivers and habitat attributes identified in our conceptual models.

Contaminants and Toxicity

There is a general awareness that exposure to contaminants can impair the health of Delta Smelt and other fishes. A few studies have documented adverse effects, but little is known regarding the thresholds at which most contaminants would be toxic to or otherwise adversely affect Delta Smelt (or their prey). Even less is known about how various contaminants may interact when they co-occur, or how their effects may be enhanced or suppressed by these interactions or by other environmental factors.

1. Focused laboratory studies may provide the most efficient way to assess effects of metals, pesticides, pharmaceutical products, or mixtures of contaminants as long as field-relevant concentrations are used. However, translating results of laboratory tests to the field remains a challenging problem (Scholz et al. 2012).
2. Significant work to understand the effect of nutrient loading from municipal sources on the food web has been done (Weston et al. 2014) (e.g., Sacramento Wastewater Treatment Plant, Parker et al. 2012). A logical next step is to conduct manipulative experiments in which effluent is reduced or shut off. This type of work has recently begun (T. Kraus, USGS, personal communication), but may require multiple iterations during a variety of seasons and environmental conditions in order to understand how such manipulations or future treatment upgrades could be used to provide desired food web responses. Monitoring should continue after any such upgrades to determine if they have the expected outcomes.

Entrainment and Transport

Evaluation of differences in entrainment among years could not be critically evaluated from salvage data; better ways to estimate, monitor, and evaluate entrainment losses due to south Delta exports are needed. Such improved estimates could be derived from experimental research on Delta Smelt and other species along with hydrodynamic modeling. Besides the need to improve the estimates of direct proportional population losses due to entrainment, similarly relevant or more important needs include assessing the influence of entrainment on key population attributes (e.g., genetics, demographics, population dynamics and viability effects).

Predation Risk

The majority of the hypotheses regarding predation risk could not be fully evaluated due to a lack of data regarding co-occurring predator and prey biomass and predation rates of predators on Delta Smelt.

1. The distribution and diet of major predators with respect to the distribution of Delta Smelt needs further investigation. For some predator species, data may already be available that describe distributions over multiple years and one data synthesis effort has already begun (Mississippi Silversides, USFWS Beach Seine Survey; analysis initiated by B. Schreier, DWR). However, data are lacking for several Striped Bass and Largemouth Bass life stages and focused studies are necessary to understand how these species' distributions overlap with the distribution of larval, juvenile, sub-adult, and adult Delta Smelt.
2. The distributional overlaps of Delta Smelt with their predators need to be described over varying conditions of turbidity, salinity, temperature, and hydrology. Linking predation risk to key environmental drivers and habitat attributes will shed light on how Delta Smelt may experience varying degrees of predation across seasons and years.

Food

Food availability is a critical aspect of Delta Smelt habitat throughout the conceptual model. However, many of the hypotheses about effects of food availability in the conceptual model could not be fully evaluated with available observational data due to incomplete information on prey densities and Delta Smelt feeding behavior throughout Delta Smelt habitat.

1. An extension of the IEP EMP into the Cache Slough complex and possibly other areas around the margins of the estuary would allow a fuller regional comparison of prey densities.
2. Another option is to make concurrent zooplankton sampling a routine part of the four major surveys monitoring Delta Smelt (SKT, 20 mm, TNS, FMWT). To varying degrees, this has been ongoing since 2005, but lack of trained staff has resulted in delayed processing of many samples and concurrent zooplankton samples have never been collected during the SKT survey. Adding appropriate zooplankton sampling and sample processing capacity to the fish monitoring surveys would allow for broader and more timely comparisons of pelagic food availability between monitoring stations with and without Delta Smelt present, similar to the analysis conducted in this report for the larvae collected during the 20mm survey (Larval Hypothesis #2).
3. Studies of Delta Smelt growth (from otoliths) and feeding habits (from stomach contents) concurrent with zooplankton sampling would maximize the utility of the concurrent prey sampling by allowing the refinement of functional response models.
4. Studies of Delta Smelt feeding behavior and prey availability with regard to amphipods and other prey that are not well sampled by any of the existing monitoring surveys could help determine the importance of these types of prey to the Delta Smelt population.

Harmful Algal Blooms

While recent research has resulted in improved understanding of the factors influencing the quantity, toxicity and location of HABs, there are still many uncertainties about their direct and indirect effects on Delta Smelt relative to other factors and about what can be done to prevent them. Furthermore and in spite of their importance to ecosystem and human health, there is still no routine quantitative monitoring program in place that specifically targets harmful algae. The TNS and FMWT surveys now include qualitative, visual assessment of *Microcystis*, but more quantitative techniques and techniques that detect additional harmful species and their toxicity would likely provide greater insights. Such techniques are increasingly available (e.g., solid phase adsorption tracking; Wood et al. 2011) and some focused studies that quantify and provide distributions of HABs have been conducted or are underway. These studies should be continued in order to address hypotheses related to the effects of HABs in the conceptual model and evaluate the utility of these techniques for routine monitoring applications.

Delta Smelt Responses

To fully evaluate the interactions of various stressors on Delta Smelt population biology, a quantitative life cycle population model is needed. While such models exist, they can be refined based on research into important aspects of Delta Smelt reproductive biology, including the reproductive output of individual Delta Smelt and the population as a whole, and how it varies with environmental conditions.

In particular, fecundity data on adult female Delta Smelt caught in the SKT have only recently been collected. This is a critical parameter, necessary to assess the reproductive potential of the population in any given year. Continued collection of fecundity data over multiple years and hydrological conditions is crucial to understanding the population response to environmental conditions in the seasons preceding reproduction. In addition, an understanding of variables controlling the number of spawning events in a year for wild Delta Smelt is necessary to understand the full reproductive potential of the population. An exploration of whether spawning events are discernible on otoliths is ongoing (Hobbs group, UC Davis); if so, retrospective analyses relating multiple spawning events to concurrent conditions (e.g., tidal phase, food availability, water temperature) may be possible.

Finally, efforts to better characterize spawning habitat and habitat attributes needed for successful egg hatching should also continue. This is needed to more fully evaluate and understand linkages between environmental drivers such as hydrology and larval recruitment. Of all the life stages of Delta Smelt, we know the least about the egg stage; Delta Smelt eggs have never been found in the wild. Because of this, we were not able to construct a life stage transition conceptual model that specifically focused on eggs. More information about spawning and egg hatching habitat is needed to fill this gap in our conceptual models and to identify management actions that would promote beneficial habitat attributes.

Mathematical Modeling

As demonstrated in this report and by others, conceptual models are useful tools for identifying and understanding key ecosystem components and relationships, but they do not quantify them and cannot be used to quantitatively define functional responses to environmental drivers or make

quantitative predictions. Furthermore, as discussed above, the simple univariate and comparative analysis approaches employed throughout this report cannot capture the effects of multiple and often interacting drivers on the Delta Smelt population as a whole and on specific processes such as growth, mortality, and reproduction. The influences of interspecific interactions and abiotic forcing factors on populations and communities in complex ecosystems such as estuaries are also difficult to directly measure in any practical way. Only mathematical models can deal with such complexities and provide quantitative assessments and predictions.

Fortunately, the number of scientific publications about Delta Smelt that include various types of increasingly sophisticated mathematical models is growing rapidly. Recent examples include mathematical models based on statistical approaches (e.g., Bennett 2005, Manly and Chotkowski 2006, Feyrer et al. 2007, Nobriga et al. 2008, Kimmerer 2008, Kimmerer et al. 2009, Feyrer et al. 2010, Thomson et al. 2010, Mac Nally et al. 2010, Miller et al. 2012, Sommer and Mejia 2013, Kimmerer et al. 2013). These efforts generally focused on habitat associations using presence/absence data from the various monitoring surveys or on changes in Delta Smelt abundance based on abundance indices generated by the monitoring surveys and the effects of multiple habitat attributes (covariates) on these changes.

There is also a rapidly developing body of population life cycle models for Delta Smelt and other SFE fish species (e.g., Blumberg et al. 2010, Maunder and Deriso 2011, Massoudieh et al. 2011, Rose et al. 2011, Rose et al. 2013a, b). These models use either a statistically-based “state–space” multistage life cycle modeling approach or a spatially explicit, individual-based simulation modeling approach. Both approaches allow for analysis of the importance of drivers that affect different life stages of Delta Smelt and vary in space and time.

Not surprisingly, results of mathematical modeling efforts to date agree strongly that no single factor can explain the observed Delta Smelt population dynamics and long-term changes in abundance. There is less agreement, however, about which factors are most important (see for example Rose et al. 2013b) and about the exact sequence and nature of their interactions that led to the 2002-3 Delta Smelt POD decline. It is possible, perhaps even likely, that the natural complexity of the estuarine ecosystem coupled with multiple human impacts will prevent definitive answers to these types of questions, especially when they are sought through overly rigid application of formal hypothetico-deductive reasoning and methods (Quinn and Dunham 1983). We agree with Rose et al. (2013b) that the inherent complexity of the system and the challenges it presents for scientists and managers alike “is perhaps the best reason to develop and compare alternative modeling approaches.” Even the most sophisticated modeling oversimplifies complex systems and includes many assumptions. This means that instead of a single modeling approach, multiple alternative conceptual and mathematical modeling approaches, from the simple to the complex, are needed to understand how complex systems work and to predict future changes with sufficient confidence to allow for effective management interventions. The following sections give a brief overview of some of the alternative mathematical modeling efforts currently underway or proposed for the future.

A comprehensive state-space modeling effort that takes advantage of available Delta Smelt abundance data from all monitoring surveys and the even larger monitoring data set about habitat attributes is currently underway (Ken Newman, FWS, personal communication) and future analyses using the individual-based model developed by Rose et al. (2013a) have been proposed (Rose et al. 2013b). As mentioned above, a full description or application of mathematical models is outside of the scope of this report, but to illustrate the utility of additional alternative approaches and further explore some of the linkages and interactions in our conceptual model,

we give three additional examples of alternative mathematical modeling approaches that may be used to further test some of the hypotheses in the conceptual models in this report. The first is a qualitative modeling approach, the second a multivariate statistical modeling approach, and the third a numerical simulation modeling approach. Each of these approaches was explored by one of the co-authors of this report. Importantly, these approaches are meant to complement, not replace state-space, individual-based, and other modeling approaches for Delta Smelt.

Furthermore, results are preliminary and included for illustrative purposes only; peer-reviewed publications of these analyses need to be completed before they can be used to draw any conclusions.

Qualitative Models

Qualitative modeling provides a theoretical foundation for understanding system behavior by minimizing the loss of generality and realism at the expense of model precision (Levins 1974, Levins 1975, Puccia and Levins 1991). Qualitative modeling is based on a mathematically rigorous approach that can be used to gain insight on community level process and to examine the consequences of intended or inadvertent human-induced perturbations in managed systems. Questions often addressed through qualitative modeling include the resilience and stability of the system and the direction of population change (Puccia and Levins 1991), the role of system structure on stability (Dambacher et al. 2003, Fox 2006) and the degree of predictability in the response of populations to perturbations (Montaño-Moctezuma et al. 2007, Hosack et al. 2009). Such questions have strong implications in terms of stability-complexity relations (May 1972, Pimm 1984, Haydon 1994) and the persistence of populations and communities following regime shifts (Baxter et al. 2010, Brook and Carpenter 2010, Capitán and Cuesta 2010, Cloern and Jassby 2012).

The increased ecological understanding of the upper SFE and the potential drivers and mechanisms underlying the interannual population responses of Delta Smelt reviewed by the FLaSH and MAST syntheses provide a strong rationale to further refine and integrate our knowledge on community level interactions and ecological drivers in this highly altered system. Towards that goal, we envision qualitative modeling as a complementary approach to other types of models to evaluate the response of Delta Smelt and other populations in the upper SFE over several temporal and spatial scales. Qualitative modeling for Delta Smelt can address some relevant system-level knowledge gaps which are usually less amenable to analyses using other modeling approaches, namely, the influence of species interactions and multiple feedback levels on community stability and population changes in response to perturbations on one or more species. For example, understanding the mechanisms leading to Delta Smelt population responses under different hydrological conditions is an area of significant interest.

Signed-digraphs are a useful representation of the structure of a system, as defined by the community matrix, and have been used in qualitative models exploring food webs (Liu et al. 2010), extinction events in communities (Vandermeer 2013), and other ecological topics of theoretical and conservation relevance. Castillo (unpublished data) used this approach to evaluate the predicted response of Delta Smelt to a sustained change in fall outflow as required in the 2008 FWS Biological Opinion. Recognizing that outflows can control X2 and the size and location of the LSZ (see Chapter 4), and affect other segments of the aquatic community supporting Delta Smelt, Castillo (unpublished data) modeled the response of subadult Delta Smelt to low (5,000 cfs; X2 = 85 km), intermediate (8,000 cfs; X2 = 81 km) and high (11,400 cfs; X2 = 74 km) fall outflow scenarios. Community composition for each outflow scenario was determined relative

to the geographical distribution of species expected to occupy the LSZ. The high outflow model included six community components: phytoplankton, zooplankton, Delta Smelt, predators of Delta Smelt, the overbite clam *Potamocorbula amurensis*, and outflow. The intermediate outflow scenario included two additional community components: the Asian clam *Corbicula fluminea* and the cyanobacteria *Microcystis aeruginosa*. The low outflow scenario included the same variables as in the intermediate flow scenario, except that the overbite clam was excluded and the Brazilian waterweed, *Egeria densa* was added. For each of these communities, community components could exhibit positive or negative feedbacks and positive or negative interactions with other community components. For each of the assumed flow conditions, the four alternative types of community interactions were assumed and each met the stability criteria, as defined by Puccia and Levins (1991). The predicted response of the Delta Smelt population was: 1) predominantly positive under the high outflow community scenario, 2) ambiguous under the intermediate outflow community scenario and 3) very ambiguous under the low outflow community scenario. According to these preliminary results, both outflow and outflow-induced changes in community composition and structure seem to play a critical role in determining the population response of Delta Smelt. These model predictions supported the hypothesis that a shift in the LSZ towards $X2 = 74$ km is a necessary condition for the fall outflow action to exert a positive influence on the Delta Smelt population. Qualitative models like these can provide useful assessments when the general direction of community interactions are understood but the data are insufficient to support a quantitative model.

Multivariate Statistical Modeling

In this report we reviewed results from many multivariate statistical modeling efforts such as the multivariate autoregressive modeling (MAR) conducted by MacNally et al (2010) to discern the main factors responsible for the POD declines and the hierarchical log-linear trend modeling by Thomson et al. (2010) that used Bayesian model selection to identify habitat attributes (covariates) with the strongest associations with abundances of the four POD fish species and determine change points in abundance and trends. The state-space life cycle modeling by Maunder and Deriso (2011) is also based on multivariate statistical modeling; an extension of this work is currently underway by Newman and others (Ken Newman, USFWS, unpublished data).

We anticipate that insight from the current conceptual model may be used to facilitate additional multivariate statistical models. As an example, we present preliminary results (Mueller-Solger, USGS, unpublished data) of univariate and multivariate statistical analyses of $X2$ relationships with annual Delta Smelt abundance indices that follow the approach in Jassby et al. (1995). The purpose is to further explore some of the hypotheses related to hydrology and the size and position of the LSZ included in our conceptual model and to illustrate the importance of considering more than one factor when trying to understand Delta Smelt dynamics. We include this brief exploration in this report because it serves as a useful and relevant example, but as noted above, we advise readers that these are preliminary results from an analysis that has not yet undergone peer review and should be viewed with caution. Moreover, individual and interactive effects of additional factors were not considered in this analysis, but are likely also important (see Chapter 8). As noted in Chapter 7, we recognize that “hydrology” by itself does not affect Delta Smelt, nor does the “ $X2$ ” index which is used in this analysis as an index of general hydrological (outflow) conditions in the estuary. As shown in our conceptual model (Fig. 38), hydrology affects Delta Smelt through the combined effects of its interactions with other dynamic drivers and stationary landscape attributes (tier 1) on habitat attributes (tier 3). Many of

these interactions have been described in this report; others should be explored further in future studies.

This analysis is intended to evaluate the effects of prior abundance, step changes, and concurrent and prior hydrological conditions in the estuary on the relative abundance of larval to early juvenile Delta Smelt (20 mm index, Fig. 3; hereafter referred to as “larval” Delta Smelt). It also considers prior hydrological conditions and the entire available abundance index time series for larval Delta Smelt provided by the 20 mm survey. The 20 mm survey, one of the newest IEP monitoring surveys, was started in 1995. Delta Smelt distribution data from this survey is heavily used to assess and manage entrainment risk. Similar to prior analyses of TNS and FMWT data (Feyrer et al. 2007, Nobriga et al. 2008), Kimmerer et al. (2009, 2013) and Sommer and Mejia (2013) used a generalized additive modeling (GAM) approach to examine the associations between Delta Smelt occurrence or catch per trawl at 20 mm survey stations and habitat attributes (salinity, temperature, turbidity, and calanoid copepod density) measured concurrently at the same stations. There have, however, been few analyses of annual abundance data from this survey. After 19 years, the 20 mm survey now provides barely enough annual abundance data points (indices) to conduct multiple regression analyses with up to two predictor variables. Clearly more years of data collection and more in-depth analyses are needed and the analyses presented here are merely a starting point.

This analysis uses annual abundance indices for larval Delta Smelt (20 mm survey, 1995-2013), adult Delta Smelt (SKT survey, 2003-2013), and subadult Delta Smelt during the previous year (FMWT survey, 1995-2013) (Fig. 3). It also uses larval recruitment indices calculated from the annual abundance indices (20 mm to SKT ratio and 20 mm to $FMWT_{Year-1}$ ratio, Fig. 46; see previous chapters for caveats regarding index ratios). Data from the SKT survey was only used for univariate analyses because the SKT index time series only has 11 data points at this time. Spring and fall X2 values were obtained by first calculating mean monthly X2 values calculated from daily X2 values provided by the DWR Dayflow database and then averaging the mean monthly X2 values for the “spring” months February to June and the “fall” months September to December. The 2002-2003 step decline in Delta Smelt abundance (Thomson et al. 2010) was introduced as a before/after factor (“Step”). Details about the data sources are provided in Chapter 3 of this report.

The multivariate analyses presented here were conducted with generalized linear modeling (GLM) following the approach of Jassby et al. (1995) and followed with a classical linear modeling (LM) approach guided by the GLM results. For the GLM, model parameters were estimated with a Poisson error distribution, a log link function describing the relationship between the predictor variable(s) and the mean, and a natural spline to represent non-linearities. The degrees of freedom for the splines were restricted to only 2 (i.e. one interior knot) because of the low number of available data points. Models requiring estimation of more than two independent parameters (aside from the intercept) were not considered for the same reason. Applying the GLM approach avoids the need for log-transforming the abundance data and using natural (quadratic) splines as smoothers allows a more natural representation of non-linearities than using polynomials.

The responses predicted by these models have a fairly high degree of precision as indicated by low values of SE/Mean and residuals were consistent with model assumptions. The results show significant univariate relationships at the $P < 0.05$ level (Table 7) between the 20 mm abundance index and spring X2, prior fall X2, and prior FMWT abundance index. The relationship is strongest with prior fall X2, followed by spring X2 and prior FMWT abundance index (Table

7). The relationship with spring X2 appears unimodal with maximum 20 mm indices associated with spring X2 values between about 55 and 70 km (Fig. 79a). The relationship with prior fall X2 appears negative (Fig. 79b), and the relationship with the prior FMWT abundance index (Fig. 79c) appears positive. Each of these univariate relationships was improved by the inclusion of one of the other predictor variables (Table 7). Relationships with spring and prior fall X2 were also improved by including the 2002-3 step change. As mentioned above, multivariate analyses with more than two predictor variables were not conducted because of the relatively small amount of available data ($n = 19$, Table 7). Based on AIC comparisons (Table 7), including the 2002 step change (introduced as a before/after factor, “Step”) somewhat improved the relationship of the 20 mm index with spring X2 (Fig. 73a) and with prior Fall X2 (Fig. 79b), but not with the prior FMWT index because that index was the basis for the analyses that detected the step change and thus already includes the step change in the actual data (Fig. 79c, model not included in Table 7). Including the prior FMWT abundance index improved the relationships with spring and fall X2 more substantially, but the model combining the effects of spring and fall X2 fit the 20 mm index data nearly as well as the model combining the effects of spring X2 and prior FMWT (Table 7).

It is interesting to note that while prior fall X2 by itself was a stronger predictor of the 20 mm index than spring X2, spring X2 was the stronger predictor when the step change or previous fall abundance were taken into account. Baxter et al. (2010) hypothesized that the shift toward higher prior fall X2 values (Fig. 17) may have contributed to an ecological “regime shift” associated with the step decline in Delta Smelt and other species. This means that prior fall X2 and the “step” factor and FMWT decline in this analysis may be related, which could explain the very similar outcomes for the two models combining spring X2 with either prior fall X2 or the prior FMWT index.

Partial residual plots show the relationship between a predictor variable and the response variable given that other independent variables are also in the model; in other words, they show the effect of one predictor variable given the effect of one or more additional predictor variables. Partial residual plots for the relationships of the 20 mm index with the combinations of spring X2 and prior fall X2 (Fig. 80 a and b) and spring X2 and prior FMWT abundance index (Fig 80 c and d) show that the general shape and direction of the relationships of the 20 mm index with each of the individual predictor variables (Fig. 79) remains intact in the models with combined predictors, but the partial residuals do not closely follow the fitted lines. This indicates that while each variable has its own, distinct effect on the 20 mm index that is maintained in the presence of the other variables, interactive effects among these variables are quite strong. In summary, low values of prior fall X2, high prior FMWT abundance, and intermediate values of spring X2 have positive associations with the abundance of larval/postlarval Delta Smelt, but the effects of individual variables are mediated by the presence of the other variables.

Because the spline degrees of freedom were strongly restricted in this GLM analysis, the results are quite similar to the results of classical linear models (LM) with log-transformed abundance data and a quadratic term to represent the unimodal non-linearity in the relationship between the 20 mm index and spring X2 (Fig. 81). We include these models here because they are more easily reproducible than the GLM models and offer simple equations for making predictions about larval abundance that can be used in adaptive management applications. As for the GLM analysis (Table 7), the best fits overall were achieved by combining spring X2 with either the step change or the prior FMWT abundance index (Table 8). All predictor combinations improved the models compared to the univariate relationships (Table 8). Based on a comparison of regression

Table 7. Summary of relationships between the 20 mm abundance index for Delta Smelt (response variable) and one or more predictor variables: n, number of observations (years); SE/Mean, model standard error (square root of mean squared residual) as proportion of mean response, P, statistical significance level for the model; R², coefficient of determination; adjusted R², R² adjusted for the number of predictors in the model; AIC, Akaike information criterion; Δ AIC, AIC differences; w (AIC), AIC weights. All relationships modeled with generalized linear models (GLM) with a Poisson error distribution, log link function, and a natural cubic spline with two degrees of freedom as a smoother for all predictor variables except “Step.”

Predictor Variable(s)	n	SE/ Mean	P	R ²	Adjusted R ²	AIC	Δ AIC	w (AIC)

coefficients and P-values, the LM relationships were statistically weaker (Table 8) than in the GLM analysis (Table 7).

Another way of including prior abundance in statistical relationships of abundance with habitat attributes and environmental drivers is to use abundance indices that are proportional to prior abundance indices, in other words, ratios of present to prior abundance indices. In this report, we used the ratios of 20 mm to SKT and 20 mm to FMWT_{Year-1} abundance indices (Fig. 46; see also caveats about these indices in Chapter 3) as larval recruitment indices from adults and subadults, respectively. We found that recruitment of larvae from adults was linearly related to spring X2 for the entire available time series (2003-2013, Fig. 82a and Table 9). The recruitment index for 2013 was higher than expected based on the other data points. The relationship of the recruitment index from subadults to next year's larvae with winter-spring X2 was also linear for the POD period after the abundance step decline in 2002 (Thomson et al. 2010), but with more scatter at higher X2 values. Interestingly, no relationship was apparent at all before the 2002 step decline when the proportional larval recruitment from then more abundant subadults was generally low (Fig. 82b and Table 9). In the current POD regime, larval recruitment from parental stock appears to be highest when flows through and out of the Delta are high and the interface between fresh and brackish water is located to the west (i.e. low X2), although it can occasionally also be high at lower flows, as was the case in 2013.

In late winter and spring 2013, CVP and SWP exports were reduced to comply with OMR flow requirements in the 2008 USFWS Biological Opinion aimed at reducing the risk of adult and

Figure 79. Plots of the Delta Smelt 20 mm survey abundance index as a function of a) spring (February-June) X2, b) previous year fall (September-December) X2, and c) Delta Smelt fall midwater-trawl abundance index in the previous year. Details of general linear models (GLM) used to fit the lines are in Table 7.

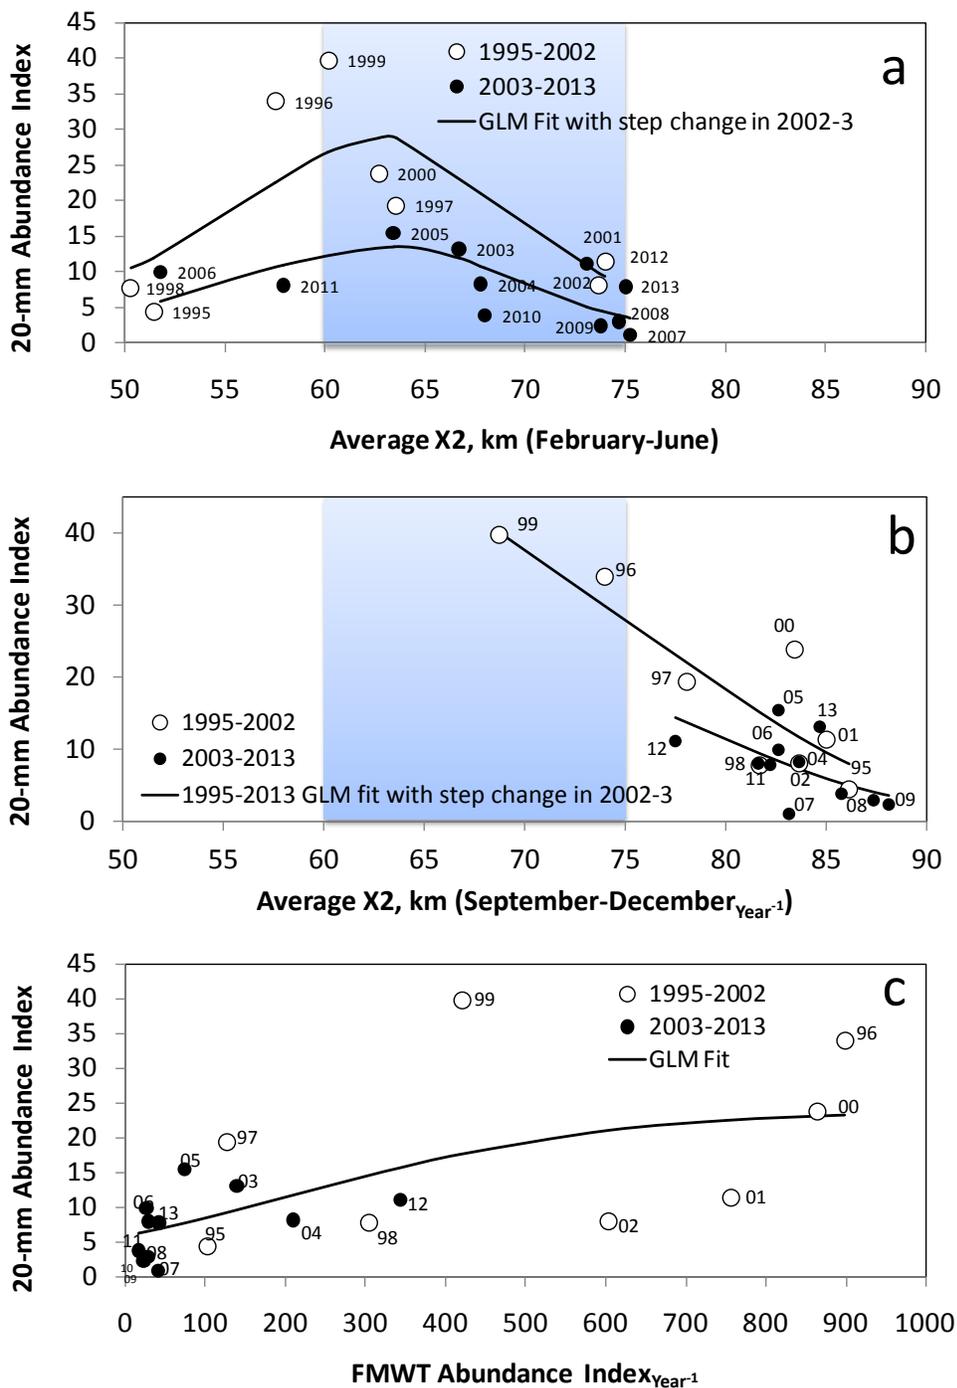

Figure 80. Plots of partial residuals for the relationships of the 20 mm index with the combinations of spring X2, prior fall X2, and prior FMWT abundance index summarized in Table 1 (panels a, b, d, and e). The plots shown here also include partial fit lines and their 95% confidence intervals. Values for the time period of analysis are shown for: c, X2; and f, the fall midwater trawl abundance index from the previous year

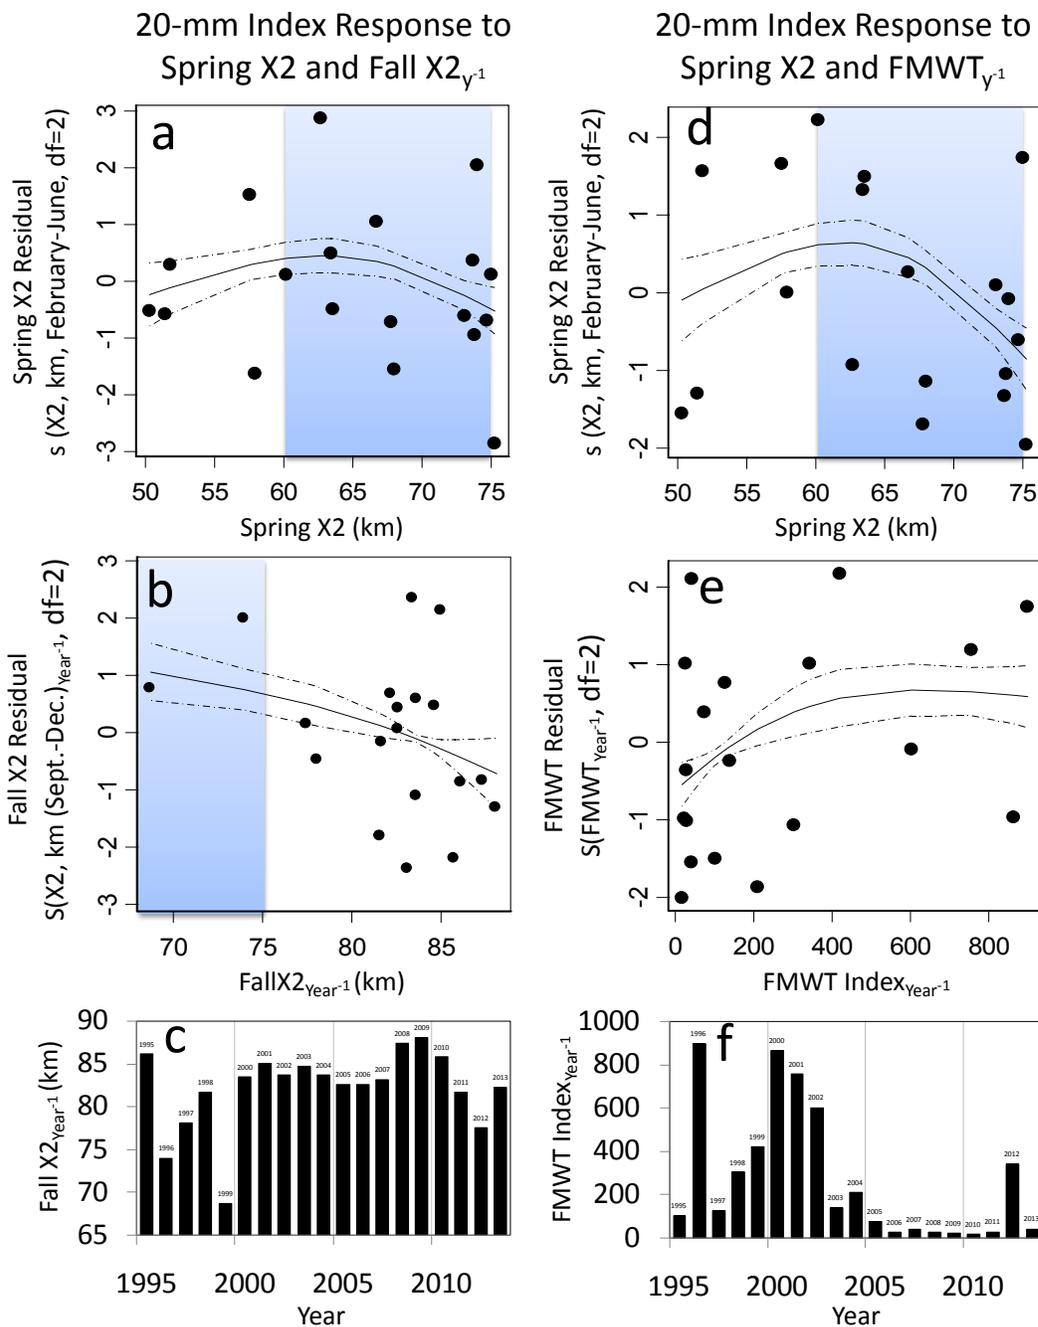

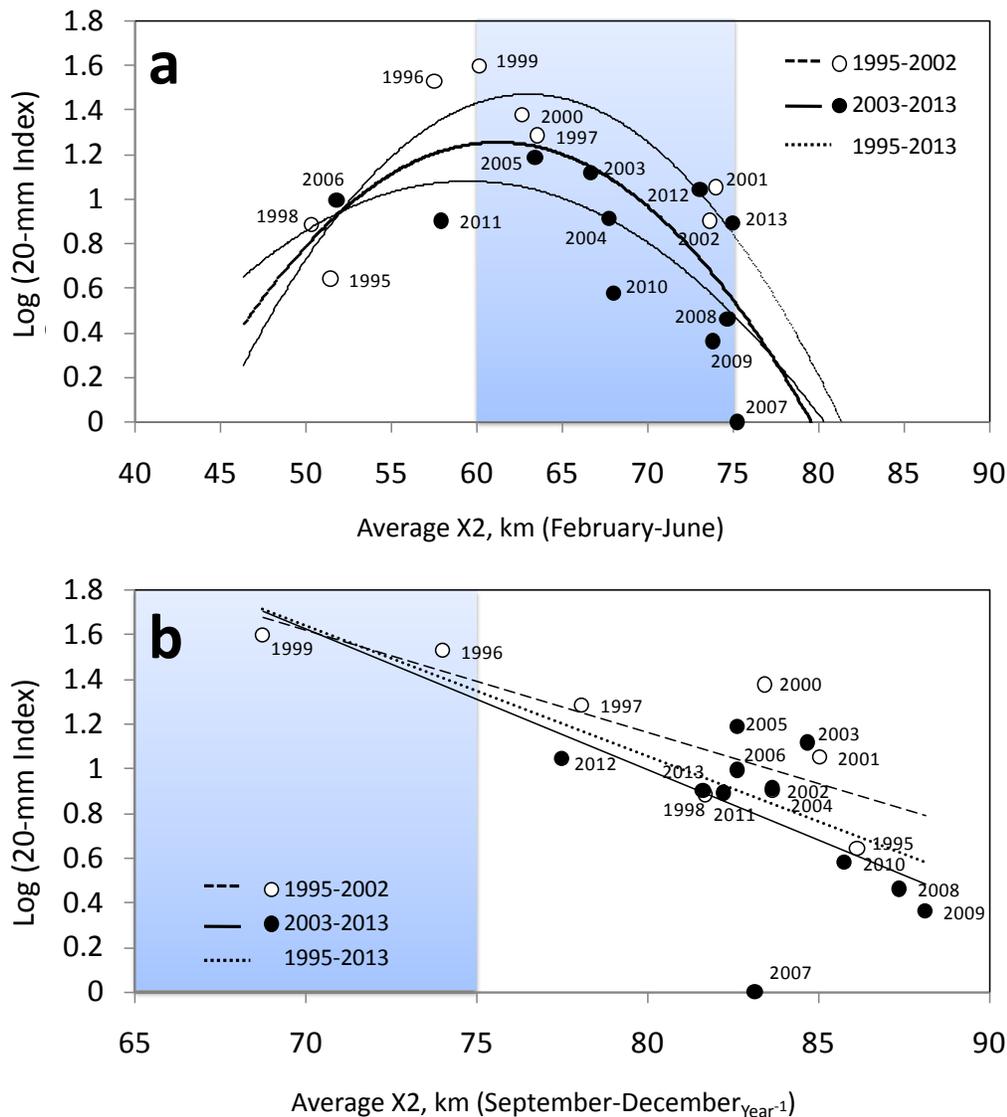

Figure 81. Plots of the Delta Smelt 20 mm survey abundance index as a function of a) spring (February-June) X2, and b) previous year fall (September-December) X2. Lines are either simple linear least squares regression (lines) or quadratic regression (curves). Details of linear models (LM) used to fit the 1995-2013 lines are in Table 8.

larval Delta Smelt entrainment into the water export pumps. This was the first time since the 2008 USFWS Biological Opinion was issued that exports were specifically reduced to lower Delta Smelt entrainment risk. In other years, flows were high enough to allow for higher export levels or export reductions to protect salmon were deemed sufficiently protective for Delta Smelt. It is possible that the intentional reduction in Delta Smelt entrainment risk in 2013 contributed to the high larval recruitment from adults during relatively low flow conditions, but additional years with similar conditions and targeted management actions as well as better estimates of entrainment and more in-depth analyses with other flow variables and flow averaging periods

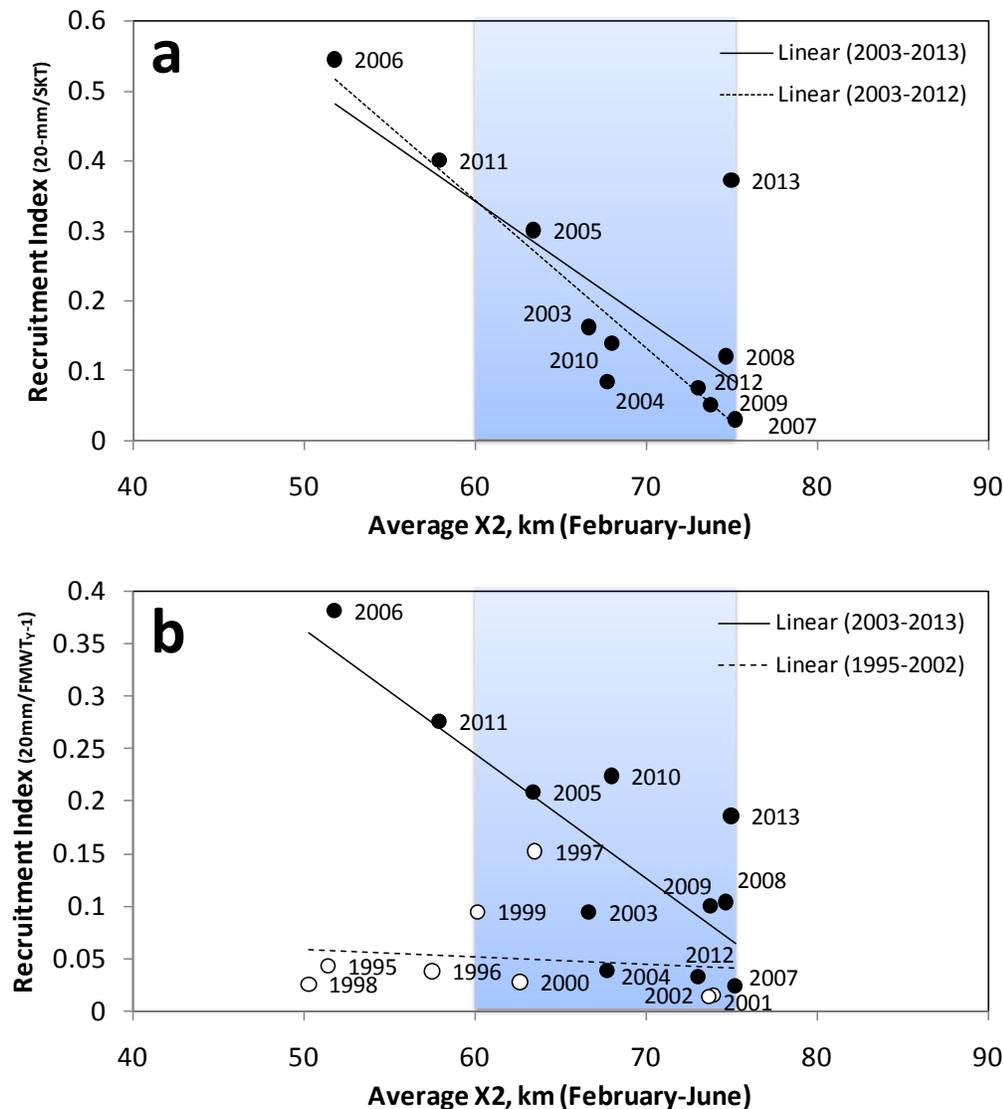

Table 8. Summary of relationships between the log-transformed 20 mm abundance index for Delta Smelt (response variable) and one or more predictor variables. All relationships modeled with simple least-squares linear models (LM). For explanation of column headings see Table 6.

Predictor Variable(s)	n	SE/ Mean	P	R ²	Adjusted R ²	AIC	Δ (AIC)	w (AIC)
Spring X2, (Spring X2) ² , log FMWT _{year-1}	19	0.237	0.000	0.745	0.694	2.1	0.00	0.85

Fall X2 _{year-1}	19	0.318	0.001	0.479	0.449	11.7	9.58	0.01
Spring X2, (Spring X2) ²	19	0.329	0.006	0.473	0.407	13.9	11.83	0.00
log FMWT _{year-1}	19	0.333	0.002	0.430	0.397	13.4	11.29	0.00

are needed to test this hypothesis and obtain a better understanding of flow effects on larval recruitment.

Overall, these preliminary findings suggest that abundance of the larval to early juvenile life stages of Delta Smelt may respond quite strongly to spring and prior fall outflow conditions. The relationships of the 20 mm index with spring X2 shown in this analysis were much stronger than relationships of the TNS and FMWT indices with spring X2 (Table 1, Fig. 17). Similarly, hydrological conditions in the fall seem to have a greater impact on subsequent abundance of larvae than on subsequent juvenile abundance (TNS index; Mount et al. 2013). This is consistent with the findings by Kimmerer et al. (2009) who noted more pronounced relationships of spring X2 with earlier than with later life stages of Delta Smelt and explained that this was “probably because the earlier life stages occupy areas that are fresher and therefore more responsive to changing flow than the more brackish regions.” While the size and location of the LSZ itself may be important for maturing adults in the fall, its interface with fresh water may be important to larvae and spawning adults. A more westward interface means a larger freshwater habitat for spawning and larval rearing that reaches into the shallow eastern region of Suisun Bay and is well connected with Suisun Marsh sloughs and, in wetter years, the Napa River. It also means a larger distance to the export pumps in the southern Delta and thus a reduced risk of entrainment for spawning adults and larvae. Interactions of flow with other drivers and habitat attributes as shown in the conceptual models in this report are likely also important. This suggests that at least

Figure 82. Adult (panel a, SKT) and subadult (panel b, FMWT the previous year) to larvae (20 mm Survey) recruitment indices (abundance index ratios) as a function of spring X2 (February-June). For 20 mm/SKT a linear regression was calculated with and without 2013, which appears to be an outlier. For 20 mm/FMWT the previous year separate regressions were calculated for the POD period (2003-2013), the period before the POD (1995-2002), and the entire data record (not shown). See Table 9 for regression results.

at present, increased Delta outflow and a more westward LSZ in fall, winter, and spring may have important beneficial effects on early life stages of Delta Smelt, but other factors (possibly including summer flows which were not included in this analysis) may be more important for their survival to adults.

Finally, similar to previously published analyses, this analysis strongly suggests that previous life stage abundance should always be taken into account in statistical explorations of habitat effects

Table 9. Summary of relationships of larval recruitment indices (abundance index ratios) for Delta Smelt (response variable) and spring X2 (predictor variable; spring: February-June): n, number of observations (years); SE/Mean, model standard error (square root of mean squared residual) as proportion of mean response, P, statistical significance level for the model; R², coefficient of determination. All relationships modeled with least-squares linear models (LM).

Index Ratio	Period	n	SE/Mean	P	R ²
20-mm/ SKT	2003- 2013	11	0.556	0.006	0.588
20-mm/ SKT	2003- 2012	10	0.270	0.000	0.918
20-mm/ FMWT _{Year-1}	2003- 2013	11	0.469	0.003	0.648
20-mm/ FMWT _{Year-1}	1995- 2002	8	1.012	0.771	0.015
20-mm/ FMWT _{Year-1}	1995- 2013	19	0.981	0.321	0.058

on Delta Smelt. Prior abundance can be introduced into these relationships as actual abundance data (e.g. abundance indices or catch per trawl data), periods of relatively constant abundance (here introduced as a “step” factor), or by combining it with present abundance in proportional abundance indices such as the index ratios used here as recruitment indices. Similar to the relationships of juveniles with spring X2 discussed in Chapter 4, the overall depressed abundance of larval Delta Smelt during the POD period that started in 2002 leads to less substantial larval abundance increases with increasing outflows and decreasing X2 values than before the onset of the POD. However, the association of high larval recruitment with high spring outflow suggests that winter and spring hydrology, through its effects on habitat attributes, may be an important driver of larval recruitment during the current POD period, although it may be less important at higher abundance levels.

In summary, this preliminary analysis provides an example of how relatively simple multivariate modeling can yield interesting insights, in this case about how prior conditions (prior fall X2), prior abundance (prior FMWT), step changes in abundance, and concurrent environmental conditions (spring X2) may all have important effects on Delta Smelt abundance in the spring. While further analyses, more sophisticated life cycle modeling, and publication in a peer-reviewed journal are needed to draw firm conclusions, these preliminary results support the idea discussed throughout this report that neither scientific understanding nor management effectiveness can be improved by only considering a single effect, or a single season or life stage. High larval recruitment is essential for setting the stage for a strong year class, but higher growth and survival through subsequent life stages are also needed to achieve and sustain higher population abundance levels.

Numerical Simulation Modeling

Quantitative simulations of the multiple factors and processes that affect Delta Smelt life stage transitions in our conceptual model are an obvious next step in the exploration and synthesis

of the information presented in this report. The purpose of simulation modeling is to represent a phenomenon or process in a way that allows users to learn more about it by interacting with the simulation (Alessi and Trollip 2001). In particular, simulations allow users to easily control experimental variables and test hypotheses. Guidance from simulation model “dry runs” can make actual laboratory and field experimentation much more efficient and effective. Simulations are also valuable in visualizing outcomes, thus further promoting learning and understanding.

The individual-based Delta Smelt model by Rose et al. (2013a, b) is an example of a complex simulation model specifically created for Delta Smelt. Another simulation modeling option is to utilize “off-the-shelf” simulation software such as the “STELLA” (Structural Thinking and Experiential Learning Laboratory) simulation construction kit (<http://www.iseesystems.com/softwares/Education/StellaSoftware.aspx>). STELLA is designed to let users easily create their own simulations using system dynamics including positive and negative causal loops, and flows, accumulations and conversions of materials.

Culberson (USFWS, unpublished data) created a simple quantitative simulation model in STELLA that includes several life stages of Delta Smelt and is based on seasonal environmental conditions and stage to stage estimates of survival. While this simulation modeling approach appears to be feasible, it remains to be seen how such an approach will approximate actual population dynamics encountered in the field and how results compare to those of other simulation models such as the individual-based life cycle model by Rose et al. (2013a,b). A user-friendly STELLA-based model can be useful in the interim, however, to explore the relative contribution of lifecycle stage and environmental covariates to the overall status of Delta Smelt abundance from year to year and to test hypotheses derived from the conceptual model. In its fullest expression, this MAST-associated lifecycle model will be useful for illustrating how multiple suites of plausible co-variates can allow for different Delta Smelt abundance outcomes. For example, it may be possible to find high abundance under degraded conditions given low entrainment losses across successive winters and springs. Conversely, it is possible to encounter low Delta Smelt abundance given otherwise good environmental and outflow conditions with significantly warmer temperatures during fall pre-adult maturation periods. Moreover, simulated changes in survival can provide a useful frame of reference to evaluate alternative outcomes of cohort size or population size attained at different life stages. For example, given the reported levels of larva, juvenile and sub-adult Delta Smelt in IEP surveys, what levels of daily survival between life stages would be required to attain the relative abundances corresponding to each of the four years being compared? Could the small anticipated differences in assumed daily survival among those four years be attributed to some combination of habitat attributes? Or, could stage-to-stage survival (e.g., percent of individuals surviving from one stage to the next) provide a more useful frame of reference to address that question? Our proposed STELLA simulation model and associated modeling exercises will comfortably allow exploration of these questions and related ideas.

This type of modeling will best be used iteratively with emerging data and within synthesis reports to identify where important gaps exist in the Delta Smelt lifecycle understanding and demonstrate how disparate information sources might be brought together to inform our smelt population estimates through time. Importantly, our model can be used in combination with the narrative description of “a year in the life” of the Delta Smelt population from the conceptual model to more effectively describe environmental and management effects on population status in the SFE. We are especially interested in using such a model to avoid single-factor outcome discussions where smelt populations are seen as the result of “one versus another” environmental

or management-related trade off, particularly when single factor analysis is aggregated over decades of data collection efforts in what we know is a constantly-changing estuary.

Figure 83 shows how output from such a model might be useful for keeping track of the variable influence of factors on overall Delta Smelt abundance across seasons within three hypothetical years. Six factors are plotted according to their sensitivity rank (their relative influence on simulated population outcomes). Specific sensitivity levels can then be identified according to the combinations of factors that emerge as important across succeeding seasons and years. Models built to simulate these influences can then be closely examined to discern how different years, year types, or management practices influence simulated abundance, and to detect where potential data gaps or inconsistencies are among the alternative conceptual models or model modes. The basis for using such an approach is a comparative one, and an absolute resolution of the size or behavior of the real Delta Smelt population is not anticipated – but remains the overall objective. Of real interest here is providing a way to interpret our emerging conceptual model within potential regime-shifts, and to capitalize on previous specifications of this model to organize our ever-improving understanding. Of additional benefit is the ability to use these models easily in “learning sessions,” where users interact with the modelers and species experts to deepen understanding of Delta Smelt biology and its relationship to Delta ecology and management.

Applications to Support Delta Smelt Management

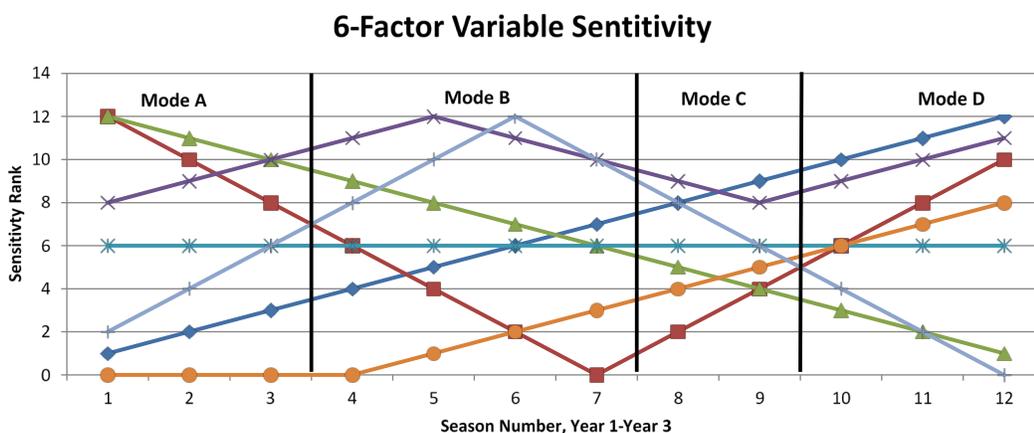

We have shown that the conceptual models in this report provide a reasonable and up to date conceptual framework that can be used to analyze and synthesize existing data and knowledge about Delta Smelt, identify critical data and information gaps, and guide new field and laboratory studies as well as mathematical modeling efforts. We have also discussed many challenges that limit our ability to reach firm conclusions and make highly confident predictions about the effects of management actions and other changes on Delta Smelt. And we have noted that science and management have to go hand in hand to constantly identify, implement, evaluate, and refine the best management options for Delta Smelt in the highly altered and ever-changing estuarine ecosystem that represents the entire range of this species.

Adaptive management is a well-established approach for systematically integrating science and management. As mentioned earlier in this report, it is increasingly required in plans for management of the San Francisco estuary, but to date, the Vernalis Adaptive Management Program (VAMP) and the Fall Outflow Adaptive Management Plan are among the few clear examples of systematically planned and implemented adaptive management in the estuary.

We end our report with examples of how our conceptual models can be used to adaptively manage and improve Delta Smelt habitat. We conclude with several recommendations for the next analysis, synthesis, and modeling efforts. These efforts are a key ingredient for the more widespread adoption and success of adaptive management strategies; without the conceptual and mathematical models provided by these efforts adaptive management of ecosystems simply cannot proceed.

Table 10 gives examples of adaptive management goals and associated uncertainties to address habitat deficiencies (“habitat problems”) identified and discussed in this report. This table is intended as an illustration of how our conceptual models can be used to inform the first three steps of the nine-step adaptive management framework developed by the DSC Delta Science Program (DSP 2013). These three steps are: 1) definition of the problem; 2) establishment of

Figure 83. Simulated output from a STELLA model for assessing sensitivity of the model to variation in model variables.

management goals and actions to address the problem; and 3) modeling of linkages between management goals and actions. The third step specifically requires conceptual or quantitative models for the purpose of evaluating outcomes of alternative management actions and identification of uncertainties and data gaps. Conceptual models are also important in the other six adaptive management steps, for example to design effective adaptive management experiments and appropriate monitoring and to analyze, synthesize and evaluate results.

Table 10 is organized around the habitat attributes identified in the conceptual models. For each habitat attribute, we describe some example categories of management actions that could be considered to improve the status of Delta Smelt. In essence, these actions represent an example “tool box” for the management of Delta Smelt.

Note that the tool box identified in Table 10 is not meant to be exhaustive. Rather, the list is intended as an example set of adaptive management actions suggested by the conceptual models. As such, the list provides no insight into the cost-effectiveness or feasibility of any of the potential actions. Moreover, we acknowledge that there is substantial uncertainty about the potential benefits of actions in the tool box. As mentioned above, identification of uncertainties about the feasibility and benefits of proposed management actions is an important step in adaptive management that can only be accomplished with the help of conceptual or quantitative models. A key point is that these studies are somewhat different than the critical data and information gaps presented earlier in this Chapter. Specifically, Table 10 emphasizes information gaps that are most relevant to specific management questions, while the earlier list focuses on needs to improve the overall scientific understanding that provides the basis for our conceptual models for Delta Smelt. Clearly, efforts to resolve uncertainties and gaps in understanding are needed in both categories. Overlapping uncertainties may highlight especially urgent data and information needs. For Delta Smelt, this includes uncertainties related to contaminants, predation, and entrainment along with interactions of physical habitat attributes with other factors.

Table 10. Example tool-box for applying the conceptual model to Delta Smelt management.

Habitat Attribute	Management Actions	Example Study Efforts
Physical Features	Increase habitat area & quality	<ul style="list-style-type: none"> -Identification of key microhabitats for each life stage and attributes. -Effects of flow/LSZ position on habitat quality, particularly key biotic habitat elements (access to prey, evasion of predators). -Approaches to maintain & expand high turbidity habitat (e.g. supply, habitat design, SAV management). -Approaches to maintain and expand habitat with moderate temperatures (e.g. channel configuration, water depth and velocity). -Evaluation of whether targeted restoration meets habitat needs (e.g. temperature, substrate, turbidity)
Chemical Features	Reduce toxicity	<ul style="list-style-type: none"> -Identification of chronic effects of contaminants. -Identification of effects of Harmful Algal Blooms. -Approaches to reduce toxicity from contaminants and HABs
Food	<ul style="list-style-type: none"> Increase pelagic production Increase access to alternative foods (e.g. epibenthic). Reduce sources of loss Manage towards higher quality foods Prevention and control of non-native species 	<ul style="list-style-type: none"> -Role of tidal wetlands as subsidy habitats (not necessarily occupied by smelt) -Ammonia-bivalve interactive effects on diatom, copepod, mysid, amphipod production. -Relative importance (contribution to smelt growth) of epibenthic foods (e.g., mysids, amphipods, aquatic insects). -Effect of bathymetry, vegetation type (and density) on access to epibenthic and pelagic foods. -Role of tidal wetlands and wetland/open-water complexes. -Approaches to reduce losses to benthic grazing (e.g. invasive clams) and/or to the suppression of bivalve populations -Value of different food types to Delta Smelt nutrition. -Effects of habitat conditions (e.g. ammonia, flow) on food quality. -Identification of nutrient sources and sinks. -Improved detection methods for invasive species -Studies to evaluate alternative control methods.
Entrainment	<ul style="list-style-type: none"> Avoid entrainment region Adjustments to timing and magnitude of exports 	<ul style="list-style-type: none"> -Identification of factors that lead to increased occupancy of South Delta. -Improved measurement of entrainment and its environmental correlates -Effects of exports and entrainment on viability (e.g. abundance, genetics, demographics). -Approaches to reduce entrainment and enhance emigration success.
Predation risk	<ul style="list-style-type: none"> Reduction of predator population Reduction of predation rate 	<ul style="list-style-type: none"> -Studies on delta smelt responses (behavior, distribution, abundance) to variation in predator abundance. -Identify habitat features that reduce predation rate (e.g. depth, turbidity, food, lower water temperatures).

Recommendations for future analysis and synthesis

Efforts to resolve the management issues listed in Table 10 or carry out the modeling and fill the critical science gaps discussed earlier in this Chapter will not succeed without an organizational commitment to continued systematic and long-term collection, synthesis and evaluation of data and information about Delta Smelt, its habitat, and important drivers of habitat and abundance changes. The importance of Delta Smelt for ecosystem and water supply management in and far beyond the SFE is widely recognized. The impressive rate at which we are learning about Delta Smelt and the estuarine ecosystem and the large amount of existing information about them is less widely recognized by many managers and even by many scientists. Part of the reason for this is that it is difficult to track the large quantity of new (since 2010) information documented in this report and even more difficult to integrate it with the previously existing information in a meaningful way. But without this integration, identification of priorities for additional scientific investigations is ad hoc and piecemeal at best and the value of new information cannot be fully realized in management applications such as those listed in Table 10.

Moreover, comprehensive adaptive management efforts simply cannot succeed without adequate conceptual and mathematical models and important science and management opportunities will be missed. Such efforts currently include the ongoing fall outflow adaptive management for Delta Smelt and new efforts called for by the new “Collaborative Science and Adaptive Management Program” (CSAMP), the California Delta Stewardship Council’s Delta Plan, and the multi-agency Bay Delta Conservation Plan (BDCP). The fact that even the incomplete draft version of our report released for public review in June 2013 already played a central role in CSAMP work planning, court documents, and elsewhere bears clear testimony to the fact that there is a great and urgent policy and management need for analysis, synthesis and conceptual models such as those provided in this report.

In consequence, we strongly recommend that there be a continued management, analysis, and synthesis effort, whether carried out by the IEP, the Delta Science Program, or some other scientist, group or agency. While it is possible for individual scientists to take on such efforts (e.g., Bennett 2005), the amount, diversity, and rapid growth of pertinent data and information suggests that team efforts may usually be a more feasible and possibly also a more effective option. Collaborative, multidisciplinary analysis and synthesis teams are also at the core of the National Center for Ecological Analysis and Synthesis in Santa Barbara, CA (NCEAS, <http://www.nceas.ucsb.edu/>), the newer National Socio-Environmental Synthesis Center in Annapolis, MD (SESYNC, <http://www.sesync.org/>) and the Delta Collaborative Analysis and Synthesis (DCAS) approach promoted by the Delta Science Program’s Delta Science Plan (DSP 2013). Important IEP POD and MAST lessons for future synthesis teams are that the role and responsibilities of all team members need to be very clear, that lines of communication need to always be open and available to all, and that there needs to be strong and fully engaged team leadership with a clearly dedicated lead author and/or lead editor for all major team products. In addition, to complete analyses and reports on schedule, it is necessary for team members to prioritize synthesis efforts for sustained periods of time, without being tasked with additional projects that may be urgent for short-term needs.

Another consideration is the type of publication that results from analysis and synthesis efforts. The IEP MAST and POD teams have written comprehensive agency reports, but would have preferred writing peer-reviewed books or monographs (e.g., published by the American Fisheries Society or by U.C. Press) had the time and resources been available to do so. Such books would be considered better scientific products with greater scientific standing and a longer life span

and would reach a much larger audience. Another approach would be to write a series of shorter articles that could be published in a special issue of a peer-reviewed scientific journal. This too would take more time and effort and would also somewhat restrict the types of topics that could be covered. Journal articles are, however, the main target for national analysis and synthesis centers such as NCEAS and SESYNC because they have the greatest scientific standing and are the most widely accepted and well established method of written science communication.

Regardless of which analysis, synthesis, and communication approach is chosen, none of these efforts can succeed without commitment of adequate funding, staffing, and other resources. The IEP MAST team that developed and wrote this report was formed in 2012 for IEP science synthesis and work planning, but it has remained a pilot-level effort that was never adequately supported. MAST work remained a part-time effort for all co-authors of this report, and for most it was an “on the side” task compared to their “regular” agency duties. There is no doubt that completion of this report could have proceeded much more rapidly with greater allocation of resources. Public and independent peer reviews of a draft version of this report (see <http://www.water.ca.gov/iep/pod/mast.cfm>) greatly improved the structure and content, but were not an original part of the MAST planning. Preparing and conducting the reviews as well as responding to the 355 specific and many more general review comments took considerable time (see also Appendix A). Other MAST tasks also added to the delays. In addition to this report, the MAST completed a synthesis report for the Fall Low Salinity Habitat (FLaSH) investigation component of the Fall Outflow Adaptive Management Program (Brown et al. 2014) and prepared a solicitation package for research proposals, which it then also reviewed.

We strongly recommend that adequate, long-term support for these types of efforts be among the highest science and adaptive management priorities for the region and the entire State of California. Given its pivotal role in adaptive management and the increasingly large amounts of new scientific data and information that are produced every year, the authors of this report, individually and as a team, cannot think of any science activity that is more urgently in need of greater support than analysis, synthesis, and communication of scientific results.

For additional analysis and synthesis efforts about Delta Smelt, we recommend that the next individual or team to take this on should:

- Build on this report by evaluating the conceptual model with more rigorous analyses that include more years of data, developing lifecycle and numerical models as discussed above, and/or using the conceptual model to develop a comprehensive list of data and information gaps and approaches to addressing these gaps in order to inform management strategies;
- Early in the process, make clear decisions about the analytical/modeling approaches to be used, the scope of the synthesis to be done, and approaches for review and communication of results;
- Evaluate additional data and information needs concerning Delta Smelt;
- Consider approaches to understand the effects of the wide variety of management actions targeting Delta Smelt, including adaptive management of fall outflow, entrainment, habitat restoration, etc (e.g., Table 10);
- Develop key “indicator” variables that can be used to track and predict the status of Delta Smelt and its habitat and serve as “performance metrics” to evaluate the success of management actions. Such variables, and a “report card” to summarize them, were considered for this report, but the MAST decided that developing them was beyond the scope of

this report and would require a fairly substantial effort that could be the main focus of an additional effort.

An additional recommendation is that an ultimate goal of these efforts should be the integration of conceptual and mathematical models such as those described in the previous section of this Chapter and the routine use of both types of models in adaptive management. Neither the recently published mathematical models nor existing conceptual models for Delta Smelt have been applied to management issues in a consistent manner. This is likely at least partially due to unfamiliarity of managers with the models and the need for specialists (model developers) to apply the mathematical and in some cases even the conceptual models to management issues in the absence of easy to use and understandable model interfaces and specifications. We also recommend a comprehensive biological modeling forum and/or more specific biological modeling teams and “summits” as recommended by the IEP Science Advisory Group (2010, available at <http://www.water.ca.gov/iep/docs/IEPModelWorkshopReview.pdf>) and, more recently, the Delta Science Plan (DSP 2013). Such groups would not only facilitate communication among modelers, but could also help make the connection from model development to model applications of interest to managers and policy makers. They would complement and could (and likely should) be integrated with the existing, California Water and Environmental Modeling Forum (CWEMF, see <http://www.cwemf.org>), which tends to focus on modeling physical processes. As with the overall analysis and synthesis teams, these groups could be implemented by the IEP, The Delta Science Program, CWEMF, or others. The chosen organizational umbrella is less important than actual implementation and involvement of appropriate local and outside scientific and management expertise. Some possible topics for these groups include:

1. Reviews and updates to existing conceptual and mathematical models
2. Further development of mathematical models of Delta Smelt population abundance drawn specifically from the conceptual models described in this report; applications and extensions of recently published models to help make management decisions and guide new modeling efforts; additional modeling efforts and future research projects to improve resolution and understanding of the particular factors identified as critical to reproduction, recruitment, survival, and growth.
3. Review and refinement of new models such as the emerging comprehensive state-space population model (Newman, personal communication); development of additional models or modules of models specifically aimed at estimating effects of inadequately monitored or difficult to measure and evaluate habitat attributes such as predation risk and toxicity; development of new “nested” and/or “linked” mathematical modeling approaches that can accommodate multiple drivers and their interactive effects across temporal and spatial scales.
4. Collaboration among physical and biological modelers, experimental and other scientists, managers, and stakeholders to develop and model management scenarios and strategies that move beyond the current focus on relatively crude distinctions among “water year types” toward a more integrative ecosystem and landscape-based management approach.

We end this report with the hope that the conceptual models and information presented will be used for achieving better management outcomes for Delta Smelt and the estuarine ecosystem on which it depends. These precious natural resources are owned by no one, but are held in public

trust by the California and U.S. governments for the benefit of all the people. We are grateful for the opportunity to serve our State and nation in the collaborative manner afforded by working under the interagency umbrella of the Interagency Ecological Program for the San Francisco Estuary.

Appendix A: How the Delta Smelt MAST Report was Written

The report titled “An updated conceptual model for Delta Smelt: our evolving understanding of an estuarine fish” (hereafter referred to as Delta Smelt MAST report) was written in 2013-2014 by the IEP Management, Analysis, and Synthesis Team (MAST). The Delta Smelt MAST report was developed through a series of report drafts and a public technical review and followed a set of general report guidelines. This report appendix describes the Delta Smelt MAST report guidelines, the report review and revisions, and report milestones.

Delta Smelt MAST Report Guidelines

Report Purpose and Approach

The Delta Smelt MAST report is a technical report intended to synthesize the latest scientific data and information on Delta Smelt, a topic of particularly high relevance to agency managers and decision makers in California. Specifically, it provides an up to date assessment and conceptual model of factors affecting Delta Smelt throughout its primarily annual life cycle and demonstrates how the conceptual model can be used in science and management. The Delta Smelt MAST report updates and redesigns previous conceptual models for Delta Smelt with new data and information since the release of the last synthesis report about the “Pelagic Organism Decline” (POD) by the Interagency Ecological Program (IEP) in 2010. It then uses the conceptual model to generate hypotheses about the factors that may have contributed to the 2011 increase in

Delta Smelt abundance and evaluate them using a simple comparative approach. The Delta Smelt MAST report ends with key conclusions, a discussion of our hypothesis testing approach, and recommendations for future work and adaptive management applications, with examples.

1. **Report Development.** The 2014 MAST report is a synthesis report developed and written by the IEP Management, Analysis, and Synthesis Team (MAST). The MAST is co-chaired by the IEP Lead Scientist and IEP Program Manager and includes senior scientists from IEP member agencies tasked with data analysis, synthesis, and work planning. The MAST report is the collective product of a dynamic and collaborative interagency team process involving focused team discussions at monthly MAST meetings, intensive conceptual model and report development at additional multi-day off-site meetings, presentations and discussions with other scientists, stakeholders, and the public (e.g., at the annual IEP workshop, meetings of the IEP Stakeholder Group and IEP Project Work Teams), and data analysis and synthesis as well as writing, integration, and revisions of report sections by MAST members with written communication via email and the MAST wiki. MAST report authors were expected to follow the MAST report guidelines described here. They were also expected to consider all internal review comments by other MAST members and members of the IEP Management and Coordinators teams as well as external technical review comments received during a 40-day public review period. Details about the public review process are given in II.
2. **Report Authorship.** The “author of record” for the 2013 MAST report is the entire IEP MAST, and the responsibility for authorship lies with the entire MAST as well. Individual authorship of report sections is not credited; the report is a product of the IEP MAST and not of any individual author or an individual IEP member agency. All current MAST members are MAST report authors and are listed alphabetically in the initial pages of the report (see III. below). Former MAST members will not be listed as authors, but will be noted as contributors. Each report section had a lead author who had primary responsibility for writing and revising the section. One designated MAST member (Larry Brown, USGS) functioned as report lead editor who compiled and integrated all sections and sent full draft report versions to the MAST for review by all MAST members. All MAST members sent their edits and comments back to Larry Brown and the section authors for revisions. The report went through multiple draft versions before its finalization.
3. **Report Organization.** The 2014 MAST report is an IEP technical report and follows the same basic organization as other IEP technical reports, including a title page, list of all authors, acknowledgements, table of contents, executive summary, an introductory section with background information and report objectives, and concise sections detailing the analysis and synthesis approach, models and hypotheses, findings, and conclusions as well as illustrative tables, figures, and full references for all citations. In response to reviewer recommendations received during the public technical review (see II.), the report was restructured and expanded from originally six to nine Chapters.
4. **Supporting Evidence.** The 2014 MAST report follows the conventions of IEP and other technical reports regarding supporting evidence, which includes the following. The rationale for any findings, conclusions, and recommendations should be fully explained in the report. Whenever possible, conceptual models and hypotheses should be evaluated through analysis of the available data. Additional supporting information should be obtained from the peer-reviewed literature or from publicly accessible reports. Related or competing hypotheses and models that have been previously published in the peer-

reviewed literature should be acknowledged and discussed in the report and conclusions should be based on even-handed, dispassionate consideration of all available evidence. Sources for all supporting data and information should be clearly identified and cited. Citation of personally communicated unpublished results (e.g. emails, memos) is permissible, but should be used sparingly.

Delta Smelt MAST Report Review and Revisions

1. **What was the purpose of the review?** The purpose of the public technical review of the draft Delta Smelt MAST report was to ensure its scientific credibility, relevance to managers and decision makers, and a transparent and legitimate process that welcomed and considered input and recommendations from other scientists, managers, stakeholders, and the public.
2. **What was expected of draft Delta Smelt MAST report reviewers?** MAST report reviewers were asked to provide written comments on any and all technical aspects of the draft report, but to pay particular attention to review criteria outlined in the MAST report review guidelines.¹
3. **Who reviewed the draft Delta Smelt MAST report?** The draft Delta Smelt MAST report released for public review on July 23, 2014, was reviewed by invited IEP staff and colleagues as well as by invited external peer reviewers and other scientists who submitted comments during the 40-day public review period, as follows.
 - a. IEP Coordinators (1 Reviewer, IEP management review)
 - b. Former MAST Members (2 Reviewers, IEP colleague scientific peer review)
 - c. Invited Subject Area Expert (1 Reviewer, IEP colleague review of contaminants sections)
 - d. Independent Scientific Peer Reviewers (3 Reviewers, external independent scientific peer review facilitated by the Delta Science Program)
 - e. Other Scientists, Stakeholders and the Public (7 Reviewers, external public review)

In addition, the IEP Coordinators were asked to review the revised, near-final version of the Delta Smelt MAST report and the executive summary and to approve the final version. The IEP Directors were briefed and invited to comment on the direction and progress of the Delta Smelt MAST report on a quarterly basis.

4. **How were external draft Delta Smelt MAST report reviewers identified, invited, and informed?** Independent Scientific Peer Reviewers for the draft Delta Smelt MAST report were identified by the Delta Stewardship Council's Delta Science Program (DSP) and Delta Lead Scientist. In accordance with the DSP "Procedures for Independent Scientific Peer Review,"² the Delta Lead Scientist determined and invited the independent scientific peer reviewers using the following selection criteria: standing in the scientific community, expertise relevant to the documents being reviewed, and free of conflict of interest.

¹ http://www.water.ca.gov/iep/docs/mast_report_process_july2013.pdf

² <http://deltacouncil.ca.gov/docs/2012-11-06/delta-science-program-procedures-conducting-independent-scientific-peer-review>

All other review was invited by email and in a notice posted on the IEP website.³ A draft of the 2013 MAST report, associated figures, and MAST report review guidelines were posted on July 23, 2013, for public technical review. The draft report release for review did not include an executive summary and conclusions. The public review period closed on August 31, 2013.

5. **How many review comments were received and where can they be accessed?** The MAST received 14 sets of review comments on the July 2013 draft MAST report. They included many general comments as well as 355 comments that referred to specific lines in the report, see table A1. All comments by external reviewers (public review comments and the review comments by the three independent scientific peer reviewers) were posted on the IEP website.⁴

6. **How were the review comments addressed?** All review comments received during the 40-day review period were compiled in an Excel spreadsheet and summarized numerically (Table A1). Review comments and procedures for addressing them were discussed by the MAST at its regular monthly meetings and during a one-day offsite meeting in November 2013. The process for addressing review comments included the following:
 - a. The lead author for each report section had the primary responsibility for addressing review comments pertaining to that section and for revising the section.
 - b. Secondary revision leads were also assigned and assisted the primary revision lead.
 - c. For each review comment in the Excel spreadsheet, it was noted whether the comment: (1) Did not suggest a revision and no revision was made; (2) Suggested a revision and a revision was made; or (3) Suggested a revision, but no revision was made, for example because it was outside of the report scope, explained elsewhere, or the lead author did not agree with the recommended revision.
 - d. Revised sections and the annotated excel spreadsheet were sent by email to the entire MAST. MAST members were alerted to all major revisions.
 - e. Major revisions were discussed with all MAST members during MAST meetings and via email.
 - f. Decisions about major revisions were made by the whole MAST; no comment implied consent.
 - g. Decisions about more minor revisions were made by the section revision leads and the report lead editor, often in consultation with some or all other MAST members.
 - h. The report lead editor (Larry Brown, USGS) compiled, further revised, and integrated all revised report sections and sent full draft report versions to the MAST for review by all MAST members. The final draft versions of the report and executive summary were also sent to the IEP coordinators for their review and approval.

<i>All Reviews To Date</i>	116	502	618	355

7. **What major changes were made to the draft report in response to review comments?** The draft Delta Smelt MAST report underwent several major changes in response to review comments. Changes include the following:
- a. The report purpose and goals were reconsidered, clarified, and somewhat expanded. Specifically, the four-year comparison of factors that may have contributed to the Delta Smelt abundance increase in 2011 was deemphasized in favor of a broader assessment and conceptual model of factors affecting Delta Smelt throughout its primarily annual life cycle and demonstrations of how the conceptual model can be used in science and management.
 - b. The report structure was substantially changed to better fit the revised report purpose and goals and to improve the organization of the large amount of information included in the report. Four new Chapters were added to describe the updated conceptual model (Chapter 5), provide a more thorough overview of Delta Smelt life history and population dynamics (Chapter 6), summarize and discuss findings and conclusions (Chapter 8), and provide recommendations and examples of future work and management applications (Chapter 9). An executive summary was also added, along with this appendix.
 - c. The content of the report was expanded to accomplish the somewhat expanded report purpose and goals, reflect previously missing information pointed out by reviewers as well as new information from the latest scientific publications, and provide conclusions and recommendations for future work and management applications.
 - d. Several reviewers commented that the simple four-year comparative approach that was used to evaluate factors that may have contributed to the Delta Smelt abundance increase in 2011 was too limited and that more years of data and more in-depth analyses and modeling were needed for this evaluation. The MAST agreed, but decided that these types of analyses would require additional

time and resources and were outside the scope of this report which emphasized synthesis of existing information over new data analyses. Instead, the MAST decided to discuss some of the benefits and limitations of analysis and synthesis approaches used in the report in Chapter 8 and existing and ongoing analyses and modeling efforts along with additional, analysis, synthesis, modeling, and other science needs and potential management applications in Chapter 9. Three examples of additional mathematical modeling approaches are also included in Chapter 9. These approaches were explored by individual co-authors of this report. Preliminary results of these analyses are given for illustrative purposes only; peer-reviewed publications of these analyses need to be completed before they can be used to draw firm conclusions.

Delta Smelt MAST Report Milestones

Note: The time line for the development, review, revision and completion of the Delta Smelt MAST report had to be adjusted repeatedly because of numerous new work assignments for individual MAST members, the large number and depth of review comments, the federal government shut-down, personnel changes, etc.

2012

March 13-16 Initial MAST off-site meeting (Marconi Center, CA) to discuss MAST products and direction and start MAST work on the 2012 IEP proposal solicitation⁵, the “FLaSH” report⁶, and the Delta Smelt MAST report (hereafter MAST report)

Sep 13-14 MAST off-site meeting (Yolo Wildlife Area, CA)

Dec 4-5 MAST off-site meeting (Clarksburg, CA)

2013

March 29 First draft MAST report completed

April 24 MAST presentation (talk) at annual IEP Workshop (Larry Brown, USGS)

May 20 Second draft MAST report completed

June 6 Third draft MAST report completed

July 23 – Aug 31 Fourth draft MAST report completed and posted on the IEP website for a 40-day review period

August 14 Draft MAST report discussion with IEP Stakeholder Group

Sep 11 Special IEP Stakeholder Group meeting about the draft MAST report

Oct 30 MAST report poster presentation at 2013 State of the Estuary Conference

Nov 14 MAST off-site meeting (UC Davis, CA)

Dec 8 Fifth draft MAST report completed

⁵ <http://www.water.ca.gov/iep/archive/2012/solicitations.cfm>

⁶ <http://deltacouncil.ca.gov/science-program/fall-low-salinity-habitat-flash-studies-and-adaptive-management-plan-review-0>

2014

Feb 3	Sixth draft MAST report completed
Feb 11	MAST presentation (talk) at DSP-SWRCB “Delta Outflows” workshop (Larry Brown, USGS)
Feb 20	MAST presentation (talk) at a meeting of the IEP Resident Fishes Project Work Team (Larry Brown, USGS)
Feb 26	MAST presentation (talk) at annual IEP Workshop (Larry Brown, USGS)
April 16	Seventh draft MAST report completed
April 17	First draft MAST report executive summary completed
April 24	Second draft MAST report executive summary completed and sent to IEP Coordinators for review
May 15	Eight draft MAST report completed and sent to IEP Coordinators for a one-week “red flag” review. This draft includes the executive summary and a description of how the MAST report was written and revised with a list of major report revisions in response to review comments (Appendix A)
June 2	Ninth draft MAST report completed and sent to IEP Coordinators for review and IEP Directors briefings
June 11	IEP Coordinators briefed on MAST report including a review of the major changes.
June 17	Agencies and stakeholders of the CAMT Delta Smelt Scoping Team briefed about the MAST report including major findings and changes since 2013.
July 2	IEP Stakeholder Group meeting to discuss MAST report revisions and completion
July 3	Coordinators approve the final draft MAST report for publication as an IEP Technical Report; when ready the draft final report will be posted on the MAST webpage ⁷ until the IEP Technical Report publication is completed and report is posted on the IEP Technical Reports webpage ⁸
July 14	MAST model presented to IEP Wetlands Conceptual Model Team.
July 29	IEP Directors meeting with presentation and discussion of final MAST report
July 30	MAST model presented to IEP Wetlands Project Work Team.
August 6	MAST briefing to Drought Operations Plan Team

Appendix B: Calculation of Annual Abundance Indices

This Appendix describes the data and methods used by 4 long-term fish monitoring surveys for calculating annual abundance indices for Delta Smelt (*Hypomesus transpacificus*). Descriptions are arranged sequentially beginning with the Spring Kodiak Trawl, which calculates an index of abundance for adult Delta Smelt, followed by the 20 mm Survey, which calculates an index

⁷ <http://www.water.ca.gov/iep/pod/mast.cfm>

⁸ <http://www.water.ca.gov/iep/products/technicalrpts.cfm>

for late-stage larvae and small juveniles; the Summer Townet Survey calculates an index for juveniles and the Fall Midwater Trawl Survey calculates an index for sub-adults. As mentioned in the main document, abundance indices are not population estimates, but they are believed to increase monotonically with increases in true population size.

Spring Kodiak Trawl

The Department of Fish and Wildlife (DFW) initiated the Spring Kodiak Trawl Survey (SKT) in 2002. The SKT replaced the Spring Midwater Trawl and provided a more effective means to monitor the distribution and reproductive status of adult Delta Smelt. Survey results provide near real-time information on the proximity of adult Delta Smelt to south Delta export facilities and can provide an indication of likely spawning areas.

The SKT includes 5 monthly Delta-wide surveys, January through May (Figure 84). Only the first 4 surveys contribute to the annual abundance index. No index exists for 2002, when only 3 surveys were conducted. The index is calculated after all data have been verified for accuracy.

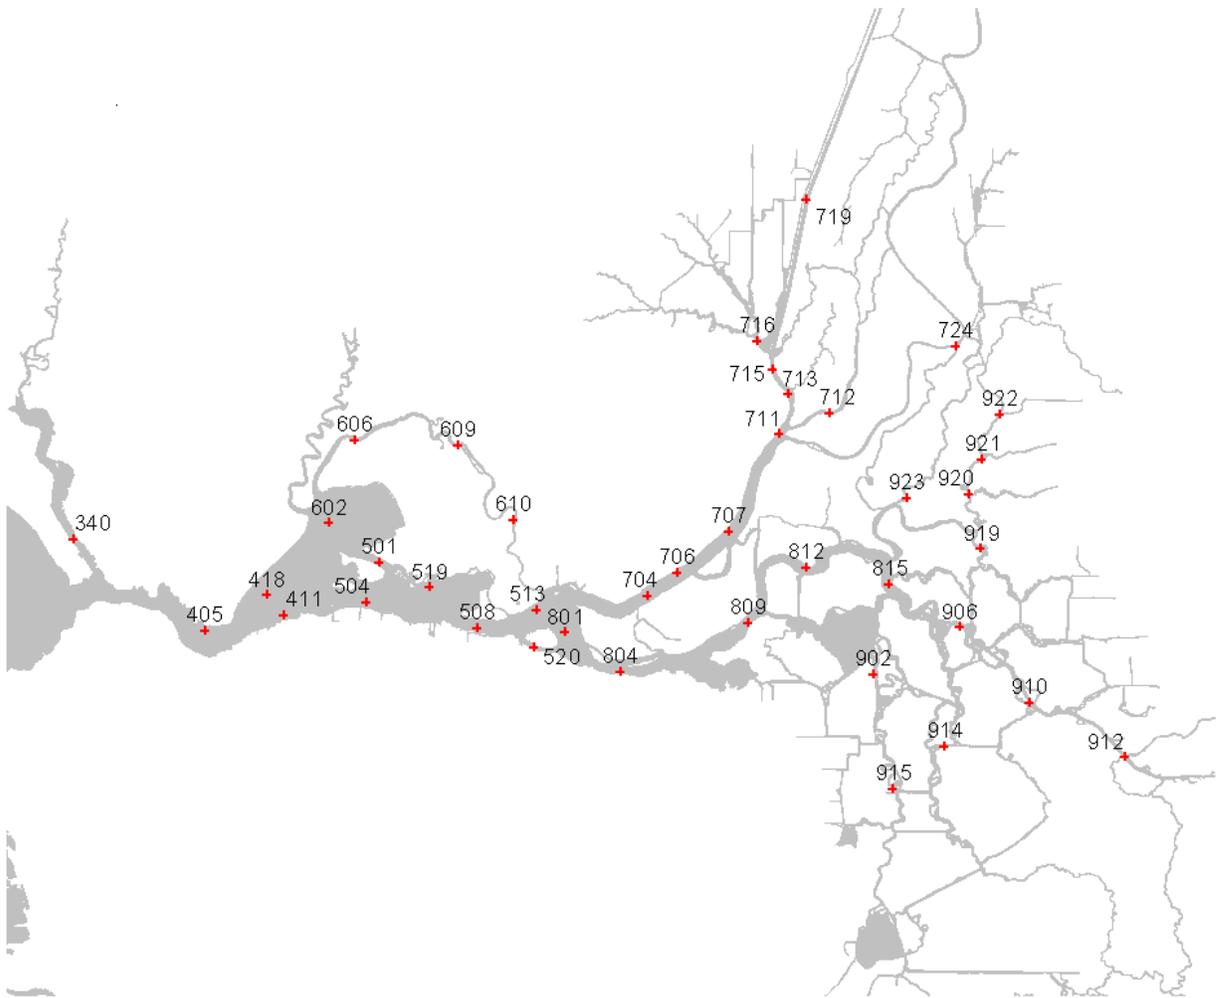

Field crews tow the net at the surface between 2 boats once for 10-min at each station per survey; 5-min surface tows are used at stations with historically high catch to limit excessive Delta Smelt take; a second 5-min surface tow is completed if Delta Smelt catch in the first tow did not exceed 50. A flow meter deployed at the start of the tow and retrieved at the end provides information on distance towed through the water. To calculate fish density, survey personnel assume that the SKT net fishes with the mouth fully opened, an area of 13.95 m² (7.62 m wide by 1.83 m deep). Volume filtered is the product of distance towed and mouth area. Volume filtered varies and by convention researchers expand catch per volume filtered (number per m³) for juvenile and adult fish to catch per 10,000 m³.

Annual abundance index calculations use adult Delta Smelt data from 39 of the 40 stations (Fig. 84). For each of the first 4 monthly surveys, adult catch per 10,000 m³ values from each station are grouped into 3 distinct regions based on geographic location: 1) the confluence and Suisun region (sites 340, 405, 411, 418, 501, 504, 508, 513, 519, 520, 602, 606, 609, 610, 801); 2) the Sacramento River and Cache Slough region (sites 704, 706, 707, 711, 712, 713, 715, 716, 719, 724); and 3) the San Joaquin River and Delta region (804, 809, 812, 815, 902, 906, 910, 912, 914, 915, 919, 920, 921, 922, 923). A monthly mean is calculated for each region and the sum of the regional means is the monthly or survey index. The sum of the 4 survey indices is the annual index.

20 mm Survey

DFW initiated the 20 mm Survey in 1995 to monitor the distribution and relative abundance of larval and juvenile Delta Smelt throughout their historical spring range in the upper San Francisco Estuary (Fig. 85), and provide near real-time information on the relative densities and proximities of these young fish to south Delta export pumps. The 20 mm Survey includes sampling on alternate weeks from mid-March through early July, typically resulting in 9 surveys per year. During each survey, field crews complete 3 oblique tows at each of the 47 stations (Fig. 85). The 20 mm Survey added stations over time, but not all contribute to annual abundance index calculation. The survey added 5 Napa River stations in 1996 for a total of 41 core stations, which are included in the annual abundance index calculations (Fig. 85, circles). In 2008, 6 non-

Figure 84. Map of Spring Kodiak Trawl Survey stations showing all currently sampled stations. Data from all stations except 719 are used in abundance index calculation.

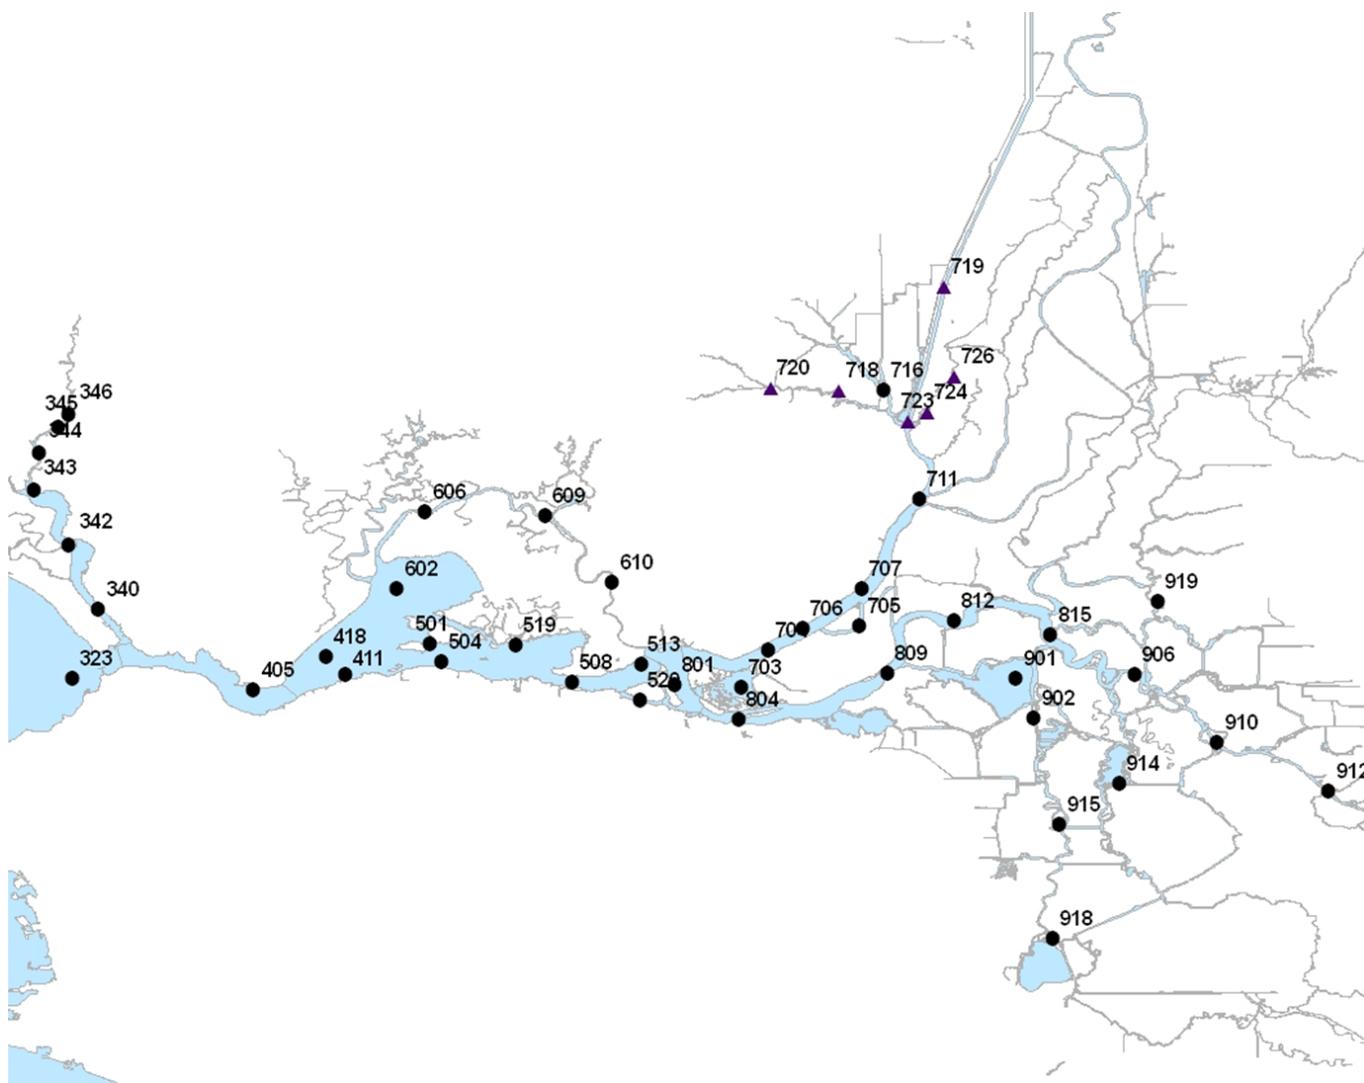

core stations were added, which are not included in the annual abundance index calculations, including Barker Slough (site 720), Lindsey Slough (site 718), Miner Slough (sites 724 and 726), and the Sacramento Deep Water Shipping Channel (n = 2; sites 719 and 723) (Fig. 85, triangles).

The 20 mm net includes a flow meter located within the mouth of the net to measure distance traveled by the net during the tow. This value is then multiplied by the fixed mouth area of the net (1.51 m²) to provide total volume filtered. The tows are then standardized to catch of Delta Smelt per 10,000 m³.

As already noted, the annual abundance index calculation uses only catch per 10,000 m³ values from the 41 index stations. For each survey, the mean fork length of Delta Smelt is calculated from measurements of the fish captured during each survey. The two surveys just before the average fork length reached 20 mm and the 2 surveys just after the average fork length reached 20 mm are included in the annual abundance index calculation. For these 4 surveys the geometric

Figure 85. Map of 20 mm survey stations showing all currently sampled stations. Data from all core stations are used in abundance index calculation.

mean of the catch of Delta Smelt per 10,000 m³ is calculated across the 41 core stations. The geometric mean for each survey is calculated as the arithmetic mean of $\log_{10}(x+1)$ -transformed values of Delta Smelt catch per 10,000 m³ across the 41 core stations. The resulting value is then back-transformed (including subtraction of 1) for the calculation of the annual abundance index. The annual abundance index is calculated as the sum of the geometric means of the 4 selected surveys.

Summer Townet Survey

The Summer Townet Survey (TNS) was started by DFW in 1959 to produce an annual index of summer abundance for age-0 Striped Bass (*Morone saxatilis*). In the mid-1990s, DFW staff developed an abundance index calculation for Delta Smelt. Annual abundance indices for Delta Smelt have been calculated for the period 1959 through the present, except for 1966-1968. The

TNS Survey samples 32 historic stations, 31 of which contribute to index calculation (labeled as “core stations,” Fig. 86). Currently sampled TNS stations range from eastern San Pablo Bay to Rio Vista on the Sacramento River and to Stockton on the San Joaquin River (Fig. 86). In 2011, TNS added 8 supplemental stations in the Cache Slough and the Sacramento River Deepwater Ship Channel region to increase spatial coverage and better describe Delta Smelt range and habitat (Fig. 86). Historically, TNS sampling began when age-0 Striped Bass achieved a mean fork length of 20 mm based on larval sampling, typically in mid-June to early July, and ended when age-0 Striped Bass surpassed a mean size of 38.1 mm fork length. Since 2003, TNS has consistently included 6 surveys annually, running on alternate weeks from early June through mid- to late August.

Field crews perform at least two 10-min oblique tows at most stations. A third tow is conducted when any fish were caught during either of the first 2 tows. At least 1 tow is completed at each of the new Cache Slough and Sacramento River Deepwater Ship Channel stations. To reduce Delta Smelt take, field crews only perform a second tow at these stations if Delta Smelt catch from the first tow is less than 10. Delta Smelt catch per tow data are used for index calculation.

The annual abundance index for Delta Smelt is the arithmetic mean of the abundance indices from the first 2 surveys conducted each year. Delta Smelt abundance indices for each biweekly survey are calculated by summing catch across all tows for each index station, multiplying the summed catch by a station weighting factor representing the water volume of that station (Table B1); then the volume-weighted catches are summed across all 31 index stations and the sum divided by 1000.

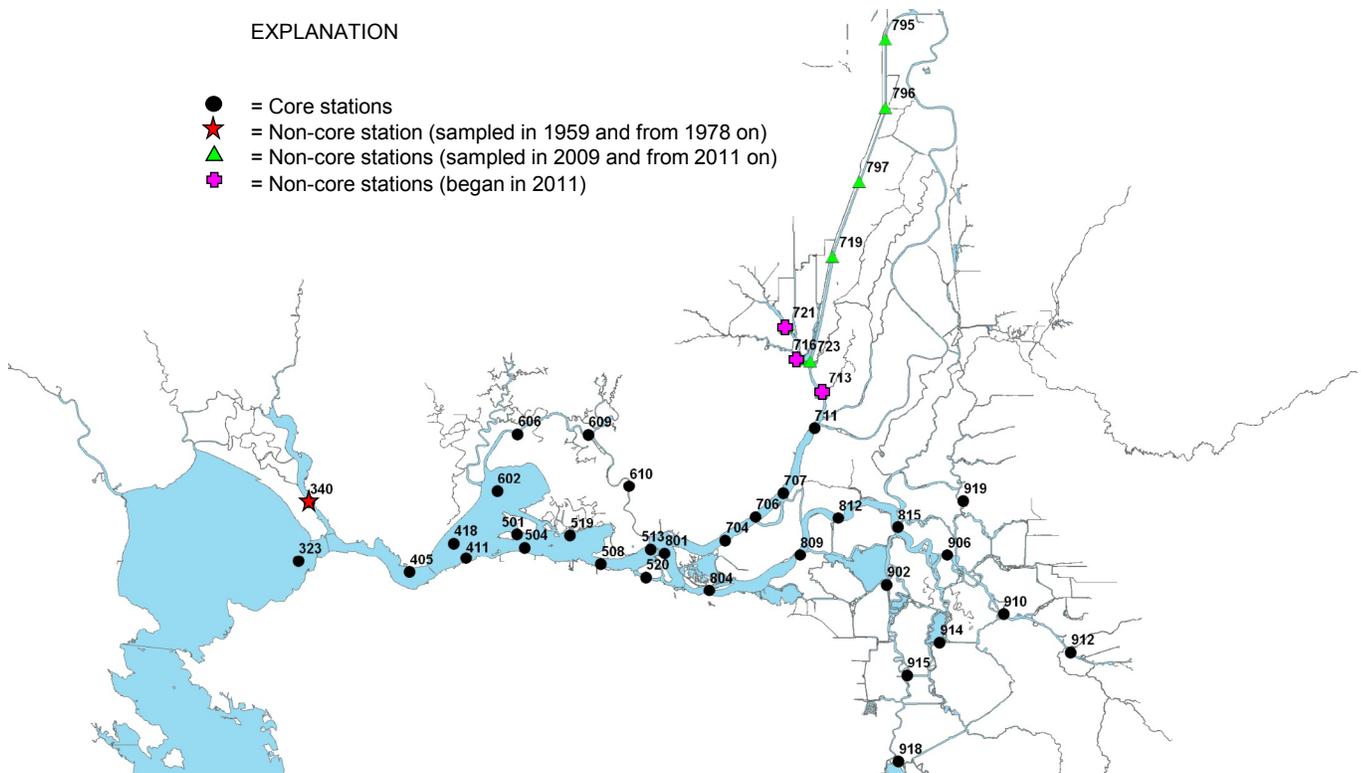

The annual abundance index for age-0 Striped Bass is calculated using similar methods, except the first two surveys are not used. Instead, abundance indices from the 2 surveys that bound the date when the fish reach a mean fork length of 38.1 mm are used; this frequently occurs after several surveys have been completed in a field season.

Fall Midwater Trawl Survey

DFW began the Fall Midwater Trawl Survey (FMWT) in 1967 to provide an annual index of relative abundance and information on the distribution of age-0 Striped Bass for the fall period. Later, DFW staff developed abundance and distribution information for other upper-estuary pelagic fishes, including Delta Smelt. Surveys have been conducted in all years from 1967 to present, except 1974 and 1979. The FMWT survey currently samples 122 stations monthly (Fig. 87), from September through December. Station locations range from San Pablo Bay to Hood on the Sacramento River, and from Sherman Lake to Stockton on the San Joaquin River (Fig. 87). Currently, annual abundance index calculations use catch data from 100 of the 122 stations sampled monthly, but the number of stations used for the index has varied through time. Table 12 contains the complete list of stations used for abundance index calculation for FMWT ($n = 117$), including historical stations (underlined) that must be included for proper calculation of past indices, but are not included in calculations for recent years. The remaining 22 stations were added in 1990, 1991, 2009, and 2010 to improve our understanding of Delta Smelt habitat use (Fig. 87). At each sampling station, field crews perform a single, 12-min oblique tow monthly.

Delta Smelt catch per tow data are used for calculation of the annual abundance index. Individual survey indices are calculated by first grouping the 100 core stations (Fig. 87) into 14 regions based on their location (Table 12). Survey indices are calculated by averaging Delta Smelt catch

Figure 86. Map of summer townet survey stations showing all currently sampled stations. Data from all core stations are used in abundance index calculation.

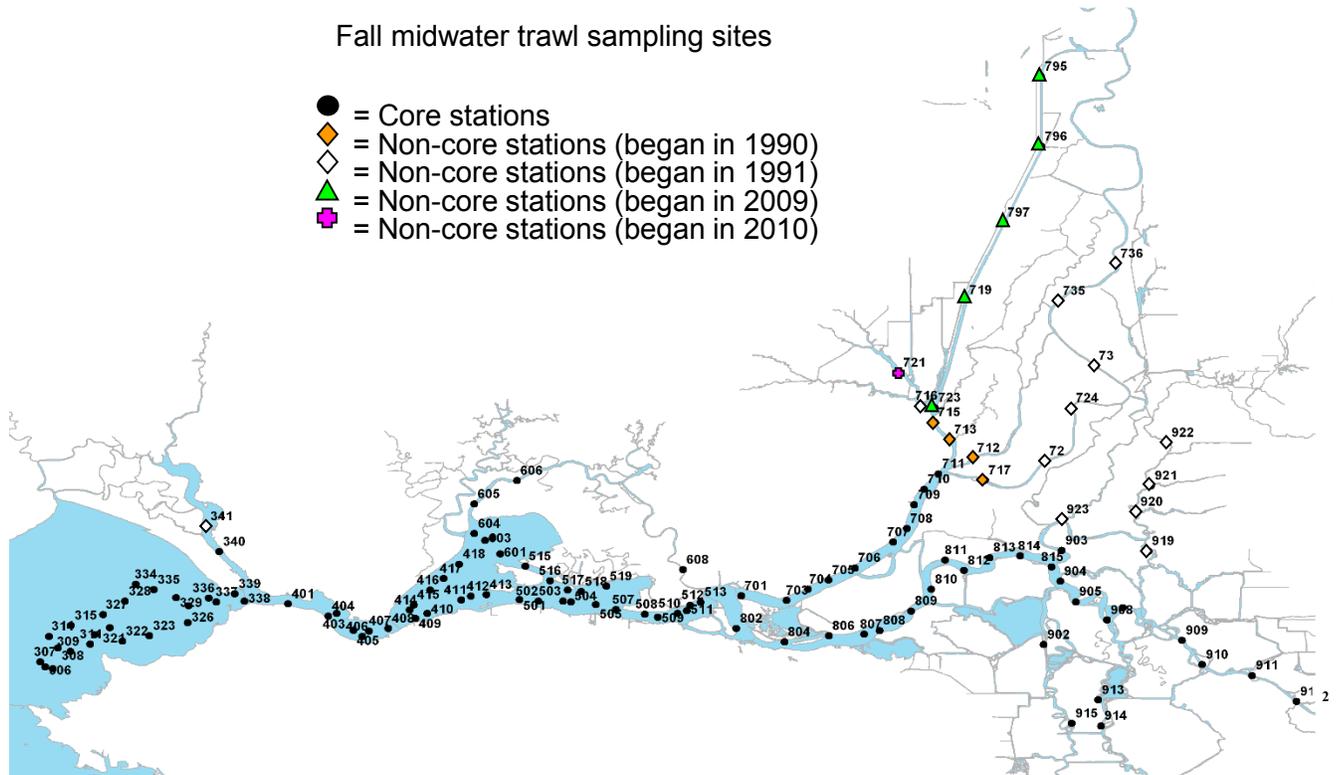

across index stations within each region, multiplying these regional means by their respective weighting factors (i.e. a scalar based on water volume; Table 12), and summing the weighted values. Annual abundance indices are calculated as the sum of the 4 survey abundance indices (i.e. September through December).

Table B1. Station weighting factors for stations used in calculations of the summer townet survey annual abundance indexes. Regions are geographic areas designated by the California Department of Fish and Wildlife. See fig. 86 for station locations.

Possibility of natural producing spring-run Chinook salmon in the Stanislaus and Tuolumne Rivers

Currently Central Valley spring-run Chinook salmon are listed as threatened under the Endangered Species Act (ESA). This species was first listed in 1999. Historically in the San Joaquin River system spring-run Chinook are thought to have been one of the most viable runs, but were not listed under the original ESA listing as it was presumed by 1950, that the entire run of spring-run Chinook salmon was extirpated from the San Joaquin River (Fry 1961). The former spring run of the San Joaquin River has been described as “one of the largest Chinook salmon runs anywhere on the Pacific Coast” and numbering “possibly in the range of 200,000-500,000 spawners annually” (CDFG 1990).

Analyzing the historic data and information provided specifically on the Tuolumne and Stanislaus rivers, there is high probability based on records coupled with current data that natural (fish that naturally spawned in river systems and whose parents did as well) occurring spring-run Chinook are still present in small numbers. Here it is discussed where spring-run originally used these river systems.

On the Tuolumne River, Clavey Falls (10-15 ft. high) at the confluence of the Clavey River, may have obstructed the salmon at certain flows, but spring-run salmon in some numbers undoubtedly ascended the mainstem a considerable distance. The spring-run salmon were most likely stopped by the formidable Preston Falls at the boundary of Yosemite National Park (~50 mi upstream of present New Don Pedro Dam), which is the upstream limit of native fish distribution (CDFG 1955 unpublished data).

Spring run Chinook also originally occurred in the Stanislaus River. Spring-run probably went up the system considerable distances because there are few natural obstacles (Yoshiyama et al. 1998). Much of the spawning occurred on the extensive gravel beds in the 23-mi. stretch from

Riverbank upstream to Knights Ferry, which is essentially on the Valley floor at approximately 213 feet in elevation. Upstream of Knights Ferry, where the river flows through a canyon, spawning was (historic observations of spring-run) and is (fall-run) concentrated at Two-mile Bar (~1 mi above Knights Ferry) but also occurs in scattered pockets of gravel (Yoshiyama et al. 1998). Historically, the spring run was the primary salmon run in the Stanislaus River, but after the construction of dams which regulated the stream flows (i.e., Goodwin Dam and, later, Melones and Tulloch dams); the fall run became predominant (CDFG 1972 unpublished report).

Recent information suggests that perhaps a self-sustaining (capable of reproducing without hatchery influence) population of spring-run Chinook is occurring in some of the San Joaquin River tributaries, most notably the Stanislaus and the Tuolumne Rivers. Snorkel surveys (Kennedy T. and T. Cannon 2005) conducted between October 2002 to October 2004 on the Stanislaus River identified adults in June 2003 and June 2004 between Goodwin and Lovers Leap. Additionally on the Stanislaus, snorkel surveys also observed Chinook fry in December 2003 at Goodwin Dam, Two Mile Bar, and Knights Ferry, which they interpreted as an indication of spawning occurring in September, which is earlier than when fall-run Chinook salmon would be spawning in the river.

FISHBIO a fisheries consultant has operated a resistance board weir coupled with a Vaki RiverWatcher video monitoring system on the Stanislaus since 2003 and on the Tuolumne since 2009. Information obtained from this monitoring indicates that adult Chinook salmon are passing upstream of these weirs at a time period that would historically indicate a spring-run timing. Looking specifically at the months from February to June almost annually since observation began, some adult Chinook are migrating upstream (Table 1). It should be noted that the weir has not always operated past December due to study design or non-conductive river conditions. For example in 2007, 11 phenotypic spring-run Chinook were observed passing the weir between May and June on the Stanislaus. Future monitoring will determine if these fish are a typical occurrence or an anomaly (Anderson et al. 2007). Further personal observations by fisheries biologist from other agencies (CDFG & USFWS) that are familiar with these systems have accounts of seeing adult Chinook holding in these river systems in summer months (CDFG & USFWS, Personal comm.). If this is the case then genetic testing would be needed to confirm that these fish are in fact naturally producing spring-run Chinook and not hatchery strays, *i.e.*

Feather River. Otolith analysis may be the best way to confirm this by matching chemical signatures specific to each river system. Additionally there is no segregation barrier in place for spring-run and fall-run and it is likely that fall-run are superimposing on spring-run redds (Wikert, Personal Comm.). A further analysis looking at these tributaries rotary screw trap (RST) data helps support the suggestion of self-sustaining spring-run by looking at length at date criteria and comparing it to known spring-run Chinook populations on Sacramento River tributaries. RST data provided by Stockton United State Fish and Wildlife Service (USFWS) corroborates with the adult timing, by indicating that there are a small number of fry migrating out of the Stanislaus and Tuolumne at a period that would coincide with spring-run juvenile emigration (Tables 2 & 3).

Additionally during snorkel and kayak surveys in April, May and June of 2013 with CDFW, USFWS and NMFS staff the author observed a large number of adult Chinook in the upper reaches of the Stanislaus River below Goodwin Dam.

ABSTRACT

Blooms of toxin-producing *Microcystis aeruginosa* occur regularly in freshwater systems throughout California, but until recently potential impacts in the coastal ocean have been largely ignored. Twenty-one sites in and around Monterey Bay were surveyed for evidence of microcystin toxin (2010–2011) at the land–sea interface. Following this initial survey four major watersheds in the Monterey Bay area were surveyed (2011–2013) for microcystin concentration, nutrients, alkalinity and water temperature to identify potential environmental factors correlated with the abundance of microcystin at the land–sea interface. During the first year microcystin was detected in 15 of 21 sites. Data from years two and three were analyzed by principal components analysis and mixed effects model. Results indicated that coastal nutrient loading (nitrate, phosphate silicate, ammonium, urea), were statistically significant predictors of the microcystin concentrations in the watersheds with clear evidence for seasonality at some sites. Microcystin was frequently at highest concentration in the autumn; however, at some locations high levels of toxin were measured during spring. Because this toxin has the ability to biomagnify and persist within food webs, elevated levels within the watershed may decrease potential for health and survival of wildlife and humans exposed to freshwater and marine waters. The widespread occurrence of microcystin at low to moderate levels throughout the year and throughout the sampled watersheds demonstrates the potential difficulty for management.

1. Introduction

Harmful algal blooms (HABs) are a global problem in both freshwater and marine ecosystems. The prevalence of HABs and subsequent toxic events may be intensified by a warming climate in tandem with increases in environmental degradation and eutrophication (Zehnder and Gorham, 1960; Welker and Steinburg, 2000; Guo, 2007; Paerl and Huisman, 2008; Davis et al., 2009; Kudela, 2011). Production of the toxin microcystin by the cyanobacterium *Microcystis aeruginosa*, was originally recognized by Ashworth and Mason (1946) in American waters in the 1940s. *M. aeruginosa* blooms are now common in lakes and rivers throughout North America, including California (Chen et al., 1993; Lehman et al., 2005). *M. aeruginosa* bloom formation and consequent toxin generation increases with environmental variables such as: high nutrient supply, elevated light levels, and warm temperatures (Zehnder and Gorham, 1960; Tsuji et al., 1994;

Jacoby et al., 2000; Welker and Steinburg, 2000; Paerl and Huisman, 2008; Davis et al., 2009; Paerl and Otten, 2013a, 2013b).

Recently toxins associated with the ostensibly freshwater cyanobacterium *Microcystis aeruginosa* have been detected in the near-shore marine ecosystem of central California, and have been confirmed as a danger to the health of sea otters feeding near ocean outflows of freshwater systems (Miller et al., 2010). *M. aeruginosa* is fairly salt-tolerant and microcystin toxins can be stable and environmentally persistent in both saltwater and freshwater habitats (Robson and Hamilton, 2003; Ross et al., 2006; Tonk et al., 2007; Miller et al., 2010). In addition to direct toxic effects, exposure of aquatic organisms to elevated concentrations of microcystins may negatively affect all levels of the food web (Demott and Moxter, 1991; Malbrouck and Kestemont, 2006; Richardson et al., 2007; Miller et al., 2010).

In 2007, numerous sea otters were found dead in Monterey Bay with signs of liver failure (Miller et al., 2010). Biochemical testing confirmed the presence of microcystin toxin with associated lesions in the livers of 21 otters. Because the occurrence of phytoplankton derived biotoxins are a common phenomenon in Monterey Bay, the otters were evaluated for domoic acid, okadaic acid, nodularin, yessotoxin and anatoxin-A. Otters that were found

positive for microcystin toxin were negative for all other toxins in the tissues. A few of the microcystin positive otters were also found to have low levels of domoic acid in the urine. However, this is a common finding during necropsy of stranded sea otters from this region, due to domoic acid being broadly dispersed in the sediments of Monterey Bay (Goldberg, 2003; Miller et al., 2010). Freshwater to marine transfer of microcystins was confirmed in areas where sea otters had been recovered, and uptake of microcystins by marine invertebrates and environmental persistence in seawater were demonstrated experimentally (Miller et al., 2010). At this time, potential population-level impacts of these biotoxins on otters and other coastal wildlife remains undetermined. The freshwater to marine transfer of microcystin to the Monterey Bay National Marine Sanctuary waters described by Miller et al. (2010) has the potential to cause major environmental harm. The stability of microcystin allows it to accumulate (van der Oost et al., 2003), and microcystin toxin has been shown to biomagnify and persist in the environment and the food web (Sivonen and Jones, 1999; Dionisio Pires et al., 2004; Kozłowski-Suzuki et al., 2012; Poste and Ozersky, 2013). Despite the confirmation of microcystin poisoning in marine mammals, the source of these toxins is unclear. Pinto Lake, California was identified as a “hotspot” for toxin production and subsequent transfer to the coastal ocean but this source was not consistent with the location of many of the otters (Miller et al., 2010), which were distributed throughout Monterey Bay, suggesting other, less obvious, sources of toxin to the coastal environment.

We took a wide ranging watershed-based approach to identify the potential pathways leading to microcystin contamination in coastal ecosystems in and around Monterey Bay, CA. Since initial surveys of other potential “hotspots” for toxin production were unsuccessful (Miller et al., 2010) via grab sampling, we deployed Solid Phase Adsorption Toxin Tracking (SPATT) samplers throughout the Monterey Bay area to provide a temporally integrated assessment of potential freshwater sources (Kudela, 2011). Because toxin frequency of occurrence, persistence, and associated environmental drivers may potentially be propelling this freshwater toxin into a sensitive and protected marine sanctuary, our overarching goals were to identify the freshwater sources of microcystin to the Monterey Bay ecosystem, and to identify the

underlying environmental drivers influencing toxin production in this area.

2. Materials and Methods

2.1. Initial survey

We surveyed 21 freshwater, estuarine, and marine locations in and around the Monterey Bay area at the land–sea interface (June 2010–July 2011) for microcystin toxin presence and concentration (Fig. 1A). Sites included small and large rivers, estuaries, and near-shore marine locations traversing the six watersheds that surround Monterey Bay (Fig. 1A). Each site was sampled monthly using SPATT (Kudela, 2011). SPATT bags were constructed using 3 g DIAION® HP-20 resin (Sorbert Technologies Inc., Georgia, USA) placed between two 3 inch × 3 inch squares of 100 μM Nitex bolting cloth (Wildlife Supply Company, Product No. 24-C34), and secured in a Caron Westex 2.5 in flex embroidery hoop (Caron International, Ontario, Canada). SPATT was activated by soaking each bag in 100% MeOH, for 48 h, and then rinsed with de-ionized water (Milli-Q), and stored in fresh Milli-Q until deployment (Mackenzie et al., 2004; Lane et al., 2010). When deployed at the beginning of each month, SPATT bags were suspended below the surface of the water, and secured with twine to a stake near the edge of the water. This allowed each bag to be suspended in the water, while being weighed down by the ring so that it remained below the surface. Toxin concentration values are reported as nanogram toxin per gram resin. SPATT toxin concentration levels are not directly comparable to grab sample values (ppb, or μg/L), but previous studies suggest a rough correspondence of 10:1 for SPATT to grab samples (Kudela, 2011), i.e. 10 ng/g SPATT is equivalent to an average concentration of 1 ppb microcystin during SPATT deployment.

2.2. Time-series

In years two and three (August 2011–August 2013) sampling locations were reduced to four major affected watersheds in the Monterey Bay area: the Big Basin watershed, Pajaro River watershed, Salinas River watershed, and the Carmel River

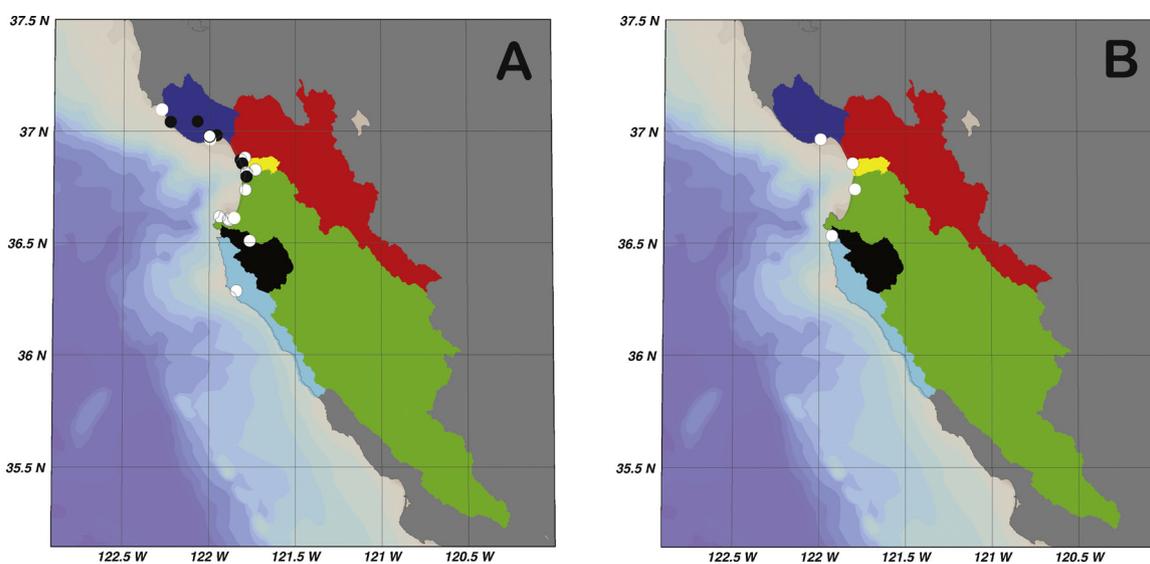

Fig. 1. Map of Monterey Bay, California, USA. (A) Sampling locations in year one (2010–2011) and sampling locations affected by microcystin toxin in year one. White symbols represent sites that were positive for microcystin, black symbols represents sites that were sampled but negative for microcystin toxin. (B) Sampling locations in year two (2011–2013). The watersheds, from north to south, are: Big Basin (dark blue), Pajaro River (red), Bolsa Nueva (yellow), Salinas River (green), Carmel River (black), Santa Lucia (light blue). Ocean bathymetry is indicated with shading. Maps created using Ocean Data View (ODV) and Exelis Visual Information Solutions (ENVI).

watershed. These four sampling locations were determined by the initial year one survey to be highly impacted by microcystin toxin. SPATT was deployed weekly at each site and whole water was collected and analyzed for temperature, ammonium, urea, nitrate, phosphate, silicate, and total toxin, with the whole water samples corresponding to the deployment and recovery dates for SPATT. With the exception of alkalinity, which was monitored only in year three (August 2012–August 2013), all other variables were measured in both years two and three. Temperature was monitored using Hobo Pendant[®] Temperature/Light Data Loggers (8K-UA-002-08; Onset Computer Corporation, Massachusetts, USA). When data loggers were unavailable for use due to theft or loss, field thermometers were employed in situ ($-10/110$ °C; Enviro-safe[®]; HB Instrument Company, Pennsylvania, USA). Ammonium, urea, nitrate, phosphate and silicate samples were collected in the field, immediately filtered ($0.7 \mu\text{M}$ GF/F filter), into 25 mL Falcon[™] centrifuge tubes, and were stored frozen until processing. The average time until processing was less than one month. Ammonium was analyzed using the OPA method and RFU values were obtained via fluorometer (TD-700; Turner Designs, California, USA) as described by Holmes et al. (1999). Urea was analyzed using a Varian Cary 50 Bio UV/Visible Spectrophotometer (Varian Medical Systems, California, USA) following methods described by Mulvenna and Savidge (1992). Nitrate, phosphate, and silicate were analyzed using a Lachat QuikChem 8500 Flow Injection Analyst System and Omnion 3.0 software (Lachat Instruments; Hach Company, Colorado, USA). Alkalinity was determined using Total Alkalinity Test Strips, 0–240 mg/L (Hach Company, Colorado, USA) in the field. Whole water was also collected in the field.

2.3. Toxin analysis

Microcystin-LR, RR, YR, LA was analyzed by liquid chromatography/mass spectrometry (LCMS) with electrospray ionization (ESI) with selected ion monitoring (SIM) on an Agilent 6130 with a Phenomenex Kinetix (100×2.10) C18 column. The method was adapted from Mekebri et al., 2009 with minor modifications to account for the choice of column and LCMS/SIM instead of tandem mass spectrometry (Kudela, 2011). Briefly, a gradient-elution method was used with HPLC water (solvent A) and LCMS acetonitrile (solvent B), both acidified with 0.1% formic acid, as the mobile phase. The gradient was as described in Mekebri et al. (2009), starting with 95:5 solvent A:B and ending with 25:75 at 19 min, held for 1 min, then followed by a 5 min equilibration at initial conditions prior to injection of the next sample. Samples were calibrated with standard curves (for each batch of samples) using pure standards (Fluka 33578 and Sigma–Aldrich M4194). Standards were run again at the end of the run for sample runs lasting more than 8 h.

Whole water was collected in the field, returned to the lab, where 3 mL of whole water was mixed with 3 mL of 10% methanol. Samples were then sonicated using a sonic dismembrator (Model 100; Thermo Fisher Scientific, Massachusetts, USA) for 30 s at ~ 10 W, filtered ($0.2 \mu\text{M}$ nylon syringe filter), and analyzed by direct injection of $50 \mu\text{L}$ onto the LCMS. SPATT samples were processed as described by Kudela (2011). Briefly, SPATT were recovered from the field and stored frozen until processing. The resin was transferred to a disposable chromatography column and sequentially extracted with 10, 20, 20 mL 50% methanol. Each extract ($50 \mu\text{L}$) was analyzed by LCMS and total toxin was determined by summing the individual extracts. Values are reported as $\mu\text{g/L}$ (=ppb) for whole water and ng/g resin for SPATT. The Minimum Detection Limit (MDL) was 0.05 ng/g for SPATT and 0.10 ng/mL (ppb) for whole water. Values <MDL were considered non-detect (zero) for statistical analysis. While it is

possible that compound other than microcystins could be falsely identified, it would require the compounds to exhibit the same mass and retention time as the standards making false positives unlikely.

2.4. Statistics

Microcystin toxin presence, concentration, and persistence were evaluated at each sampling location in year one, and for each watershed during years two and three. Data for both the discrete grab samples and the SPATT toxin concentrations were pooled for the analysis. The relationship between environmental variables (date, temperature, nitrate, phosphate, silicate, ammonium, urea) and microcystin were evaluated graphically and statistically. Because there was multicollinearity within the data from years two to three, a PCA was run to account for this, and the variables were grouped into components for further analysis (Zar, 1999; Quinn and Keough, 2002). A mixed effects model was chosen to account for autocorrelation caused by the seasonality component. Because of this autocorrelation the components (date and temperature) that comprised seasonality were removed from the PCA and added back into the model independently. When the model was run, components from the PCA (PC1 and PC2), and temperature were run against microcystin toxin. Date was added back into the model and was set as the random effect, with microcystin toxin concentration set as the fixed effect. This model is appropriate due to the nature of the flexibility it provides for correlated data (Quinn and Keough, 2002; Seltman, 2013). Variables used in the model were transformed via square root transformation to meet assumptions of normality, and $\alpha = 0.05$. From the results of the model, both negative and positive relationships between environmental variables and microcystin concentration were examined, and statistical significance was obtained. PCA and mixed effect model statistical tests were conducted using Systat 13.1 (Systat Software Inc., Chicago, Illinois, USA). The relationship between microcystin concentration and alkalinity was investigated via simple bivariate correlation using IBM SPSS Statistics 21 (IBM Corporation, Armonk, New York, USA).

To investigate any statistical relationship between river discharge and toxin presence, microcystin toxin concentration was compared to river discharge data (USGS, 2014) for each of the four watersheds. Data for the comparison were obtained from the United States Geological Survey (USGS) National Water Information System Web Interface database, and river discharge data were reported in cubic feet per second. Data were analyzed via simple bivariate correlations using IBM SPSS Statistics 21 and the significance was set at $p = 0.05$. Cross correlation function analysis (CCF) was evaluated using Systat 13.1 for effectiveness of introducing temporal lags into the data.

3. Results

3.1. Survey results (2010–2011)

In year one, 15 out of 21 locations surveyed in the Monterey Bay area were positive for microcystin toxin concentration (Fig. 1A; Table 1). There were noticeably high levels of toxin in the autumn season, and at some sites, such as the Carmel River and Salinas River, there were also noticeable spring season peaks in toxin concentration (Fig. 2). From our first year of data, four watersheds (Big Basin, Pajaro River, Salinas River, Carmel River) were identified as persistently toxic; this directed our sampling in years two and three. Toxin concentration values varied from undetectable to 20 ng/g.

The number of observations where SPATT was deployed and also recovered, is represented by OBS, the number of months positive for microcystin toxin is measured in ng/g and is represented by POS. The range, mean, and standard deviation represented by SD, are also provided.

3.2. Time series (2011–2013)

In year two, all four watersheds (Fig. 1B) exhibited an increase in microcystin toxin presence compared to year one (Table 2). In year three, all watersheds again exhibited similar or increased occurrences of microcystin toxin. As was seen in year one, high values of microcystin toxin concentration were observed in both autumn and spring seasons (Fig. 3), but in years two and three this seasonal pattern was evident in all four watersheds.

The PCA produced three significant principal components (Table 3). Principal component one (PC1) was comprised of ammonium and urea (21.02% variance explained), principal component two (PC2) was comprised of temperature and date (19.97% variance explained), and principal component three (PC3) was comprised of nitrate, phosphate and silicate (19.83% variance explained). All of the variables loaded positively with the exception of silicate. These PCA components were used in place of direct environmental variables to account for multicollinearity within the data. The seasonality component (date and temperature) produced an autocorrelation within the data. Seasonality was therefore removed and the PCA was re-run; two significant components were produced and grouped similarly. PC1 was comprised of ammonium and urea (29.36% variance explained), and PC2 was comprised of nitrate, phosphate, and silicate (27.25% variance explained). PC1, PC2 and temperature were then run in a mixed effects model against the presence and amount of microcystin toxin with date set as the random effect. The model showed that microcystin toxin concentration had a statistically significant relationship to all tested variables ($p < 0.05$; Table 3). Nitrate, phosphate, ammonium and urea were negatively associated with microcystin concentration within the model. Because silicate loaded negatively in the PCA, it was considered positively associated with microcystin in the model, while temperature was negatively associated with microcystin in the model (Table 3). The results of a CCF analysis indicated significant correlations between toxin concentration and individual environmental factors with temporal lags of three weeks. However, when the data were lagged, the overall model was greatly weakened. Microcystin

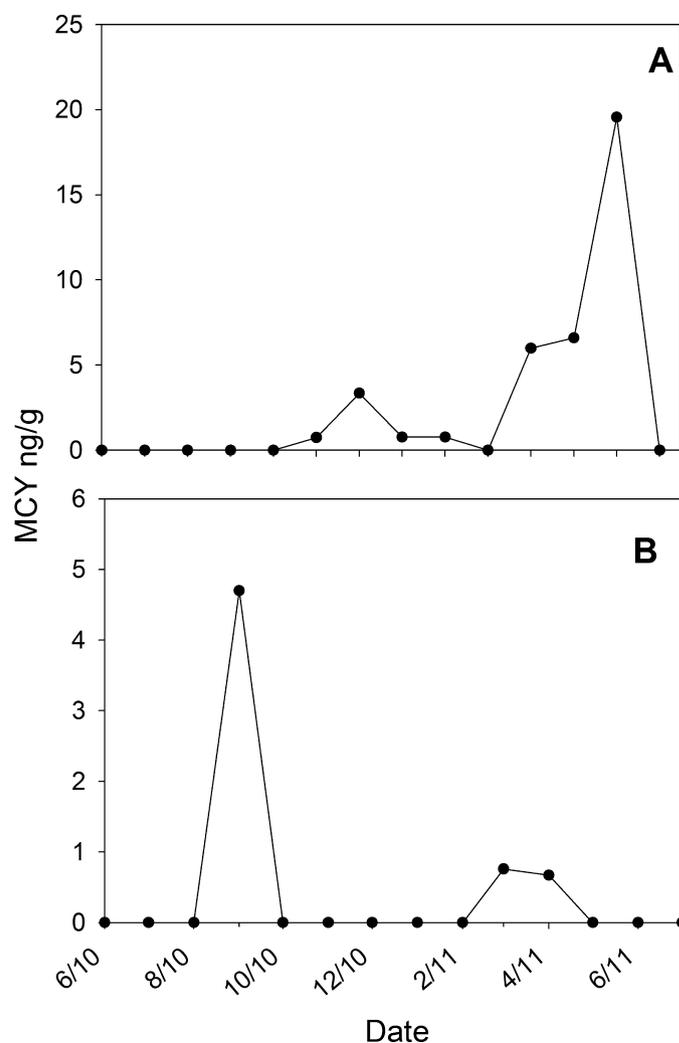

Fig. 2. Microcystin toxin (MCY) time series from SPATT samplers (ng toxin per gram resin) for two locations (A). Carmel River (B). Salinas River, during year one (June 2010–July 2011).

toxin concentration remained significantly related to all tested variables ($p < 0.05$). For this reason we present the statistical results without lags.

Bivariate correlations showed negative correlation with alkalinity and positive correlation with river flow. Alkalinity had a significant negative correlation ($p < 0.05$) with microcystin concentration (Fig. 4). River discharge and microcystin toxin concentration were significantly positively correlated for Big Basin, Pajaro River, and Carmel River watersheds ($p < 0.05$). Salinas River exhibited a weak, non-significant ($p > 0.05$) correlation. The results of CCF analysis indicated that a lag of four weeks may better align the data and increase the strength of the correlation. When the data were lagged all watersheds again were positively correlated; however, only the Pajaro River and Carmel River watersheds exhibited statistically significant correlations ($p < 0.05$).

4. Discussion

The results from this study show a serious condition at the near-shore interface in the Monterey Bay area, consistent with previous reports (Miller et al., 2010). In year one, approximately half of all tested locations were positive for microcystin toxins at some time during the year. We believe these toxins are being produced by

Table 2
Survey data for microcystin toxin and environmental variables from four watershed locations at the land–sea interface in Monterey Bay in years two and three (2011–2013).

Alkalinity		40–240	131.19	73.52
Temperature		7.00–20.66	13.41	2.98
	Microcystin	0–104.31	7.78	16.69

Microcystin toxin found in SPATT is measured in ng/g, microcystin toxin found in water samples is measured in ppb. The measured environmental variables: ammonium (μM), urea (μM), nitrate (μM), phosphate (μM), silicate (μM), alkalinity (mg/L), temperature ($^{\circ}\text{C}$) are shown. The range, mean, and standard deviation represented by SD, are also provided.

Microcystis aeruginosa in the nearshore freshwater environment and have the potential to be subsequently transported to the marine environment. Miller et al. (2010) found that cells lysed in seawater after 48 h; there is also possibility for some cells to be carried to the marine environment, lyse, and then release toxin. Monterey Bay is at high risk for this type of problem due to the nature of the surrounding land which is highly populated and widely used for agriculture. However, we believe this may be a phenomenon in other near-shore marine systems that have not been monitored for this particular toxin, and therefore, have gone unnoticed.

The use of SPATT technology allowed us to access time integrative toxin survey data simultaneously at many different locations, thus providing more than a “snapshot” of information such as would be obtained with intensive surveying. While SPATT was originally developed to mimic shellfish toxicity, its use has proven to be more beneficial and easy to use for toxin monitoring as compared to other popular monitoring methods like the use of shellfish testing, rote phytoplankton surveys, and whole water sampling (Mackenzie et al., 2004; Lane et al., 2010; Mackenzie, 2010; Kudela, 2011).

The occurrence of two dominant peaks, in spring and autumn, indicate an unexpected seasonal pattern of microcystin toxin for all primary watersheds in the Monterey Bay area. It is widely accepted that bloom formation is largely driven by light and nutrient availability, and often water stagnation (Zehnder and Gorham,

1960; Webb and Walling, 1992; Tsuji et al., 1994; Jacoby et al., 2000; Welker and Steinburg, 2000; Jeong et al., 2003; Paerl and Huisman, 2008; Davis et al., 2009; Paerl and Otten, 2013a). This often leads to a seasonal pattern, with optimal conditions for bloom formation occurring in summer and autumn seasons. (Reynolds et al., 1981; Paerl, 1988; Lehman et al., 2008; Moisander et al., 2009). This seasonal characteristic has similarly been identified in nearby waterways like the San Francisco Estuary (Lehman et al., 2005, 2008; Moisander et al., 2009). Additionally, Miller et al. (2010) reported that the Monterey Bay area generally experiences increases in microcystin presence and concentration in freshwater lakes and rivers during autumn. The patterns of microcystin presence and concentration observed during this study suggest that microcystins are likely present throughout the year. In years two and three microcystin toxin increased or remained elevated at all locations and the spring/autumn peaks persisted. While only three years in duration, these results suggest that microcystin production and subsequent transfer to the coastal environment has the potential to be a persistent issue in the Monterey Bay area.

The statistical analysis exhibited a distinct delineation between variables. Ammonium, urea, nitrate, and phosphate all exhibited a negative association with toxin in the model. We infer that the negative relationship was caused by biological drawdown of nutrients; toxin is produced by cells which are stimulated by the high nutrient levels, but toxin concentrations can become

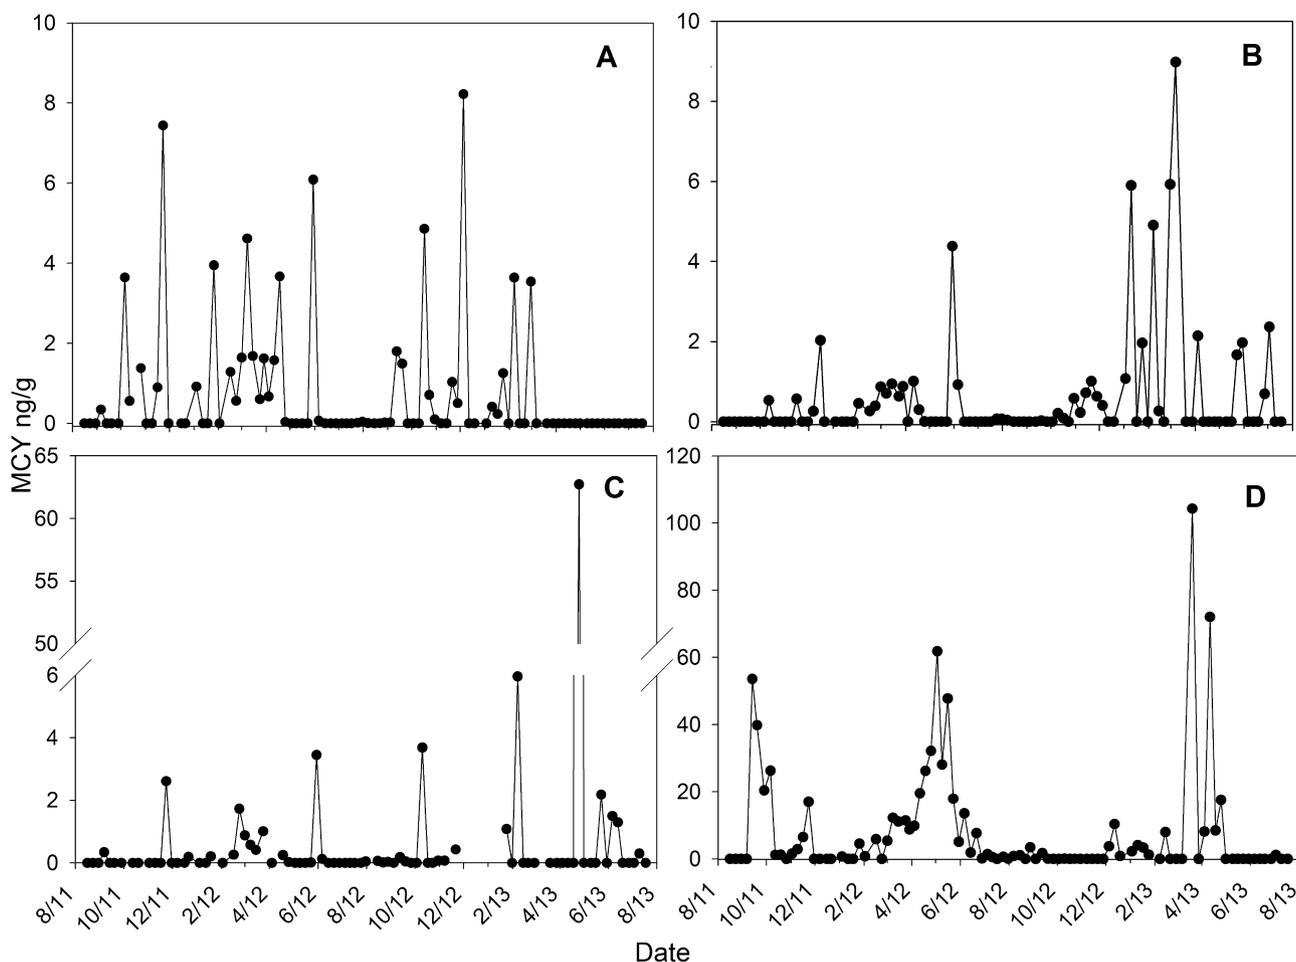

Fig. 3. Microcystin toxin from SPATT (MCY; ng/g) time series from August 2011 to August 2013. (A) Big Basin watershed; (B) Pajaro River watershed; (C) Salinas River watershed; (D) Carmel River watershed.

uncoupled from cell growth and nutrient concentrations due to cell lysis and differences between cell toxin quota and cell growth. Given the likely disconnect between toxin production and detection (SPATT were deployed for one week to one month), there is consistency with nutrient enrichment leading to increased algal biomass, with subsequent toxin production. Low nutrient levels would then be correlated with elevated toxins due to the time lag. This theory could be tested by identifying lagged correlations between nutrients and toxins, but our toxin data are integrative (SPATT) while the nutrients were collected at the time of SPATT recovery (with a coarse time scale relative to nutrient dynamics), precluding such an analysis. The assertion we present is

Table 3

Results from the mixed effects model evaluating principal components, and temperature versus microcystin toxin.

Variable	Estimate number	<i>p</i> -value
PC1		
Urea	−0.1240	0.0520
Ammonium		
PC2		
Nitrate	−0.9200	0.0060
Phosphate		
Silicate		
Temperature	−0.0480	0.0020

The first principle component is represented by PC1 and contains the variables urea and ammonium. The second principal component is represented by PC2 and contains variables nitrate, phosphate and silicate. The associated estimate numbers and *p*-values from the model are provided.

consistent with the relationship between microcystin concentrations and silicate concentrations identified in the model. Silicate was positively associated with microcystin. Silicate is not utilized by *Microcystis aeruginosa* and consequently remained in the environment while other nutrients were presumably biologically drawn down in the absence of diatom blooms. The link between

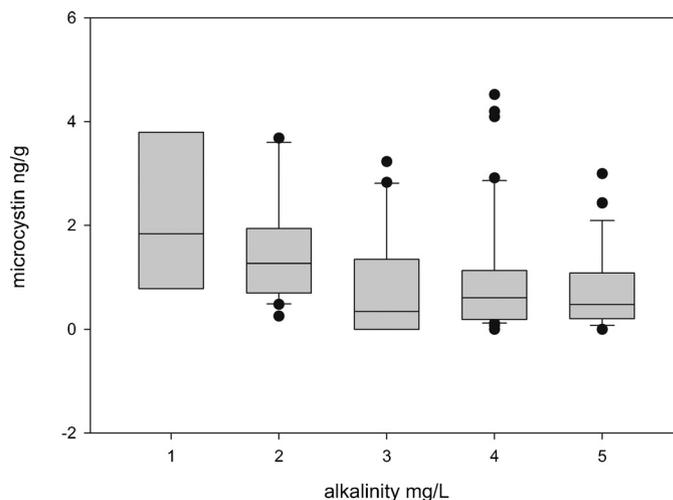

Fig. 4. Alkalinity versus microcystin toxin box plots. Data for all locations from August 2012 to August 2013 was pooled, zeros were removed and microcystin toxin data was square root transformed.

macronutrients, particularly ammonium and urea, and toxin concentrations, and the relatively high nutrient concentrations point to anthropogenic loading as a significant driver of toxin accumulation in these watersheds (Kudela et al., 2008), consistent with other studies (Paerl et al., 2001; Paerl, 2008; Schindler and Vallentyne, 2008; Wilhelm et al., 2011).

Temperature, unexpectedly, exhibited a negative association with microcystin toxin within the model. Several studies have demonstrated the link between elevated and increasing temperature and the frequency of toxic blooms (Butterwick et al., 2005; Reynolds, 2006; Paerl and Huisman, 2008, 2009). However, the phenomenon of a non-correlative relationship between microcystin toxin and temperature has been seen previously, where elevated toxin concentrations have been associated with a range of temperatures (van der Westhuizen and Eloff, 1985; Amé and Wunderlin, 2005; Davis et al., 2009; Kudela, 2011). This may be indicative of a non-linear relationship between the two variables, possibly driven by different growth–temperature responses for different toxigenic cyanobacteria (Paerl and Otten, 2013a, 2013b).

The inverse relationship between alkalinity and microcystin was expected. This dynamic has been documented previously (Aboal et al., 2005); additionally alkalinity has been correlated with shifts in algal groups when ammonium is available to provide the source of nitrogen (Brewer and Goldman, 1976). River flow had positive correlations with microcystin toxin before and after time lags. Before the data were lagged there were more significant positive correlations; after lags, all sites were positively correlated, but fewer were significant. Many studies have highlighted that stagnancy of water is associated with increased cell density of *Microcystis* (Christian et al., 1986; Reynolds, 1992; Jeong et al., 2006; Lehman et al., 2008). Lehman et al. (2008) also found that *Microcystis* cell density was positively correlated with flow at some locations in the San Francisco Estuary. Cell density was highest during periods of lowest river flow, and toxin was potentially produced during subsequent stagnant, long retention-time periods. The weak positive correlations identified in this study suggest that while river flow has an effect on toxin concentration, it is not be the dominant effect. Other contributors to toxin abundance with stronger relationships, such as nutrient loading, appear to have a greater influence on toxin levels.

Presence of microcystin toxins is often indicative of an unhealthy ecosystem (Miller et al., 2012). Within the Monterey Bay region, toxins are present and persistent in the four major watersheds flowing into the Monterey Bay National Marine Sanctuary. Despite the persistence of this toxin in California watersheds and the potential negative impacts to humans and wildlife, microcystins are not routinely monitored by federal, state or local management agencies. Because this toxin has the capacity for accumulation, biomagnification, and persistence within food webs, elevated levels within the watershed may increase the possibility for morbidity and mortality of wildlife and humans in terrestrial, estuarine, and marine waters. Additionally there is increasing evidence to support chronic exposure to microcystins as a significant threat to wildlife and humans (Bury et al., 1995; Wiegand et al., 1999; Jacquet et al., 2004; de Figueiredo et al., 2004; Malbrouck and Kestemont, 2006; Wang et al., 2010). Thus, even the low but detectable levels identified in this study may be indicative of a potentially unhealthy ecosystem. It is possible that low levels of microcystins are endemic to California and therefore a natural component of the ecosystem. The lack of baseline studies makes this assertion difficult to test, but this study provides a reasonable baseline for assessing future changes in toxins within the Monterey Bay watersheds.

Cyanobacterial harmful algal bloom events are often intensified by anthropogenic activities such as discharge of sewage, as well as both urban and agricultural practices that cause nutrient rich

runoff to flow into local watersheds (Zehnder and Gorham, 1960; Fogg, 1969; Reynolds, 1987; Paerl, 1988; Davis et al., 2009; Paerl et al., 2011). Because cyanobacteria have the capacity to thrive in water with both low and high nutrient concentrations, these organisms have the potential to outcompete other algal groups and dominate affected watersheds (Falconer and Humpage, 2005). The combined effect of high growth response to nutrient input and the ability to outcompete other organisms creates the potential for microcystin toxin to overwhelm affected ecosystems.

The extensive manifestation of microcystin at low to moderate levels throughout the year and throughout all major watersheds in the Monterey Bay area exhibits the potential complication of managing environmental impacts, and ecosystem disruptions. Management agencies have long grappled with the problem of microcystin toxins in inland watersheds. However, the ubiquity of microcystin at the land–sea interface in the Monterey Bay area represents a new management obstacle. Decisions made at the terrestrial level in the proximity of the marine environment may now impact freshwater, estuarine, and marine ecosystems, particularly given the demonstrated capacity for bio-accumulation in commercially harvested shellfish (Miller et al., 2010). New management plans and implementations may now have to regard this freshwater epidemic as an expanding and pervasive problem.

Acknowledgments

We would like to thank Dr. Melissa Miller and the Marine Wildlife Veterinary Care and Research Center (MWVCRC) for volunteer support for the first six months of sampling. We thank Kendra Negrey for methodological guidance, Rob Franks for laboratory support, and Dr. Pete Raimondi for statistical advice. This work was completed with salary and tuition assistance from the NOAA Nancy Foster Scholarship program (CMG)NOAA award number: NA10SEC4810031 and with partial support from the Central and Northern California Ocean Observing System (CeN-COOS), funded by NOAA. Abstract.—We examined factors affecting fish entrainment at California's State Water Project and Central Valley Project, two of the largest water diversions in the world. Combined, these diversions from the upper San Francisco Estuary support a large component of the municipal and agricultural infrastructure for California. However, precipitous declines in the abundance of several estuarine fish species, notably the threatened delta smelt *Hypomesus transpacificus*, have generated major concern about entrainment as a possible cause of the declines. We examined a 13-year data set of export pumping operations and environmental characteristics to determine factors affecting entrainment (as indexed by salvage at fish screens) and the potential for manipulation of these factors to improve conditions for fish. Entrainment of three migratory pelagic species—delta smelt, longfin smelt *Spirinchus thaleichthys*, and striped bass *Morone saxatilis*—was primarily determined by the seasonal occurrence of particular life stages close to the export facilities. We also found that the direction and magnitude of flows through the estuary and to the export facilities were reasonable predictors of pelagic fish entrainment. Entrainment of resident demersal species (prickly sculpin *Cottus asper* and white catfish *Ameiurus catus*) and littoral species (Mississippi silverside *Menidia audens* and largemouth bass *Micropterus salmoides*) was not explained by diversion flows, although large numbers of individuals from these species were collected. Our study suggests that entrainment of pelagic species can be effectively reduced by manipulating system hydrodynamics.

Worldwide, more than 50% of freshwater runoff is diverted from natural waterways, producing substantial impacts on aquatic resources (Postel 1992, 2000, 2005; Kingsford 2000). Estuaries are particularly sensitive to water diversions because reduced freshwater inflows can alter sediment budgets (Wright and Schoellhamer 2005), water quality (Lane et al. 1999; Monsen et al.

2007), biological productivity (Jassby and Cloern 2000; Jassby 2005), and distribution of invertebrates (Stora and Arnoux 1983; Rodriguez et al. 2001; Kimmerer 2002a; Massengill 2004) and fishes (Kimmerer 2002a; Feyrer et al. 2007). Natural mortality for young fishes is very high (Houde 1987); entrainment adds additional mortality that can compromise population resilience (Barnthouse et al. 1983; Stevens et al. 1985; Boreman and Goodyear 1988; Pawson and Eaton 1999; Bennett 2005; Kimmerer 2008). A better understanding of how the timing and magnitude of water diversions influence fish entrainment can help managers reduce entrainment of fish and any impacts

diversions may have on fish populations (Barnthouse et al. 1988).

The tidal freshwater region of the San Francisco Estuary, the Sacramento–San Joaquin Delta (hereafter, the Delta), is a key nursery area for many resident and migratory fishes. The Delta also contains two of the largest water diversions in the world: the pumps of the State Water Project (SWP) and the federally operated Central Valley Project (CVP), which can jointly export $28 \times 10^6 \text{ m}^3$ of water/d from the Delta and up to $8 \times 10^9 \text{ m}^3$ of water/year. The SWP provides drinking water for over 23 million Californians. Water exports from the Delta also help fuel an estimated US\$25 billion annual agricultural economy, the largest agricultural economy in North America and one of the largest in the world.

Water demands often exceed supplies in California, resulting in conflicts over the allocation of freshwater among beneficial uses (Mount 1995; Service 2007). In recent years, these conflicts have increased because many pelagic fishes in the estuary have dropped to record low abundances while demands for water have increased (Sommer et al. 2007). Historically, many fishes in the estuary responded favorably to wetter years because high inflows usually improved spawning and rearing conditions in the estuary (Stevens and Miller 1983; Sommer et al. 1997; Kimmerer et al. 2001; Bennett 2005; Feyrer et al. 2007; Rosenfield and Baxter 2007). The strength of these relationships has diminished during the last few years for several possible reasons, including habitat changes, water diversions, food web alterations, and stock–recruitment effects (Sommer et al. 2007). As a consequence of declining pelagic fish populations and the resulting conflicts over water use, resource managers face a major crisis in the upper San Francisco Estuary (Service 2007).

The biological focus of water conflicts in the estuary is the native delta smelt *Hypomesus transpacificus*, a small, near-annual fish (Family Osmeridae) that is listed as threatened under the California Endangered Species Act (CESA) and the federal Endangered Species Act (ESA). Although many factors have been identified as stressors for delta smelt in the estuary (Bennett and Moyle 1996; Bennett 2005; Sommer et al. 2007), water diversions are perhaps the most readily “manageable” because export operations can be altered to reduce losses of fish or improve habitat conditions. For example, freshwater flow to the estuary is managed so that salinity is less than 2 practical salinity units at three control points in the estuary (Jassby et al. 1995) for a varying number of days between February and June (Kimmerer 2002b). This salinity standard, known as X_2 , was implemented because many species show

increased abundance, survival, or other positive responses to freshwater flows (Jassby et al. 1995; Kimmerer 2002a; Dege and Brown 2004; Feyrer et al. 2007).

There is considerable concern about the number of fish entrained at the export facilities. Unlike the X_2 –fish relationships, there is no direct evidence that entrainment affects population-level responses of fish. However, reductions in entrainment are obviously desirable given the status of pelagic fishes in the estuary; better information is needed about the factors that influence the timing, duration, and magnitude of entrainment losses. Because there are excellent long-term data sets on fish abundance, water quality, and hydrology in the Delta, we reasoned that it should be possible to identify the factors that have a strong influence on fish losses. In this paper, we compare long-term trends of hydrology, biological variables, and water quality with trends in the collection of several kinds of fishes counted at large fish facility louvers situated in front of the large export pumps. To develop a broader understanding of the effects of water diversions, we examined fishes from several representative groups: (1) pelagic fishes (delta smelt, longfin smelt *Spirinchus thaleichthys*, and striped bass *Morone saxatilis*); (2) littoral fishes (largemouth bass *Micropterus salmoides* and Mississippi silverside *Menidia audens*); and (3) demersal fishes (prickly sculpin *Cottus asper* and white catfish *Ameiurus catus*). These species are particularly important for protection (e.g., delta smelt and longfin smelt), for supporting recreational fisheries (e.g., largemouth bass and striped bass), or because they are numerically dominant species in their communities (e.g., prickly sculpin and Mississippi silverside). Our questions were (1) what are the long-term patterns in entrainment at the SWP and CVP; and (2) what factors influence entrainment of these fishes from the estuary on interannual and intra-annual scales? We hypothesized that pelagic fishes would show strong patterns in entrainment related to water project operations, while patterns in littoral and demersal fishes would be less evident. Our intent was to develop information that would provide insight into potential management actions that can be implemented at the SWP and CVP and perhaps at water diversions in other regions.

Study Area and Background

The Sacramento and San Joaquin rivers drain into the San Francisco Bay through the Delta (Figure 1). The Delta has been transformed over the last century from a large, contiguous marsh ecosystem into a channelized, armored-levee network of dredged sloughs (Conomos et al. 1985) that is unstable in structure and subject to dramatic change (Moyle 2008).

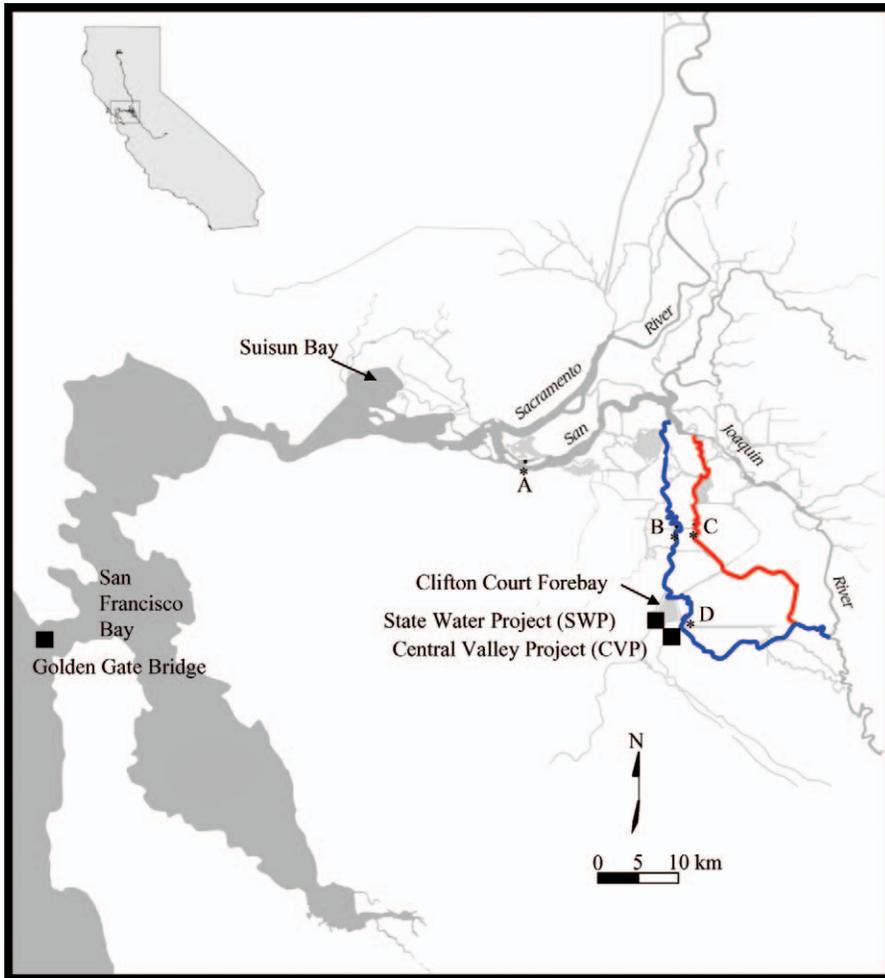

FIGURE 1.—Map of the San Francisco Estuary and the Sacramento–San Joaquin Delta, California. The State Water Project (SWP) and Central Valley Project (CVP) export and fish facilities are located in the southern Delta. The SWP and CVP water exports are best measured by combined daily tidal net flow of the Old River (blue line) and the Middle River (red line). Continuous monitoring stations for water temperature and specific conductance (A), Old River flow (B), Middle River flow (C), and turbidity (D) are indicated.

Upstream dams and diversions have substantially altered the hydrograph. Spring flows are approximately one-tenth of what they would be without the operation of upstream reservoirs (Knowles 2002). In contrast, late-summer and fall flows are now higher than what they were historically (Knowles 2002) because reservoir releases are made to fulfill export demands and to maximize storage capacity in upstream reservoirs for flood control. Releases are also made to produce suitable habitat for Chinook salmon *Oncorhynchus tshawytscha* below the reservoirs (National Marine Fisheries Service 2004).

The SWP Harvey O. Banks Pumping Plant is

operated by the California Department of Water Resources (CDWR), and the CVP Jones Pumping Plant is operated by the U.S. Bureau of Reclamation. The CVP and SWP both divert water from Old River, a tidal slough that intersects the lower San Joaquin River. Even at minimal exports, SWP and CVP operations can cause the tidally averaged flow in the Old River, Middle River, and other adjacent channels in the southern Delta to reverse and flow landward towards the diversions (Arthur et al. 1996; Monsen et al. 2007). The SWP can export water from the Delta at a rate of up to 292 m³/s, and the CVP can export water at up to 130 m³/s. At the entrance of the SWP are five gates

(6.1 × 6.1 m) that are opened and closed on a tidal basis (Le 2004). Behind the gates is Clifton Court Forebay, a relatively shallow (average depth ~ 2 m), 9.2-km² staging reservoir for SWP exports and the California Aqueduct (Kano 1990).

In front of the CVP and SWP pumps are fish salvage facilities designed to capture entrained fishes (Arthur et al. 1996; Brown et al. 1996; Bowen et al. 1998). The Tracy Fish Collection Facility on the CVP and the Skinner Fish Facility on the SWP use large behavioral louvers to steer fish into bypass structures, where the fish are counted and identified (Brown et al. 1996; Bowen et al. 1998). Daily salvage counts for each species at each facility are calculated by the following:

$$N_{di} = \sum_{p=1}^{P_{di}} \frac{N_{dpi}M_{dpi}}{m_{dpi}}, \quad (1)$$

where N_{di} is the total daily salvage at facility i (SWP or CVP), P_{di} is the number of time periods sampled during day d at facility i , N_{dpi} is the number of fish counted at facility i during time period p (min) on day d , M_{dpi} is the duration (min) of a fish salvage period p on day d for facility i , and m_{dpi} is the duration (min) of the subsampling interval during a fish salvage period p on day d for facility i . Typically, there are 12 sample periods/d. From each species, 20 individuals greater than 20 mm fork length (FL) are measured. Captured or "salvaged" fish are put into aerated tanks on trucks and then released back into the Delta downstream of the facilities. The term "salvage" is used by convention because the targeted Chinook salmon and striped bass are assumed to be saved from entrainment and released unharmed downstream (Brown et al. 1996). Other fish, particularly delta smelt, are likely to have low survival rates in the handling process (Swanson et al. 1996); therefore, under the federal ESA such fish are considered to be lost from the population upon collection (U.S. Fish and Wildlife Service 2005).

In this paper, we use salvage as an index of entrainment. Actual entrainment losses at the SWP and CVP are unknown because fish are not sampled continuously and because the louvers are less than 100% effective (Brown et al. 1996; Puckett et al. 1996; Bowen et al. 1998). Louver efficiency varies by species, life stage, and probably facility (Bowen et al. 1998, 2004), but for the purposes of this paper we assume that louver efficiencies are constant within and among years. The SWP salvage data also do not include additional fish losses in the Clifton Court Forebay as a result of predation before reaching the louvers (Gingras 1997) or within the holding tanks themselves (Liston et al. 1994). We assume that

relative predation losses in the forebay have remained constant among years in the absence of monitoring of predator numbers. Finally, prior to 1993, identification of fishes by technicians was focused on striped bass and Chinook salmon, with little consistency in the identification and counting of other fishes (Brown et al. 1996). In 1993, the California Department of Fish and Game (CDFG) emphasized accurate identification of all species. We only analyzed data collected since 1993.

Life History Traits of the Fishes Examined

The delta smelt is a near-annual species that resides in brackish waters around the western Delta and Suisun Bay region of the estuary (Moyle 2002). In the winter (December to April), prespawning delta smelt migrate to tidal freshwater habitats for spawning, and larvae rear in these areas before emigrating down to brackish water (Bennett 2005). Adult longfin smelt may also migrate into the Delta during the winter for spawning, generally moving up from San Francisco Bay or the Pacific Ocean (Rosenfield and Baxter 2007). Longfin smelt are native to the Pacific coast and generally spawn in brackish and freshwater of the estuary when 2 years old (Rosenfield and Baxter 2007), although some will live for up to 3 years (Moyle 2002). Longfin smelt were recently proposed for listing under CESA and the federal ESA (Bay Institute et al. 2007).

Striped bass, introduced to the San Francisco Estuary in 1879, generally migrate during the spring from saltwater (ocean or bay waters) to freshwater for spawning. Some age-1 and adult striped bass will return upstream during the fall (Stevens 1979). Age-0 striped bass generally rear in the Delta and Suisun Bay during the late spring and summer, and most then migrate to the San Francisco Bay or Pacific Ocean during the fall (Stevens 1979).

Resident fishes selected for analyses included the most abundant littoral and demersal fish species in the Delta (Feyrer and Healey 2003; Grimaldo et al. 2004; Nobriga et al. 2005; Brown and Michniuk 2007). The littoral species we chose were largemouth bass (introduced to California in 1891), which are strongly associated with submerged aquatic vegetation (Grimaldo et al. 2004; Nobriga et al. 2005), and Mississippi silversides (introduced to California in 1967), which are most often found in open-shoal areas. The demersal species analyzed were prickly sculpin (native), the larvae of which commonly occur in the water column (Grimaldo et al. 2004), and white catfish (introduced to California in 1874), the most abundant demersal species recorded in the salvage during the last two decades (Brown et al. 1996).

TABLE 1.—Summary of model inputs used to examine salvage of pelagic, demersal, and littoral species at the State Water Project and Central Valley Project fish facilities in the Sacramento–San Joaquin Delta, California. Life stage was determined from the length files in the salvage database. Mean fork lengths (FL; with SD) of life stages are also provided. Analyses were performed at interannual (inter) and intra-annual (intra) time scales depending on available monitoring data (na = no available data). Variables are combined Old and Middle River flows (OMR; m³/s) water temperature (WT; °C), turbidity (T; nephelometric turbidity units), zooplankton abundance (ZA), position of the 2-*psu* (practical salinity units) isohaline (X_2), and California Department of Fish and Game survey indices (FMWT = fall midwater trawl; TNS = tow-net survey; 20 mm = survey for juvenile fish \geq 20 mm FL).

Species	Life stage	FL (mm)	Inter	Intra	Period	Years	Variables
Delta smelt	Age 0	29 (5)	Yes	Yes	May–Jun	1995–2005	OMR, WT, T, ZA, 20 mm
	Adult	67 (7)	Yes	Yes	Dec–Mar	1993–2005	OMR, WT, T, ZA, X_2 , FMWT
Longfin smelt	Age 0	30 (6)	Yes	Yes	Apr–May	1995–2005	OMR, WT, T, ZA, X_2 , 20 mm
	Adult	89 (24)	Yes	Yes	Dec–Feb	1993–2005	OMR, WT, T, ZA, X_2 , FMWT
Striped bass	Age 0	43 (35)	Yes	Yes	Jun–Aug	1995–2005	OMR, WT, T, ZA, X_2 , TNS
	Age 1	114 (47)	Yes	na	Jan–Mar	1993–2005	OMR, WT, T, ZA, X_2 , TNS
Prickly sculpin	Age 0	31 (8)	Yes	Yes	May–Jul	1995–2005	OMR, WT, T, ZA, X_2 , 20 mm
	Adult	80 (20)	Yes	na	Jan–Mar	1995–2005	OMR, WT, T, ZA, X_2
White catfish	Age 0	47 (17)	Yes	Yes	Jun–Aug	1995–2005	OMR, WT, T, ZA, X_2 , 20 mm
	Age 1, adult	136 (69)	Yes	na	Jan–Mar	1993–2005	OMR, WT, T, ZA, X_2
Mississippi silverside	Age 0	34 (11)	Yes	Yes	Jun–Aug	1995–2005	OMR, WT, T, ZA, X_2 , 20 mm
	Adult	69 (17)	Yes	na	Jan–Mar	1993–2005	OMR, WT, T, ZA, X_2

	Age 1, adult	116 (79)	Yes	na	Jan–Mar	1993–2005	OMR, WT, T, ZA, X_2

Methods

Data Sources

For each species, adult and age-0 life stages were estimated from length measurements that were made between December 1992 and 2005 and that were reported in the salvage database. Because not all of the fish counted on each day were measured, we estimated the total number of age-0 fish and age-1 and older fish in the daily counts by extrapolating the proportion of each life stage in the fish measured to the expanded counts for each day. We omitted one data point for longfin smelt from April 7, 1998, when 616 longfin smelt were recorded during the salvage count at 0400 hours (California Fish and Game 2007). We doubt the accuracy of this record because it occurred during a high-flow period (e.g., San Joaquin River, >594 m³/s; Old and Middle rivers, >288 m³/s), when salvage is generally low and when fish dispersion should be high, resulting in a catch that is spread out over a few days or hours. The highest upstream observation of larval longfin smelt in the CDFG 20-mm survey (sampling of young fish between March and July) that year was in San Pablo Bay (Dege and Brown 2004), corroborating our logic that longfin smelt salvage should have been very low.

The daily salvage data for each species (SWP and CVP combined) were plotted to show general recruitment patterns. Inspection of these plots allowed us to identify the primary months when each species was salvaged (Table 1). For example, the historical data showed that more than 90% of the total adult delta smelt collections occurred between December and

March ($>99\%$ in 8 of 13 years) and that over 90% of the longfin smelt collections occurred from December to February, so we used these winter months to define the peak adult entrainment period for these species.

Factors that May Affect Entrainment

To determine factors that influence salvage of fishes at the CVP and SWP, we compiled data on hydrodynamics, water quality, and biological factors (Table 1). The data sources that we used for pelagic fishes were somewhat more extensive than for other species because these fish are of special management significance in the estuary (Service 2007; Sommer et al. 2007). These data sets are described below.

Hydrodynamic and water quality variables.—Combined Old and Middle River daily net flows (nontidally averaged) were used instead of actual SWP and CVP water diversions to determine entrainment effects because these daily net flows reasonably measure the hydrodynamic “pull” of the exports (Arthur et al. 1996; Monsen et al. 2007) when used at the time scale applied in our analyses. Old and Middle River flow integrates a complex set of factors, including flows from the large and small tributaries, daily and neap-spring tidal variation, local agricultural diversions, and wind. Old and Middle River flows are measured daily using acoustical velocity meters (installed by the U.S. Geological Survey) located near Bacon Island (Figure 1; Arthur et al. 1996). Total inflow (m³/s) is the sum of the Sacramento River, San Joaquin River, and Yolo Bypass inflows and several smaller tributary inflows that enter the Delta (Interagency Ecological Program 2007).

Continuous water temperature and specific conductance data were compiled from a gaging station located on the lower San Joaquin River near Antioch (State Water Resources Control Board 1978). Turbidity data were obtained from a continuous monitoring sensor located in the Old River at the entrance to the SWP.

Abundance and distribution.—Abundance of fish in the vicinity of the diversions can have a major effect on entrainment (Sommer et al. 1997). Hence, we included estimates of abundance near the diversions in our analyses of factors that may affect salvage rates. The data differed depending on life stage and number of years of survey data. For age-0 fishes, we used mean annual abundances from the Delta locations in the CDFG 20-mm survey during concurrent salvage periods for all species except striped bass. The CDFG 20-mm survey, which began in 1995, typically samples young fish during each neap tide between March and July (Dege and Brown 2004). For age-0 striped bass, we evaluated the number of young fish near the diversions using the Delta index from the CDFG tow-net survey (TNS), which is used to quantify abundance of age-0 striped bass (38 mm FL; Turner and Chadwick 1972; Kimmerer et al. 2001). For striped bass, our data set included all years between 1993 and 2005 except for 1995 and 2002, when indices were not calculated for this species.

We used X_2 to test whether the distribution of adult delta smelt, longfin smelt, and striped bass during the month prior to their salvage period influenced annual salvage or intra-annual salvage numbers. X_2 is an effective measure of pelagic fish distribution in the estuary (Jassby et al. 1995; Kimmerer 2002b; Dege and Brown 2004; Feyrer et al. 2007). The effect of year-class strength was examined using the CDFG fall midwater trawl survey index (Moyle et al. 1992; Kimmerer et al. 2001) for the pelagic fishes. Similar analyses were not conducted on adult demersal and littoral species because there is currently no reliable monitoring program for these fishes in the estuary.

Prey abundance.—Zooplankton abundance from the CDFG 20-mm survey (Delta stations only) was assumed to reflect favorable habitat conditions that either promoted greater residence times or survival of age-0 fishes in the Delta, thereby resulting in greater entrainment risk and salvage. This assumption is probably valid for delta smelt, whose summer–fall survival is linked to zooplankton abundance between July and October (Kimmerer 2008). Only calanoid copepodids and copepods were used from the zooplankton data since these are the dominant prey consumed by delta smelt (Nobriga 2002). For the other fishes, we used total zooplankton abundance

(Delta stations only) because they are known to have more diverse diets (Feyrer et al. 2003).

Data Analysis

Relationships between water quality and hydrodynamic variables were identified using locally weighted scatterplot smoothers (i.e., LOWESS; Venables and Ripley 2002) and visual inspection of bivariate plots. A reduced set of environmental parameters was then selected to compare with salvage data. To remove the effect of autocorrelation within each variable and the large number of zeros in the salvage database, analyses were focused on intra-annual and interannual trends by averaging independent and dependent variables into bimonthly or monthly and annual time periods. Intra-annual models were limited to life stages and species for which data were available (Table 1).

We used ordinary least-squares regression to test whether intra-annual and interannual salvage patterns were influenced by physical and biological factors. Statistically significant models were identified using best-subset procedures. Combined Old and Middle River flows constituted the export effect in each model because this variable has been shown to be a good index of diversion flow when examined at the time scales (i.e., intra- and interannual) explored here (Monsen et al. 2007). If inclusion of this variable did not contribute significantly to the model, it was omitted and the remaining variables were examined using the best-subset procedure. The best subsets were determined using Akaike's information criterion (AIC) values; AIC penalizes for increasing the number of free parameters but rewards goodness of model fit (Venables and Ripley 2002). Where the data failed to meet assumptions of normality (Anderson–Darling test: $P < 0.05$), the data were log transformed. Nonlinear least-squares regression was used for cases in which a linear relationship was deemed unsuitable based on visual inspection of the regression plots (i.e., curvilinear fits) and AIC values.

For adult delta smelt and longfin smelt, the intra-annual salvage data were partitioned into monthly averages to determine which factors might influence the timing of salvage. The interaction of Old and Middle River flows and X_2 position in the month prior was examined for adult smelt to see whether their salvage was influenced by their proximity (i.e., distribution) to the SWP and CVP before they migrated upstream. We expected that X_2 would have little or no effect on adult smelt salvage during periods when Old and Middle River flows were strongly seaward. Turbidity was used in the model to test whether salvage followed large precipitation in the basin, otherwise known as “first flush” events. Turbidity

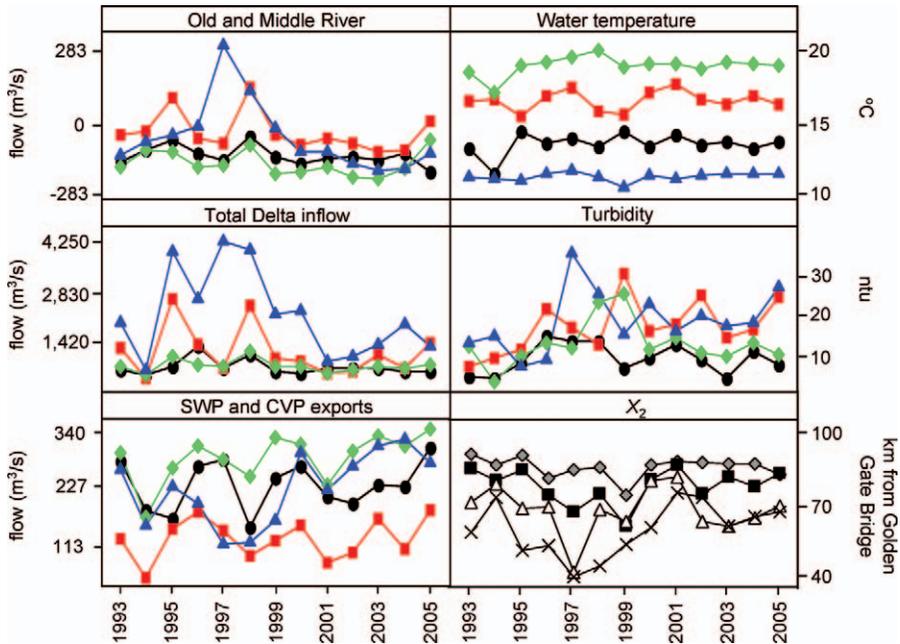

FIGURE 2.—Physical variables used to examine State Water Project (SWP) and Central Valley Project (CVP) fish salvage dynamics in the Sacramento–San Joaquin Delta, California, by season and year (blue triangles = winter, January–March; red squares = spring, April–June; green diamonds = summer, July–September; black circles = fall, October–December; ntu = nephelometric turbidity units). Mean monthly position of the 2-psu (practical salinity units) isohaline (X_2 ; km from the Golden Gate Bridge; Jassby et al. 1995) by year is also shown (gray diamonds = November; black squares = December; white triangles = January; × symbols = February).

was used in lieu of total river inflow since these variables were significantly correlated with each other at the monthly level (averaged daily data) during our study period ($r = 0.32$, $df = 142$, slope = 0.003, $P < 0.001$; excluding 9 months of missing turbidity data). For age-0 fishes, the intra-annual analyses were conducted on data divided into bi-monthly periods coincident with the CDFG 20-mm survey to test the factors influencing when age-0 fish (≥ 20 mm FL) show up in the salvage.

Results

Environmental Factors and Salvage Data

Combined Old and Middle River flows were negative or “reverse” during 47 of the 52 seasons examined (Figure 2). The most notable trend was a decrease in Old and Middle River flows during winter months corresponding to increased exports during the same period. Temperatures were generally consistent among years. Overall, the indices of adult pelagic fish abundance from CDFG monitoring surveys declined during the study period, but indices for age-0 fishes and zooplankton abundances were variable, with no obvious trend (Figure 3).

Between December 1992 and July 2005, the SWP and CVP salvaged 590,310 delta smelt, 122,747 longfin smelt, and over 32 million striped bass (Figure 4). Large numbers of littoral and demersal fishes were salvaged: 1,385,880 prickly sculpin, 3,214,687 Mississippi silversides, 596,827 largemouth bass, and 5,060,035 white catfish. Beginning in 1999, salvage of adult delta smelt and longfin smelt increased, with their highest salvage years being 2003 and 2002, respectively. Adult Mississippi silverside and largemouth bass numbers increased between 1999 and 2005, but these numbers are generally lower than numbers recorded in the early 1990s.

Salvage of age-0 native fishes (delta smelt, longfin smelt, and prickly sculpin) was highest during the spring, whereas salvage numbers of introduced species were higher in summer months (Figure 5). First salvage of adult delta smelt occurred within days of “first flush” events marked by sudden increases in river inflows and turbidity (Figure 6).

Statistical Approach

Old and Middle River flows, turbidity, and water temperature were selected as the predictor variables in

the salvage, following no obvious trends between them in the bivariate plots except for turbidity and combined Old and Middle River flows. Monthly averaged turbidity and combined Old and Middle River flows were moderately correlated during the study period ($r = 0.33$, $df = 142$, $slope = 0.018$, $P < 0.001$) but this relationship is driven during periods when Old and Middle River flows are extremely positive, which only occurred in a handful of months during periods of extreme high inflow. Therefore, turbidity was left in the models because it is a good indicator of pelagic habitat (Feyrer et al. 2007) and of seasonal river inflow. Specific conductance was significantly correlated with the combined Old and Middle River flows ($r = 0.32$, $df = 146$, $slope = -3.84$, $P < 0.001$) and therefore was eliminated from regression analyses to avoid confounding interpretations deriving from multicollinearity.

Factors Affecting Age-0 Salvage

The only model that explained interannual age-0 delta smelt salvage was that incorporating zooplankton (calanoid adults and copepods) abundance from the CDFG 20-mm survey (Figure 7). For age-0 longfin smelt, the Old and Middle River flow variable was the only parameter that explained interannual salvage abundance. Year-class strength was the only predictor of age-0 striped bass salvage. Prickly sculpin salvage was positively correlated with water temperature, and white catfish salvage was positively correlated with seaward Old and Middle River flows (Figure 7), but otherwise there were no significant predictors of salvage for age-0 resident fish. At the intra-annual scale, the best model that explained age-0 delta smelt salvage included Old and Middle River flows, turbidity, and CDFG 20-mm survey abundance (Table 2). For longfin smelt, Old and Middle River flows and 20-mm survey abundance were important predictors.

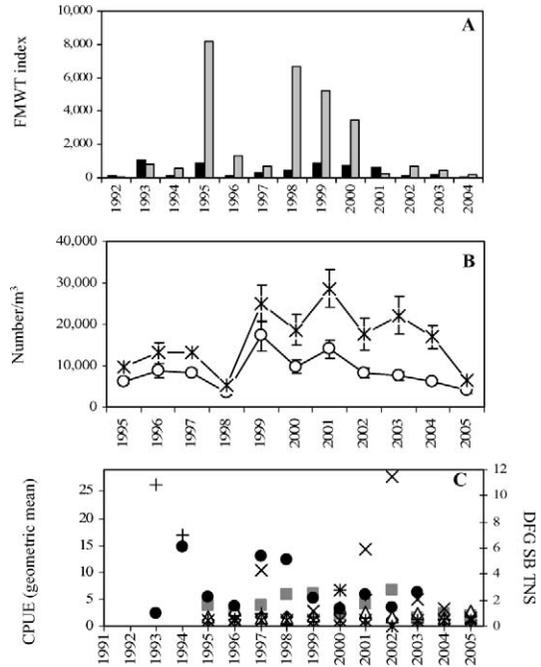

FIGURE 3.—Biological variables used to examine salvage dynamics in the State Water Project and Central Valley Project, California, by year: (A) annual delta smelt (black bars) and longfin smelt (gray bars) index values from the California Department of Fish and Game (CDFG) fall midwater trawl (FMWT) survey, 1992–2004; (B) mean abundance of calanoid copepods (open circles) and all zooplankton (stars) in the CDFG 20-mm survey; and (C) annual abundances (geometric mean of catch per unit effort, CPUE) of delta smelt (black circles), longfin smelt (× symbols), prickly sculpin (open triangles), largemouth bass (stars), Mississippi silversides (open diamonds), and white catfish (gray squares) from the CDFG 20-mm survey (primary y-axis) and Delta index for striped bass (SB) from the CDFG tow-net survey (TNS; plus symbols; secondary y-axis).

TABLE 2.—Regression coefficients and statistics for models that best explained intra-annual salvage (\log_{10} transformed) of age-0 delta smelt and longfin smelt at the State Water Project and Central Valley Project, California, between 1993 and 2005. See Table 1 for averaging periods and summary of all factors examined (OMR = combined Old and Middle River flows, m^3/s ; T = turbidity, nephelometric turbidity units; 20-mm survey = index from the California Department of Fish and Game survey of young fishes). The best models, as determined by the lowest value of Akaike’s information criterion (AIC), are highlighted in bold. Not all significant models are shown.

Factors Affecting Age-1 and Adult Salvage

For the pelagic fishes, the best models of interannual salvage were based on Old and Middle River flows (Figure 8). We found no significant models for age-1 and older demersal and littoral fishes. At the intra-annual time scale, the interaction between the previous month's X_2 and the combined Old and Middle River flows was significant for explaining delta smelt salvage (Table 3). We found no significant model for longfin smelt at the intra-annual time scale.

Discussion

Understanding factors that influence the entrainment of fishes in the estuary is essential for developing management alternatives to protect fishes of concern. Few studies have examined patterns and mechanisms explaining fish losses at the CVP and SWP over the years (Stevens and Miller 1983; Stevens et al. 1985; Brown et al. 1996; Sommer et al. 1997; Bennett 2005; Kimmerer 2008), despite the fact that they are two of

the largest continuous fish sampling devices in the world. There have also been relatively few studies of the direct effects of water diversions from riverine and tidal ecosystems (Nobriga et al. 2004; Moyle and Israel 2005). Valuable information has been obtained about power plant entrainment impacts (Kelso and Millburn 1979; Boreman and Goodyear 1981, 1988; Hadderingh et al. 1983; Henderson et al. 1984); in some cases, power plant studies have revealed broader patterns of fish community dynamics (Love et al. 1998; Maes et al. 1998). Here, we show that fish losses are influenced by both biological and physical factors and provide insights into the seasonal behavior of fish in the Delta.

Life Stage

The most obvious trend in the salvage data is that far more age-0 fishes are entrained than age-1 and older fishes. This result was expected since there are simply more age-0 fishes than older age-classes and because smaller fishes are often more vulnerable to entrainment flows (Hadderingh et al. 1983; Henderson et al. 1984;

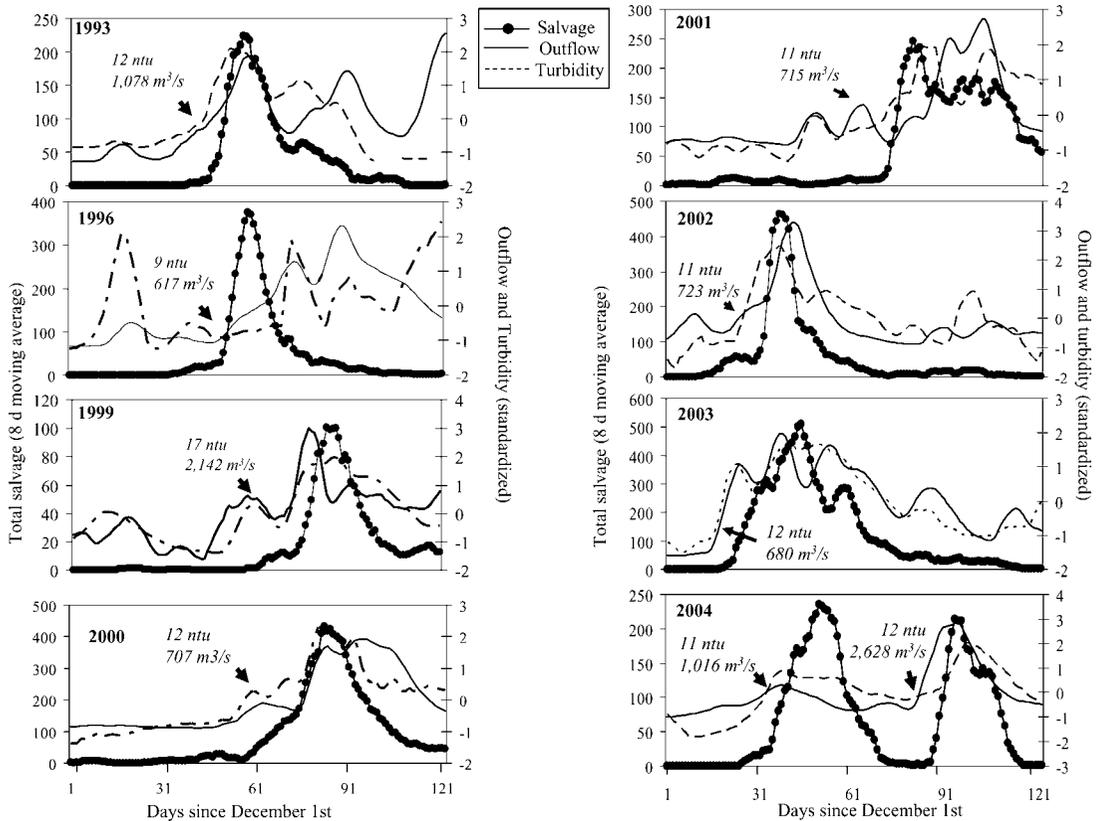

FIGURE 6.—Eight-day running averages of adult delta smelt salvage, total outflow (m^3/s), and turbidity (nephelometric turbidity units, ntu) for the eight most abundant delta smelt salvage years between December 1992 and April 2005 at the State Water Project and Central Valley Project, California. Total outflow and turbidity were standardized to a mean of zero.

sions. Though nearshore and demersal fishes can account for a large percentage of the numbers and biomass entrained in water diversions (Nobriga et al. 2004) or cooling water withdrawals (Hadderingh et al. 1983; Boreman and Goodyear 1988; Love et al. 1998), vulnerability is often highest during pelagic life stages or during periods of increased activity (e.g., feeding). Each group showed strong seasonality in entrainment (salvage), but there were major differences in the apparent effect of environmental conditions, including water exports. Specifically, exports as indexed by Old and Middle River flows play a major role in the salvage of pelagic fishes, but no similar pattern was observed in the littoral and demersal fishes. This is consistent with our hypothesis that the usual behaviors (i.e., strong habitat fidelity) of these fish limit their susceptibility to export flow effects. This result was somewhat surprising given that millions of age-0 littoral and demersal fishes are salvaged each year. Better sampling in these habitats may reveal mechanisms underlying entrainment of these fishes or mechanisms that show

why the abundance of these species has increased in recent years (Brown and Michniuk 2007) despite large removal by the water diversions.

Seasonal Patterns

Seasonal variation in entrainment is a common pattern observed at water diversions, often reflecting adult migrations (Jensen et al. 1982), age-0 recruitment (Love et al. 1998) or shifts in habitat use in relation to diversion intakes (Turnpenney 1988; Maes et al. 1998). Our investigation reveals that native fishes (delta smelt, longfin smelt, and prickly sculpin) are more vulnerable to exports during winter and spring months, whereas introduced fishes (striped bass, Mississippi silverside, largemouth bass, and white catfish) are more often salvaged during late spring and summer. The seasonal entrainment patterns observed here are consistent with patterns in the Delta; native species mostly spawn and recruit earlier in the year when temperatures are cooler ($\sim 8\text{--}16^\circ\text{C}$), whereas introduced species typically recruit during the summer when temperatures are warmer

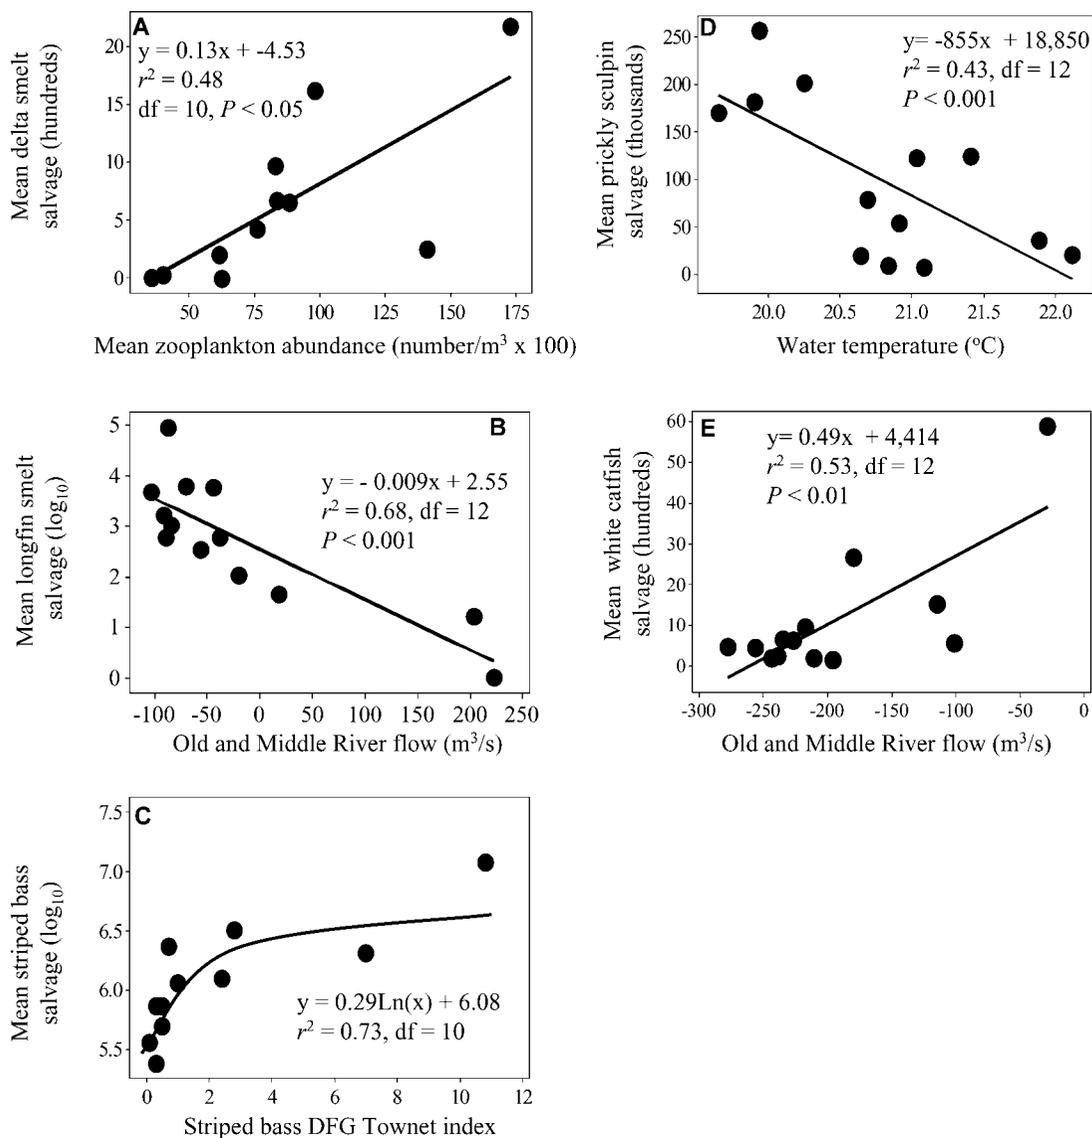

FIGURE 7.—Relationships between (A) age-0 delta smelt annual salvage in the State Water Project and Central Valley Project, California, and zooplankton abundance; (B) longfin smelt salvage and combined flow of the Old and Middle rivers; (C) striped bass salvage and the California Department of Fish and Game (DFG) tow-net survey index; (D) prickly sculpin salvage and water temperature; and (E) white catfish salvage and Old and Middle River flow. No other parameters explained the salvage of these species. See Table 1 for averaging periods.

(>15°C; Moyle 2002; Feyrer and Healey 2003; Feyrer 2004; Grimaldo et al. 2004; Bennett 2005). For the smelts, the salvage data indicate that few fish were entrained between July and November (Figure 5), mostly because the smelts' distribution shifts seaward during this period (Dege and Brown 2004; Noriga et al. 2008), whereas for resident species the seasonality in entrainment is more likely explained by habitat use.

Prey Availability

Prey availability may play a role in losses of fish at the export facilities. Annual salvage of age-0 delta smelt was best predicted by zooplankton (calanoid copepod) abundance. Kimmerer (2008) showed that survival of delta smelt between summer and fall was explained by zooplankton biomass. High zooplankton abundance may increase the survival and residence

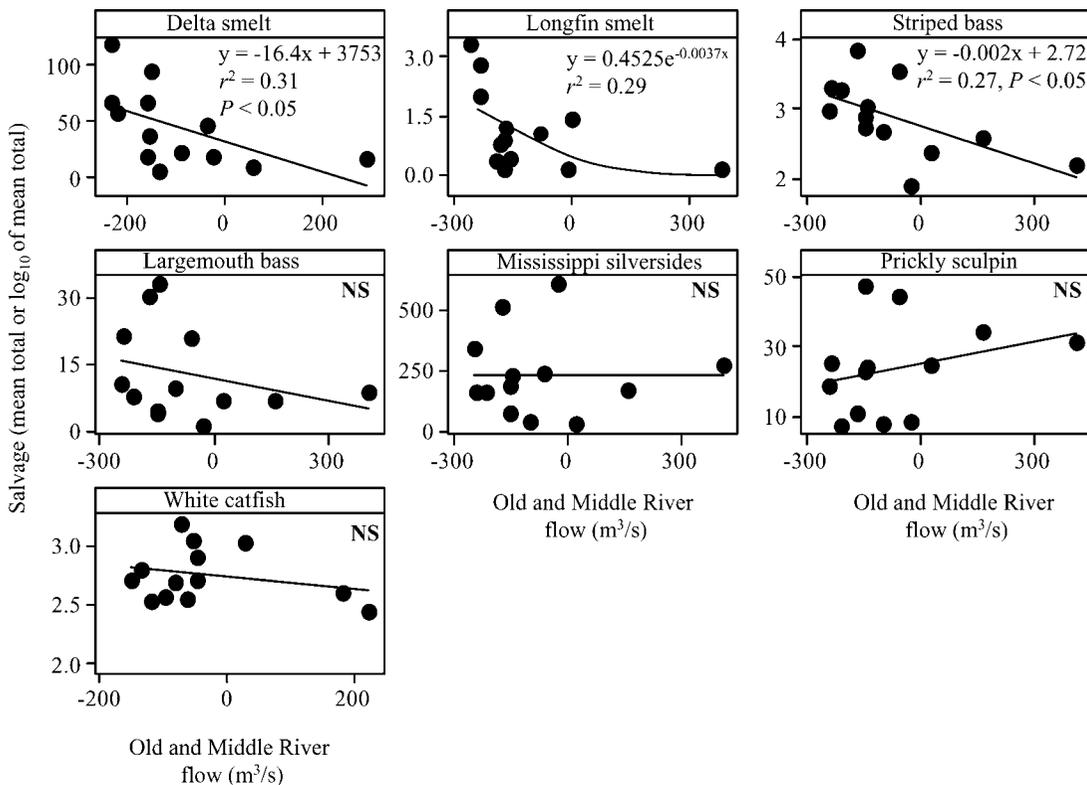

FIGURE 8.—Relationships between annual salvage of age-1 and older fishes in the State Water Project and Central Valley Project, California, and the combined flow of the Old and Middle rivers. For pelagic fishes (delta smelt, longfin smelt, and striped bass), Old and Middle River flow was the only variable that explained salvage. Regression models were not significant (NS, $P > 0.05$) for littoral (Mississippi silverside and largemouth bass) or demersal (white catfish and prickly sculpin) species.

time of age-0 delta smelt in the Delta, thereby increasing their entrainment risk in the southern portion of the Delta. Our study does not address whether entrainment represents a large source of mortality for delta smelt, but Kimmerer (2008) showed that high entrainment during dry years can result in large population losses for delta smelt.

Year-Class Strength

Similar to Sommer et al. (1997), our salvage analyses suggest that entrainment patterns may be affected by year-class strength. Specifically, we found that the number of age-0 striped bass salvaged was well predicted ($r = 0.81$) by their numbers in the TNS (Delta stations only) conducted by CDFG. Because Old and Middle River flows were not found to be a significant predictor of age-0 striped bass, we believe the relationship between striped bass salvage and year-class strength highlights the importance of localized effects (Stevens et al. 1985). In the case of age-0 striped bass, fish losses are probably episodic when large aggregations become entrained over short

intervals. The longer averaging period used in our study may obscure these sorts of short-term relationships with environmental conditions responsible for movements of schools or changes in behavior. For example, in recent years, water exports have been managed at low levels in April and May to protect delta smelt and emigrating Chinook salmon, but the exports quickly increase in June (Figure 2; see Old and Middle River flow panel) when these species move downstream. The transition in exports between May and June could be the reason why age-0 striped bass salvage increases substantially in June (Figure 5). Our study was not designed to capture such intermonthly variability, but we recognize its importance for understanding salvage patterns at daily to weekly time scales.

Age-0 delta smelt salvage at the intra-annual scale was related to the abundance of these fish in the Delta, but Old and Middle River flows and turbidity were also strong predictors. Thus, for delta smelt, the mechanisms influencing entrainment within a year is probably a measure of the degree to which their

physical habitat overlaps with the hydrodynamic "footprint" of the Old and Middle River flows. A similar result was found for age-0 longfin smelt, where Old and Middle River flows and year-class strength (from the CDFG 20-mm survey) were found to be significant predictors (Table 2) of salvage. Although spring represents a low-export period during which Old and Middle River flows are typically slightly negative (Figure 2), entrainment risk for age-0 smelts is likely to be high when they often spawn and rear in the Delta, which happens frequently for delta smelt (Nobriga et al. 2008). For adult delta smelt and longfin smelt, year-class strength did not predict salvage at the interannual level, but X_2 (used as an index of their distribution) was a predictor for delta smelt salvage at the intra-annual scale when Old and Middle River flows were negative. This result suggests that the role of population size in determining the number of adult smelt salvaged is very small when Old and Middle River flows are seaward but is probably much more important when flows are in the reverse direction, as was noted by Kimmerer (2008) for delta smelt.

Hydrodynamics

A common question in studies of riverine ecosystems is whether fish move with flow. This is a difficult question to address without direct field observations using approaches such as telemetry, a relatively impractical approach for rare and fragile species like the delta smelt (Swanson et al. 1996; Bennett 2005). Moreover, flow is especially complex in estuaries, where short- and long-term variation in tidal flow dominates. Nonetheless, the relatively strong relationships between Old and Middle River flows and the annual adult delta smelt, longfin smelt, and age-1 striped bass entrainment (salvage) indicate that fish are at least partially moving with reverse net flow towards the export facilities. In contrast, juvenile white catfish exhibited a positive relationship between salvage and seaward Old and Middle River flow, suggesting that their salvage is driven by upstream recruits that become vulnerable to entrainment when advected towards the export facilities.

Management Implications

The recent sharp decline of pelagic fish populations in the estuary has increased scrutiny of water diversion impacts in the estuary (Service 2007; Sommer et al. 2007). Though many factors have been identified as candidates for the recent decline (e.g., low food web productivity, contaminants, and water quality), CVP and SWP diversions represent one of the most directly observable sources of mortality. Our study was not designed to address the most important management

issue: whether these water diversions have population-level effects. Population-level consequences have been best studied for striped bass. Striped bass larval production was historically explained by river flows and southern Delta exports (Stevens et al. 1985). However, Kimmerer et al. (2001) found that export effects were small and sporadic, primarily occurring during the first several months of life. Moreover, striped bass population dynamics is best explained by density dependence between age-1 and age-2 year-classes, a bottleneck that dampens variation from effects early in life (Kimmerer et al. 2000). However, our analyses indicate that if there are years when density dependence is relaxed, then age-0 striped bass losses could be reduced by managing export flows during periods when these fish are abundant in the Delta.

The degree to which water exports have population-level effects on delta smelt is poorly understood. However, losses of delta smelt are perhaps greatest during winter, which represents the main period of adult delta smelt migration and spawning. We observed that recent increases in winter salvage of delta smelt (Figure 4) were associated with higher exports and reverse Old and Middle River flows (Figure 2). These changes were coincident with the low numbers of pelagic fishes in 2000 (Sommer et al. 2007), so it is possible that export losses of adults and their offspring contributed to the recent decline of delta smelt. Bennett (2005) and Kimmerer (2008) provide evidence that losses of larvae produced from these spawners can be substantial; however, the extent to which entrainment losses affect delta smelt population dynamics is unclear. Modeling studies by Bennett (2005) indicate that effects of exports on delta smelt growth and survival are very difficult to detect, so this issue remains unresolved.

Even if the population-level effects of fish entrainment are not well understood, the rapid decline of pelagic fish populations in the San Francisco Estuary has resulted in a substantial interest in finding ways to reduce losses. Traditionally, water diversion impacts are mitigated with placement of diversion screens (Moyle and Israel 2005). The SWP and CVP have fish louvers for this purpose, although they were designed primarily for Chinook salmon (Brown et al. 1996) and other species and life stages have not been adequately addressed. Hence, improvements in fish louver or screen design (e.g., positive barrier screens) could reduce losses of some of the species that we studied (Moyle and Israel 2005). Approach velocity criteria are already implemented for striped bass at 0.30 m/s, but this only provides protection for fish in the vicinity of the water diversions (State Water Resources Control

Board 1978). The present study suggests that water diversion impacts can be mitigated on a larger scale by altering the timing of exports based on the biology of fishes and changes in key physical and biological variables. Such a strategy has been used on the Hudson River, New York, where export reductions at three power plants successfully reduced the number of striped bass entrained during the winter months (Barnthouse et al. 1988). Combined with other efforts to reduce mortality, this seems to have permitted a dramatic restoration of the striped bass population on the Hudson River (Daniels et al. 2005).

The present study also suggests that fish losses can be managed through careful consideration of hydrodynamics and water quality. For example, minimizing reverse flows during periods when delta smelt and longfin smelt are migrating into the Delta could substantially reduce mortality of the critical adult life stage. The relationship between salvage of adult delta smelt and combined Old and Middle River flows (Figure 8) indicates that entrainment can be managed through manipulation of exports. Because the Old and Middle River flow variable improved the models for longfin smelt and striped bass salvage, this variable has reasonably broad applications. In addition, the significant effect of turbidity on adult delta smelt salvage (Table 2) suggests that reducing exports during periods of high outflows could reduce losses of this imperiled fish. One possibility is the implementation of an export reduction during the period immediately after the first flush, when turbidities in the Delta increase to over 10 nephelometric turbidity units (Figure 6).

Similarly, monitoring of the salinity in the estuary gives a good indication of fish distribution (Kimmerer 2002a; Dege and Brown 2004; Feyrer et al. 2007) and hence the potential for fish to be affected by water diversions. As a consequence, exports during higher outflow conditions or when X_2 is downstream would be expected to result in lower pelagic fish losses, an effect noted by Sommer et al. (1997). Temperature monitoring could also assist in the management of some species. For example, if prickly sculpin losses were a concern, exports could be adjusted according to water temperature, the only variable that significantly predicted age-0 prickly sculpin salvage (Figure 7). Overall, the native fishes examined here, and presumably other early spawning native fishes in the Delta, should benefit from a reduction in water exports between December and June. However, if such an export reduction is mitigated by increased exports in fall, then delta smelt habitat could be affected (Feyrer et al. 2007). In contrast, this study illustrates how ineffective it would be to manage the exports to reduce entrainment of largemouth bass or other littoral species

because these fish occupy habitat that probably buffers them from entrainment.

In summary, long-term monitoring data from two of the world's largest water diversions show that patterns of entrainment vary substantially with life history and season and that entrainment interacts in complex ways with hydrodynamics, water quality, and biological variables. Our findings demonstrate that integrated approaches to reduce entrainment are needed as part of a broader effort to restore imperiled fishes in the San Francisco Estuary, especially in light of rapid estuarine change (Moyle 2008). Some of these observations have already been incorporated into management of the San Francisco Estuary (Kimmerer 2002b; U.S. Fish and Wildlife Service 2005). While our findings are in many respects unique to the complex hydrodynamics and exceptionally large water diversions of the San Francisco Estuary, our demonstration of the importance of factors such as seasonality, species differences, fish year-class strength, food availability, and water quality should have application to fish entrainment in other geographical areas.

Acknowledgments

We want to thank the CDWR South Delta Program, Interagency Ecological Program, and San Francisco Estuary Program for funding and support. We also thank Russ Gartz, Kelly Souza, Cathy Ruhl, Jay Simi, and Robert Duvall for assistance with data collection and handling. Matt Nobriga, Larry Brown, Bill Bennett, Fred Feyrer, and the Delta Smelt Working Group provided helpful discussions and feedback about the data analyses and interpretation. The manuscript was improved by suggestions from two anonymous reviewers.

Abstract

Analysis of a series of historical bathymetric surveys has revealed large changes in morphology and sedimentation from 1856 to 1983 in San Pablo Bay, California. In 1856, the morphology of the bay was complex, with a broad main channel, a major side channel connecting to the Petaluma River, and an ebb-tidal delta crossing shallow parts of the bay. In 1983, its morphology was simpler because all channels except the main channel had filled with sediment and erosion had planed the shallows creating a uniform gently sloping surface. The timing and patterns of geomorphic change and deposition and erosion of sediment were influenced by human activities that altered sediment delivery from rivers. From 1856 to 1887, high sediment delivery ($14.1 \times 10^6 \text{ m}^3/\text{yr}$) to San Francisco Bay during the hydraulic gold-mining period in the Sierra Nevada resulted in net deposition of $259 \pm 14 \times 10^6 \text{ m}^3$ in San Pablo Bay. This rapid deposition filled channels and increased intertidal mudflat area by 60% (37.4 ± 3.4 to $60.6 \pm 6.2 \text{ km}^2$). From 1951 to 1983, $23 \pm 3 \times 10^6 \text{ m}^3$ of sediment was eroded from San Pablo Bay as sediment delivery from the Sacramento and San Joaquin Rivers decreased to $2.8 \times 10^6 \text{ m}^3/\text{yr}$ because of damming of rivers, riverbank protection, and altered land use. Intertidal mudflat area in 1983 was $31.8 \pm 3.9 \text{ km}^2$, similar to that in 1856. Intertidal mudflat distribution in 1983, however, was fairly uniform whereas most of the intertidal mudflats were in the western part of San Pablo Bay in 1856. Sediment delivery, through its affect on shallow parts of the bay, was determined to be a primary control on intertidal mudflat area. San Pablo Bay has been greatly affected by human activities and will likely continue to erode in the near term in response to a diminished sediment delivery from rivers.

1. Introduction

The spatial and temporal distribution of sedimentation, including the processes of deposition, transport, and erosion, is fundamental information for making sound decisions on a wide variety of management issues for estuaries. Sedimentation changes bathymetry and therefore habitat extent and distribution. Bathymetric changes, in turn, affect flow patterns and tidal exchange, which are important in sediment, salt, larval, and nutrient transport (e.g., Uncles and Peterson, 1996;

Monismith et al., 2002). Predicting natural and anthropogenic changes to ecosystems and designing successful restoration projects require knowledge of patterns of deposition and erosion. For example, intertidal mudflat extent is controlled by sedimentation. Planning maintenance of shipping channels and disposal sites for dredged material is better done with the knowledge of the distribution of natural sediment accumulation and erosion. Contaminant transport and cycling are also influenced by sedimentation (Marvin-DiPasquale et al., 2003; Schoellhamer et al., 2003). Deposition of clean sediment can isolate contaminated sediment, or conversely, erosion may expose contaminated sediments deposited at some time in the past (Higgins et al., 2005, 2007). At a longer time scale, planning for estuarine ecosystem change requires understanding

how natural changes in the environment (e.g., sea-level rise, drought periods) and human activities, such as water management, affect sedimentation.

Although knowledge of long-term trends in deposition and erosion are important for proper management of estuarine ecosystems, it is difficult to gain this knowledge from short field experiments or other traditional methods. A long-term, large-scale perspective of the sediment system is possible, however, by analyzing a long sequence of bathymetric surveys.

This paper presents a history of bathymetry, deposition, erosion, and intertidal flat change in San Pablo Bay, California from 1856 to 1983 and relates it to changes in sediment delivery to the bay. This history was developed using computer analysis and display of hydrographic and topographic surveys made by the U.S. Coast and Geodetic Survey and the National Ocean Service (NOS). This study is not the first one addressing bathymetric change in San Pablo Bay (Gilbert, 1917; Smith, 1965; Ogden Beeman and Associates and Ray Krone and Associates, 1992) but is the most comprehensive to date.

2. Setting

San Pablo Bay is a circular bay in the northern part of the San Francisco Estuary, California (Fig. 1). The bay is shallow – two-thirds of it is less than 2 m deep at mean lower low water (MLLW). The average depth of San Pablo Bay at mean tide is 3.7 m. A deep (11–24 m, average 12 m) main channel in its southern part connects Central San Francisco Bay in the west to Carquinez Strait in the east. This channel, which averages about 2.5 km in width, is an important control on San Pablo Bay's hydrodynamic regime (Gartner and Yost, 1988) and sediment-delivery pattern (Ruhl et al., 2001).

Winds are predominantly northwesterly and are strongest during the spring and summer, with average wind speeds of approximately 3 m/s on the west shore (Hayes et al., 1984). Winter storms, which occur about twice a month, cause southeasterly and southerly winds that can exceed 18 m/s in velocity

(Conomos and Peterson, 1976). Diurnal winds are strongest during the summer, with typical afternoon wind speeds of 9 m/s, which is three times faster than morning winds (Miller, 1967).

Forcing at time scales ranging from seconds to decades influences the hydrodynamic regime of San Pablo Bay. Waves generated by moderate winds have heights of 0.5 m and periods of 2 s (Klingeman and Kaufman, 1965). Because of the short wave periods, wave orbital velocities decay rapidly with depth and interact with the bottom only in the shallow parts of the bay (e.g., water depths of less than 3 m for a 2 s period wave). Winter storms can generate larger waves with periods of 5 s in the San Francisco Bay system (Putnam, 1947). Besides generating waves, winds generate mean currents that persist for hours or days. At a longer time scale, tides and tidal currents are important. Tides in San Pablo Bay are mixed semidiurnal (form numbers of 0.71–0.77; Cheng and Gartner, 1984). Tidal currents are greatest in the main channel, with spring tide velocities of more than 1 m/s, decreasing in shallower water to 0.4 m/s in 2-m water depth (Cheng and Gartner, 1984; Gartner and Yost, 1988). The average tidal range is 1.8 m (National Oceanic and Atmospheric Administration, 1986). Water level in the study area also varies at a longer time scale. Sea level, measured by a tide gauge near the entrance to the San Francisco Estuary (Golden Gate) (Lyles et al., 1988), rose at an average rate of about 1.3 mm/yr, or about 17 cm, during the period of hydrographic surveys (1856–1983).

Bottom-sediment grain size in San Pablo Bay reflects local hydrodynamics and sediment source. Median grain size ranges from 2.3 μm at a low-energy point in the center of the bay to 430 μm in the energetic main channel near Carquinez Strait (Locke, 1971). Except for the main channel and several shallow areas, sediment consists predominantly of mud – more than half of the bay contains sediment with a median grain size of less than 5 μm .

Sediment deposited in San Pablo Bay is transported from the Sacramento and San Joaquin Rivers (after passing through

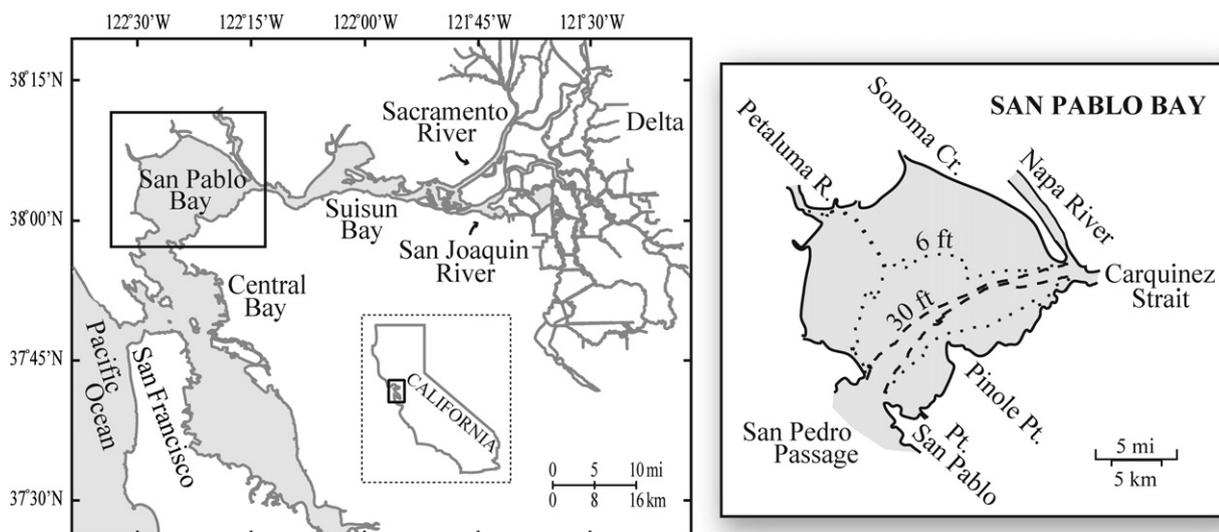

Fig. 1. Location of study area in the San Francisco Estuary, California.

Suisun Bay and Carquinez Strait), from Central San Francisco Bay, and from local streams. From 80 to 90% of the sediment reaching the San Francisco Estuary is delivered by the Sacramento and San Joaquin Rivers (Smith, 1965; Krone, 1979; Porterfield, 1980).

3. Methods

Data from six bathymetric surveys were modeled using surface modeling software with similar methods as have been reported by Sherwood et al. (1990), Hopkins et al. (1991), List et al. (1994), Jaffe et al. (1998), Cappiella et al. (1999), and Gibbs and Gelfenbaum (1999). A continuous surface representation (surface grid) of each bathymetric survey was created by using Topogrid, an ArcInfo module that utilizes a discretised thin plate spline interpolation technique (Wahba, 1990). Topogrid is designed for modeling drainage basins and represents estuarine morphology well. Input data were a combination of point soundings and hand-drawn depth contours (Jaffe et al., 1998). Topogrid uses an iterative interpolation technique where the contours are first used to establish general morphology of the surface and then both contours and point soundings are used to refine the grid. Each historical bathymetric surface is defined by more than 300,000 grid cells (each 50-m square).

Creation of accurate surface grids involved several steps (Jaffe et al., 1998). For the 1856, 1887, 1898, and 1922 surface grids, data were taken from Mylar copies of the original 1:20,000 NOS Hydrographic Sheets (H-sheets). Contours from these sheets were checked for accuracy, and additional contours were added in areas where point soundings were sparse. The annotated H-sheets were scanned and registered to a common horizontal datum (NAD27), using latitude/longitude graticules and hard shoreline features on a National Wetlands Inventory digital map (<http://wetlands.fws.gov/>). Point soundings and depth contours were digitized from the registered image. For the 1951 and 1983 surface grids, digital soundings from the NOS Geophysical Data System for Hydrographic Survey Data (National Oceanic and Atmospheric Administration, GEODAS v. 3.3) were used. For all years, input data were gridded, and the grids were compared with the input data to check for problem areas. The final step was another gridding after adding point soundings and contours so as to force grids to accurately represent historical bathymetry.

Once surface grids were revised to meet an acceptable level of error, change grids were generated by differencing surface grids and applying a vertical correction to bring surveys to a common vertical datum. The vertical correction was necessary because MLLW, the reference for soundings of each bathymetry survey, was not constant because of relative sea-level change and different averaging periods for the tidal data. In general, the averaging period was 19 years, which is the 18.6-year tidal epoch extended to an entire year to remove bias from seasonal water level fluctuation. However, tidal records in San Pablo Bay were not continuous for the entire study period, and it was necessary to use the longer tidal record at the Golden Gate tide station to determine vertical-datum corrections (Dedrick, 1983; Jaffe et al., 1991). These change grids were used to

identify patterns of change and to calculate the volumes and rates of deposition, erosion, and net sedimentation for each survey period.

4. Error analysis

4.1. Grid errors

Two types of error are associated with the grids — bias and random error. Bias enters from inaccuracies in determining the relation of MLLW datums for different surveys and from grid representation differing from the sounding values because of modeling algorithms. Random error is associated with sounding inaccuracy. Sounding errors are randomly distributed in space and independent of each other.

Uncertainty in the MLLW datum varies with the calculation method. For the last two bathymetric surveys, 1951 and 1983, MLLW datums are known (calculated from data collected for a tidal epoch at the long-term tide station near the Golden Gate). For the first bathymetric survey, in 1856, a 2-month average of MLLW measured at temporary tide staffs located in San Pablo Bay was used, and the relation of this datum to subsequent datums is more uncertain. By examining tidal records at the Golden Gate tide station, which was operational during the 1856 bathymetric survey, the relation of the 1856 datum to the datums used in later surveys can be estimated. For example, the 1887 H-sheets include notes indicating that a temporary tide station was operational in San Pablo Bay during the survey (February and March). If this 2-month-long record was used to establish the MLLW datum, and the tides behaved similarly to those at the Golden Gate, the datum would be 1.68 m (values from the Golden Gate tide staff used for reference). An alternative method for calculating the MLLW datum is to compare simultaneous measurements at the temporary tide station in San Pablo Bay with those at the Golden Gate tide station to establish a 19-year epoch (Swanson, 1974). This method yields an MLLW datum of 1.64 m referenced to the Golden Gate tide staff. The difference between the two methods is 0.040 m. To be conservative, because we do not know which method was used, we assume the error in the MLLW datum from 1856 to 1887 to be 0.040 m. Using similar reasoning, the errors in the MLLW datums for the periods 1887–1898, 1898–1922, and 1922–1951 are 0.094, 0.061, and 0.006 m, respectively.

The second source of bias, grid representation differing from the sounding values because of modeling algorithms, was estimated by comparing the modeled surface to original soundings. The average bias for all soundings during each survey period ranged from -0.07 to -0.01 m. The magnitude of this error indicates how well the grids honor the soundings. The difference between grid bias for each survey period is included in the error for net sedimentation even though it was removed.

The magnitudes of sounding errors are larger than the biases. Because sounding errors are random and have a zero mean, they do not influence estimates of net sedimentation. The sum of a large group of soundings that are both deeper and shallower than the actual depths results in cancellation of error and

a true average depth, although, each individual sounding contains some errors. The error criteria for bathymetric surveys have changed over time (Adams, 1942; Schalowitz, 1964; Sallenger et al., 1975). For example, in the early surveys, sounding error, determined by comparing independent estimates at trackline crossings, was not allowed to exceed 8 cm in water depth of less than 1.5 m. Trackline-crossing errors were examined in the field. Lines with trackline-crossing errors exceeding the error criteria were resurveyed (Schalowitz, 1964).

4.2. Intertidal mudflat area error

The error in intertidal mudflat area was estimated by assuming that MLLW (bayward edge of intertidal mudflat) could be either 0.076 m (1/4 foot) too deep or too shallow. This estimate is conservative – the actual error is probably less because of stringent sounding-error criteria for shallow soundings (Schalowitz, 1964; Sallenger et al., 1975).

5. Results

5.1. Historical bathymetric and sedimentation change in San Pablo Bay

San Pablo Bay changed markedly between 1856 and 1983. The resultant changes in morphology and sedimentation patterns are depicted in images of the bathymetry and sedimentation grids, which are based on more than 215,000 depth soundings (Fig. 2a, b).

5.1.1. Change from 1856 to 1887

In 1856, San Pablo Bay had a complex morphology with several channels and small river deltas (Figs. 2a and 3). A broad main-channel system connected the Point San Pedro pass (offshore of San Pablo Point) in the west to Carquinez Strait in the east. The main-channel system had a northern branch (average depth, approximately 8 m; maximum depth, 12 m) and a more developed southern branch (average depth, approximately 13 m; maximum depth, 27 m). The channel system had a maximum width of 5 km (Figs. 2a and 3). A well-developed channel connected the main channel to the Petaluma River in the northwest. An ebb-tidal delta offshore of Sonoma Creek restricted exchange between it and the bay (Figs. 1 and 2a). From 1856 to 1887, San Pablo Bay filled by $259 \pm 14 \times 10^6 \text{ m}^3$ (average rate of $8.3 \pm 0.4 \times 10^6 \text{ m}^3/\text{yr}$) as massive volumes of sediment released by hydraulic gold mining in the Sierra Nevada foothills entered the bay (Table 1, Fig. 2b). This influx of sediment decreased depth by an average of about 85 cm. Almost the entire bay was depositional (89%, Table 1). Parts of the main-channel margin accreted more than 4 m as it narrowed (Figs. 2a, b and 3). The primary erosional areas were the deepest part of the main channel, deeper parts of the channels in the west, and an ebb-tidal delta offshore of Sonoma Creek.

5.1.2. Change from 1887 to 1898

San Pablo Bay likely continued to fill from 1887 to 1898 (Fig. 2a, b), although the error in estimates of net sedimentation

allows for possible net erosion. The rate of net sedimentation, $1.0 \pm 3.4 \times 10^6 \text{ m}^3/\text{yr}$, decreased markedly from the earlier period (Table 1). A major factor in slowing sedimentation was the outlawing in 1884 of discharge of hydraulic-mining debris to rivers, which greatly reduced the volume of sediment entering the Sacramento–San Joaquin River Delta (hereafter referred to as the Delta) and San Francisco Bay. The main channel deepened and narrowed (Figs. 2a, b and 3). Side channels continued to fill, decreasing the connection between the bay and rivers. For example, the channel offshore of the Petaluma River decreased in width from 3.4 to 2.3 km at its bayward limit during this period as a reduced tidal prism caused by diking of tidal marshes resulted in a decreased shear-stress in the bottom of the channel, which favors deposition (see Friedrichs, 1995 for a theoretical treatment of this process). Shallows in the western part of the bay changed from depositional to either stable or erosional (Fig. 2b). Overall, about half of the bay was depositional, and half was erosional (Table 1).

5.1.3. Change from 1898 to 1922

From 1898 to 1922, a net volume of $41 \pm 20 \times 10^6 \text{ m}^3$ of sediment, an average rate of $1.7 \pm 0.9 \times 10^6 \text{ m}^3/\text{yr}$, was deposited in San Pablo Bay (Table 1). During this period, approximately two-thirds of the bay was depositional, especially in the shallow areas (<2-m depth) (Fig. 2b). The channel extending from the Petaluma River filled to a point where dredging (indicated by straight path with a dogleg cutting through intertidal mudflat, Fig. 2a) was required to allow ships to travel upriver. The primary erosional areas were the western shallows and the main channel, which continued to deepen (Figs. 2a, b and 3).

5.1.4. Change from 1922 to 1951

From 1922 to 1951, the rate of net sedimentation in San Pablo Bay was similar to the rate during the preceding 24 years. A net volume of $52 \pm 3 \times 10^6 \text{ m}^3$ of sediment, an average rate of $1.8 \pm 0.1 \times 10^6 \text{ m}^3/\text{yr}$, was deposited. The shallows were primarily depositional, and most erosion occurred in vicinity of the main channel; overall, about two-thirds of the bay was depositional. The straight section of the 30-foot contour lines in the southeast delineates an area of dredging (less than a quarter the length of the main channel). The center of the main channel continued to deepen (Figs. 2a, b and 3).

5.1.5. Change from 1951 to 1983

San Pablo Bay lost sediment overall from 1951 to 1983 in contrast to the previous ~100 years when the bay was filling with sediment. A net volume of $23 \pm 3 \times 10^6 \text{ m}^3$ of sediment, an average rate of $0.7 \pm 0.1 \times 10^6 \text{ m}^3/\text{yr}$, eroded from San Pablo Bay (Table 1). More than two-thirds of the bay (70%, Table 1) was erosional with the northern and northeastern shallows and the margins of the main channel depositional. Klingeman and Kaufman (1965) also observed deposition on the main-channel margins in a short study that used naturally occurring radioactive tracers. Dredging of the main channel near Pinole Point averaged about $0.2 \times 10^6 \text{ m}^3/\text{yr}$ from 1955 to 1983 (Ogden Beeman and Associates and Ray Krone and Associates, 1992) and is easily identified by the straight 30-foot contours in Fig. 2a. The dredged material was disposed

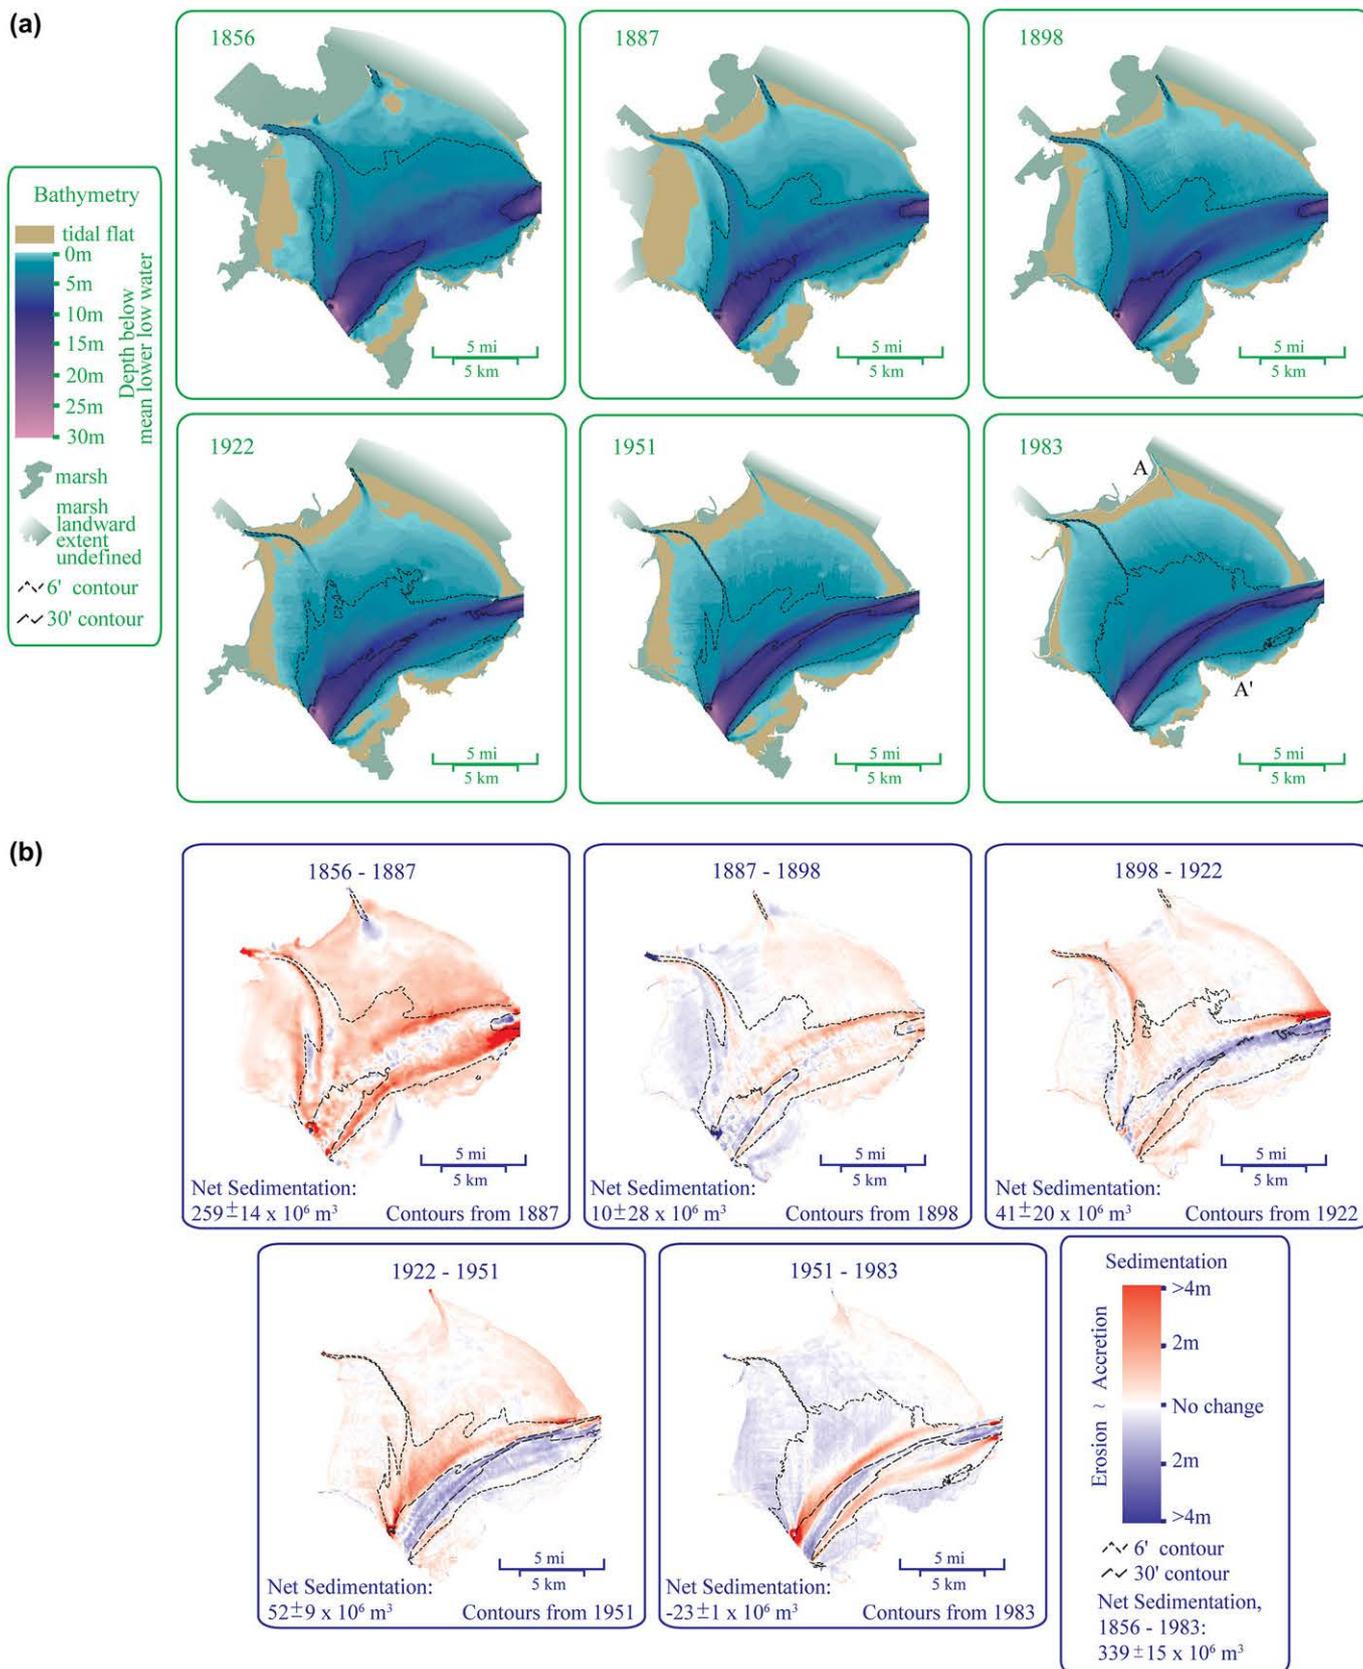

Fig. 2. (a) Color-shaded bathymetry maps of San Pablo Bay for 1856–1983, (b) color-shaded sedimentation maps of San Pablo Bay for 1856–1983. An overall decrease in depth of the bay is shown by lighter green colors in (a) and migration of the 6-foot contour bayward. The massive accretion during the hydraulic-mining period is shown in the 1856–1887 period in (b) by red shading. The erosion during the 1951–1983 period, which occurred as damming of rivers increased and land use changed, is shown by blue shading.

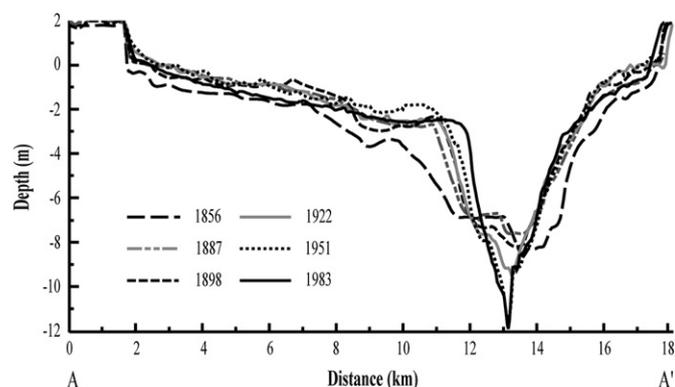

Fig. 3. Profile of San Pablo Bay floor along line A–A' (Fig. 2a) for period 1856–1983. Note that main channel has narrowed and deepened and shallows have filled over time. Most of this change occurred from 1856 to 1887 when hydraulic mining resulted in unusually high sediment delivery to San Pablo Bay.

within San Pablo Bay and did not contribute to the net loss of sediment.

5.2. A simple model for sedimentation in San Pablo Bay

Net sedimentation in San Francisco Bay results from the difference between sediment delivery from rivers, primarily through episodic flood deposition, and sediment loss from wind, wave, and tidal processes that erode the bay (Krone, 1979). A simple model for sedimentation in San Pablo Bay is that processes controlling sediment loss have not varied greatly over time and the net sedimentation reflects fluctuations in delivery rate.

The rate of sediment delivery to San Pablo Bay has changed over time in response to human activities. For instance, delivery rate increased greatly beginning in the 1850s as debris from hydraulic gold mining in the Sierra Nevada foothills was transported to the bay. Gilbert (1917, p. 67) estimated that sediment delivery before hydraulic mining “amounted to perhaps 2 million cubic yards per year” ($1.5 \times 10^6 \text{ m}^3/\text{yr}$). Approximately $1.675 \times 10^9 \text{ m}^3$ of hydraulic-mining debris was created from 1849 to 1909 (Gilbert, 1917, p. 43). Although the coarser fraction remained in the foothills, filling stream valleys by as much as 10 m (Gilbert, 1917), the finer fraction, silt and clay, was carried to the bay quickly by the Sacramento and San Joaquin Rivers. Gilbert (1917, p. 50) estimated that $1.146 \times 10^9 \text{ m}^3$ of sediment (average rate of $14.1 \times 10^6 \text{ m}^3/\text{yr}$) was transported to San Francisco Bay between 1849 and 1914. This is approximately 70% of the debris created by hydraulic mining (Gilbert, 1917, p. 46).

The California Supreme Court (Sawyer Decision) stopped discharge of mine tailings to rivers in 1884 resulting in a great decrease in the rate of sediment delivery by the early 1900s. Porterfield (1980, Table 20) estimated that the Sacramento and San Joaquin Rivers delivered an average of 5.04×10^6 metric tons/yr ($5.90 \times 10^6 \text{ m}^3/\text{yr}$, using his estimate of bulk sediment density of 53.2 lb/ft^3 [0.85 g/cm^3]) of sediment to San Francisco Bay from 1909 to 1959. Smith (1965) estimated a similar, but lower, sediment delivery to the bay for the period 1924 to 1960 of 4.04×10^6 metric tons/yr ($4.74 \times 10^6 \text{ m}^3/\text{yr}$, assuming a bulk sediment density of 0.85 g/cm^3). The delivery rate continued to decrease in the late 1900s. An average of 2.38×10^6 metric tons/yr ($2.79 \times 10^6 \text{ m}^3/\text{yr}$, assuming a bulk sediment density of 0.85 g/cm^3) of sediment was delivered to the bay from 1956 to 1990 (Ogden Beeman and Associates and Ray Krone and Associates, 1992, Table 5).

The decrease in the sediment-delivery rate during the late 1900s has multiple causes, including damming of rivers. From the 1940s to the 1970s, many dams were built to meet California's need for water (Porterfield, 1980). One consequence of dam building was a decrease in sediment delivery to the San Francisco Estuary (McKee et al., 2006; Wright and Schoellhamer, 2004). Sediment delivery is decreased not only by trapping sediment behind the dam but also by decreasing peak flows on the river, diminishing their capacity to transport sediment stored in the river system. Sediment transport is related to flow speed to the third or fourth (or higher) power (Van Rijn, 1993), and so decreasing flow speed greatly affects sediment transport and supply downstream. The volume of sediment trapped behind reservoirs on tributaries of the Sacramento River from 1940 to 2001 was greater than the decrease in suspended-sediment transport in the Sacramento River about 100 km below the dams during that same period (Wright and Schoellhamer, 2004). During this period and earlier, other human activities impacted sediment delivery to the San Francisco Estuary (Wright and Schoellhamer, 2004). Rivers were channelized, decreasing the sediment loss to flood plains and marshes, and riverbanks were stabilized, decreasing the sediment gain from riverbank erosion. Logging, urbanization, agriculture, and grazing increased sediment loads. The last two hydrographic surveys of San Pablo Bay (1951 and 1983) correspond to a period when damming and other human activities had caused a net decrease in sediment delivery to the San Francisco Estuary (Krone, 1979; Wright and Schoellhamer, 2004; McKee et al., 2006).

Comparison of net sedimentation and rate of sediment delivery in San Pablo Bay indicates similar trends (Fig. 4a).

Table 1
History of deposition, erosion, and net sedimentation in San Pablo Bay

Period	Net sedimentation (10^6 m^3)	Sedimentation rate			Surface area		
		Net ($10^6 \text{ m}^3/\text{yr}$)	Deposition ($10^6 \text{ m}^3/\text{yr}$)	Erosion ($10^6 \text{ m}^3/\text{yr}$)	Total (km^2)	Percent depositional	Percent erosional
1856–1887	259 ± 14	8.3 ± 0.4	8.8	−0.4	304	89	11
1887–1898	11 ± 36	1.0 ± 3.4	5.5	−4.5	296	54	46
1898–1922	41 ± 20	1.7 ± 0.9	3.5	−1.8	290	63	37
1922–1951	52 ± 3	1.8 ± 0.1	3.4	−1.6	280	68	32
1951–1983	$−23 \pm 3$	$−0.7 \pm 0.1$	1.7	−2.4	275	30	70

Annually, the volume of sediment deposited appears to be approximately 3×10^6 – 5×10^6 m³ less than the sediment delivery from the Sacramento and San Joaquin Rivers and local streams (local stream sediment delivery was about 0.3×10^6 m³/yr during the first part of the 20th century; Porterfield, 1980). The decrease in sediment delivery resulted in net erosion for the last time period, 1951–1983. This erosion, as well as changes in sedimentation during earlier periods, was reflected in morphologic change, including change in intertidal mudflats.

5.3. Intertidal mudflat change

The intertidal mudflat area in San Pablo Bay changed from 1856 to 1983 in response to sediment-delivery fluctuations (Fig. 4a, b). The abundant supply of sediment from hydraulic mining resulted in deposition in the shallows and a 60%

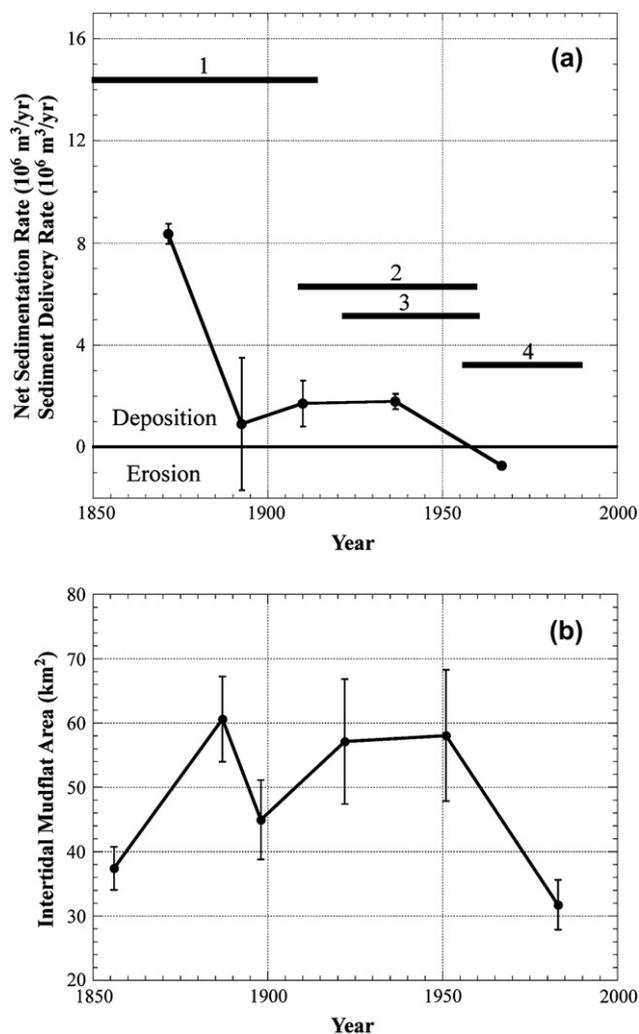

Fig. 4. (a) Net sedimentation and (b) intertidal mudflat area in San Pablo Bay from 1856 to 1983. Horizontal lines are sediment-delivery estimates: 1, Gilbert (1917) for 1850–1914; 2, Smith (1965) for 1924–1960; 3, Porterfield (1980) for 1909–1959; 4, Ogden Beeman and Associates and Ray Krone and Associates (1992) for 1956–1990. Error bars on net-sedimentation rates and intertidal mudflat area are described in Section 5. Note that San Pablo Bay was erosional for the last.

increase in intertidal mudflat area (37.4 ± 3.4 to 60.6 ± 6.6 km²) from 1856 to 1887.

The distribution of intertidal mudflats also changed significantly over time. In 1856, intertidal mudflats in the northern, eastern, and southeastern parts of the bay were narrow. These intertidal mudflats, as well as the one in the western part of the bay, widened from 1856 to 1887. From 1887 to 1898, land reclamation on the west shore of the bay and natural processes elsewhere in the bay decreased its intertidal mudflat area by about 15 ± 6 km² (Fig. 2a). Intertidal mudflat loss in the western and northern parts of the bay and gain in the eastern part of the bay resulted in a fairly uniform intertidal mudflat width in 1951 (Fig. 2a). Erosion resulted in a decrease in intertidal mudflat area from 58.0 ± 10.2 km² in 1951 to 31.7 ± 3.9 km² in 1983, an average loss of 0.82 km²/yr from 1951 to 1983.

5.4. Sedimentation in similar dynamical regions

Bay-averaged net sedimentation, though indicative of the general state of San Pablo Bay, does not describe the distribution and size of depositional and erosional areas. This information is exploited in an analysis of similar dynamical regions to assess sedimentation processes and sediment transport pathways. Here we used the patterns of deposition and erosion, and the spatial variation of tidal and wind–wave energy, to define 11 regions with coherent behavior (Fig. 5). Shallows extended to a depth of about 1.8 m and were divided into five regions, with boundaries at creeks or headlands. Boundaries of the other six regions were allowed to change over time to follow edges of large areas with either deposition or erosion.

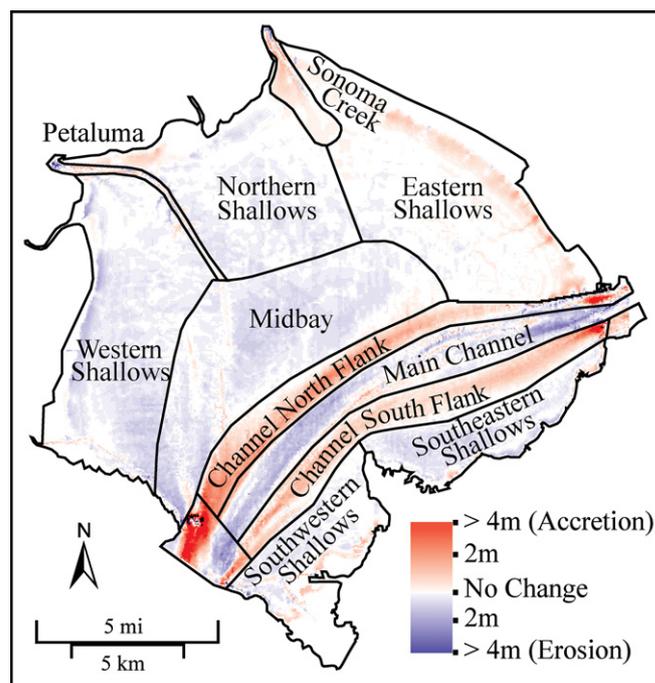

Fig. 5. Similar dynamical regions overlain on sedimentation in San Pablo Bay from 1951 to 1983. Regions were defined using the depth and patterns of erosion and deposition, which varied throughout the study.

Net-sedimentation rates in the 11 regions varied over time and, like net sedimentation for the entire bay, changed with sediment delivery to the bay. From 1856 to 1887, all regions except the Sonoma Creek ebb-tidal delta exhibited net deposition as large volumes of hydraulic-mining debris entered San Pablo Bay (Table 2). From 1951 to 1983, the most erosional period, some areas still had significant deposition (Table 2). The margins of the main channel (Channel North Flank and Channel South Flank) were depositional during all periods causing it to narrow (Figs. 2a, b and 3; Table 2). Channel deepening accompanied the narrowing during all periods except from 1856 to 1887 (Fig. 3). The eastern shallows were the only nonchannel region with net deposition during all periods. Net sedimentation in the shallows generally decreased throughout the study period (Fig. 6a).

The timing and pattern of net sedimentation in the shallows are important because of the relation between sedimentation in the shallows and intertidal mudflat area. From 1856 to 1887, the shallows exhibited net deposition (Fig. 6a) and intertidal mudflat area increased in all parts of San Pablo Bay (Fig. 6b). Net sedimentation in all the shallows decreased from 1887 to 1898, possibly because of a decrease in sediment delivery as hydraulic mining was abruptly stopped in 1884, by disequilibrium (unstable morphology), by diking of mudflats, or by a combination of these factors. Although net sedimentation decreased, the eastern shallows were still depositional.

The response of the intertidal mudflats reflected the net sedimentation in the shallows (Fig. 6a, b and 7). The intertidal mudflat area rapidly decreased after 1887 in the western part of the bay, was nearly stable in the northern and southeastern parts of the bay, and increased in the eastern part of the bay. During the last period (1951–1983), both net sedimentation and intertidal mudflat area decreased in all regions of the bay (Fig. 6a, b).

6. Discussion

6.1. Does a simple model for sedimentation work?

The simple model (presented in Section 5.2) of sediment delivery from rivers controlling net sedimentation in San Pablo

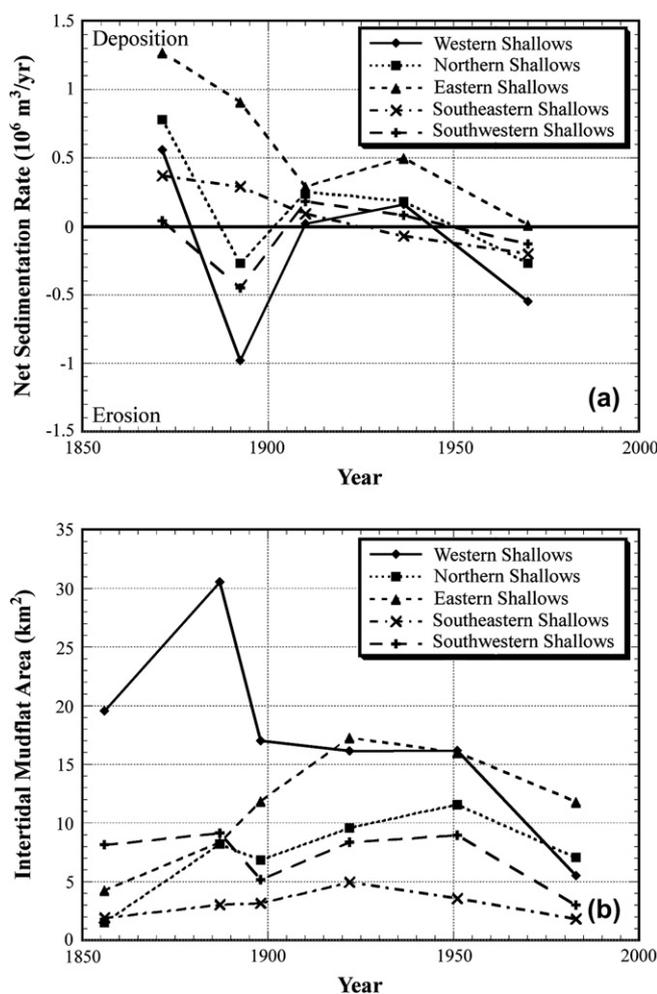

Fig. 6. Net-sedimentation rates in shallows (a) and intertidal mudflat area (b) by dynamical region.

Bay assumes that other processes that deliver and remove sediment from San Pablo Bay are constant over time. This assumption can be examined in the sediment budget for San Pablo Bay (terms and connections shown in Fig. 8). The difference between the rate of sediment delivery from rivers and the net-sedimentation rate in San Pablo Bay, S_{SPB} , is given by

Table 2
History of net-sedimentation rates for dynamically similar regions in San Pablo Bay. Regions are defined in Fig. 5

Region	Net-sedimentation rate (cm/yr)				
	1856–1887	1887–1898	1898–1922	1922–1951	1951–1983
Western Shallows	0.6	-1.0	0.0	0.2	-0.5
Petaluma Channel	0.4	0.2	0.5	0.0	0.0
Northern Shallows	0.8	-0.3	0.3	0.2	-0.3
Sonoma Creek, ETD	-0.1	0.1	0.0	0.0	0.0
Eastern Shallows	1.3	0.9	0.3	0.5	0.0
Midbay	1.3	-0.6	0.3	0.7	-0.5
Channel North Flank	1.2	1.6	0.2	1.2	0.6
Main Channel	0.1	-0.1	-1.1	-1.0	-0.3
Channel South Flank	2.2	0.7	0.3	-0.1	0.4
Southwestern Shallows	0.0	-0.5	0.2	0.1	-0.1
Southeastern Shallows	0.4	0.3	0.1	-0.1	-0.2

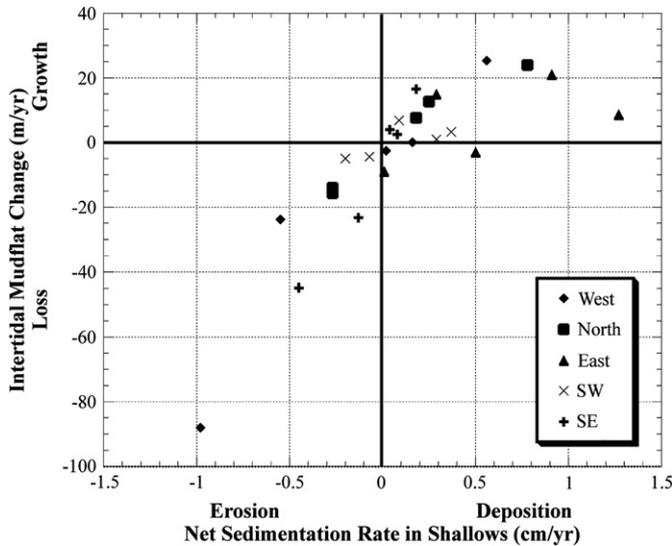

Fig. 7. Relation of net sedimentation in shallows (depth, ~ 1.8 m, Fig. 5) and average intertidal mudflat width.

$$Q_{SSJ} + Q_L - S_{SPB} = S_D + S_{SBCS} + M_D + M_{SBCS} + M_{SPB} + E_{CS} + E_{CB} + BP - Q_{CBSPB} \quad (1)$$

where Q_{SSJ} is the sediment-delivery rate from the Sacramento and San Joaquin Rivers to the Delta, Q_L is the sediment-delivery rate from local streams (primarily Napa and Sonoma Creeks and the Petaluma River), S_D is the net-sedimentation rate in Delta channels and flood plains, S_{SBCS} is the net-sedimentation rate in the Suisun Bay region and Carquinez Strait, M_D is the sediment deposition rate in tidal marshes of the Delta, M_{SBCS} is the sediment deposition rate in tidal marshes of the Suisun Bay region and Carquinez Strait, M_{SPB} is the sediment deposition rate in tidal marshes of San

Pablo Bay, E_{CS} is the rate that sediment eroded in San Pablo Bay is transported to Carquinez Strait, E_{CB} is the rate sediment eroded in San Pablo Bay is transported to Central San Francisco Bay, BP is the rate of sediment bypassing San Pablo Bay, and Q_{CBSPB} is the rate of sediment delivery from Central Bay to San Pablo Bay.

Eq. (1) can be simplified by neglecting small terms and those that are accounted for elsewhere. Assuming that marshes accrete to keep up with relative sea-level rise, the sediment deposition rates in marshes M_D , M_{SBCS} , and M_{SPB} are small relative to the other terms. For example in San Pablo Bay, the rate of deposition on marshes for 1856, when tidal-marsh extent was the largest (244 km², Van Royen and Siegel, 1959), was less than 0.4×10^6 m³/yr (244 km² marsh \times 1.4 mm/yr). Significant parts of the tidal-marsh area were reclaimed for agriculture by 1887 (Fig. 2a). Reclamation reduced tidal-marsh area in San Pablo Bay to 55 km² in 1980 (Dedrick, 1993). After 1887, M_{SPB} is a very small term in the budget, on the order of 0.1×10^6 m³/yr. Similarly, M_D and M_{SBCS} have decreased over time. Tidal-marsh area in the Suisun Bay region decreased from 265 km² in 1800 to 55 km² in 1998 (Goals Project, 1999). Marsh deposition in the Delta, which decreased over time with levee building and diking, was likely a small term in the sediment budget after the late 1800s.

Although no estimates of E_{CS} have been published, flow measurements from Burau et al. (1993) at the west end of Carquinez Strait indicate that sediment eroded from San Pablo Bay is transported upestuary during neap tides when gravitational circulation results in upestuary near-bottom flows. During spring tides, flow and sediment transport are from Carquinez Strait to San Pablo Bay throughout the water column. Ganju and Schoellhamer (2006) used Acoustic Doppler Current Profiling (ADCP) and suspended concentration data to calculate suspended-sediment flux at the east end of Carquinez Strait, approximately 10 km from San Pablo Bay. At this location,

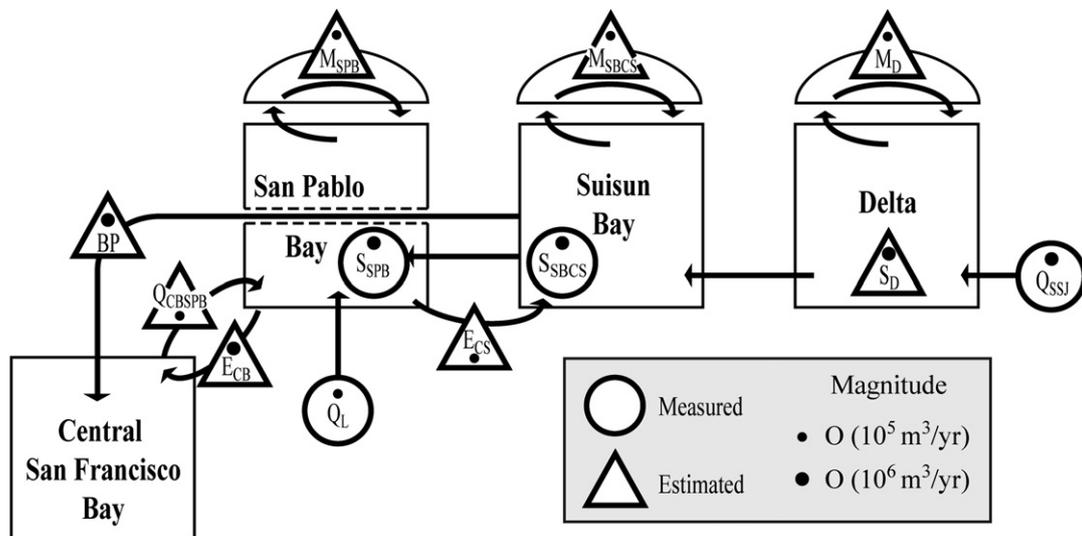

Fig. 8. San Pablo Bay sediment budget schematic. Arrows indicate direction of sediment exchange. Circles indicate measured sediment budget components. Estimated components are indicated by triangles. The order of magnitude for sediment volume rates is indicated by the size of the dot within the budget component. The notation used is Q is sediment delivery, S net sedimentation, M marsh deposition, E transport of eroded sediment, and BP is sediment bypassing.

suspended-sediment flux driven by gravitational circulation dominates during the dry months when there was a strong longitudinal salinity gradient. During the driest of years, the annual net suspended-sediment flux was upestuary. Fortunately, for balancing of the sediment budget, we need not estimate E_{CS} because it is accounted for in the net-sedimentation rates of Carquinez Strait, Suisun Bay and the Delta (if the sediment makes it that far).

Likewise, we need not account for upestuary sediment transport from Central Bay to San Pablo Bay, Q_{CBSPB} , because it is accounted for in the net-sedimentation rates of San Pablo Bay.

Neglecting small terms and those implicit in other terms and rearranging, Eq. (1) simplifies to:

$$BP + E_{CB} = Q_{SSJ} + Q_L - S_{SBCS} - S_{SPB} - S_D \quad (2)$$

To evaluate Eq. (2), we recalculated net-sedimentation rates for the same period as for river sediment-delivery estimates by weighting the rates listed in Table 1 with the percentage of time represented during each period (Table 3). The sum of the terms to the right of the equal sign, except for net sedimentation in the Delta (S_D), is well constrained by data and decrease over time (Porterfield, 1980; Cappiella et al., 1999; this analysis). S_D was accounted for in the 1850–1914 sediment-delivery estimate by Gilbert (1917) and assumed to be $1.0 \times 10^6 \text{ m}^3/\text{yr}$ thereafter based on estimates by Wright and Schoellhamer (2005) and Smith (1965).

E_{CB} is a potentially large term that can be estimated from the volumes of eroded and deposited sediment (Table 1) and the sediment delivery from rivers and the net sediment in the Delta, Suisun Bay, and Carquinez Strait (Table 3). The volume of eroded sediment is not equivalent to E_{CB} because (1) redeposition of eroded sediment in San Pablo Bay results in the volume of eroded sediment overestimating E_{CB} , and (2) new sediment replacing eroded sediment that was removed from San Pablo Bay results in the volume of eroded sediment underestimating E_{CB} . From 1956 to 1990, the minimum E_{CB} value (i.e., all eroded sediment redeposited in San Pablo Bay) is $0.7 \times 10^6 \text{ m}^3/\text{yr}$ ($2.4 \times 10^6 \text{ m}^3/\text{yr}$ eroded minus $1.7 \times 10^6 \text{ m}^3/\text{yr}$ deposited; Table 1). The maximum E_{CB} value for this period,

which occurs if all the sediment entering San Pablo Bay (from local streams, the Sacramento and San Joaquin Rivers, and net erosion from Suisun Bay and Carquinez Strait) were initially deposited, eroded, and removed from San Pablo Bay to the Central Bay is $5.1 \times 10^6 \text{ m}^3/\text{yr}$ ($3.1 \times 10^6 \text{ m}^3/\text{yr}$ from rivers and local streams plus $1.3 \times 10^6 \text{ m}^3/\text{yr}$ from erosion of Suisun Bay and Carquinez Strait plus $1.7 \times 10^6 \text{ m}^3/\text{yr}$ deposited in San Pablo Bay minus $2.4 \times 10^6 \text{ m}^3/\text{yr}$ eroded from San Pablo Bay; Tables 1, 3). These estimates neglect losses to marshes, which are relatively small. Using this approach, the ranges of E_{CB} values for 1850–1914, 1909–1959, and 1924–1960 are $0-7.7 \times 10^6$, $0-6.6 \times 10^6$, and $0-5.7 \times 10^6 \text{ m}^3/\text{yr}$; respectively. The averages of E_{CB} values during the periods 1850–1914, 1909–1959, 1924–1960, and 1956–1990 are 3.8×10^6 , 3.3×10^6 , 2.8×10^6 , and $2.9 \times 10^6 \text{ m}^3/\text{yr}$, respectively, yielding a grand average of $3.2 \times 10^6 \text{ m}^3/\text{yr}$; the average E_{CB} value for the 1900s is $3.0 \times 10^6 \text{ m}^3/\text{yr}$, an admittedly crude estimate of E_{CB} . Future research using sediment transport modeling could refine this estimate.

Assuming that $E_{CB} = 3.0 \times 10^6 \text{ m}^3/\text{yr}$ gives sediment bypassing rates of 4.9, 2.4, 1.3, and $1.1 \times 10^6 \text{ m}^3/\text{yr}$ for the periods 1850–1914, 1909–59, 1924–60, and 1956–90, respectively (Table 3). The decrease in BP during the study period is not unexpected. BP is scaled by the magnitude and frequency of floods. Larger floods transport more sediment through San Pablo Bay. This greater bypassing is caused both by stronger flows advecting sediment through the bay faster and higher sediment concentrations that commonly accompany stronger flows. More frequent floods increase cumulative sediment bypassing. Dams are designed to decrease both the magnitude and frequency of floods. With the increased damming of the Sacramento and San Joaquin Rivers and their tributaries, sediment bypassing of San Pablo Bay has likely decreased.

An additional factor to consider in sediment bypassing is that the relation between sediment concentration and flow magnitude (sediment–discharge rating curve) for rivers feeding San Pablo Bay is also changing. Wright and Schoellhamer (2004) showed that, for the same flow, the sediment concentration (and, thus, sediment transport) decreased for the Sacramento

Table 3
Major terms in sediment budget for San Pablo Bay (terms also shown in Fig. 8). Erosional loss from San Pablo Bay to Central San Francisco Bay, E_{CB} , is assumed to be constant over time and assigned a rate of $3.0 \times 10^6 \text{ m}^3/\text{yr}$. Sediment from the Sacramento and San Joaquin Rivers bypassing San Pablo Bay (primarily during floods), BP, is calculated to balance the sediment budget. When a constant rate of erosional loss of sediment from San Pablo Bay is assumed, sediment bypassing decreases as sediment delivery decreases, which is the expected relation

Period	Sediment delivery from rivers $Q_{SSJ} + Q_L$ ($10^6 \text{ m}^3/\text{yr}$)	Net sedimentation upestuary ^a $S_{SBCS} + S_D$ ($10^6 \text{ m}^3/\text{yr}$)	Net sedimentation in San Pablo Bay S_{SPB} ($10^6 \text{ m}^3/\text{yr}$)	San Pablo Bay loss ^b E_{CB} ($10^6 \text{ m}^3/\text{yr}$)	Sediment bypassing BP ($10^6 \text{ m}^3/\text{yr}$)
1850–1914	14.1	1.0	5.2	3.0	4.9
1909–1959	6.2	–0.8	1.6	3.0	2.4
1924–1960	5.0	–0.9	1.6	3.0	1.3
1956–1990	3.1	–0.3	–0.7	3.0	1.1

^a Net sedimentation in the Delta, S_D , is accounted for in the 1850–1914 sediment-delivery estimate (Gilbert, 1917) and assumed to be $1.0 \times 10^6 \text{ m}^3/\text{yr}$ thereafter based on estimates by Wright and Schoellhamer (2005) and Smith (1965).

^b E_{CB} , erosional loss from San Pablo Bay to Carquinez Straits and Suisun Bay is accounted for in S_{SBCS} ; Q_{SSJ} , sediment delivered from the Sacramento and San Joaquin Rivers at the entrance to Suisun Bay; Q_L , sediment delivered from local streams; S_{SBCS} , change in sediment storage in the Suisun Bay area and Carquinez Strait; E_{CB} , erosional loss (flux of eroded material) from San Pablo Bay to Central San Francisco Bay; BP, sediment from the Sacramento and San Joaquin Rivers that bypasses San Pablo Bay.

River from 1957 to 2001. The Sacramento River contributes 80–90% of the sediment to the bay (Porterfield, 1980). Assuming sediment concentrations are not greatly modified when traveling from the river source to San Pablo Bay, this change in the sediment–discharge rating curve also would contribute to a decrease in BP.

The magnitude and trend of sediment bypassing rates, though reasonable, are only estimates and strongly depend on estimates of the rate at which eroded sediment is removed from San Pablo Bay. If this rate has decreased (or increased) over time, the above analysis would predict a corresponding equal increase (or decrease) in sediment bypassing.

In summary, a strong correlation exists between sediment-supply and net-sedimentation rates in San Pablo Bay (Fig. 4a), complicated, however, by uncertainty in sediment bypassing and sediment removal rates, two large terms in the sediment budget that have likely changed over time. Past sediment-supply and net-sedimentation rates are consistent with a constant (at the decadal time scale) sediment removal rate and sediment bypassing that has decreased over time. However, this solution is not a unique balance of the sediment budget. To increase our ability to predict net sedimentation, we must improve our understanding of the processes that cause bypass and removal of sediment from San Pablo Bay.

6.2. Sediment transport and redistribution within San Pablo Bay

Another level of prediction desired is the response of different parts of San Pablo Bay to fluctuations in sediment delivery. To be able to predict this response, we need to understand sediment redistribution within the bay. The data presented in Section 5.4 indicate significant sediment redistribution from the western and/or northern shallows to the eastern shallows.

Spatial and temporal trends in net sedimentation in the shallows (Figs. 2b and 6a) indicate that, for all periods, net deposition in the eastern shallows is greater than in the western or northern shallows. Interestingly, all the shallows except those in southeastern part of San Pablo Bay have similar trends in net sedimentation over time, regardless of becoming more erosional or depositional, but are offset by a constant. One explanation for this offset is that sedimentation scales with sediment delivery, with an overlay of redistribution from the western or northern shallows to the eastern shallows. This combination results in net sedimentation rates that parallel each other and are offset in magnitude after accounting for redistribution from the western shallows to the eastern shallows, mimicking observed behavior (Fig. 6a). Mechanisms for sediment redistribution from west to east are asymmetric tidal currents, with stronger flood-tide currents advecting more sediment to the east (Klingeman and Kaufman, 1965, Fig. 23) and currents generated by westerly or southwesterly winds advecting sediment to the east.

6.3. Future conditions

The morphology of San Pablo Bay will not return to that of 1856. The great influx of sediment during the hydraulic-

mining period resulted in deposition that changed morphology significantly, which, in turn, changed sediment transport patterns. Adding to this perturbation to the system was diking of tidal marshes that reduced the tidal prism and resulted, for example, in filling of channels offshore of the Petaluma River (Ganju et al., 2004 presents a conceptual model for exchange of sediment between San Pablo Bay and the Petaluma River).

Generally, San Pablo Bay will continue to erode in the near term unless its sediment delivery increases. An increase in sediment delivery is not likely with damming and water projects acting to decrease sediment delivery. The eastern shallows, which are more depositional than the other shallows, will be the last area to become erosional. The effects of sea-level rise on deposition and erosion in San Pablo Bay are unknown. A decrease in bottom shear-stress from the increase in depth in the shallower portions of the bay decreasing wave orbital velocities is expected to favor deposition, but the degree that this effect will be counteracted by changes in the magnitude and pattern of tidal currents is hard to predict without the use of a coupled hydrodynamic/sediment transport model.

The main channels will likely continue to narrow and deepen. The main channel has been narrowing and deepening since 1887, and we expect this trend to continue. We speculate that the channel deepening response was initiated by channel narrowing from high sediment loads during the hydraulic-mining period. Narrowing may have sufficiently altered bottom shear-stress distributions so that deepening was easier than widening to accommodate flow. This hypothesis may be tested by applying a three-dimensional hydrodynamic and sediment transport model. Channel evolution could be modified by restoration of tidal marshes up estuary. Restoration would result in a greater tidal prism and increased flow through the main channel and could change sedimentation rates and patterns. Sea-level rise will affect channel geometry to the degree that it alters the tidal prism.

How San Pablo Bay evolves will be important to not only its health (e.g., habitat change) but that of San Francisco Bay as a whole. For example, San Pablo Bay contains more than $100 \times 10^6 \text{ m}^3$ of hydraulic-mining debris with an average mercury concentration from 0.3 to 0.6 ppm (Jaffe et al., 1999). Erosion of this sediment will release tens of thousands of grams of mercury to the water column that could be transported throughout the San Francisco Estuary. Future conditions of San Pablo Bay will also affect tidal-marsh-restoration efforts. If San Pablo Bay continues to erode, more sediment will be needed for restoration because sediment will be required not only for the creation of tidal marshes but also for the expansion of intertidal mudflats and shallows that coexist with marsh.

7. Conclusions

Quantitative analysis of historical hydrographic surveys has been used to learn how San Pablo Bay has changed since the Gold Rush and what processes were key in causing this change. It is concluded that:

- The morphology of San Pablo Bay changed drastically from 1856 to 1983. In 1856, San Pablo Bay had a complex morphology, with a broad main channel, side channels, and an ebb-tidal delta crossing the shallower parts of the bay. In 1983, all the channels except the main channel had filled, and erosive processes planed the shallows, creating uniform, gently sloping surfaces.
 - Human activities that changed sediment delivery from rivers were a primary control on sedimentation and the evolution of San Pablo Bay. From 1856 to 1887, $259 \pm 14 \times 10^6 \text{ m}^3$ of sediment was deposited in San Pablo Bay, coinciding with a high rate of sediment delivery ($14.1 \times 10^6 \text{ m}^3/\text{yr}$) to San Francisco Bay during the hydraulic-mining period. In contrast, from 1951 to 1983, $23 \pm 3 \times 10^6 \text{ m}^3$ of sediment was eroded from San Pablo Bay as the rate of sediment delivery from the Sacramento and San Joaquin Rivers decreased to about $3 \times 10^6 \text{ m}^3/\text{yr}$.
 - Intertidal mudflat area and distribution changed throughout the study period. In 1887, intertidal mudflat area was at a maximum ($60.6 \pm 6.6 \text{ km}^2$). Intertidal mudflat area had decreased to a minimum ($31.7 \pm 3.9 \text{ km}^2$) in 1983. In 1856, intertidal mudflats were largest in the western part of San Pablo Bay, but have since become more evenly distributed.
 - Intertidal mudflat area is related to sedimentation on the shallows (<1.8-m depth), reflecting sediment delivery to the bay. Intertidal mudflat area was largest after the unusually high influx of sediment from hydraulic mining resulted in building of the shallows and intertidal mudflats, and smallest in 1983 after damming decreased sediment delivery.
 - The simple model that sediment delivery controls net sedimentation explains much of the sedimentation trend in San Pablo Bay. This model predicts that erosion will increase in the future if sediment delivery continues to decrease.

Potential Inundation Due to Rising Sea Levels in the San Francisco Bay Region

Noah Knowles¹, U.S. Geological Survey, Menlo Park, CA 94025

ABSTRACT

An increase in the rate of sea level rise is one of the primary impacts of projected global climate change. To assess potential inundation associated with a continued acceleration of sea level rise, the highest resolution elevation data available were assembled from various sources and mosaicked to cover the land surfaces of the San Francisco Bay region. Next, to quantify extreme water levels throughout the bay, a hydrodynamic model of the San Francisco Estuary was driven by a projection of hourly water levels at the Presidio. This projection was based on a combination of climate model outputs, an empirical model, and observations, and incorporates astronomical, storm surge, El Niño, and long-term sea level rise influences.

Based on the resulting data, maps of areas vulnerable to inundation were produced, corresponding to specific amounts of sea level rise and recurrence intervals, including tidal datums. These maps portray areas where inundation will likely be an increasing concern. In the North Bay, wetlands and some developed fill areas are at risk. In Central and South bays, a key feature is the landward periphery of developed areas that would be newly vulnerable to inundation. Nearly all municipalities adjacent to South Bay face

this risk to some degree. For the bay as a whole, as early as mid-century under this scenario, the one-year peak event nearly equals the 100-year peak event in 2000. Maps of vulnerable areas are presented and some implications discussed. Results are available for interactive viewing and download at <http://cascade.wr.usgs.gov/data/Task2b-SFBay>.

INTRODUCTION

An increase in the rate of rise of mean sea level is one of the primary and potentially most troublesome aspects of projected climate change. Sea level at San Francisco's Presidio tide gauge has risen at a rate of 22 centimeters (cm) per century over the last century (Flick 2003), consistent with global average rates (Church and others 2004). In recent years, the rate of global sea level rise increased significantly over that of the previous several decades (Church and White 2006; Bindoff and others 2007). As global temperatures continue to increase, sea level will continue to rise in response, probably at a greater rate than observed historically. While it is generally accepted that global climate warming will increase

¹ Corresponding author: nknowles@usgs.gov

SAN FRANCISCO ESTUARY & WATERSHED SCIENCE

rates of sea level rise, the range in projected rates is wide, due mainly to the uncertainty in the amount of meltwater from land-based ice in Greenland and Antarctica. Recent projections (Rahmstorf 2007) estimate the range of increase of global sea level by 2100 at 50–140 cm above recent levels. Another recent study (Pfeffer and others 2008) produced a somewhat higher estimate (80–200 cm), reinforcing the opinion that sea level rise during the next several decades could exceed the estimates provided by the Intergovernmental Panel on Climate Change (IPCC) Third and Fourth Assessments (IPCC 2001, 2007). Concerning the high end of the range, Pfeffer and others (2008) concluded that sea level rise is very unlikely to exceed 200 cm by 2100. Beyond 2100, however, sea levels are expected to continue to rise for several centuries due to oceanic thermal inertia (Wigley 2005).

Pioneering studies by Williams (1985, 1987) and Gleick and Maurer (1990) were the first to estimate the impacts of sea level rise in San Francisco Bay. Williams found that a 100-cm sea level rise would result in an inland shift of the estuarine salinity field of 10 to 15 kilometers (km), potentially threatening ecosystems and freshwater supplies. In their comprehensive effort, Gleick and Maurer estimated that a 100-cm sea level rise would result in losses of residential, commercial and industrial structures bordering the bay valued at \$48 billion (1990 dollars).

A detailed assessment of what areas adjacent to the bay are vulnerable to inundation due to projected sea level rise is necessary to help avoid future risk in developing residential and commercial areas, to inform infrastructure planning (for example, water treatment outflows and roadways), and to design wetland restoration efforts with the ability to adapt to future changes, among other applications. The present study uses hydrodynamic modeling in conjunction with the most accurate elevation data available to develop high-resolution maps of areas vulnerable to periodic inundation corresponding to varying amounts of sea level rise, and to a range of inundation return intervals. The data are publicly available for use in other efforts at <http://cascade.wr.usgs.gov/data/Task2b-SFBay>.

This study addresses only the question of which areas are vulnerable to inundation, as opposed to quantifying the actual risk of inundation under a future scenario. No distinction is made between vulnerable areas already protected by levees and those that are not—at the time of this study, insufficient data on levees were available to make this distinction. Thus, potential improvements to existing levees or construction of new levees are not considered. Where levees currently exist, the results presented below indicate areas that would be flooded if these levees were to fail (due to, for example, a high-water event or an earthquake). Also, shoreline erosion and the potential accumulation of sediment and organic matter in wetlands are not accounted for here. As levee data become available and as modeling capabilities improve, future studies will address such issues and directly evaluate possible mitigation actions.

In the following sections, the elevation data set and hydrodynamic modeling approach used are described. Then some key results are presented and discussed, including maps and analysis of (1) areas vulnerable to periodic inundation by extreme high-water levels, and (2) wetlands vulnerable to changing tidal datums as sea levels rise. Finally, implications of the results and important caveats are discussed.

DATA AND METHODS

Method Overview

This study uses a hydrodynamic model to simulate water levels throughout San Francisco Bay under conditions of projected sea level rise. Statistical analysis of the projected water levels provides characterization of both long-term trends in mean sea level and high-water levels associated with short-term variability at points along the bay's shoreline. These high-water levels are then compared to nearby land-surface elevations to determine areas vulnerable to inundation around the bay. The same evaluation is also performed for high and low tidal datums. The focus here is on evaluating specific amounts of sea level rise, which can then be associated with particular future dates according to a given climate scenario, rather than focusing on specific scenarios from the

outset. Where time frames for given amounts of sea level rise to occur are considered, they are based on the range of projections by Rahmstorf (2007).

Elevation Data

To serve as the foundation of this study, the highest resolution elevation data available to date were assembled and mosaicked to cover the entire region. This new data set necessarily represents a patchwork of LiDAR (light detection and ranging) data from multiple sources, photogrammetry data, and IfSAR (interferometric synthetic aperture radar) data where no better data were available. This data set contains elevation data from six sources (Figure 1):

1. FEMA LiDAR, produced by Merrick and Company for use in FEMA's Flood Insurance Rate Maps. These data were processed to a horizontal resolution of 1 m, and the vertical 95% confidence interval is ± 30 cm.
2. Sacramento-San Joaquin Delta Region LiDAR data set, produced by the California Department of Water Resources from missions flown in 2007 and 2008. The data set's horizontal resolution is 1 meter (m), and the vertical 95% confidence interval is ± 18 cm.
3. Napa watershed LiDAR from the University of California at Berkeley Data Distribution Center for the National Center for Airborne Laser Mapping (NCALM, <http://calm.geo.berkeley.edu/ncalm>). These data are from flights in 2003, the horizontal resolution is 1 m, and the vertical 95% confidence interval is ± 30 cm.
4. South Bay salt ponds LiDAR data (Foxgrover and Jaffe 2005). These data are from flights in 2004, and the horizontal resolution is 1 m. The vertical 95% confidence interval is ± 25 cm for most of the salt-pond areas, and ± 15 cm for the hard, flat surfaces which constitute most of the area vulnerable to future inundation with sea level rise in South Bay.
5. San Francisco region photogrammetric elevation data. The U.S. Geological Survey (USGS), in cooperation with the National Geospatial-Intelligence Agency (NGA), developed ground elevation data

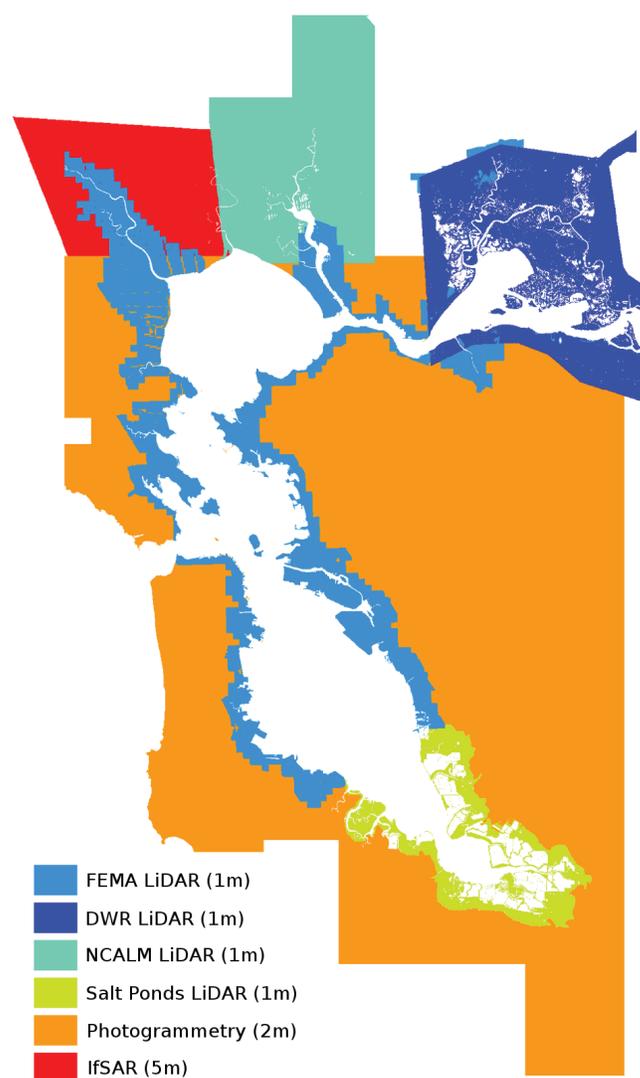

Figure 1 Sources of elevation data. Horizontal resolutions of original data are given in parentheses. All datasets were re-sampled to 2 m and merged.

from flights in 2003 at a horizontal resolution of 2 m for the purpose of producing orthorectified images. We assembled the tiles of elevation data and adjusted them to the North American Vertical Datum of 1988 (NAVD88) datum using the GEOID03 model, resulting in a data set covering the greater bay-delta region (Coons and others 2008). Vertical accuracy was not rigorously determined, but we estimate the 95% confidence interval as ± 50 cm.

SAN FRANCISCO ESTUARY & WATERSHED SCIENCE

6. Intermap IfSAR data, produced using synthetic aperture radar methods, were obtained to fill gaps in the Petaluma River and Sonoma Creek watersheds. These data are not ideal, as they have a 5-m horizontal posting and a vertical 95% confidence interval of ± 100 –200 cm. However, at the time of this writing they are the most accurate data available for the portions of that area not covered by the other data sets.

All elevation data were referenced to NAVD88 in the Universal Transverse Mercator projection (zone 10). Where necessary, the conversion to NAVD88 was made using the GEOID03 model (http://www.ngs.noaa.gov/PC_PROD/GEOID03).

These six data sets were resampled to a common horizontal resolution of 2 m using the nearest-neighbor method, then merged after comparison in areas of overlap. Agreement between all overlapping data sets was good, with slight average positive biases (10–20 cm) of the photogrammetry and IfSAR relative to the LiDAR data sets. This bias makes sense as all of the LiDAR data sets represent “bare-ground” elevations, whereas the photogrammetry and IfSAR data include the height of vegetation. As such, any estimates of inundation vulnerability in areas covered by the photogrammetry and IfSAR data sets may be considered conservative. However, of the six sources used to produce the composite elevation data set, the four LiDAR data sets, all with vertical 95% confidence intervals of less than 30 cm, together constitute 88% (at a minimum—more depending on the amount of sea level rise being evaluated) of the area vulnerable to inundation as presented in this paper.

The last step in developing the regional elevation data set was to mask out open water, as none of the measurement methods described above produce reliable results over water. First, a water mask produced by Foxgrover and Jaffe (2005) for the South Bay LiDAR data based on return characteristics was used to mask open water in the part of the bay covered by that data set. Next, two shoreline data sets representing the mean high water (MHW) tidal datum were used to mask data below this datum throughout the bay. Outside the mouth of San Francisco Bay, the shoreline was extracted from the National

Oceanic and Atmospheric Administration (NOAA) National Shoreline data set (<http://shoreline.noaa.gov/data/datasheets>). Inside the bay, another data set was available—a shoreline coverage extracted from the San Francisco Estuary Institute (SFEI) EcoAtlas (<http://www.sfei.org/ecoatlas>). The SFEI and NOAA shoreline data sets were checked against orthoimages from 2003, and it was qualitatively determined that the SFEI shoreline was more accurate. The two shorelines were clipped and joined at the Golden Gate, and used to remove all elevation data below the MHW tidal datum (due to this cutoff, the results discussed below generally exclude mud flats). As of this writing, the resulting composite data set represents the most accurate elevation data publicly available (excluding the IfSAR data which are under a restrictive license) covering the San Francisco Bay region.

Hydrodynamic Model Configuration and Validation

To assess what land elevations around the bay are vulnerable to periodic inundation, estimates of high-water levels throughout the bay must be generated. These high water excursions are the result of tides, storm surge, and other dynamic processes, requiring the use of a hydrodynamic model for this task. This model is used to produce a single 100-year projection of hourly water levels throughout the bay for use in the subsequent analysis. TRIM-2D (Cheng and others 1993) is a numerical model that uses a semi-implicit finite-difference method for solving the two-dimensional shallow water equations in San Francisco Bay. The model uses a 200 m horizontal grid with nearly 50,000 grid cells and is configured here with a six-minute time step. Note that these spatial and temporal resolutions are more than sufficient to capture the highest frequency of water-level variability addressed in this work—semi-diurnal. The model is driven solely by water-level time series at its seaward and landward boundaries, which are translated in phase and amplitude from the tide gauges with sufficiently long records nearest these boundaries, namely the Presidio and Port Chicago stations (Figure 2). Cheng and others (1993) demonstrated that the TRIM-2D hydrodynamic model accurately reproduces the historical amplitudes and phases of tidal constituents throughout the bay.

MAY 2010

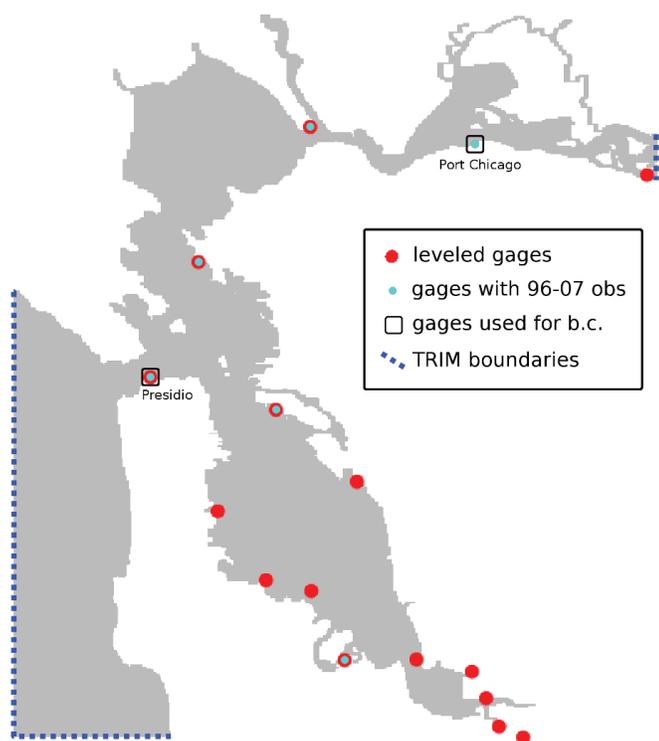

Figure 2 Key sites and features relevant to configuration and validation of TRIM-2D. The model grid is in gray. Gauge sites whose elevation relative to NAVD88 is known are in red. Gauges with data covering the validation period 1996–2007 are in bright blue. The two gauges whose data are used to derive conditions at the model boundaries (dotted blue lines) are in black squares.

The TRIM-2D model was chosen because it is capable of performing the century-long simulation needed to address the effects of long-term climate change in a reasonable amount of time. While the ideal model for this study would have a boundary condition much farther upstream than Port Chicago to avoid boundary issues and would directly simulate the hydrodynamics of inundated areas, such a model is not yet publicly available. Those proprietary models which do include such features are currently too computationally demanding to perform the needed runs in a reasonable amount of time.

The TRIM-2D model in its native configuration simulates water levels relative to mean lower-low water (MLLW), but water levels relative to NAVD88 are needed for comparison with the elevation data. The model takes as input a datum file, which was previ-

ously configured relative to the MLLW tidal datum. By adjusting this file appropriately, the model can be reconfigured to generate output water heights relative to NAVD88. To accomplish this reconfiguration, heights of MLLW relative to NAVD88 from 15 leveled tide gauges throughout the bay (Figure 2) were obtained from NOAA (<http://tidesandcurrents.noaa.gov>). These heights were then interpolated using the method of regular splines with tension (Mitasova and Hofierka 1993) to produce a MLLW adjustment grid. This grid was used in the new input datum file to TRIM-2D, and the resulting simulated water heights are referenced to NAVD88. While NOAA produces a similar datum adjustment grid for the bay region (<http://vdatum.noaa.gov>), the version available at the time of this study was deemed too inaccurate to use, as its source data did not include enough tidal stations in South Bay or near the delta, and spot checks against tidal datums from leveled tide gauges revealed inconsistencies.

With the model's datum adjusted, the calibration coefficients used to translate the boundary forcings from the nearby tide gauges to the model boundaries needed to be retuned. To this end, the model was run repeatedly over the period 1996–2007. This validation period was chosen because hourly water-level observations at six sites throughout the bay (Figure 2), including the gauges used to generate the boundary conditions, were available for the full period. The calibration coefficients were iteratively adjusted to minimize differences between simulated and observed mean sea level and average daily tidal range at these six sites.

Hydrodynamic Model Inputs

TRIM-2D requires two time series as inputs—water levels at six-minute intervals at the Presidio and Port Chicago sites—which are then mapped using calibrated coefficients to serve as the model's boundary conditions (Figure 2). A 100-year projection of mean sea level at the Presidio location was produced by Cayan and others (2009) using the method of Rahmstorf (2007), based on global mean temperatures as projected by the CCSM3 global climate model (<http://www.cesm.ucar.edu>) under the A2 greenhouse

SAN FRANCISCO ESTUARY & WATERSHED SCIENCE

gas emissions scenario (Figure 3). This model projects a $\sim 4.5^{\circ}\text{C}$ ($\sim 8.1^{\circ}\text{F}$) increase in global average surface air temperatures by 2100. This is a relatively high (but not the highest) amount of warming among the ensemble of IPCC Fourth Assessment model results (IPCC 2007). Using the Rahmstorf method, this warming corresponds to a 139-cm rise in mean sea level, which corresponds to the upper end of the range of sea level rise projections in his 2007 paper.

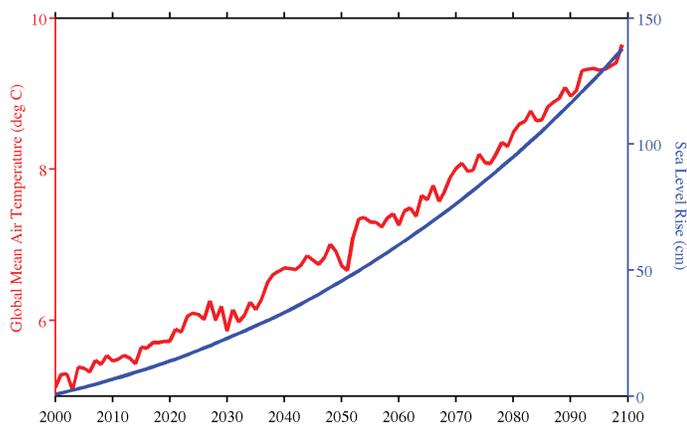

Figure 3 Annual global mean surface air temperatures (red) from the CCSM3-A2 GCM output, and corresponding relative sea level rise (blue) from the Rahmstorf model

This method provided the secular trend in water levels at the Presidio, but water levels vary under the influence of several forces over multiple time scales. Astronomical tides, storm surges, storm-related pressure drops, and El Niños are all major contributors to water-level variability. The result of these and other forces is that water levels reach successively higher peak water levels at longer time scales. Figure 4 illustrates the historical (1900–2000) average daily, monthly, and yearly high-water levels compared to hourly data for a typical year (2006) at the Presidio.

To incorporate this variability into the projected water-level time series, historical variability was superposed on the projected long-term trend in mean sea level. To do this, hourly water-level data (1900–1999) from the Presidio gauge were detrended using a least-squares linear fit to remove any historical sea level rise signal. A few small gaps in the historical data were filled using hindcast astronomical tides

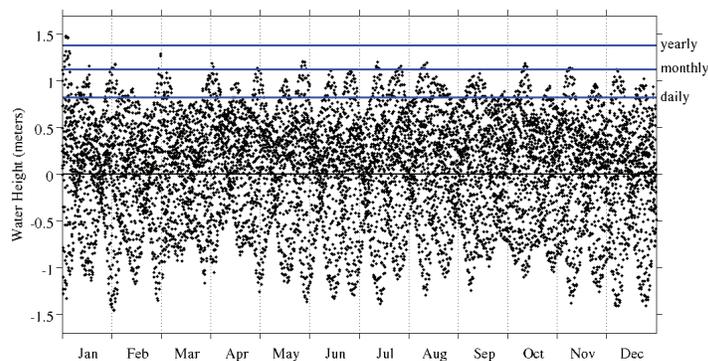

Figure 4 Hourly water levels at the Presidio for a typical year (2006), showing average historical (1900–2000) daily, monthly, and yearly high water levels

(Cheng and Gartner 1984). The resulting 100-year detrended time series, which contained variability over periods ranging from tidal to decadal scales, was added to the secular trend provided by Cayan to produce a 100-year projection of hourly water levels at the Presidio. This use of historical short-term variability (defined here as any variability other than the long-term trend) to represent future short-term variability requires two assumptions—first, that the probability distribution of short-term variability will remain unchanged under the climate change projections, and second, that these short-term variations and the secular component of the water-level time series at the Presidio site are linearly superposable. Cayan and others (2008) found the first of these assumptions to be true. The second follows as a reasonable approximation from the fact that the amplitude of both components— $O(1\text{ m})$ —is considerably smaller than the average depth near the Presidio site— $O(100\text{ m})$. This is because in sufficiently deep water, surface waves do not interact with the bottom and are thus unaffected by relatively small changes in mean depth.

With the first of the two required TRIM-2D input time series thus obtained, the Port Chicago time series was next produced. Lacking more than a few decades of data at the Port Chicago site, the approach used for the Presidio site was unworkable. The chosen solution was to map the Presidio time series to Port Chicago using a temporal version of the technique of constructed analogues (Hidalgo and others 2008). In this approach, the historical water-level time series

MAY 2010

(1996–2007) at the two stations were used to create a “map” which generates a 100-year hourly water-level projection at Port Chicago based on the Presidio projection described above. Specifically, the Presidio projection was stepped through five days at a time, with the preceding and succeeding days included to make a week of data. Each of these seven-day periods was expressed as a linear combination of the 22 best-matching (using RMS error) seven-day periods from the historical Presidio record (22 was found to be the optimal number of matches). The same coefficients in this optimal linear combination were then applied to the corresponding seven-day periods from the historical Port Chicago record to produce the estimate of Port Chicago water levels for the corresponding projected five-day period, after dropping the first and last days (which were included to minimize boundary effects in the procedure). One constraint on the method is that matching weeks were restricted to the same quarter of the year as the target week, allowing some accounting of the influence of the annual cycle of storm surges and freshwater flow.

Stepping through the 100-year Presidio projection in this manner, a corresponding 100-year projection of hourly water levels was developed for the Port Chicago station. The described procedure was applied to the non-secular component of the Presidio projection, and the Rahmstorf secular trend was then added to the resulting Port Chicago time series. A more complete description of the original method (as applied to spatial fields instead of time series) is given in Hidalgo and others (2008).

Projecting future Port Chicago water levels based on historical water levels assumes that amplitudes are unchanged as mean depth increases. Recent test runs using a Delft3D model of the bay-delta (van der Wegen, personal communication) suggest that increasing mean sea levels would result in increased tidal amplitudes at Port Chicago, meaning the results presented here are conservative, particularly in the landward reach of the estuary. These same test runs also indicate that any attenuation between the Presidio and Port Chicago sites of the long-term sea level rise signal would be negligible, justifying the method described above.

A validation run of the above procedure was performed, in which a portion of the historical Presidio record (1996–2007) was mapped to Port Chicago, with the procedure modified to exclude the target week from being selected as one of the matching patterns. The resulting “mapped” Port Chicago time series agreed well with the actual observed time series, with an RMS error of 6 cm (compared to an average daily tidal range of 148 cm) and a correlation coefficient of $r > 0.99$.

Both the Presidio and the Port Chicago 100-year hourly projections were interpolated from an hourly to a six-minute time step, and a week of hindcast astronomical tides were prepended to allow for model spin-up. A run of TRIM-2D was performed using these inputs (with a real-world run time of three weeks), resulting in a 100-year projection of six-minute gridded water heights throughout San Francisco Bay corresponding to a sea level rise of 139 cm by 2100.

ANALYSIS

Based on the projections of gridded water-level time series, water-height fields were developed corresponding to combinations of (1) specific amounts of sea level rise, and (2) specific return intervals (for example, 100-year high water with 50-cm sea level rise). This was accomplished by first separating the water-level time series of each model grid cell into a long-term trend and a detrended short-term variability time series. The long-term trend was estimated as the optimal second-degree least-squares fit to the full time series, and the residual was the short-term variability. Using the parameters of the long-term fits, the bay-wide, mean water-height field that corresponds to a specific amount of sea level rise could then be determined, providing (1) above. These fits to the long-term trends were sufficiently robust that for the subsequent analysis, it was decided they could reasonably be extended a few years beyond the end of the fitted data to represent a sea level rise of 150 cm, which would have occurred in an extended CCSM3-A2 scenario in 2105.

Return intervals represent the average period between events of a certain magnitude (corresponding to

SAN FRANCISCO ESTUARY & WATERSHED SCIENCE

“return levels”), such as floods, and are widely used for a variety of purposes, such as design and planning, regulation, and insurance requirements. High-water levels corresponding to specific return intervals associated with short-term variability were calculated next using the detrended 100-year time series at each grid cell. For periods less than a year, these series were long enough that water-level extremes could be robustly calculated simply as the corresponding mean. Mean daily higher-high water (MHHW) levels and mean daily lower-low water (MLLW) levels were calculated in this manner.

Return intervals of one year and longer were evaluated by applying the generalized extreme value (GEV) distribution, formulated by Fisher and Tippett (1928). Fisher and Tippett showed that block maxima, or a series of maxima each calculated over a specific time interval (for example, annual high-water levels), are characterized by the cumulative distribution function given in Equation 1.

Equation 1

$$F(x; \mu, \sigma, \xi) = \begin{cases} \exp\left\{-\left[1 + \xi\left(\frac{x - \mu}{\sigma}\right)\right]^{\frac{1}{\xi}}\right\}, & 1 + \xi\left(\frac{x - \mu}{\sigma}\right) > 0 \\ \exp\left\{-\exp\left[-\left(\frac{x - \mu}{\sigma}\right)\right]\right\}, & \xi = 0 \end{cases}$$

The cumulative distribution function of Equation 1 was fit to the annual maxima of the detrended time series in each grid cell throughout the bay using the maximum-likelihood method¹, also developed by Fisher (1922). This resulted in values of the parameters μ , σ , and ξ for each grid cell. The most important of these parameters, ξ , is called the shape parameter and determines the shape of the extreme tail of the probability distribution of the process being characterized—in this case water-level variability. For all points on the bay grid, $\xi < 0$, representing a short-tailed process. This indicates relatively small differences between high-water levels for progressively longer return intervals. The inverse of Equation 1 was

then used to determine water-level heights throughout the bay for a given return interval, corresponding to a specific value of the cumulative distribution function.

Finally, for a specified amount of sea level rise we can determine the gridded mean water level throughout the bay using the parameters describing the long-term trend. For a specified return interval we can determine the associated water-height field using the GEV parameters, or, in the case of tidal time scales, using the corresponding mean high water or mean low water values. Adding the projected mean water levels to those characterizing short-term events allows the water-level extremes of the bay to be characterized, both probabilistically and through time for any combination of sea level rise and return interval.

This approach assumes that the simulated 100-year, water-level time series can be separated into a long-term trend and short-term variability with the latter component being stationary (a requirement of the GEV analysis), thus extending to the entire bay the assumption that the short-term variability is independent of the long-term trend. While this assumption was clearly reasonable near the deeper waters of the Presidio site, it is not obviously so in the shallower parts of the bay where surface waves may interact with the bottom. To test this assumption, a separate hydrodynamic simulation was carried out in which the long-term sea level trend was removed from the boundary conditions, leaving only the short-term component. The last few years of the 100-year projection were simulated in this manner, and the results were compared to the detrended signal derived from the output of the original simulation. If short-term variability is indeed independent of the long-term trend in mean sea level, the two should be identical. The test run showed very slightly higher peak water levels—0(1 cm)—only in the shoals of the bay, indicating that short-term variability in those near-shore areas is dampened negligibly by the increase in mean depth with sea level rise, justifying the approach used here.

Importantly, a benefit of this approach is that the results are not limited to the particular climate scenario used (in this case, CCSM3-A2). That is, the

¹ All analysis and figures were produced using GRASS/QGIS, Matlab, and R statistical analysis software.

results are not dependent on time elapsed in the scenario but instead on the specific amount of sea level rise that has occurred. By specifying this amount along with the statistics of the short-term variability (which, being stationary through time and across scenarios, are independent of the scenario chosen), the results are completely specified. Choosing a high-end scenario for the base simulation made it possible to parameterize and subsequently evaluate a large range of potential future sea level rise.

Using the approach described above, water-level extremes were determined for different values of sea level rise and return interval for each of the nearly 50,000 points in the TRIM-2D, 200-m horizontal grid. In particular, sea level rise was evaluated in half-meter increments: 0, 50, 100, and 150 cm. In Rahmstorf's projections (2007), these amounts of sea level rise would be reached in roughly the following time frames, respectively: present-day, 2050–2100, 2080–, and 2105– (the projections do not extend far enough into the future to provide end dates for the highest two values). For each of these four cases, the inverse of Equation 1 was used to determine the water-height fields corresponding to return intervals of 1, 10, 50, 100, and 500 years. Water-height fields for the tidal datums MLLW and MHHW were also determined for the four sea level rise values. Multiple intermediate amounts of sea level rise were also evaluated, but most results presented below focus on the half-meter increments.

Finally, each water-height field was compared at all points along the bay's shoreline to the adjacent land surface elevation data to assess what areas would be inundated (at least as often as the specified return interval, on average) by water at these heights, resulting in the inundation maps and data presented in the next section. A final data set used to portray vulnerable areas in terms of land cover type was the National Land Cover Data set of 2001 (NLCD01; Homer and others 2007).

Potential sources of error in this analysis include the source elevation data, particularly errors in adjusting the LiDAR data for dense vegetation to achieve "bare earth" elevations. As mentioned earlier, the effect of present or future levees, potential accumulation of

sediment and organic matter, and shoreline erosion are not included in this study. Further, attenuation of short-term variability over inundated areas has not been accounted for; therefore, vulnerability to inundation may be overstated for areas well removed from the bay's (and the TRIM-2D model's) present-day shoreline. The estimates presented in this study have not taken into account the effect of wind waves on water levels, nor, in the long term, the possibility of tsunamis. The effect of high freshwater inflows on stage are accounted for, but only corresponding to historical climate; increased winter flood peaks associated with climate warming (for example, Knowles and Cayan 2002) would likely produce greater inundation vulnerabilities than presented here, especially in the northern part of the estuary.

Finally, subsidence of the land surface may exacerbate some of the vulnerabilities presented here; conversely, long-term uplift may do the opposite. Bürgmann and others (2006) used IfSAR data to determine that recent magnitudes of tectonic vertical deformation have been small in the bay region (<0.5 mm/yr along the bay shoreline). Changes in groundwater levels in the Santa Clara Valley caused isolated subsidence near the southern tip of the bay of up to 30 mm/yr during the last century (Poland and Ireland 1988), though improved groundwater management has led to a more stable land surface there more recently (Galloway and others 1999; Schmidt and Bürgmann 2003).

A more widespread process is the ongoing consolidation of sediments and bay mud in filled areas adjacent to the bay, resulting in subsidence of up to 17 mm/yr (Ferretti and others 2004). Also, consolidation and compaction of organic sediments is common in managed wetlands. This is particularly evident in the Suisun marsh LiDAR data in the North Bay, although ongoing subsidence rates there are not well documented. These last two processes suggest that the results presented here are likely to underestimate the possible impacts of sea level rise, as wetlands and man-made fill dominate the low lying areas around the bay.

RESULTS AND DISCUSSION

Potential Inundation Due to Extreme High-water Levels

Extreme high-water levels pose the most serious threat of overtopping or breaching levees, which would cause flooding in currently protected areas. Under sea level rise, the threat to such areas would increase. Also, low-lying areas not currently vulnerable (and therefore not yet protected by levees) would become increasingly subject to inundation. Sea level rise would bring qualitatively different types of risks for wetlands, so they are excluded from the results in this section and are discussed in the next section.

Figure 5A shows areas whose elevations are below the adjacent average 100-year high-water levels under conditions of present mean sea level in blue, and under conditions of a (high-end) 150-cm increase in mean sea level in red. For clarity, intermediate values of sea level rise are not shown in this and subsequent maps; for smaller values of sea level rise, the red areas would be smaller. An interactive, high-resolution presentation of these results, with 50-cm increments individually color-coded, is available at <http://cascade.wr.usgs.gov/data/Task2b-SFBay>.

To better understand what types of land are at risk, Figure 5B shows the areas vulnerable to 100-year

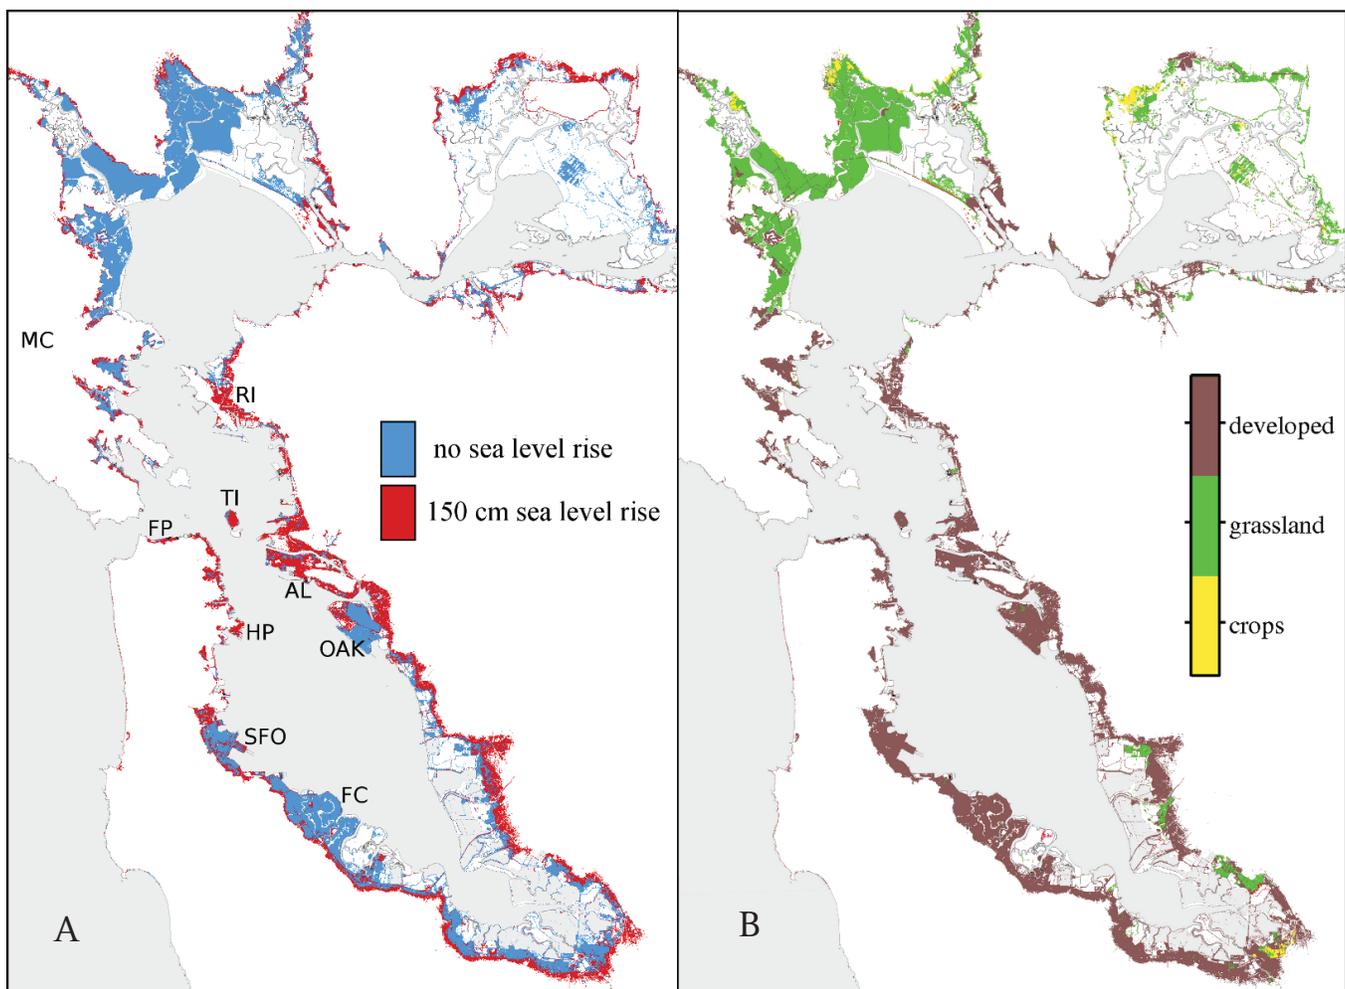

Figure 5 (A) Areas inundated or vulnerable to inundation under 100-year high-water levels for present-day (blue) and 150-cm sea level rise (red). Wetlands are excluded from these figures.

MAY 2010

inundation, expressed in terms of land cover types based on the NLCD01 data set.

Most of the areas indicated as presently vulnerable to inundation in Figure 5A (in blue) are behind levees and would only be inundated if those levees breached or were overtopped. These areas include crops and grasslands (mostly grazed pasture) that are primarily in North Bay, San Francisco and Oakland International Airports, and developed areas based on man-made fill, such as Foster City in South Bay. A primary concern is that with sea level rise, pressure on existing levees, and thus the risk of breaches, would be greatly increased. The potential for levee overtopping would also increase. In all these locations, existing levees would need to be raised and fortified to reduce the risk of these outcomes.

Other key areas of concern evident from Figure 5 include the municipal and industrial areas that are not currently vulnerable to 100-year high-water levels but would be under this future scenario. These areas (in red) run from Hunters Point to Fort Point in San Francisco, and include portions of eastern Marin, the Richmond peninsula, much of the East Bay shoreline including the former Naval Air Station at Alameda, and virtually all of Treasure Island. These are developed areas that would require some new levees and additions to any existing protection if flooding is to be prevented.

This ring of developed areas that would be newly vulnerable to inundation extends to South Bay, here falling upland of wetlands (existing or in restoration) and in some cases, upland of other (already vulnerable) developed areas. Many of these areas are already behind levees; they simply represent lands that are not currently at risk if these levees breached but would be at risk under the future scenario. Nearly all municipalities adjacent to South Bay (or adjacent to wetlands adjacent to South Bay) would face this risk to some degree, and again, existing protection would need to be improved. Another important concern for developed areas here is the survival of existing and future restored wetlands (the South Bay Salt Pond Restoration Project), which will depend on the ability of these wetlands to accrete material quickly enough to keep pace with sea level rise (wetlands are

discussed more in the next section). If the wetlands of South Bay were submerged by rising water levels, one consequence would be that wave energy would be less attenuated and erosional forces against protective upland levees would increase.

Figure 6 quantifies the different types of land at risk for a range of sea level rise amounts in terms of total vulnerable area in each land-use category. Excluding wetlands, the dominant categories of land cover around San Francisco Bay are grasslands and developed areas. The total area of vulnerable grassland would change little with sea level rise. Most newly vulnerable areas as a result of sea level rise would be the developed areas surrounding Central and South bays (see Figure 5). These also constitute the vulnerable areas with the greatest potential economic loss.

Excluding wetlands, today, a total area of about 310 km² is inundated or vulnerable to inundation under 100-year high-water levels; this consists almost entirely of grasslands and developed areas already protected by levees. Under a 50-cm sea level rise (projected by 2053 in the CCSM3-A2 scenario), the total vulnerable area would increase by 20% to 372 km², and under a 150-cm sea level rise (2105), the total vulnerable area would increase by almost 60% to 495 km². The largest change in area of a vulnerable land cover type would occur for developed areas. Vulnerable developed area would nearly double with a 150-cm sea level rise, from 157 km² to 311 km². These estimates assume no change in land-use assign-

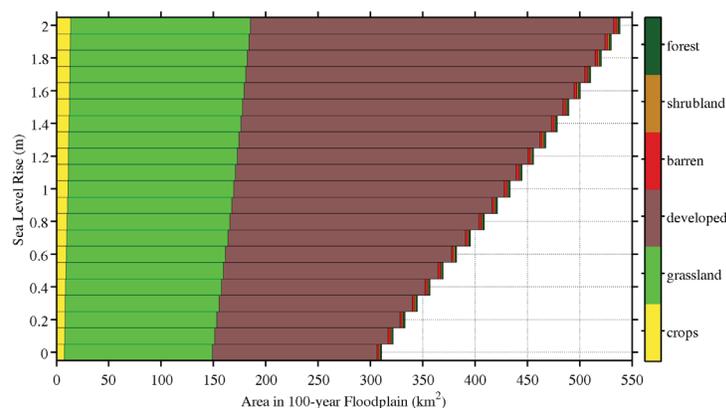

Figure 6 Total area around San Francisco Bay, excluding wetlands, vulnerable to inundation by 100-year high-water levels for a range of sea level rise, broken down into land-cover categories

SAN FRANCISCO ESTUARY & WATERSHED SCIENCE

ments over time; it is possible that some of the land currently assigned to other categories will ultimately be developed, resulting in an even greater value for total vulnerable developed area.

Figure 7 shows the bay-wide mean high-water levels and total area vulnerable to inundation for four values of sea level rise (0, 50, 100 and 150 cm) and five different return intervals (1, 10, 50, 100 and 500 years). As described earlier, water-level variability in the bay is a short-tailed process ($\xi < 0$), evidenced here by the progressively flatter response of water level and vulnerable area with increasing return interval. It should be noted that the 500-year return levels should include the effects of a potential tsunami, but the evaluation of such effects is beyond the scope of this investigation. Inclusion of tsunami effects would increase the 500-year return levels substantially. Under the high-end scenario of Rahmstorf (2007) (to which the CCSM3-A2 projection corresponds), the one-year peak event would nearly equal today's 100-year peak event by mid-century. This would not occur until 2100 under the low-end scenario (~50-cm sea level rise in 2100).

Wetlands and Changing Tidal Datums

There are about 400 km² designated in the NLCD01 as wetlands around San Francisco Bay, including the South Bay Salt Ponds, Napa Wetlands, and Suisun Marsh, among others. Figure 8 shows the amount of total wetland area, according to present-day wetland elevations, that would lie below projected future tidal datums as sea level rise progresses.

Some of the wetland area that appears as currently near the lower end of the tidal range consists of managed wetlands behind levees and other control structures. In those cases, sea level rise would threaten levee integrity and the ability to manage the wetlands for their desired uses. Wetlands not behind levees would gradually shift lower in the tidal range if elevations were to remain at their present levels. A 110-cm sea level rise would more than double the area of wetlands below local mean sea level (LMSL).

Figure 9 illustrates the spatial pattern of this shift, relative to MLLW, for the Napa and Suisun wetlands.

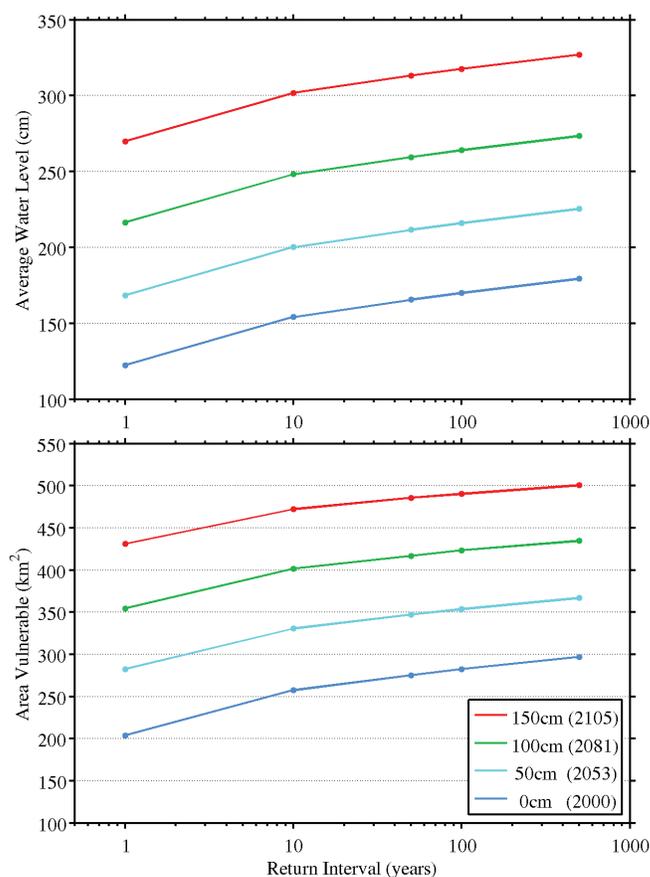

Figure 7 Bay-average water level relative to mean sea level (upper) and total area around San Francisco Bay, excluding wetlands, vulnerable to inundation (lower) versus return interval for four values of sea level rise. The earliest year in which each level is projected to be reached (using the high-end CCSM3-A2 projection) is indicated in the legend. Low-end projections do not produce a 50-cm sea level rise until around 2100.

Portions of Suisun Marsh are already subtidal. Under a 100-cm sea level rise, most of today's Suisun Marsh would be in the subtidal zone. With a 150-cm sea level rise, Napa Wetlands would be as well. Similar results are obtained for the South Bay Salt Ponds (not shown).

It is very important to note that Figures 8 and 9 ignore the dynamic nature of wetlands, particularly their ability to accrete organic and mineral sediment. The purpose here is to illustrate the magnitude of the potential changes which these processes would need to counter.

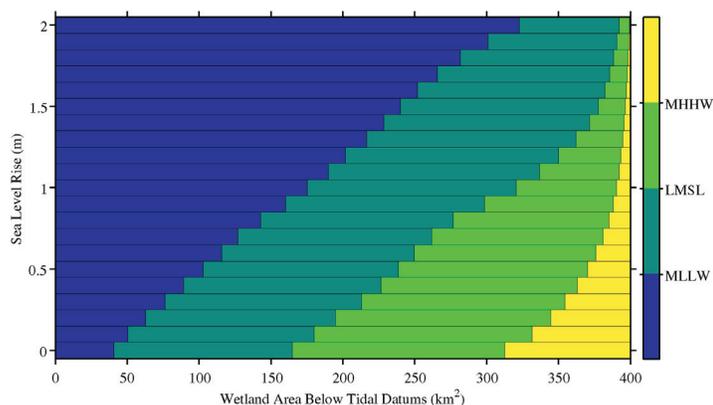

Figure 8 Total wetland area relative to fields of mean daily higher-high water levels (MHHW), local mean sea level (LMSL), and mean daily lower-low water levels (MLLW). These results are based on present-day elevations and ignore the potential for vertical accretion and lateral migration of wetlands in response to sea level rise.

The results of this study indicate that, to maintain their current positions in the tidal range, existing wetlands around San Francisco Bay would require 150, 330, or 530 million cubic meters (Mm^3) of (organic plus mineral) sediment² for respective sea level rise amounts of 50, 100, and 150 cm. Because sea-level projections over the coming century are generally quadratic in time, as typified by Figure 3, the rate of rise would increase linearly, starting at the present-day value of 20 to 30 mm/yr. The “break-even” sediment accumulation rate would also increase linearly, starting at the corresponding value of roughly $0.6 \text{ Mm}^3/\text{yr}$. Recent projections suggest that sea level could rise as little as 50 cm, or as much as 150 cm, by 2100. In the first case, the required accumulation rate would increase to $2.4 \text{ Mm}^3/\text{yr}$ by 2100 (corresponding to a sea level rise rate of 6.7 mm/yr), averaging $1.5 \text{ Mm}^3/\text{yr}$ over the century. In the second, the required rate would reach $10.1 \text{ Mm}^3/\text{yr}$ by 2100 (25.6 mm/yr), averaging $5.3 \text{ Mm}^3/\text{yr}$. If leveed wetlands remained isolated from sediment supplies despite higher sea levels, these sediment volumes would be smaller. However, those levees would require substantial

² These are estimates of the volume of accretion that would be required to maintain the vertical position within the tidal range of wetland areas already below MHHW, and to keep elevations of the remaining wetland areas just above MHHW. These values ignore depth increases in most mudflats, in subtidal shallow water habitat, and in wetland areas lacking elevation data due to the presence of open water at the time of data acquisition.

improvements to hold, and some common management practices, such as seasonal gravity draining of leveed wetlands managed as waterfowl habitat, would eventually become impossible in the absence of significant accretion.

To give the above sediment flux values some context— in recent years, inorganic sediment input to the bay from the delta and local tributaries has averaged roughly $1.9 \times 10^6 \text{ Mg/yr}$ (Schoellhamer and others 2005; McKee and others 2006), though there is evidence that the delta portion of this supply has been in decline (Wright and Schoellhamer 2004). Depending on the density estimate used (D. Schoellhamer, personal communication), this amounts to roughly 1.5 to $3.8 \text{ Mm}^3/\text{yr}$, of which only about 10% has been depositing on wetlands (Schoellhamer 2005).

Wetland deposition rates are likely to increase as presently leveed wetlands become tidally connected through restoration actions (Schoellhamer 2005) and possibly as a result of levee breaches induced by sea level rise. Nonetheless, Ganju and Schoellhamer (2010) show that even under an extremely modest rate of sea level rise, present-day inorganic sediment supply may not suffice to keep the shallowest areas of Suisun Bay from getting deeper, which may have similar implications for the adjacent wetlands.

Although the topic of sustainable wetland restoration is complex (for example, Orr and others 2003) and beyond the scope of this study, it is worth noting here some other important factors that could contribute to wetland survival in the context of rising sea levels. For instance, dredged material from the bay may come to play a greater role in augmenting wetland elevations (Johnck and others 2009). Also, Drexler and others (2009) found that in tidal freshwater marshes in the delta, vertical accretion of peat ranged from 0.3 to 4.9 mm/yr over the past 6,000 years, indicating that given suitable conditions, peat formation can play an important role in mitigating the effects of sea level rise. There is even evidence that, at least in some parts of the bay, wetlands are capable of keeping pace with even higher rates of relative sea level rise than have been discussed here. In far South Bay, rates of sedimentation and organic accumulation were sufficient to allow salt marshes

SAN FRANCISCO ESTUARY & WATERSHED SCIENCE

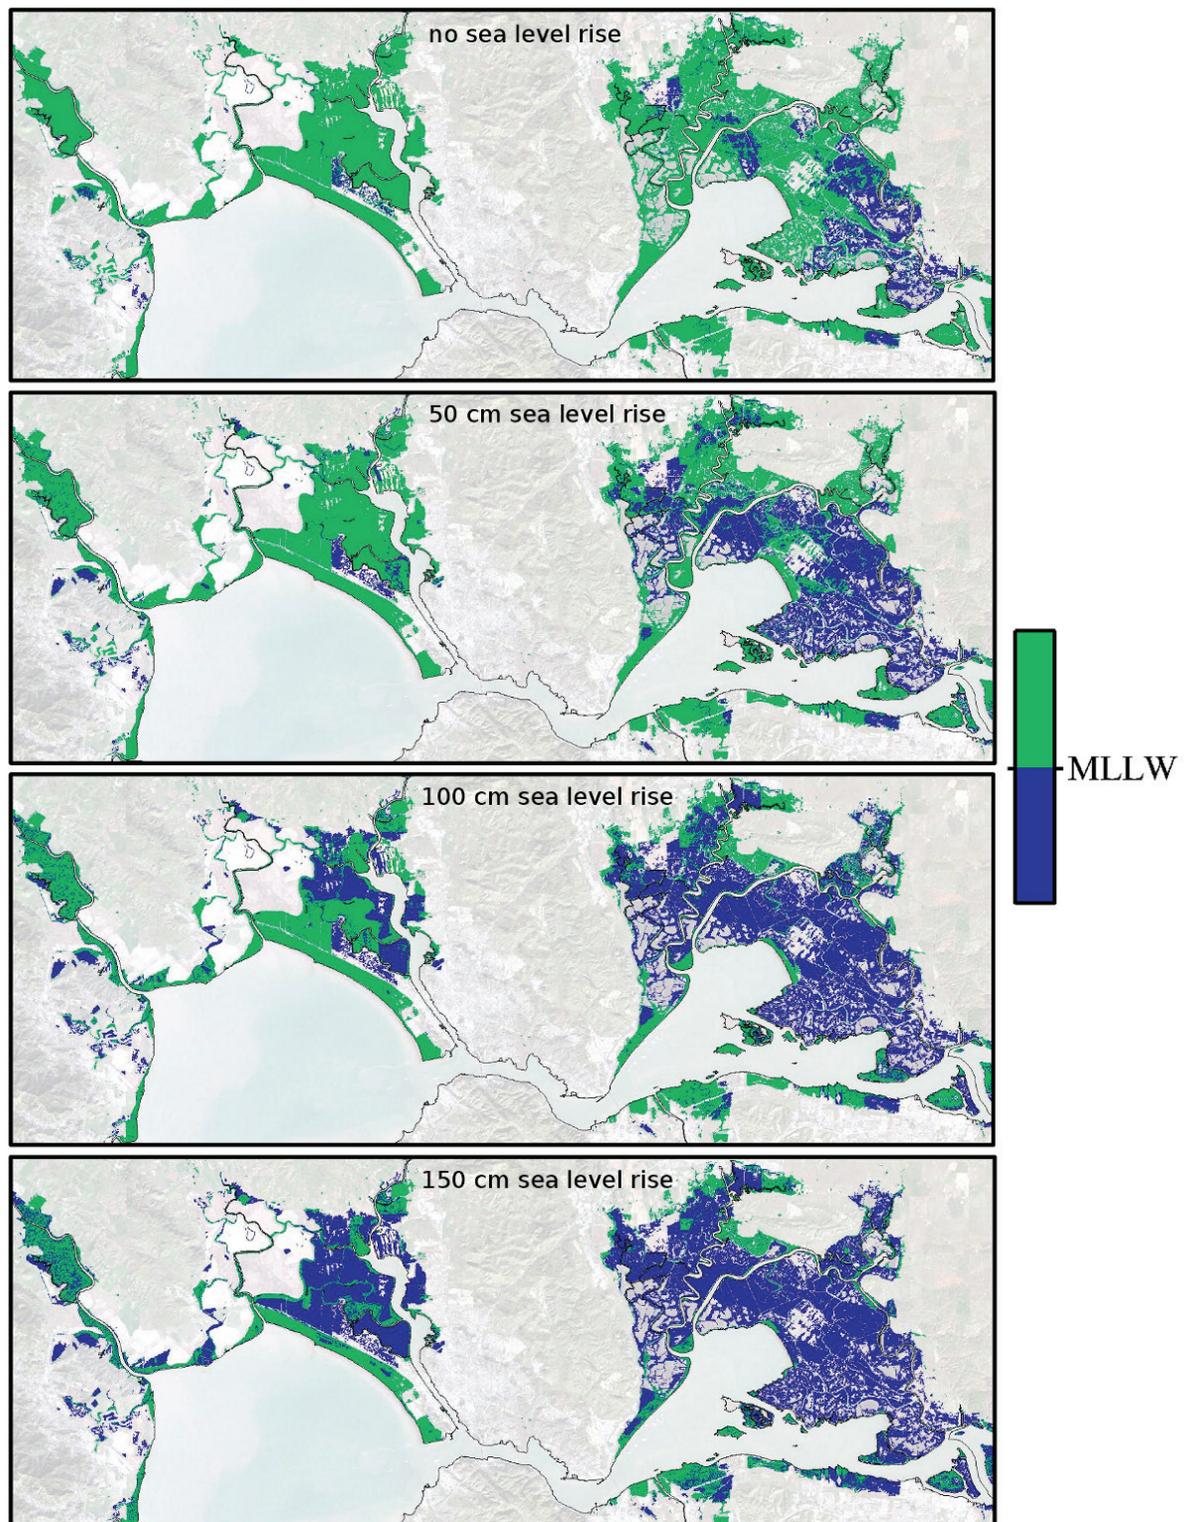

Figure 9 Wetland elevations relative to the MLLW tidal datum for four values of sea level rise. Napa wetlands are left-of-center, and Suisun Marsh is on the right. These results are based on present-day elevations and ignore the potential for vertical accretion and lateral migration of wetlands in response to sea level rise.

to compensate for an estimated one meter of subsidence due to groundwater extraction over only a few decades (Patrick and DeLaune 1990; Watson 2004). However, far South Bay has been shown to be a particularly strong depositional environment relative to other areas of San Francisco Bay (Foxgrover and others 2004; Jaffe and Foxgrover 2006). Another wetland survival mechanism not discussed above is migration to adjacent upland areas. Though this possibility is generally limited in the highly developed bay region, some promising candidate areas exist (Enright and others 2007).

CONCLUSIONS

The main features of inundation around San Francisco Bay associated with potential sea level rise have been presented here. Results for several different values of sea level rise were given, and it should be re-emphasized that these results apply regardless of when a given amount of sea level rise is reached. Some major concerns associated with sea level rise were discussed—survival of existing wetlands, inundation of currently unprotected developed areas, increased risk of failure and overtopping of existing levees, and increased consequences of such failures as more areas become vulnerable are all real dangers. However, many other complications could also occur. For example, sanitation districts around the estuary are concerned that as sea level rises, seawater could backflow into their drainage systems, causing local flooding and sanitation problems. The risks of such problems occurring will increase gradually with sea level rise, but are associated with specific events within a given year. The largest events are most likely to occur during winter storms, particularly those coinciding with a spring tide. El Niño events also lead to higher water levels and increased risk (Cayan and others 2008).

The projected changes have many implications for those living in this region. Municipal planners will need to carefully consider the increasing risks of development in low-lying areas. Changing recurrence levels will require that flood insurance maps be redrawn regularly. Local groundwater pumping will need to continue to be carefully managed to avoid

subsidence. Transportation infrastructure will be threatened. Economic and policy implications of these and other changes are discussed in reports, based in part on the results presented here, by Heberger and others (2008) and BCDC (2009).

As mentioned in the “[Data and Methods](#)” section, these results can be applied to a wide range of climate change scenarios. For example, scenarios representing higher greenhouse gas emissions in the future can result in projections of large warming and sea level rise. In such a high-end scenario, conditions in 2100 may most closely resemble the results presented here for the 150-cm sea level rise amount. Conversely, estimates of sea level rise under the most optimistic of scenarios, representing lower greenhouse gas emissions, range from 45 to 70 cm by 2100 (Moser and others 2008). In this case, the 50-cm scenario may correspond to conditions in 2100. In terms of a specific result, referring to [Figure 7](#), this means that under the most optimistic scenario, in 2100 the 1-year peak event would nearly equal today’s 100-year peak event.

It is important to note, however, that global CO₂ emissions in recent years have tracked the highest scenarios considered to date in the IPCC Assessments (TCD 2009), and the results corresponding to the high-end scenarios of sea level rise presented in this study should be seriously considered as future possibilities. Further, sea level rise is expected to continue well beyond this century. Vellinga and others (2008) estimate the high end of possible sea level rise by 2200 to be 1.5 to 3.5 m, and Schubert and others (2006) provide a mid-range estimate, corresponding to a 3°C warming, of 3 to 5 m by 2300.

Understanding and successfully adapting to these changes will require a fuller knowledge of the likely consequences and the types of actions required. An example of a gap in our current knowledge is the need for a better understanding of the adaptability of existing and restorable wetlands and the dependence of the survival of these wetlands on the bay’s sediment budget. Another very important missing piece of information is a better characterization of levee heights and their recent changes due to subsidence or uplift, and an associated regional data base.

SAN FRANCISCO ESTUARY & WATERSHED SCIENCE

Inundation data layers from this project are publicly available at <http://cascade.wr.usgs.gov/data/Task2b-SFBay> in the hope that the high-resolution regional data produced for this analysis will be useful for other regional and local studies and planning efforts.

Key words: *Microcystis*, cyanobacteria, toxic, estuary, harmful algal bloom

Abstract

The first distribution, biomass and toxicity study of a newly established bloom of the colonial cyanobacteria *Microcystis aeruginosa* was conducted on October 15, 2003 in the upper San Francisco Bay Estuary. *Microcystis aeruginosa* was widely distributed throughout 180 km of waterways in the upper San Francisco Bay Estuary from freshwater to brackish water environments and contained hepatotoxic microcystins at all stations. Other cyanobacteria toxins were absent or only present in trace amounts. The composition of the microcystins among stations was similar and dominated by demethyl microcystin-LR followed by microcystin-LR. *In situ* toxicity computed for the >75 μm cell diameter size fraction was well below the 1 $\mu\text{g l}^{-1}$ advisory level set by the World Health Organization for water quality, but the toxicity of the full population is unknown. The toxicity may have been greater earlier in the year when biomass was visibly higher. Toxicity was highest at low water temperature, water transparency and salinity. Microcystins from the bloom entered the food web and were present in both total zooplankton and clam tissue. Initial laboratory feeding tests suggested the cyanobacteria was not consumed by the adult copepod *Eurytemora affinis*, an important fishery food source in the estuary.

Introduction

Microcystis aeruginosa is a common freshwater cyanobacterium that blooms in eutrophic lakes and reservoirs throughout the world including the United States, Canada, Australia, New Zealand, South Africa and Japan (Paerl, 1988; Carmichael, 1995; Watanabe, 1995; Downing et al., 2001). It has also been observed in estuaries including the Neuse River estuary (Paerl, 1988) and the Potomac River estuary (Sellner et al., 1993) in the USA, the Swan River estuary in Western Australia (Robson & Hamilton, 2003) and the Patos Lagoon Estuary in Southern Brazil (Yunes et al., 1996). A bloom of the colonial form of *M. aeruginosa* has also been observed in the northern reach of San Francisco Bay Estuary (NSFE), California

between June and November since 1999 (Lehman & Waller, 2003). The single-celled form of *M. aeruginosa* is currently a common cyanobacterium in NSFE but was not identified as a dominant genus in the phytoplankton community between 1975 and 1982 (Lehman & Smith, 1991). Total cyanobacteria biomass has increased throughout the NSFE coincident with a decline in diatom biomass between 1975 and 1993 (Lehman, 2000). The highest total cyanobacteria density occurred in the spring and summer of normal and critically-dry precipitation years (Lehman, 1996).

M. aeruginosa is sometimes characterized as a harmful algal bloom (HAB) species. Blooms of these species form surface scums that impede contact recreation sports, reduce aesthetics, lower dissolved oxygen concentration and cause taste and odor

problems in drinking water (Carmichael, 1995). Some of these blooms also contain hepatotoxic microcystins that cause liver tumors and cancer in wildlife and humans (Carmichael, 1995). One surface water sample collected in the NSFE in 2000 contained microcystins concentration above the World Health Organization advisory level of $1 \mu\text{g l}^{-1}$ (World Health Organization, 1998; Lehman & Waller, 2003). No further information is available on the biomass, toxicity and distribution of the *M. aeruginosa* bloom or its potential impact to human health and ecosystem function in NSFE.

Marine and coastal HABs have occurred more frequently over the past decade worldwide (Anderson & Garrison, 1997; Horner et al., 1997) and have been observed along the coast of California since 1793 (Horner et al., 1997). Most of these blooms were associated with dinoflagellates that produced paralytic shellfish poisoning (PSP) or diatoms that produced domoic acid poisoning (DAP). It is assumed that coastal marine HABs enter estuaries along the west coast of North America although *in situ* growth was identified in Puget Sound (Horner et al., 1997). Coastally derived HABs contrast with the freshwater *M. aeruginosa* blooms that are assumed to enter estuaries from upstream during high streamflow events (Robson & Hamilton, 2003).

The colonial form of *M. aeruginosa* adds to an already extensive list of introduced species in San Francisco Estuary with adverse impacts. Approximately 212 species were introduced into the estuary since 1850 (Cohen & Carlton, 1995).

The previous dominant phytoplankton species were identified as cryptogenic, not clearly native or introduced. The potential adverse impact of this HAB on the estuary is large. Water from the northern region is used directly for drinking water and irrigation and the region is an important recreational area for sport fishing and water contact sports. The estuary is habitat for many anadromous commercial and recreational fish including striped bass and Chinook salmon and is a feeding ground for marine mammals. The estuary also contains many threatened or endangered aquatic organisms including the fish Delta smelt and winter run Chinook salmon and many of these endangered fish species are declining (Bennett & Moyle, 1996; California Bay-Delta Authority, 2000). Some of this decline may be linked to the

quantity and quality of the phytoplankton carbon available at the base of the food web (Lehman, 1992; Mueller-Solger et al., 2002; Feyrer et al., 2003; Lehman, 2004).

The purpose of this study is to develop initial information on the spatial distribution, toxicity, algal biomass and environmental conditions associated with the occurrence of the colonial *M. aeruginosa* bloom in the NSFE. Such information is needed to develop focused research and monitoring programs that evaluate the current and future impact of this bloom on estuarine processes.

Study area

The NSFE consists of an inland Delta that flows into a chain of downstream marine bays – Suisun, San Pablo and San Francisco – and creates one of the largest estuaries on the west coast of North America. The estuary stretches from the Pacific Ocean in the west to the tidal head at Greens Landing on the Sacramento River and Vernalis on the San Joaquin River. The inland Delta varies between fresh and brackish water conditions with season and water-year type and contains 200 km² of waterways formed by the Sacramento River on the north and the San Joaquin River on the south. Together these two rivers drain 47% of the runoff in California. The Sacramento River is the larger of the two rivers with an average runoff of 27 million m³ compared with 10 million m³ for the San Joaquin River. Depth varied from a few meters in the Delta to 13 m in the shipping lanes. The tide is semidiurnal and reaches 2 m throughout the region. Tidal velocities can reach 30 cm s⁻¹ in the Bay and are associated with tidal excursions of 10 km.

Materials and methods

Field and laboratory sampling

The spatial distribution of the *M. aeruginosa* bloom was identified by observation of surface waters during mid-day on September 12, 2003. *M. aeruginosa* biomass and toxicity was sampled on October 15, 2003 at 14 stations throughout the same area identified in September. Stations were selected that represented different habitat types or

use including recreational swimming (station 23), shallow water habitat (stations 41 and 42), deep river channel (stations 11–13), anadromous and native fish habitat (stations 11–43) and agricultural and drinking water (stations 43–45; Fig. 1). Colonies were sampled by horizontal surface tows of a 0.72 m diameter plankton net fitted with a 75 μm mesh screen on the cod end. Sampling a large size fraction assured that the sample primarily contained the colonial form of *M. aeruginosa*. Net tows were conducted at the center of the channel at a speed of 60 m min^{-1} and lasted 1–10 min depending on bloom biomass. Horizontal net tows were used to obtain a quantitative and integrated sample of the bloom which had a patchy distribution. Total volume of the sample

was determined from an attached General Oceanics 2030R flowmeter. Water temperature and specific conductance were also measured at each station using a freshly calibrated YSI 85 sonde. Specific conductance was converted to salinity by first converting the specific conductance values to chloride concentration (g l^{-1}) using station specific regression equations and then converting chloride concentration to salinity (ppt) using the equation: $\text{salinity} = 1.80655 \times \text{chloride}$ (Unpublished data, California Department of Water Resources; APHA et al., 1998).

Water samples containing algal biomass were stored at 4 $^{\circ}\text{C}$ and filtered within 2 h onto GF/F glass fiber filters. Filters for microcystins analysis were wrapped in aluminum foil and frozen until

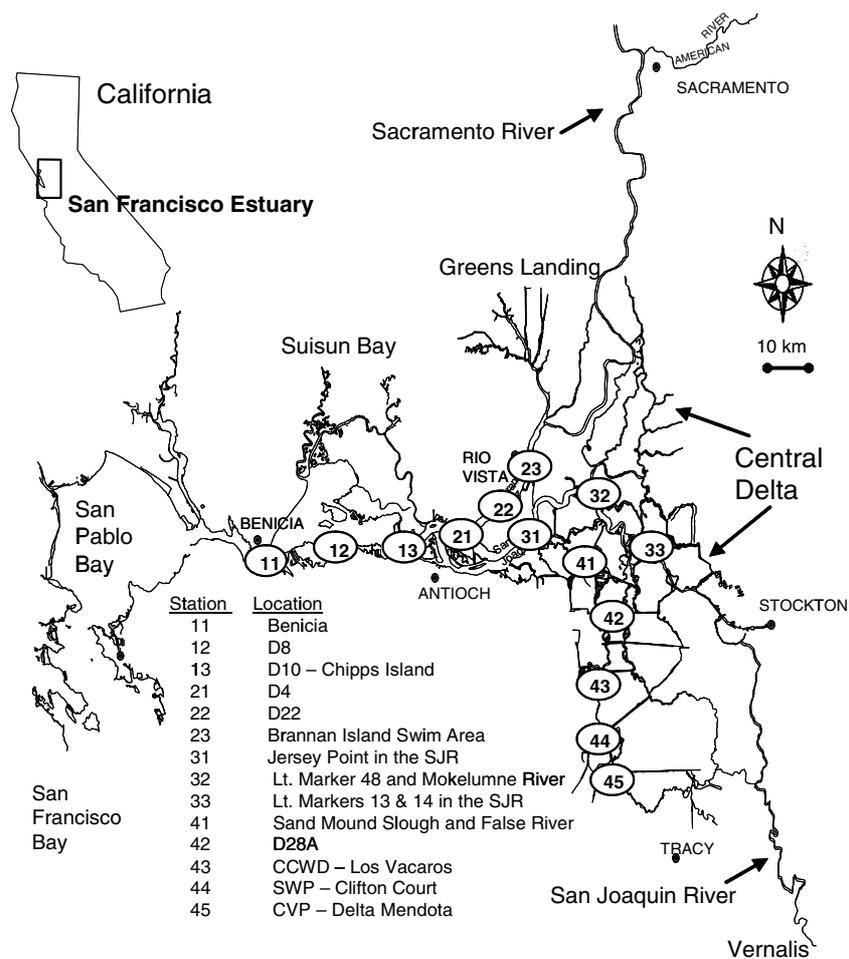

Figure 1. Map of upper San Francisco Bay Estuary with sampling station location.

laboratory analysis. Filters for chlorophyll *a* analysis were treated with magnesium carbonate as a preservative and frozen until laboratory analysis (US EPA, 1983). Sample replication was 20%. In addition, a 50 ml water sample was preserved and stained with Lugol's solution for phytoplankton cell identification with an inverted microscope (Utermohl, 1958).

The presence of microcystins in the food web was assessed by the presence of microcystins in zooplankton and clam tissue. Zooplankton were sampled at 5 stations by horizontal net tows of a 0.7 m diameter plankton net fitted with a 150 μm mesh on the cod end. Zooplankton were kept at 4 °C and were separated by hand from *M. aeruginosa* in the water sample within 48 h using a dissecting microscope. The final zooplankton sample was rinsed in distilled water and frozen until analysis. Clams were obtained using a ponar dredge. The tissue was removed from the clam shell, rinsed in distilled water and frozen until analysis.

An initial study to determine the feeding of the adult copepod *Eurytemora affinis* (Copepoda: Calanoida) on *M. aeruginosa* was evaluated by laboratory feeding tests. Six groups of 20 laboratory grown animals were each placed in a 500 ml flask containing 200 ml of 1 ppt L16 culture medium. This culture medium is a synthetic culture medium modified with vitamin B₁₂, biotin vitamins and soil extract that was useful for culturing zooplankton and algae because it had an ionic composition similar to that in many eutrophic lakes (Lindstrom, 1983). Zooplankton were held in the culture medium and not fed for 3.5 h. Previous experiments indicated a 50% reduction in gut chlorophyll *a* within 10 min of being placed in the 1 ppt L16 culture medium (Hall unpublished data). Copepods in three flasks were transferred to GFC glass fiber filters for replicate chlorophyll *a* analysis (Marker et al., 1980). An additional 150 ml of *M. aeruginosa* biomass equivalent to 146 $\mu\text{g l}^{-1}$ of chlorophyll *a* was added to the remaining three flasks. *M. aeruginosa* colonies were obtained from the Delta that day and separated from other phytoplankton by pipette with repeated washes in natural water filtered through a 0.45 μm pore size Nucleopore filter. Treatment flasks were incubated for 24 h at 20 °C and a 16:8 light:dark cycle. At the end of the incubation

period, animals were removed from the media, placed on GFC glass fiber filters and the filters were immediately frozen until analysis for chlorophyll *a* concentration.

Toxicity testing

Filters for toxin analysis were extracted by sonication with 10 ml of 50% methanol containing 1% acetic acid, clarified by centrifugation, and the extract used for analysis of the different toxins. Zooplankton were lyophilized first then extracted as above. Clams were extracted using a 50% acidified methanol in a Waring Blender. Addition of purified microcystin-LR, microcystin-YR, microcystin-RR, anatoxin-a and saxitoxin to wet filters or lyophilized zooplankton, followed by their extraction as described above recovered greater than 90% of all five toxins. To determine the recovery of microcystin from the clam samples, it was necessary to split the crude homogenate into two parts and add a known amount of microcystin spiked into one fraction. Recoveries of microcystin from these tissues ranged from 50 to 65%. This value was then used to correct the unspiked fraction for loss of microcystins during extraction.

Total microcystins concentration in plant and animal tissue was initially assessed using the protein phosphatase inhibition assay (PPIA) technique. Assays were run in 96-well plates containing 0.1 mU enzyme (recombinant protein phosphatase 1A, catalytic subunit, Roche Applied Science), 1.05 mg para-nitrophenyl phosphate (Sigma Biochemical) and 10 μl of sample or microcystin-LR (Sigma Biochemical) using the method of Carmichael & An (1999). The rate of phosphate hydrolysis was calculated from the change in absorbance at 405 nm over 1 h and compared to the control (no added microcystin-LR) and standards containing between 6 and 40 $\mu\text{g l}^{-1}$ microcystin-LR. Blanks (no enzyme, no toxin), unknowns, standards, and controls were all run in duplicate.

Samples with the highest levels of total microcystins were further analyzed by high pressure liquid chromatography (HPLC) to identify the specific microcystins in the sample. Samples were separated using a Dupont Ace 4.6 \times 250 5 μ C18 column and a two-step linear gradient of 30–70% acidified acetonitrile to acidified water at 0.8 ml/min (Harada, 1995). Detection was either

mass selective using electrospray ionization (LCMS, Agilent 1100 series MSD) and by UV absorbance using a Waters model 996 photodiode array detector (PDA) between 210 and 300 nm. For LCMS, all ions between 900 and 1250 amu were combined to form the total ion chromatograph and potential microcystins identified on the basis of their molecular ions and retention times. For PDA detection, potential microcystins were identified on the basis of having an absorbance maximum at 239 nm in their UV spectrum and on their retention times.

Anatoxin-a was determined by HPLC after derivatization with 7-fluoro-4-nitro-2,1,3-benzoxadiazole (NBD-F) (James & Sherlock, 1996). The PSP toxins (saxitoxin, neosaxitoxin, and gonyautoxins 1–4) were measured by HPLC with fluorescent detection using the electrochemical oxidation system (Boyer & Goddard, 1999) to form fluorescent derivatives.

Analysis

Because of the small sample size, differences in the means for variables among regions were determined using the Kruskal–Wallis nonparametric technique. Multiple comparisons were evaluated using least significant differences and correlation was evaluated using Spearman rank correlation coefficients. All analyses were conducted using Statistical Analysis System software (SAS Institute, Inc., 2004)

Results

Distribution

M. aeruginosa colonies >75 μm diameter were present in surface samples at all stations sampled in October (Fig. 1). The bloom distribution in October was the same as that observed in September. Sampling stations represented a wide range of habitat types from marine water habitat at the western end of Suisun Bay to freshwater habitat upstream in the Sacramento, Old and San Joaquin rivers. Chlorophyll *a* concentration in concentrated surface net tows ranged from 4 to 554 $\mu\text{g l}^{-1}$ and was significantly different among regions ($p < 0.01$; Table 1). The highest chloro-

phyll *a* concentrations ($p < 0.05$) were measured in the San Joaquin and Old rivers compared with the Sacramento River and Suisun Bay. *In situ* chlorophyll *a* concentration associated with the >75 μm diameter size fraction ranged between 0.7 and 74.6 $\text{m } \mu\text{g l}^{-1}$ based on an expansion of the net sample concentration to tow volume. How much of the surface chlorophyll *a* concentration was composed of *M. aeruginosa* is unknown but phytoplankton identification samples suggested most of the cells were *M. aeruginosa*. The chlorophyll *a* concentration of all size fractions in a Van Dorn sample taken at 1 m depth was 1–3 $\mu\text{g l}^{-1}$ throughout the region on October 15 (unpublished data, California Department of Water Resources) and probably represents the background concentration of other algae in the water column because *M. aeruginosa* was near the surface during the day.

The environmental conditions associated with the bloom varied among regions. Water temperature, salinity and Secchi disk depth were all significantly different among regions ($p < 0.01$). The high phytoplankton biomass and microcystins concentration in the San Joaquin and Old rivers were accompanied by a combination of higher ($p < 0.05$) water temperature, lower salinity ($p < 0.05$) and higher ($p < 0.05$) water transparency (Fig. 2) than the Sacramento River and Suisun Bay. Chlorophyll *a* concentration was more closely associated ($p < 0.01$) with warmer water temperature ($r = 0.66$) and higher Secchi disk depth ($r = 0.70$) and lower salinity ($r = -0.71$) than microcystins concentration ($p < 0.05$; $r = 0.54$, $r = 0.52$ and $r = -0.52$, respectively). Nutrient concentrations were high and nonlimiting throughout the area. Median dissolved inorganic nitrogen and soluble reactive phosphorus were 0.41 and 0.06 mg l^{-1} respectively (unpublished data, California Department of Water Resources).

Toxicity

Microcystins were present at all stations but concentrations differed ($p < 0.01$) among regions. Both the San Joaquin and Old rivers had higher ($p < 0.05$) microcystins concentration than the Suisun Bay region downstream. The microcystins

Table 1. Comparison of chlorophyll *a*, microcystin, anatoxin-a (ATX) and PSP concentration in concentrated net tow samples normalized to a 1 min tow for the >75 μm cell diameter size fraction of the *Microcystis aeruginosa* bloom and microcystin concentration in zooplankton and clam tissue at sampling stations in the northern San Francisco Bay Estuary

were dominated by a demethyl microcystin-LR that comprised between 47 and 66% of the microcystins followed by microcystin-LR that comprised 9 to 23% (Table 2). *In situ* microcystins concentration based on net tow volume was much lower than the concentrated net samples (compare Fig. 3 and Table 1). Similar net tow volume computed from net size, time and tow speed and those computed from the current meter values taken during the tow suggested the volume sampled was a good estimate of total sample volume.

Toxicity generally increased with chlorophyll *a* concentration but the association was not linear (Table 1). The microcystins to chlorophyll *a* and the microcystins to total pigment ratio differed widely among stations (Fig. 4) and was high when water temperature, water transparency and salinity were comparatively low (Fig. 5). The lowest microcystins to chlorophyll *a* ratios occurred at salinities greater than 5 ppt and suggested salinity was an important factor controlling toxicity. The highest toxicity was measured near the transition zone between fresh and brackish water at station 22 on the Sacramento River (Fig. 4).

The algal tissue samples were also tested for the cyanobacterial neurotoxins, anatoxin-a and PSP toxins such as saxitoxin. PSP toxins were not detected at measurable concentrations in any of the samples. Anatoxin-a was not detected or occurred in trace amounts in concentrated 1 min net tow samples at stations 31 (0.1 g l^{-1}) and 33 ($0.4 \text{ } \mu\text{g l}^{-1}$; Table 1).

Food web impact

The animal tissue of lower food web organisms contained small amounts of microcystins. Microcystins concentration ranged from 1 to $3.5 \text{ } \mu\text{g}$ microcystins (g dry weight^{-1}) in zooplankton tissue and was $0.02 \text{ } \mu\text{g}$ microcystins (g dry weight^{-1}) in clam tissue (Table 1). The concentration in animal tissue was not a function of the microcystins concentration per unit chlorophyll *a* measured at the station (compare Table 1 and Fig. 4).

M. aeruginosa was not eaten by the adult copepod *E. affinis* in initial laboratory feeding studies. The chlorophyll *a* content of initial animals was $0.07 \pm 0.01 \text{ } \mu\text{g}$ (100 animals^{-1}) and was not different from the $0.05 \pm 0.01 \text{ } \mu\text{g}$ (100 animals^{-1}) of incubated animals. *E. affinis* was observed in the zooplankton samples used for toxicity assays.

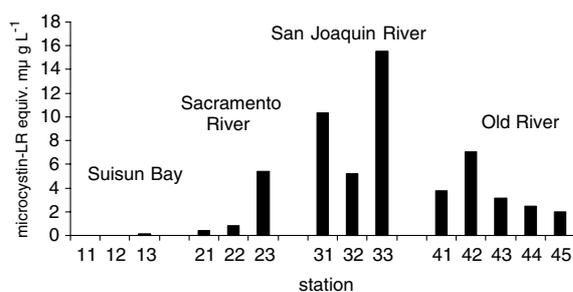

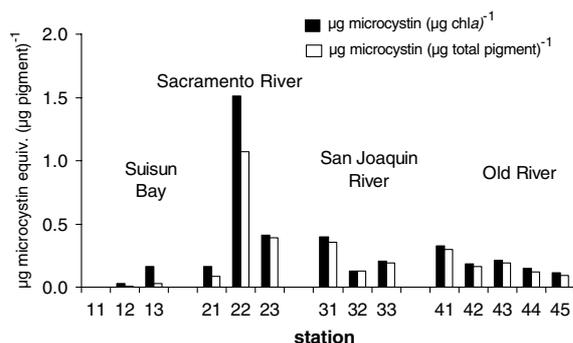

Discussion

Distribution

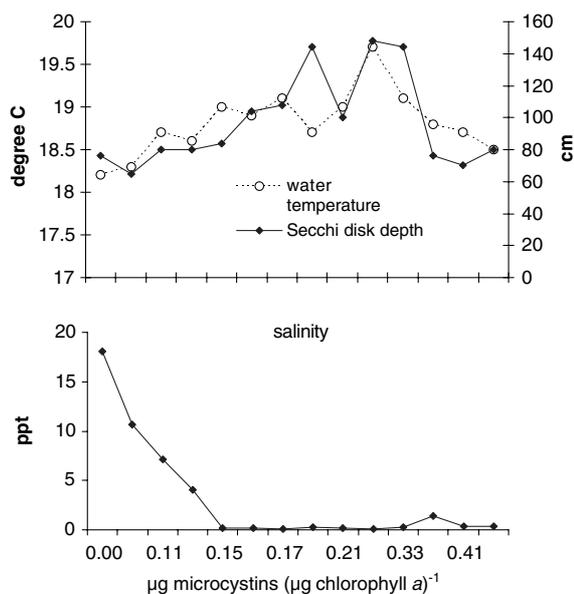

The colonial form of *M. aeruginosa* occurred throughout the NSFE at salinities from 0.1 to 18 ppt and habitats from shallow flooded islands

Table 2. Percent composition of microcystins in selected *Microcystis aeruginosa* tissue samples

to deep shipping channels in the summer and fall of 2003. *M. aeruginosa* is a common cyanobacterium worldwide but its growth is restricted to salinity less than 7 ppt (Robson & Hamilton,

Figure 5. Variation of salinity, water temperature and Secchi disk depth with the microcystins to chlorophyll *a* ratio.

2003). Growth at low salinities may partially explain the higher biomass measured in the Delta portion of the estuary where salinity was less than 5 ppt. The absence of a visible *M. aeruginosa* bloom in the tributaries upstream suggested growth occurred within the Delta. *M. aeruginosa* blooms also developed within the estuary from cells seeded from upstream during high streamflow in the Swan Estuary in Western Australia (Robson & Hamilton, 2003). *Microcystis* spp. develop

readily from vegetative colonies in shallow water sediments (Brunberg & Blomqvist, 2003) and it is probable the bloom developed in the shallow areas of the Delta from either resident vegetative colonies or colonies seeded from upstream and spread downstream into the deep river channels with the wind and tide. Local biomass peaks in shallow water stations such as Brannon Island was probably produced by aggregation by wind and tide (Paerl, 1988).

The *M. aeruginosa* bloom was associated with high light, warm water temperature, shallow water and eutrophic conditions. This agrees with research in which water column stability, nutrient loading, light availability, water temperature, organic matter and habitat for seeding were identified as conditions needed for development and persistence of *M. aeruginosa* blooms (Paerl, 1988; Reynolds et al., 1981). Water temperature in September and October was somewhat below the optimum water temperature of 28 °C (Christian et al., 1986) but higher water temperature occurred earlier in the season when the bloom was visibly larger (unpublished data, California Department of Water Resources). Surface irradiance of 2000 $\mu\text{Em}^{-2} \text{s}^{-1}$ and Secchi disk depth of 140 cm indicated light in the water column was above the limiting level of 186 $\mu\text{Em}^{-2} \text{s}^{-1}$ (Christian et al., 1986). Median dissolved inorganic nitrogen and soluble reactive phosphorus concentrations were high and nonlimiting. *M. aeruginosa* is associated with eutrophic conditions and appeared to be more closely associated with the total nitrogen and phosphorus concentrations than the nitrogen to phosphorus ratio (Downing et al., 2001).

The colonial *M. aeruginosa* bloom in NSFE was caused by the geographic expansion of a harmful cyanobacteria bloom into a freshwater and brackish water habitat. The recent geographic expansion of harmful diatom and dinoflagellate algal bloom species through both regional spread and the occurrence of new species are well known for marine habitats (Anderson & Garrison, 1997). Many species introductions have occurred in the San Francisco Estuary since the 1850s (Cohen & Carlton, 1995). The colonial form of *M. aeruginosa* is the first recorded toxic phytoplankton bloom in the northern reach of the estuary. It may also be the first clearly known introduced phyto-

plankton bloom species in the San Francisco Estuary because the genus *Microcystis* was not observed in phytoplankton samples between 1975 and 1982 (Lehman & Smith, 1991). Previous phytoplankton bloom species were identified as cryptogenic, not clearly native or introduced (Cohen & Carlton, 1995). It is unknown if the colonial form of *M. aeruginosa* that appeared in 1999 was merely an aggregation of the single-celled form now present in the estuary or a new strain. *M. aeruginosa* colonies can congregate into larger colonies under stable conditions (O'Brien et al., 2004).

Toxicity

M. aeruginosa was a toxic cyanobacteria strain because it contained hepatotoxic microcystins at all stations. Traces of the neurotoxin anatoxin-a occurred at two stations but are usually not produced by *M. aeruginosa* (Sivonen & Jones, 1999). The trace amount of anatoxin-a at these two stations probably represent the background level in this ecosystem because these stations also contained some of the higher microcystins concentrations. It is unlikely that both the anatoxin-a and microcystins originated in the same cyanobacterium. The presence of both hepatotoxins and anatoxin-a was only reported for a *M. aeruginosa* bloom in Japan in association with the microcystins LR and RR (Park & Watanabe, 1995).

Microcystin toxicity is highly variable but the microcystin-LR found in the *M. aeruginosa* bloom in NSFE is a powerful hepatotoxin associated with both acute and chronic liver damage (Kaya, 1995). The toxicity of the demethyl microcystin-LR in NSFE is unknown. Microcystins are associated with toxicity to birds and fish and are suspected as a cause of human cancer in China and Australia (Carmichael, 1995; Kaya, 1995). The bloom probably originated from a single population of a microcystin-LR producer that spread throughout the region with the tide and wind because microcystins samples had a similar percent microcystin composition.

Acute *in situ* microcystins toxicity was probably low within the >75 μm cell diameter size fraction for humans and aquatic organisms. Total microcystins concentration in NSFE was well below the Australian and Canadian suggested water quality

standard for humans of 0.5–1 $\mu\text{g l}^{-1}$ (Carmichael, 1995) and the World Health Organization advisory level of 1 $\mu\text{g l}^{-1}$ (World Health Organization, 1998). It was also below the lower limit of the 48 h LC_{50} of 450 $\mu\text{g l}^{-1}$ for zooplankton (Hanazato, 1995). However, the *in situ* microcystins concentrations were probably conservative estimates of the bloom toxicity because net tows can underestimate the microcystins content by as much as 10-fold (J. Makarewicz, unpublished observations). This is probably a combination of cells passing through the net and the effect of the frontal boundary causing an overestimate of the amount of water that actually passed through the net. *In situ* toxicity may have been higher at locations where high water residence time, wind, channel morphology and tide aggregated biomass (Paerl, 1988). This was supported by microcystins concentration in concentrated net samples that were orders of magnitude higher than the suggested water quality advisory levels. Toxicity may also be higher earlier in the season when the bloom appears to have larger biomass (S. Waller, personal communication).

A variable microcystins to chlorophyll *a* ratio indicated chlorophyll *a* was not a reliable indicator of microcystin toxicity. The ratios of microcystins to chlorophyll *a* concentration calculated for Suisun Bay and the San Joaquin and Old rivers were within the range of 0.1–0.4 μg microcystins (μg chlorophyll *a*)⁻¹ typically measured for *Microcystis* spp. (Sivonen & Jones, 1999). The high μg microcystins (μg chlorophyll *a*)⁻¹ ratio of 1.5 measured at station 22 may be a function of the unique environmental conditions at this station where freshwater and brackish water converge. Toxicity varies with environmental conditions and was highest at intermediate water temperature and light intensity in culture experiments (van der Westhuizen & Eloff, 1985). The highest toxicity in this study occurred at relatively low water temperature, water transparency and salinity and contrasted with the lowest toxicity that occurred at relatively low water temperature and water transparency but high salinity.

Food web impact

Microcystins entered the base of the food web and were measured in both total zooplankton and

clam tissue. The maximum microcystins concentration of 3.5 μg (g dry wt)⁻¹ in zooplankton tissue was low compared with the 75–1387 μg (g dry wt)⁻¹ measured for zooplankton in Lake Kasumigaura (Watanabe et al., 1992). The direct toxicity of *M. aeruginosa* to zooplankton is reduced because it comprises only a small percentage of the zooplankton diet (Sellner et al., 1993). A combination of mechanical interference and feeding selectivity limits its use by zooplankton as a food source (Hanazato, 1995). The limited use of *M. aeruginosa* at the base of the food web in NSFE was suggested by initial laboratory feedings studies for the adult copepod *E. affinis*, but use varies by species, developmental stage, total food availability and structural form of the cyanobacteria (e.g., colonial) (DeMott et al., 1991; Reinikainen et al., 1994; Ghadouani et al., 2004). Even low microcystins concentration at the base of the food web poses a threat to the upper food web because microcystins may bioaccumulate. Tissue of the cladocera *Bosmina* spp. contained microcystins concentration that was 202% higher than in the co-occurring algal tissue (Park & Watanabe, 1995).

The impact of *M. aeruginosa* on the quantity and quality of phytoplankton biomass available to the food web may be a greater threat to the NSFE food web than toxicity. Total phytoplankton biomass is low at the base of the food web in NSFE compared with other estuaries because high turbidity limits phytoplankton growth (Jassby et al., 2002). *M. aeruginosa* blooms can reduce the growth of other phytoplankton because their surface habit limits light transmission into the water column and allows them to out compete other phytoplankton that cannot tolerate high light and water temperatures at the surface (Robarts & Zohary, 1992). Dissolved microcystins associated with the bloom may also inhibit consumption of the available desirable phytoplankton food by zooplankton (DeMott et al., 1991).

Both the quantity and quality of phytoplankton biomass appear to be important for the NSFE food web because they were correlated with long-term changes in zooplankton and *Neomysis mercedis* carbon (Lehman, 1992, 2004) and laboratory growth studies suggested local *Daphnia* grew best on phytoplankton carbon (Mueller-Solger et al., 2002). The loss of phytoplankton

food resources due to the *M. aeruginosa* bloom would add an additional impact to the phytoplankton biomass in the estuary already reduced by grazing of the clam *Potamocorbula amurensis* that was introduced into the estuary in 1987 (Jasby et al., 2002). Fish in the estuary partially adjusted to this loss of phytoplankton biomass by shifting their diet, but these shifts were not sufficient to prevent the decline in many fish species (Bennett & Moyle, 1996; Feyrer et al., 2003).

Beneficial use impact

The *M. aeruginosa* bloom is a potential threat to beneficial use in NSFE. NSFE provides agricultural and drinking water for local and upstream users. High microcystins concentration occurred in river channels used to divert water into storage reservoirs for the State Water Project and Federal Central Valley Project that supply water throughout California. Diversion of water into these reservoirs may also provide the seed needed to spread *M. aeruginosa* blooms and associated taste and odor problems into drinking water supplies. NSFE is also economically important because of its recreational use. *M. aeruginosa* blooms impact recreation through direct contact and ingestion that can cause skin and eye irritation, hay fever symptoms, dizziness, fatigue and stomach upset (Carmichael, 1995). High exposure water sports in the region include swimming, sail boarding, water skiing and wading. High microcystins concentration was measured at Brannon Island, a popular swimming beach. Sport fishing is also an important economic resource and could be impacted because of the health risk associated with ingestion of concentrated microcystins in animal tissue caused by bioaccumulation (Magalhaes et al., 2003). Wind-concentrated scums often contain microcystins concentrations that are toxic to animals and livestock, an important issue in this agricultural region. In addition, high biomass produced by blooms and the associated decomposition could eventually impact fishery production through its influence on dissolved oxygen concentration. Upstream migration of the threatened species Chinook salmon was blocked by low dissolved oxygen concentration in the San Joaquin River (Hallock et al., 1970) and low dissolved oxygen

concentration adversely impacts the health of aquatic organisms (Breitburg, 2002). High biomass can also enhance trihalomethane production, a cancer causing substance associated with chlorination of drinking water containing organic matter and an important concern in NSFE.

Because of its impact on so many beneficial uses, a regular monitoring will be needed to determine the yearly rate of expansion and toxicity of *M. aeruginosa* and the environmental factors that affect its development. The presence of microcystins in the food web suggested more information is needed on the presence of these toxins in the food web, potential pathways among trophic levels and how these change over time. Such information will be needed to assess the magnitude of the impact of *M. aeruginosa* on beneficial use in the estuary and to assess the need for a long-term management plan to control its development and toxicity.

Conclusion

This paper documents the first occurrence of a harmful algal bloom of the colonial form of *M. aeruginosa* in San Francisco Estuary. Initial surveys conducted in 2003 indicated this bloom occurred throughout the freshwater to brackish water regions of the estuary and contained hepatotoxic microcystins at all stations sampled. Microcystins were characterized by demethyl microcystin-LR followed by microcystin-LR. *M. aeruginosa* may also be the first known introduced phytoplankton species to the estuary.

The toxicity and widespread distribution of *M. aeruginosa* in NSFE demonstrated the potential of this organism to negatively impact many beneficial uses in NSFE and suggested that an active and long-term monitoring program is needed to assess the potential long-term human and ecological impacts.

Acknowledgements

This study was funded by the NOAA Coastal Ocean Program (COP) in partnership with the National Office for Marine Biotoxins and Harmful Algal Blooms at Woods Hole Oceanographic

Institution and the COP Monitoring and Event Response for Harmful Algal Blooms (MERHAB) program, the California Department of Water Resources and U.S. Bureau of Reclamation as a part of the San Francisco Bay-Delta Interagency Ecological Program. M. Satachwell at the State University of New York provided the protein phosphatase assays. E. Santos and L. Brenn assisted with monitoring.

Abstract A bloom of the cyanobacteria *Microcystis aeruginosa* was sampled over the summer and fall in order to determine if the spatial and temporal patterns in cell density, chlorophyll *a* (chl *a*) concentration, total microcystins concentration, and percent microcystins composition varied with environmental conditions in San Francisco Estuary. It was hypothesized that the seasonal variation in *Microcystis* cell density and microcystin concentration was ecologically important because it could influence the transfer of toxic microcystins into the aquatic food web. Sampling for *Microcystis* cell density, chl *a* concentration, total microcystins concentration and a suite of environmental conditions was conducted biweekly at nine stations throughout the freshwater tidal and brackish water regions of the estuary between July and November 2004. Total microcystins in zooplankton and clam tissue was also sampled in August and October. *Microcystis* cell density, chl *a* concentration and total microcystins concentration varied by an order of magnitude and peaked during August and

September when P_m^B and α^B were high. Low stream-flow and high water temperature were strongly correlated with the seasonal variation of *Microcystis* cell density, total microcystins concentration (cell^{-1}) and total microcystins concentration (chl *a*) $^{-1}$ in canonical correlation analyses. Nutrient concentrations and ratios were of secondary importance in the analysis and may be of lesser importance to seasonal variation of the bloom in this nutrient rich estuary. The seasonal variation of *Microcystis* density and biomass was potentially important for the structure and function of the estuarine aquatic food web, because total microcystins concentration was high at the base of the food web in mesozooplankton, amphipod, clam, and worm tissue during the peak of the bloom.

Introduction

Microcystis aeruginosa (*Microcystis*) is a common freshwater cyanobacterium in freshwater lakes and reservoirs worldwide (Federal Environmental Agency, 2005). It also occurs in rivers that form estuaries including the Potomac River and the Neuse River in the USA, the Swan River in Australia and the Guadiana River in Spain and Portugal (Sellner et al., 1988; Pearl, 1988; Rocha et al., 2002; Orr et al., 2004).

Microcystis is considered a cyanobacterial harmful algal bloom (CHAB) species because it produces surface scums that impede recreation sports, reduce aesthetics, lower dissolved oxygen concentration and cause taste and odor problems in drinking water (Carmichael, 1995). *Microcystis* also produces toxic microcystins that are powerful hepatotoxins associated with liver cancer and tumors in humans and wildlife (Carmichael, 1995).

The toxicity of *Microcystis* blooms negatively impact phytoplankton, zooplankton, and fish production directly or indirectly through the transfer or accumulation of toxins in the food web (Kotak et al., 1996; Ibelings et al., 2005; Sedmak & Elerseck, 2005; Malbrouck & Kestemont, 2006). *Microcystis* also affects aquatic community structure and function by impacts on feeding success or food quality for zooplankton and fish (Rohrlack et al., 2005; Malbrouck & Kestemont, 2006). The abundance of cyanobacteria further affects total carbon production by causing a shift from large to small zooplankton species (Fulton & Pearl, 1987; Smith & Gilbert, 1995).

Microcystis blooms vary over the summer and fall in response to environmental factors that influence bloom initiation and those that sustain bloom growth. Since *Microcystis* does not contain heterocysts that produce nitrate from atmospheric nitrogen, both high nitrogen, and phosphorus are needed for blooms to develop (Pearl et al., 2001). Bloom initiation requires water temperature above 20°C (Jacoby et al., 2000), but accumulation of high biomass, requires long residence time for this slow growing species (Reynolds, 1997). Blooms also develop faster in vertically stable environments that allow the buoyant *Microcystis* colonies to rise to the surface of the water column where they out compete other phytoplankton for light (Huisman et al., 2004). Other factors such as high pH and turbidity or low carbon dioxide concentration enhance growth of *Microcystis* over other phytoplankton once the bloom is established, but are not required for bloom initiation or growth (Shapiro, 1990). Most of the information on the importance of environmental factors for *Microcystis* bloom development and persistence is obtained from freshwater lakes and reservoirs, less is known about the relative importance of environmental factors in estuaries, particularly nutrient-rich estuaries like San Francisco Estuary (SFE).

The cause of *Microcystis* blooms and their potential impact on estuarine productivity is an important concern for SFE where a bloom of *Microcystis* first appeared in 1999 (Lehman et al., 2005). Little is known about the seasonal variation of *Microcystis* cell density, biomass and toxic microcystin concentration, the environmental factors that affect the seasonal variation of the bloom or its impact on the structure and function of the estuarine food web. Data from a single sampling day in October 2003 indicated *Microcystis* was widely distributed across the freshwater to brackish water reaches of the estuary and contained the hepatotoxic microcystin-LR (Lehman et al., 2005). The bloom was associated with high and non-limiting nitrogen and phosphorus concentration, high water temperature and high water transparency but values from this single sampling day were not sufficient to assess the importance of these variables. The presence of total microcystins in zooplankton and clam tissue also suggested the toxins in the bloom might impact the aquatic food web.

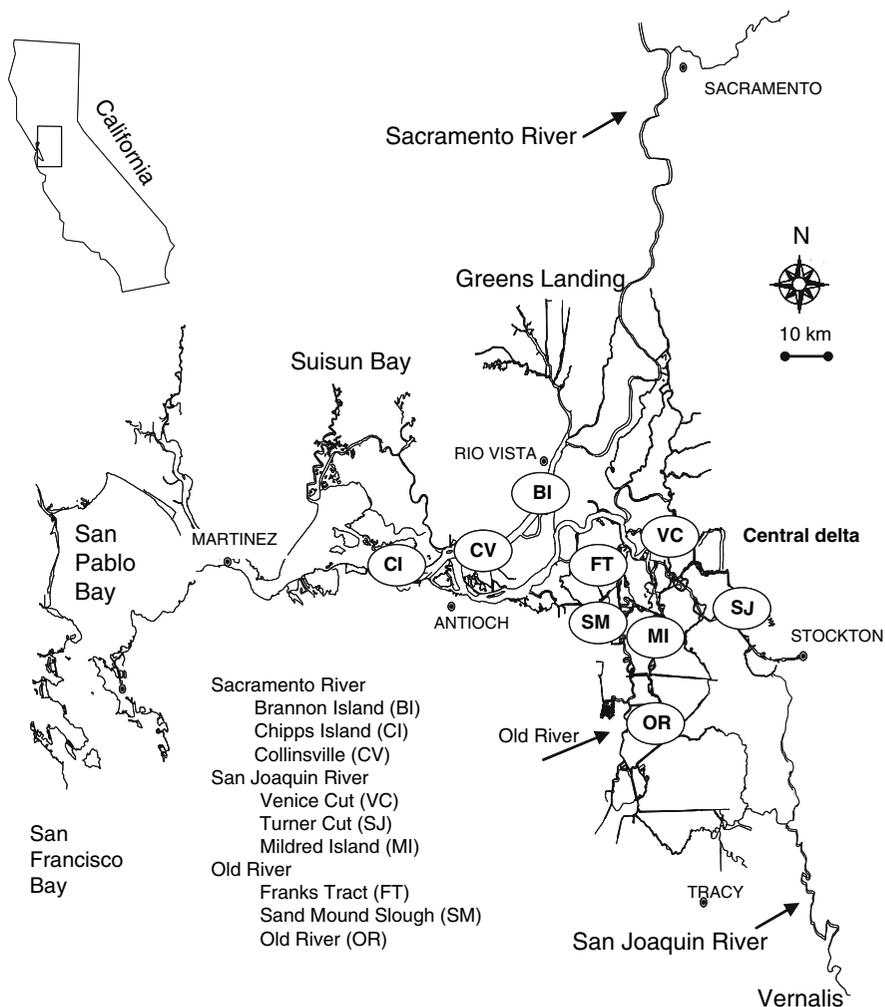

The purpose of this study was to quantify the seasonal variation of *Microcystis* cell density, chlorophyll *a* (chl *a*) concentration, microcystins concentration and the presence of microcystins in the tissues of lower aquatic food web organisms and to determine how these variables are influenced by environmental conditions in SFE. Understanding the influence of environmental conditions on the seasonal variation of the *Microcystis* bloom and its associated microcystins concentration is potentially important for management of fishery production in SFE, where the food web is dependent on phytoplankton and zooplankton production and characterized by a long-term decrease in fish, zooplankton and diatom carbon (Lehman, 2004; Sommer et al., 2007).

Materials and methods

Study area

SFE consists of an inland delta that flows into a chain of downstream marine bays—Suisun, San Pablo and San Francisco—and creates one of the largest estuaries on the west coast of North America (Fig. 1). The inland delta formed by the Sacramento River (SAC) on the north and the San Joaquin River (SJR)

Fig. 1 Map of San Francisco Estuary showing location of sampling stations

on the south contains 200 km² of waterways. SAC is the largest of the rivers with an average discharge of 4795 m³ s⁻¹ compared with 400 m³ s⁻¹ for SJR over the July through October period of this study. Other rivers influence streamflow in the delta including the Mokelumne (MOKE) and Cosumnes (CSR) Rivers with average discharge of 21 m³ s⁻¹ and 6 m³ s⁻¹, respectively. An important feature of the delta is the large amount of water removed for agriculture that causes average reverse streamflow of 1578 m³ s⁻¹ in Old River (ODR) and 1339 m³ s⁻¹ in SJR during August and September (<http://www.waterdata.usgs.gov/nwis>). Depth varies in the delta from a few meters in the flooded islands in the center of the delta to 13 m in the main river channels. Tides in the delta reach 2 m in height with tidal velocities up to 30 cm s⁻¹ and tidal excursions of 10 km.

Field and laboratory sampling

Chl *a* concentration, *Microcystis* cell density and microcystin (total and individual) concentration were sampled biweekly between July 13 and November 3, 2004 at nine stations throughout the freshwater to brackish water reaches of SFE. Selected stations represented different habitat types or beneficial use including recreational swimming (BI), shallow water habitat (MI and FT), deep river channel (CV, VC and SM), native fish habitat (SJ and CI) and agricultural and drinking water supply (OR; Fig. 1). *Microcystis* colonies were sampled by horizontal surface tows of a 0.72 m diameter plankton net fitted with a 75- μ m mesh screen (Lehman et al., 2005). Use of a smaller mesh net (40 μ m) was not possible because the net became clogged with heavy sediment. Water

temperature, specific conductance, pH, dissolved oxygen, and turbidity were also measured at each station using a Yellow Springs Instrument (YSI) 6600 sonde. Depth of the euphotic zone was estimated from Secchi disk depth. Photosynthetically active surface irradiance (PAR) was measured at 15 min intervals in Langleys at Antioch, CA using an Eppley phyroheliumeter (<http://www.iep.water.ca.gov>). Langleys were converted to mole quanta using linear correlation with LiCOR quantum sensor values ($r^2 = 0.91$; $P < 0.01$).

Surface water samples were collected by van Dorn water sampler and immediately stored at 4°C. Algal biomass was filtered within 2 h onto Millipore APFF glass fiber filters (0.7 µm pore diameter). Filters for microcystins analysis were folded, wrapped in aluminum foil and frozen at -80°C until analysis. Filters for chl *a* (corrected for phaeophytin) and phaeophytin analysis were treated with 1 ml of saturated magnesium carbonate solution as a preservative and frozen at -14°C until analysis (method 10200H, APHA et al., 1998). Phytoplankton for identification and enumeration were preserved and stained with Lugol's iodine solution and species were counted at 700X using the inverted microscope technique (Utermöhl, 1958). Sample replication was 10%.

Water samples for dissolved ammonium, nitrate-plus-nitrite, soluble reactive phosphorus, and silicate concentration were filtered through 0.45 µm pore size Millipore HATF04700 nucleopore filters. Filtered samples plus raw water samples for total phosphorus were stored at -14°C until analysis by colorimetric techniques (US EPA, 1983; USGS, 1985). Total suspended solids concentration was determined by standard methods (APHA et al., 1998). Daily average streamflow, air temperature, and water temperature were obtained from hourly data collected by the Interagency Ecological Program (<http://www.iep.water.ca.gov>).

Net primary productivity and community respiration (phytoplankton and bacteria) were measured for a single station each sampling day by 4–6 h incubations at 0.075 m depth near Antioch, CA (Fig. 1) using the dissolved oxygen light and dark bottle incubation technique (Vollenweider, 1974). Values obtained from incubating bottles in a light gradient were used to compute the photosynthetic capacity from the chl *a* specific light saturated rate of photosynthesis (P_m^B , mg C

(mg chl *a*)⁻¹ h⁻¹), the photosynthetic efficiency from the chl *a* specific initial slope (α^B ; mg C (mg chl *a*)⁻¹ (mole quanta m⁻²)⁻¹) and the photoinhibition parameter from the chl *a* specific negative slope of the P-I curve above light saturation (β^B , mg C (mg chl *a*)⁻¹ (mole quanta m⁻²)⁻¹; Lehman et al., 2007). These parameters were used to compute integrated gross (GP_{ez} , mg C m⁻² h⁻¹) and areal (GP_{ez}) primary productivity of the euphotic zone.

Zooplankton including mesozooplankton, amphipods, worms, and jellyfish were sampled at CV, SM, SJ, and MI by horizontal tows of a 0.7 m diameter plankton net fitted with a 150 µm mesh. Zooplankton tissue was kept at 4°C and separated by pipette from *Microcystis* in the water sample using a dissecting microscope within 48 h of sampling. The final zooplankton tissue sample was rinsed in distilled water and frozen at -80°C until analysis. Clams were collected using a ponar dredge. The muscle tissue was removed from the shell, rinsed in distilled water and frozen at -80°C until analysis.

Microcystin analysis

Filters and animal tissue for microcystin analysis were extracted and assessed for total microcystins using the protein phosphate inhibition assay (PPIA). Samples with high levels of total microcystins were further analyzed by high pressure liquid chromatography (HPLC) to identify the specific microcystins in the sample (Lehman et al., 2005).

Statistical analysis

Statistical analyses included correlation and single and multiple comparisons using analysis of variance. Kruskal-Wallis nonparametric analysis of variance was used when the assumptions of the analysis (normally distributed data and homogeneity of variance) were not met. Canonical correlation analysis was computed using log-transformed values in order to minimize differences in variance produced by differences in absolute size and adjust for nonhomogeneity of variance among variables. All statistical analyses were computed using Statistical Analysis System software (SAS Institute Inc., 2004).

Results

Microcystis spatial and temporal variation

Chl *a* concentration and *Microcystis* cell density in the net tow samples were greatest in SJR (Fig. 2). Average chl *a* concentration was 7-fold greater ($P < 0.05$) in SJR compared with SAC ($P < 0.05$; mean 97 ± 70 , 34 ± 36 , and 14 ± 18 ng l⁻¹ for SJR, ORD and SAC, respectively). Among stations,

chl *a* concentration was greatest ($P < 0.05$) at the shallow flooded island and slow moving river channel stations MI and SJ in SJR and lowest at the fast flowing river channels CI and CV in SAC. *Microcystis* cell density varied in a similar fashion to chl *a* concentration among rivers and was greatest ($P < 0.05$) in SJR followed by ODR and SAC (Fig. 2). Cell densities were low in the net tows and exceeded 20,000 cells ml⁻¹ only three times at MI, two times at SJ and VC in SJR and once at OR and

Fig. 2 Mean and standard deviation (vertical bar) of chlorophyll *a* concentration in the >75 μ m algal size fraction, log *Microcystis* cell density and areal gross primary productivity in the euphotic zone at stations in San Francisco Estuary between July and October 2004

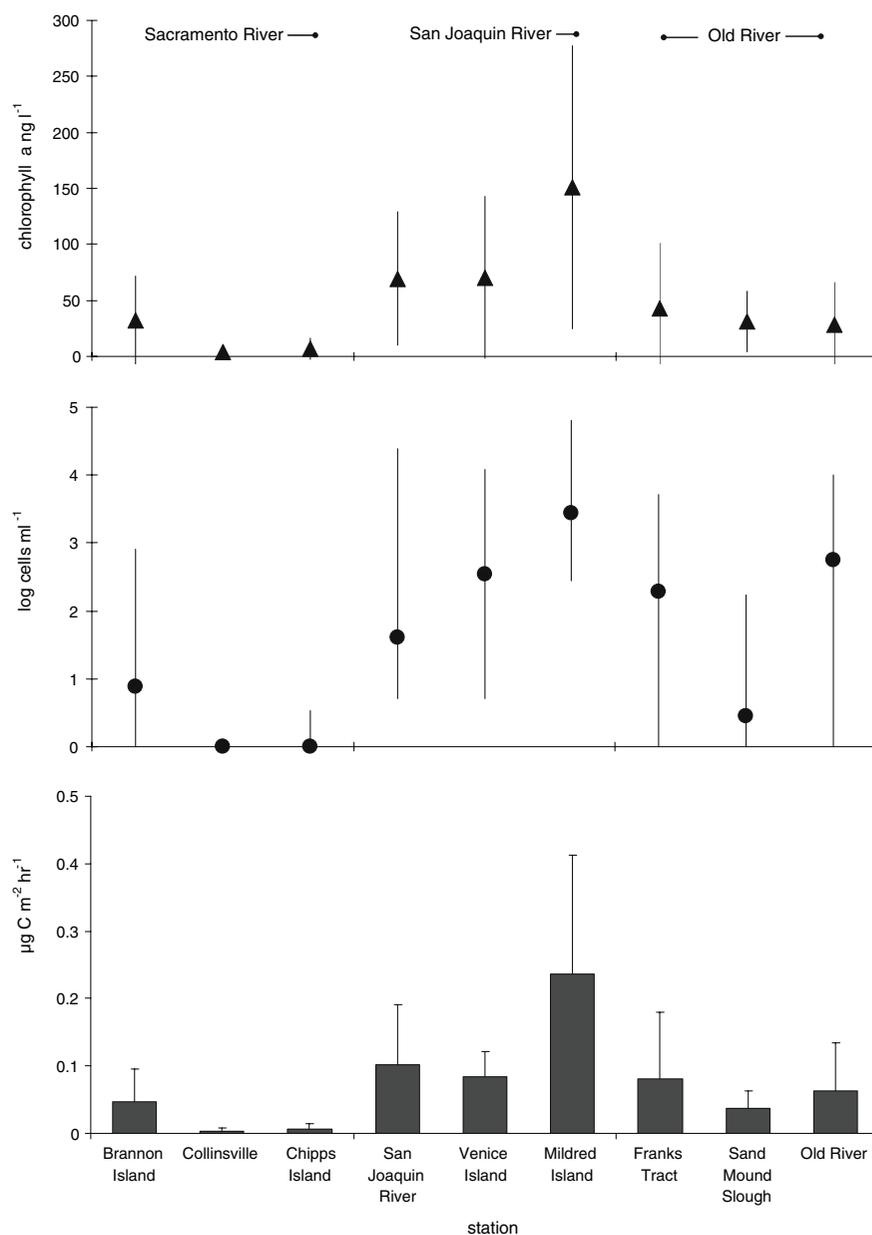

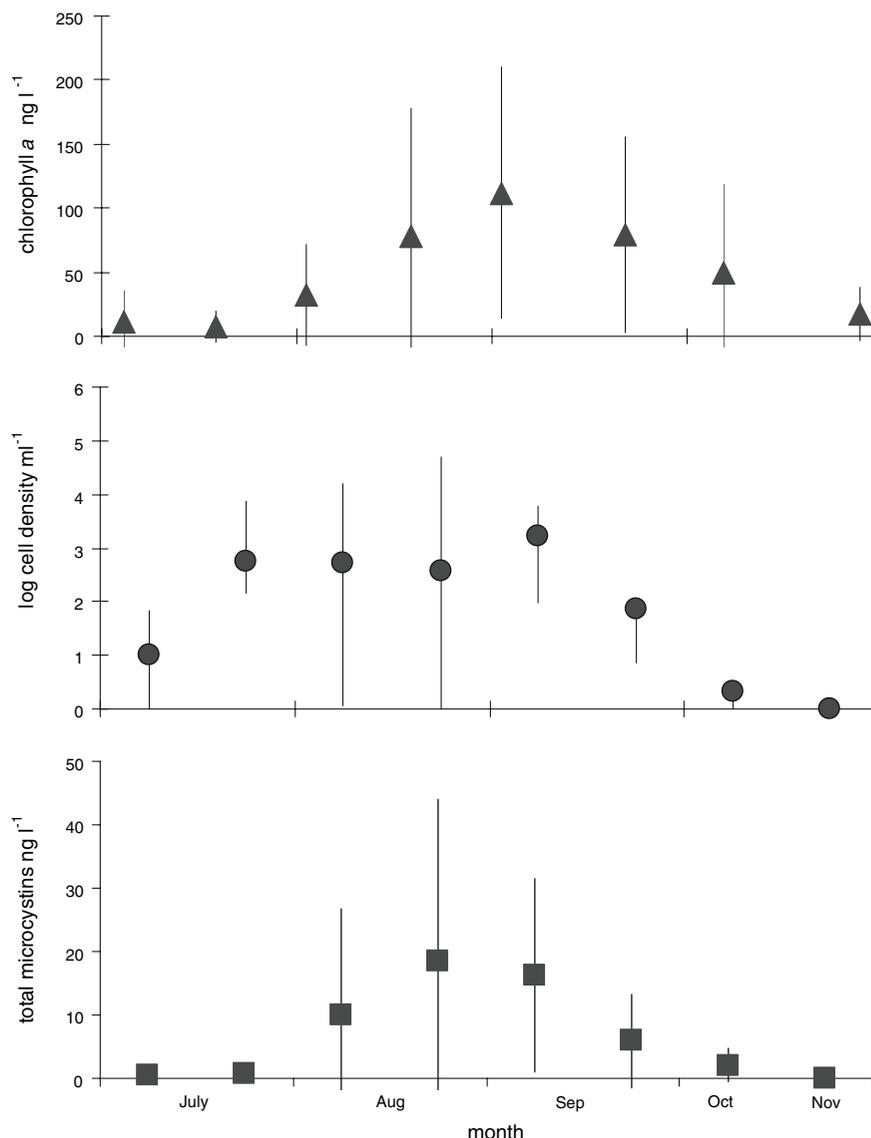

Fig. 3 Mean and standard deviation (vertical bar) of chlorophyll *a* concentration in the >75 μm algal size fraction, log *Microcystis* cell density ml^{-1} and total microcystins concentration among months between July and November 2004 in San Francisco Estuary

FT in ODR. The maximum cell density was $22,480,000 \text{ cells ml}^{-1}$ at MI.

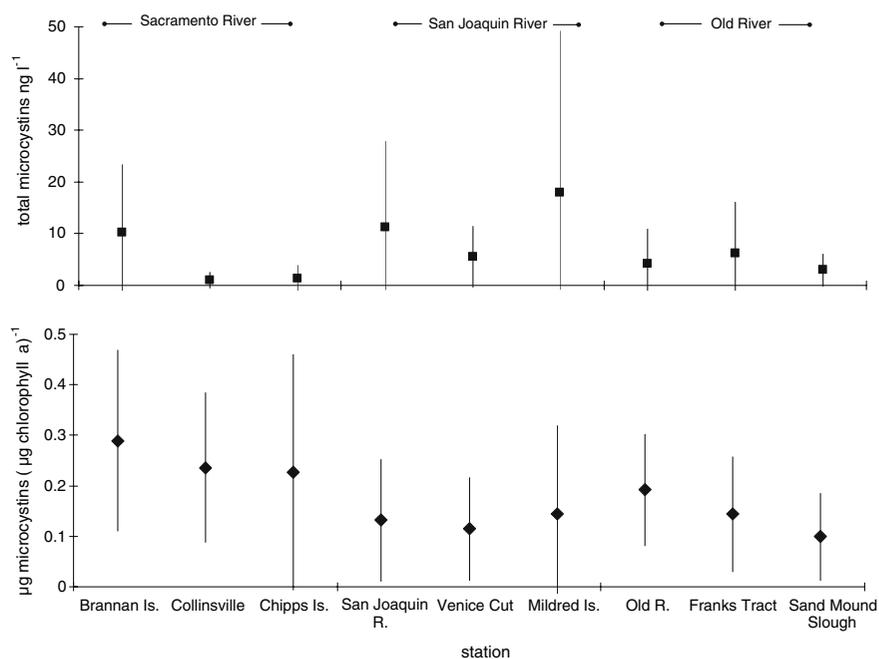

Average chl *a* concentration was 3-fold greater ($P < 0.05$) in August and September than July, October and November ($75 \pm 66 \text{ ng l}^{-1}$ and $22 \pm 29 \text{ ng l}^{-1}$, respectively; Fig. 3). This pattern differed somewhat among rivers, with peak chl *a* concentration occurring earlier ($P < 0.05$) in SJR (August) than SAC (September). Chl *a* concentration was equally high in August and September for ODR. Chl *a* concentration did not vary with *Microcystis* cell density which was consistently high ($P < 0.05$) between late July and early September (Fig. 3). *Microcystis* cell density also did

not have a strong seasonal pattern among rivers except in SJR where cell density was greatest ($P < 0.05$) in August and September.

Areal GP_{ez} was greater ($P < 0.01$) at stations in SJR and ODR than SAC (141 ± 70 , 67 ± 26 and $19 \pm 24 \text{ ng C m}^{-2} \text{ h}^{-1}$, respectively; Fig. 2) but did not differ among rivers when normalized to chl *a* concentration. Areal GP_{ez} and GP_{ez} normalized to chl *a* concentration were also greatest ($P < 0.01$) in September even though respiration ($\text{chl } a)^{-1}$ was highest that month. The seasonal variation of GP_{ez} mirrored changes in the photosynthetic parameters P_{m}^{B} , α^{B} and β^{B} which were high in August and

Table 1 Photosynthetic parameters and respiration normalized to chlorophyll *a* concentration computed from the photosynthesis-irradiance curve and light and dark bottle dissolved oxygen incubations for three stations sampled between August and October, 2004

Date	Sampling station	P_m^B mg C (mg chl <i>a</i>) ⁻¹ hr ⁻¹	α^B mg C (mg chl <i>a</i>) ⁻¹ (mole quanta m ⁻²) ⁻¹	β^B mg C (mg chl <i>a</i>) ⁻¹ (mole quanta m ⁻²) ⁻¹	Respiration mg C (mg chl <i>a</i>) ⁻¹ hr ⁻¹
August 27	Franks Tract	1.15 ± 0.12	2.52 ± 0.15	0.11 ± 0.07	-0.73 ± 0.06
September 9	Old River	2.38 ± 0.33	1.54 ± 0.26	0.11 ± 0.11	-1.76 ± 0.07
September 28	Mildred Island	2.13 ± 0.50	0.88 ± 0.37	–	-0.88 ± 0.03
October 18	Old River	0.36 ± 0.03	0.42 ± 0.10	0.06 ± 0.01	-0.10 ± 0.07

Fig. 4 Mean and standard deviation (vertical bar) of total microcystins concentration and total microcystins (chl *a*)⁻¹ for stations in the San Francisco Estuary between July and November 2004

September (Table 1). However, the seasonal variation in primary productivity and the photosynthetic parameters was large. Areal GP_{cz} varied by two orders of magnitude while P_m^B and α^B varied 6-fold (Fig. 4; Table 1). By comparison, there was a little seasonal variation in β^B which varied by a factor of 2.

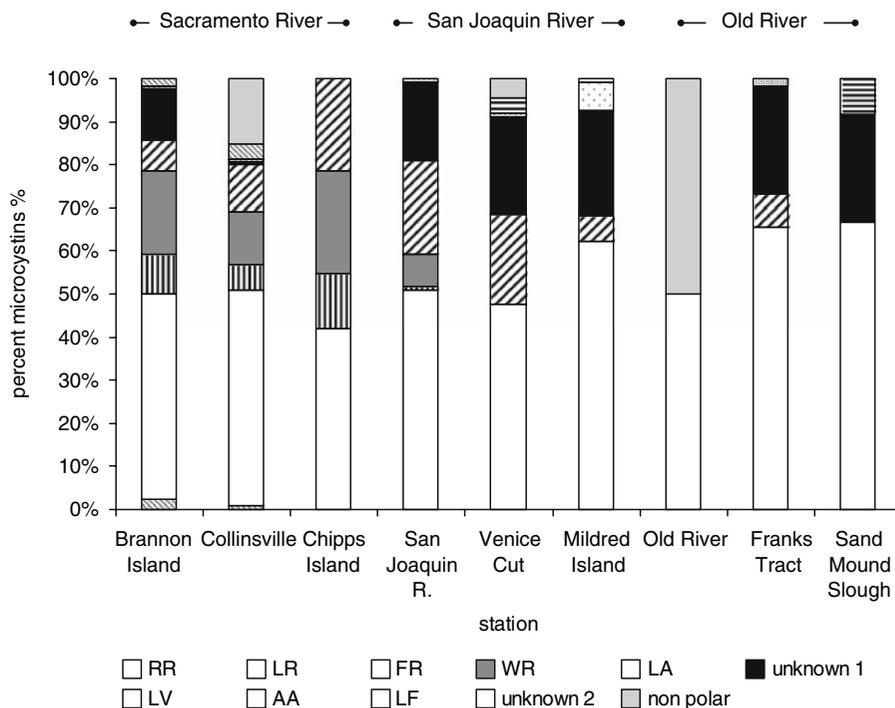

Microcystins concentration

Total microcystins concentration ranged from 0.01 ng l⁻¹ to 81 ng l⁻¹ in net tows and was 2-fold greater ($P < 0.05$) in SJR than the other rivers (Fig. 4). This contrasted with total microcystins concentration (chl *a*)⁻¹ which was 2-fold greater ($P < 0.05$) in SAC compared with SJR. Among

months, average total microcystins concentration was an order of magnitude greater ($P < 0.05$) in August and September for the whole estuary (12.64 ± 17.46 ng l⁻¹ and 0.85 ± 1.56 ng l⁻¹, respectively; Fig. 3), but the monthly pattern differed among rivers. Total microcystins concentration was greatest ($P < 0.05$) in August for SJR and September for SAC and was equally high in August and September for ODR. Total microcystins (chl *a*)⁻¹ did not differ among months for SAC and ODR but was greater ($P < 0.05$) in August for SJR.

A suite of 11 microcystins contributed to the spatial and temporal variation in total microcystins concentration (Fig. 5). Microcystin-LR comprised the greatest percent (54%) of the total microcystins at all stations followed by microcystin-unknown 1 (14%) and microcystin-LA (11%). The percent

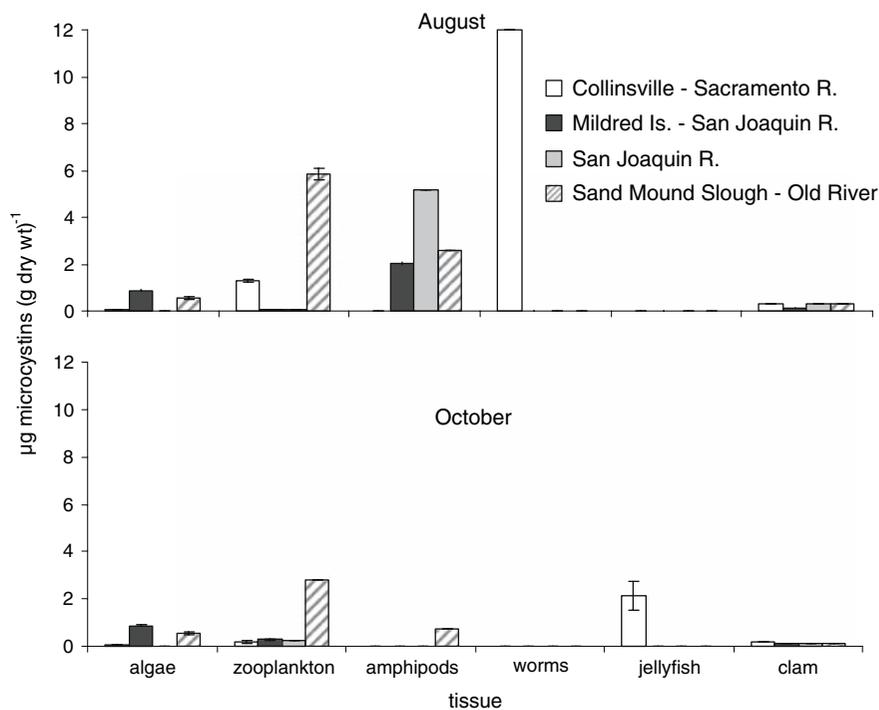

Fig. 5 Average percent composition of microcystin congeners in algal tissue between July and November 2004 in San Francisco Estuary

composition of most microcystins did not differ significantly among rivers, except for microcystin-FR and microcystin-WR which were an order of

magnitude greater ($P < 0.01$) in SAC and microcystin-LA which was at least 2-fold greater ($P < 0.05$) in SJR than ODR.

Fig. 6 Total microcystins concentration in algal and animal tissue at four stations in the San Francisco Estuary during August and October 2004

The microcystin composition was also seasonally variable among rivers. Microcystin-LA was greatest ($P < 0.05$) in July for SJR. Both microcystin-FR and microcystin-WR were greatest ($P < 0.05$) in October for SAC while microcystin-LR was greatest ($P < 0.05$) in October for SJR and ODR. Further, the number of microcystins present at the stations varied over the season with a larger average number ($P < 0.01$) of microcystins occurring between September and November (2.0 ± 1.4) than between July and August (1.3 ± 1.8).

The total microcystins in the tissues of lower food web animals was generally greater in August during the peak of the bloom and lowest in October during the decline of the bloom (Fig. 6). Total microcystins in animal tissue also varied widely among animals and was often higher in worms and amphipods than mesozooplankton (12 ± 0.00 , 2.62 ± 1.88 , 1.34 ± 2.05 μg microcystins (g dry wt.)⁻¹, respectively). However, average total microcystins concentration in mesozooplankton tissue (e.g. *Eurytemora affinis* and *Pseudodiaptomus forbesii*) was still 3–6 fold greater than in the algae (*Microcystis* and surface algae) and clam tissue (0.50 ± 0.37 and 0.21 ± 0.10 μg microcystins (g dry wt.)⁻¹, respectively). Among rivers, total microcystins concentration in mesozooplankton tissue appeared to be greater in ODR than SAC and SJR (5.8 ± 1.70 , $0.18 \pm .65$, 0.15 ± 11 μg microcystins (g dry wt.)⁻¹, respectively). A more quantitative statistical comparison of the spatial and

temporal variation in total microcystins content in animal tissue was precluded by small sample size; two samples per animal type per station.

Environmental factors

Chl *a* concentration and *Microcystis* cell density varied with physical and chemical conditions among rivers. The greatest chl *a* concentration and cell density occurred in SJR which had the lowest chloride, low total suspended solids and soluble reactive phosphorus concentration and high nitrate concentration (Table 2). The second highest chl *a* concentration and cell density occurred in ODR which like SJR had low chloride and total suspended solids concentration, but also had relatively low nitrogen and phosphorus concentration and high specific conductance. SAC with the greatest total microcystins concentration (chl *a*)⁻¹ had the highest chloride, total suspended solids and dissolved nitrogen and phosphorus concentration and the lowest specific conductance among rivers. These differences in chemical conditions were accompanied by differences in streamflow which was an order of magnitude greater ($P < 0.05$) for SAC than SJR. Water temperature was not significantly different among rivers.

Microcystis growth rate in the euphotic zone also varied with physical and chemical conditions. GP_{ez}

Table 2 Mean and standard deviation of physical and chemical variables measured for the Sacramento, San Joaquin and Old Rivers between July and November 2004

Variable	Sacramento River	San Joaquin River	Old River	Significance at $P < 0.05$ level
Chloride (mg l ⁻¹)	1259.81 ± 1175.95	34.91 ± 21.21	121.54 ± 48.64	1, 2, 3
Specific conductance (μS cm ⁻¹)	4.18 ± 3.72	66.25 ± 126.24	123.92 ± 261.17	1&2, 2&3
Secchi disk depth (cm)	60.67 ± 20.50	129.37 ± 37.66	139.73 ± 26.29	1, 2, 3
Total suspended solids (mg l ⁻¹)	20.60 ± 11.14	3.80 ± 2.06	3.79 ± 1.75	1&2, 1&3
Water temperature (°C)	19.84 ± 2.83	21.03 ± 3.68	20.95 ± 3.52	None
Nitrate (mg l ⁻¹)	0.32 ± 0.07	0.36 ± 0.22	0.19 ± 0.10	1&3, 2&3
Ammonia (mg l ⁻¹)	0.06 ± 0.03	0.05 ± 0.04	0.02 ± 0.02	1, 2, 3
Total phosphorus (mg l ⁻¹)	0.10 ± 0.02	0.08 ± 0.03	0.06 ± 0.01	1, 2, 3
Soluble reactive phosphorus (mg l ⁻¹)	0.08 ± 0.09	0.05 ± 0.01	0.05 ± 0.01	1&2, 1&3
N:P molar ratio	12.19 ± 3.63	15.97 ± 7.49	9.25 ± 4.59	1&3, 2&3
S:N molar ratio	20.76 ± 4.88	24.07 ± 10.59	35.93 ± 13.89	1&3, 2&3

Significant differences between rivers at the $P < 0.05$ level are indicated by a comma

increased with water temperature ($r = 0.56$, $P < 0.01$) and decreased with specific conductance and chloride ($r = -0.49$, $P < 0.01$ and $r = -0.68$, $P < 0.01$, respectively). GP_{ez} was also correlated with streamflow but the direction of the correlation differed among rivers with a positive correlation for SAC ($r = 0.46$, $P < 0.01$) and a negative correlation for SJR ($r = -0.51$, $P < 0.01$). The difference in these correlations may be due to the correlation between streamflow, dissolved salts, and water temperature. Streamflow was positively correlated with water temperature and negatively correlated with specific conductance and chloride ($r = 0.70$, $P < 0.01$; $r = -0.45$, $P < 0.01$; $r = -0.30$, $P < 0.01$, respectively) in SAC. In contrast, streamflow was negatively correlated with water temperature and positively correlated with specific conductance in SJR ($r = -0.74$, $P < 0.01$ and $r = 0.32$, $P < 0.01$). The streamflow pattern also differed between SAC and SJR with consistently low streamflow ($P < 0.05$) in SJR, but a gradual decrease in streamflow ($P < 0.05$) over the bloom season in SAC. GP_{ez} was also negatively correlated with total irradiance in the euphotic zone as suggested by the negative correlation between GP_{ez} and Secchi disk depth ($r = -0.24$, $P < 0.05$). This contrasted with the negative correlation between total suspended solids or dissolved solids and GP_{ez} ($r = -0.35$, $P < 0.01$ and $r = -0.67$, $P < 0.01$, respectively). GP_{ez} was also negatively correlated ($P < 0.05$) with ammonium, nitrate and soluble reactive phosphorus concentration and the N:P ratio. Nutrient concentration (Table 2) remained above limiting values for dissolved inorganic nitrogen, soluble reactive phosphorus and silica of 0.02 mg l^{-1} , 0.002 mg l^{-1} and 0.15 mg l^{-1} , respectively (Jassby, 2005). Average N:P ratios were also less than 16 between July and November and less than 10 during the peak of the bloom in August and September.

Canonical correlation analysis

Microcystis cell density was strongly correlated with streamflow and water temperature in canonical correlation analysis. Eleven water quality and seven streamflow variables that were significantly ($P < 0.05$) correlated with *Microcystis* cell density were included in the canonical correlation analysis

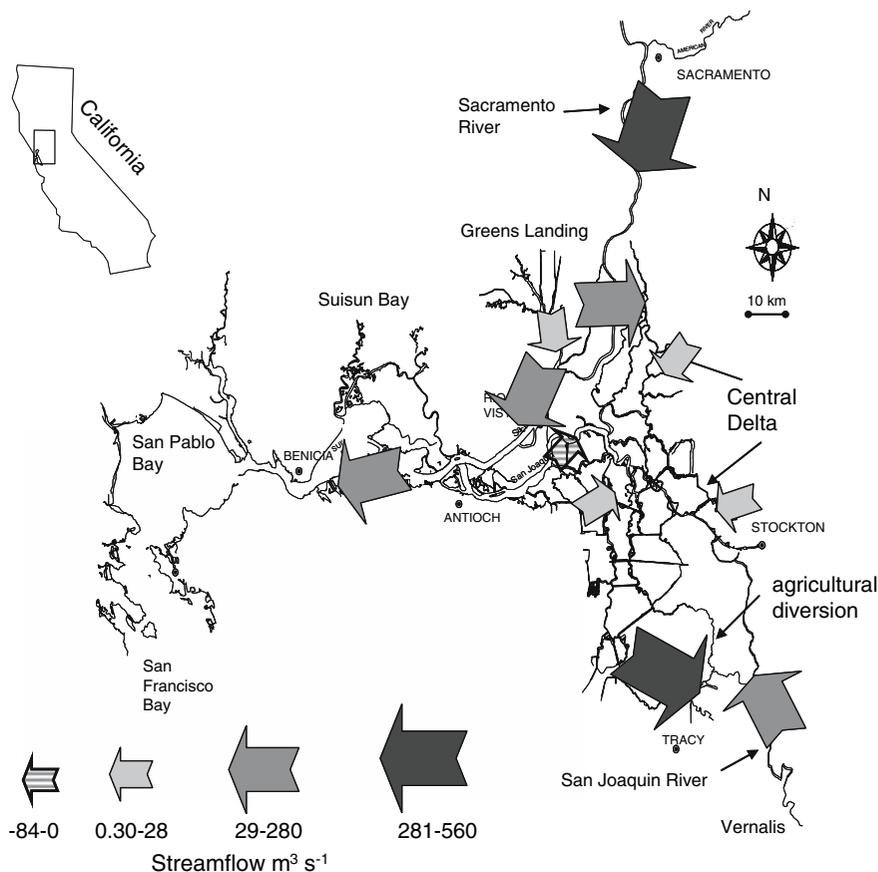

Table 3 Standardized coefficients for variables on the first significant canonical environmental variable computed by canonical correlation analysis to describe the variability of *Microcystis* cell density for data collected between July and November 2004

Variable	Standardized coefficient
<i>Microcystis cell density</i>	
East side streamflow	4.77
Contra Costa Canal pumping	1.31
Water temperature	1.04
Total dissolved solids	0.92
Silica:phosphorus molar ratio	0.48
Old River agricultural diversion	0.46
Total phosphorus	-0.05
Nitrate	-0.12
Ammonia	-0.17
Specific conductance	-0.21
N:P molar ratio	-0.43
Total suspended solids	-0.48
Miscellaneous agricultural diversions	-0.54
Chloride	-0.73
Si:N molar ratio	-0.78
Mokelumne River streamflow	-1.99
Sacramento River streamflow	-2.20
San Joaquin River streamflow	-3.03
Variance explained	59%

(Table 3). The canonical environmental variable created from these variables was significant and described 59% ($P < 0.01$) of the variation in *Microcystis* cell density between July and November. Standardized coefficients for each variable suggested high streamflow in the eastern delta, low streamflow in the SJR, SAC and MOKE, high water diversion near the city of Contra Costa and high water temperature accounted for most of the variability in cell density. However, correlation between individual environmental variables and the canonical environmental variable suggested water temperature ($r = 0.56$, $P < 0.01$), Si:N ratio ($r = -0.52$, $P < 0.01$), ammonium concentration ($r = -0.51$, $P < 0.01$) and streamflow in the MOKE and SJR ($r = -0.50$, $P < 0.01$ and $r = -0.45$, $P < 0.01$, respectively) contributed to the variance described by the canonical environmental variable.

The streamflow variables in the canonical analysis were correlated ($P < 0.05$) with a larger set of measured and computed streamflow variables

Fig. 7 Map of San Francisco Estuary indicating the mean of selected streamflow variables for August and September 2004

available for the estuary including the Sacramento, Cosumnes, Mokelumne, and San Joaquin Rivers flow, east side tributary flow, Contra Costa, State Water Project and Central Valley Project water diversion flow and streamflow past Jersey Point, and Rio Vista (<http://www.iep.water.ca.gov>). When these streamflow variables were averaged over August and September, high *Microcystis* cell density coincided with relatively low streamflow in the central delta, high streamflow in SAC, moderate streamflow in SJR and reversed (upstream arrow) streamflow in the southern delta produced by high diversion flow (Fig. 7).

The correlation between environmental conditions and *Microcystis* cell density varied among rivers. In SJR, *Microcystis* cell density was positively correlated with MOKE streamflow ($r = 0.52$, $P < 0.01$) and negatively correlated with agricultural diversion near the city of Tracy and the N:P ratio ($r = -0.67$, $P < 0.01$; $r = -0.47$, $P < 0.05$). In ODR, *Microcystis* cell density was negatively correlated with

streamflow in the MOKE ($r = -0.52$, $P < 0.01$) and SJR ($r = -0.52$, $P < 0.01$) and positively correlated with water temperature ($r = 0.52$, $P < 0.01$) and Secchi disk depth ($r = 0.42$, $P < 0.05$). In SAC, *Microcystis* cell density was positively correlated with both water temperature ($r = 0.65$, $P < 0.01$) and Secchi disk depth ($r = 0.47$, $P < 0.05$).

Microcystis also occurred within a narrow range of environmental conditions. *Microcystis* cells first appeared when water temperature reached 20°C. *Microcystis* cells were present at total suspended solids concentrations between 100 mg l⁻¹ and 500 mg l⁻¹, specific conductance between 0.1 mS cm⁻¹ and 0.3 mS cm⁻¹, Si:N ratios between 20 and 50 and ammonium concentration between 0.01 mg l⁻¹ and 0.03 mg l⁻¹. *Microcystis* cells also occurred, when streamflow was 28.32–35.40 m³ s⁻¹ in SJR and 0.85–1.13 m³ s⁻¹ in MOKE.

Total microcystins concentration (cell)⁻¹ and total microcystins (chl *a*)⁻¹ were also strongly correlated with streamflow in separate canonical correlation

Table 4 Standardized coefficients for variables on the first significant canonical environmental variable computed by canonical correlation analysis to describe the variability of total microcystins (cell^{-1}) and total microcystins (chlorophyll a) $^{-1}$ for data collected between July and November 2004

	Standardized coefficient
<i>Microcystins (cell)$^{-1}$</i>	
East side streamflow	4.77
Contra Costa Canal pumping	1.31
Water temperature	1.04
Total dissolved solids	0.92
Silica:phosphate molar ratio	0.48
Old River agricultural diversion	0.46
Total phosphorus	-0.05
Nitrate	-0.12
Ammonia	-0.17
Variance explained	59%
<i>Microcystins (chlorophyll a)$^{-1}$</i>	
Specific conductance	-0.21
Nitrogen:phosphate molar ratio	-0.43
Total suspended solids	-0.48
Miscellaneous agricultural diversions	-0.54
Chloride	-0.73
Silica:nitrogen molar ratio	-0.78
Mokelumne River streamflow	-1.99
Sacramento River streamflow	-2.20
San Joaquin River streamflow	-3.03
Variance explained	32%

analyses (Table 4). Nine water quality and streamflow variables that were significantly ($P < 0.05$) correlated with total microcystins concentration (cell^{-1}) produced a significant ($P < 0.01$) canonical environmental variable that described 32% ($P < 0.01$) of the variation in total microcystins (cell^{-1}). Large standardized coefficients within the canonical environmental variable suggested east side streamflow, municipal water diversion at the city of Contra Costa and water temperature were positively correlated with microcystins concentration (cell^{-1}). A somewhat different set of nine water quality and streamflow variables were correlated with total microcystins (chl a) $^{-1}$. These variables described 59% ($P < 0.01$) of the variance in total microcystins concentration (chl a) $^{-1}$. Large standardized coefficients on the significant canonical environmental variable indicated total microcystins concentration (chl a) $^{-1}$ was greater at low streamflow in SJR, SAC, and MOKE.

Environmental constancy

Environmental variability may further influence the seasonal variation of *Microcystis* cell density and total microcystins concentration. *Microcystis* cell density was greater in August and September when the variance in daily streamflow was low ($P < 0.05$; Table 5). The greatest number of microcystins occurred in September and October ($P < 0.01$)

Table 5 Coefficients of variation computed for daily streamflow and water temperature between July and October for locations throughout the estuary

	Coefficient of variation			
	July (%)	August (%)	September (%)	October (%)
<i>Streamflow</i>				
San Joaquin River	9	10	6	36
Sacramento River	5	6	10	18
Mokelumne River	64	16	9	23
East streamflow	8	8	6	35
Agricultural diversion	5	6	10	17
Total agricultural export	12	5	8	21
Significantly different	*			*
<i>Water temperature</i>				
San Joaquin River	2	2	5	9
Sacramento River	2	2	5	9
Significantly different			*	*

Significant difference in variance at the $P < 0.01$ level are indicated by a star (*)

during the decline of the bloom when the variance in daily water temperature was highest ($P < 0.01$). The variance in daily water temperature was influenced by daily air temperature which were correlated at Stockton on the San Joaquin River ($r = 0.50$, $P < 0.01$, $n = 96$) and Rio Vista on the Sacramento River ($r = 0.56$, $P < 0.01$, $n = 97$) between July and November 2004.

Discussion

Distribution

Microcystis occurred throughout SFE from freshwater habitats in SJR and ODR to brackish water habitats in SAC during the summer and fall of 2004. *Microcystis* was probably more widely distributed than the 2004 study suggests because *Microcystis* cells were found as far seaward as Martinez in 2003 (see Fig. 1 for location; Lehman et al., 2005). The consistently higher *Microcystis* cell density in SJR and ODR compared with SAC suggests optimum conditions for *Microcystis* growth occurred in the central delta. It is unlikely that *Microcystis* grew outside of the freshwater habitats in the central delta where salinities are commonly less than 5 ppt (Lehman et al., 2005) because *Microcystis* does not grow at salinities above 7 ppt (Robson & Hamilton, 2003). Instead, *Microcystis* cells were probably transported from the central delta with streamflow, wind and tide to more brackish water habitats downstream where they might survive, but not grow (Pickney et al., 1997). Low cell density in SAC was probably a combination of dilution and cell death at high chloride. High salinity conditions encountered during seaward transport could cause *Microcystis* colonies to lyse, aggregate, and settle to the bottom in Chesapeake Bay (Sellner et al., 1988; Orr et al., 2004).

Microcystis cell density and chl *a* concentration peaked during the summer and fall between August and September in 2004. *Microcystis* cell density and biomass commonly peak during the summer and fall when they occur in freshwater lakes and reservoirs (Watson et al., 1997). *Microcystis* also occurs during the summer and fall in the low salinity regions of some estuaries including the Swan River estuary, Australia, the Los Platos Estuary, Brazil, and the Potomac and Neuse River estuaries in the USA

(Pearl, 1988; Robson & Hamilton 2003; Sellner et al., 1993; Yunes et al., 1996). In SFE, peak *Microcystis* chl *a* concentration and cell density in August and September were associated with high GP_{ez} and characterized by high P_m^B , α^B and low β^B . Warm water temperature during August and September may have contributed to high P_m^B which is correlated with high water temperature for *Microcystis* populations in lakes (Robarts & Zachary 1987). August and September are also characterized by high streamflow in SAC and low streamflow in SJR that promote the warm water temperature, low salinity and low specific conductance conditions associated with high GP_{ez} .

Total microcystins concentration was highest in SJR during August and September when *Microcystis* cell density and chl *a* concentration were high, but was poorly correlated with either. Total microcystins concentration and chl *a* concentration were also poorly correlated for the single-day survey conducted in SFE during October 2003 (Lehman et al., 2005). The lack of a correlation between total microcystins concentration and chl *a* concentration is common because cellular microcystins content is uncoupled from growth rate (Utkilen & Gjølme, 1992). Total microcystins concentration was probably influenced by the relative growth of *Microcystis* strains or “genotypes” that contain different kinds of microcystins as well as the direct influence of environmental conditions on microcystin formation in *Microcystis* cells or “chemotypes” (Ouellette et al., 2006). Significant differences in the microcystins composition in SJR and SAC suggest there were at least two different genotypes or chemotypes contributing to the total microcystins concentration.

The variation of total microcystins concentration suggested the potential toxicity of *Microcystis* was variable. Eleven microcystins varied by eight orders of magnitude during the bloom in SFE. This level of variation might not be unusual because it was similar to the variation measured for *Microcystis* blooms in German lakes and reservoirs where 14 microcystins varied by four orders of magnitude (Fastner et al., 1999). The potential toxicity of the *Microcystis* bloom in SFE was strongly influenced by the presence of the hepatotoxic microcystin-LR which comprised about 54% of the total microcystins. However, the full toxicity of the bloom depends on the remaining 46% of the microcystins for which a

little is known (Zurawell et al., 2004). It is likely that the potential toxicity of the microcystins in SAC was higher than the other rivers because it had the highest total microcystins ($\text{chl } a$)⁻¹.

Environmental factors

Streamflow was a major factor controlling *Microcystis* cell density in SFE and probably influenced development of the *Microcystis* bloom directly and indirectly through a suite of environmental conditions. Since *Microcystis* has a relatively slow growth rate, long water residence time is needed for biomass to accumulate (Reynolds, 1997). Low streamflow in the central delta region coupled with high GP_{ez} , $\text{P}_{\text{m}}^{\text{B}}$, and α^{B} in August and September probably facilitated accumulation of *Microcystis* cells in SFE. Accumulation rather than growth was supported by the similar GP_{ez} ($\text{chl } a$)⁻¹ among rivers. Flushing rate was also a key factor affecting the seasonal variation of *Microcystis* blooms in the Swan River Estuary and in the Neuse River estuary where *Microcystis* blooms only develop when streamflow is below 13–15 $\text{m}^3 \text{s}^{-1}$ (Christian et al., 1986; Robson & Hamilton, 2003). A streamflow threshold was similarly suggested for SFE where *Microcystis* only occurred when SJR streamflow was 28–32 $\text{m}^3 \text{s}^{-1}$.

Microcystis probably grew well in the shallow-flooded island habitats in the central delta region of SFE where low streamflow helps to keep vertical mixing low (Jacoby et al., 2000). Low vertical mixing enables *Microcystis* colonies to float to the surface of the water column where they out compete other phytoplankton for light (Huisman et al., 2004). Such an adaptation was probably important in SFE, where phytoplankton growth is light limited due to high suspended sediment concentration (Jassby et al., 2002) and may partially explain the negative correlation between *Microcystis* cell density and Secchi disk depth. Low vertical mixing in the central delta region may also enhance phytoplankton metabolic activity and cell viability which are reduced at high mixing rates (Huisman et al., 2004; Regel et al., 2004). Low vertical mixing in the central delta was suggested by abundant large 2–3 cm wide colonies in MI, a shallow-flooded island in the center of the delta and small 1-cm wide colonies in the middle of the fast

flowing and turbulent river channels where *Microcystis* cell density was low (Lehman, personal observation). Large colonies were shown to rapidly break apart under turbulent conditions in laboratory tests (O'Brien et al. 2004).

Microcystis cell density was also positively correlated with water temperature in SFE. *Microcystis* growth begins in early summer, when water temperature above 20°C stimulates esterase activity in vegetative cells on the surface of the sediment and ceases in the fall when water temperature declines to below 20°C (Latour et al., 2004). Water temperature similarly contributed to the seasonal pattern in *Microcystis* cell density in SFE where *Microcystis* cells only occurred above 20°C. Maximum $\text{chl } a$ concentration occurred during mid-summer when water temperature reached 25°C, but this may not represent maximum growth rate of *Microcystis* which was higher at 29–32°C in laboratory studies (Robarts & Zohary, 1987). Water temperature probably influenced the spatial and temporal variation in *Microcystis* cell density among rivers because it reached 20°C sooner in SJR and ODR than SAC.

The importance of water temperature for microcystin development was suggested by the large coefficient for water temperature on the canonical environmental variable in canonical correlation analysis for total microcystins (cell)⁻¹. In lab studies, total microcystins concentration varied more with water temperature than irradiance and was highest at 20–24°C (Van der Wethuizen & Eloff, 1985; Wiedner et al., 2003); water temperatures similar to those measured in SFE during mid-summer. Water temperature primarily influences total microcystins concentration through its impact on growth rate, because cellular microcystins are only produced during log-phase growth (Lyck, 2004). The greater total microcystins concentration during mid-summer in SFE may be influenced by the high $\text{P}_{\text{m}}^{\text{B}}$ and α^{B} during this time.

It is possible environmental variability contributed to the seasonal variation in *Microcystis* cell density and the quantity and quality of microcystins in SFE. $\text{Chl } a$ and total microcystins concentration peaked in August and September when the variance in streamflow was low. Low daily variance in streamflow may promote the accumulation of *Microcystis* cells and the growth of relatively few *Microcystis* genotypes. In contrast, the high daily variance of water

temperature in September and October may contribute to the increased number of microcystins in these months through differential growth and survival of *Microcystis* genotypes or chemotypes (Ouellette et al. 2006). Daily water temperature is linked to seasonal changes in air temperature with streamflow dominating water temperature early in the season at high streamflow and air temperature dominating water temperature late in the season at low streamflow. This impact is supported by decadal change in water temperature in SFE that was inversely correlated with streamflow and positively correlated with air temperature in SJR and SAC (Lehman, 2004).

Nutrient concentration was not a driving force for variation of the *Microcystis* bloom in SFE. The high nutrient concentrations in SFE were a necessary condition for initiation of the *Microcystis* bloom because *Microcystis* requires both high nitrogen and phosphorus concentration for growth (Paerl et al., 2001). However, the persistence and variation of the bloom was not nutrient driven because nutrient concentrations were consistently an order of magnitude greater than limiting values throughout the water column in SFE (Jassby 2005). Nutrient ratios are generally important for cyanobacterial bloom formation (Paerl et al., 2001) with *Microcystis* blooms occurring at an N:P ratio <15 (Jacoby et al. 2000). The average N:P ratio of 10 (range 6–10) in August and September was favorable for *Microcystis* growth in SFE. The lesser influence of nutrients on *Microcystis* cell density and total microcystins concentration was supported by the low coefficients for nutrient concentration and nutrient ratios in the canonical correlation analyses.

Food web impact

The spatial and temporal variation of *Microcystis* cells might affect the presence of toxic microcystins in the estuarine food web in SFE. The high concentration of total microcystins in lower food web organisms during the peak of the *Microcystis* bloom suggested there was a direct link between microcystins in algal tissue and microcystins in the tissue of aquatic animals. Microcystins concentration was also high in the tissue of food web animals during the peak of the bloom in central Alberta Lakes, Canada

(Kotak et al., 1996). Microcystins in zooplankton and other lower food web animals can occur from active and passive ingestion of algal tissue, even though *Microcystis* may not be selectively grazed (DeBernardi & Giussani, 1990; DeMott & Moxter, 1991; Sellner et al., 1993).

The greater microcystins concentration in animal than algal tissue suggested microcystins were transferred and perhaps biomagnified through the aquatic food web in SFE. Microcystins were also transferred through food web organisms in the Alberta Lakes, Canada, Lake IJsselmeer, the Netherlands and Lakes Rotoiti and Rotoehu in the Czech Republic (Kotak et al., 1996; Ibelings et al., 2005; Wood et al., 2006). Detritus feeders may be an important transfer agent of microcystins into the SFE food web because total microcystins concentrations were high in amphipod and worm tissue. Detrital grazers were also thought to be the primary pathway for the transfer of microcystins into the food web in Alberta lakes (Kotak et al., 1996). Unexpectedly, clams which fed directly on phytoplankton may not be an important source of microcystins to the food web in SFE. Clam tissue had the lowest total microcystins content among the animals tested in 2004 and low microcystins content compared with zooplankton tissue in 2003 (Lehman et al., 2005). Mollusks could accumulate microcystins, but tissue content is often low due to the rejection of *Microcystis* colonies or rapid depuration of toxins from tissue (Prepas et al. 1997).

The *Microcystis* bloom probably did not cause acute toxicity to aquatic food web organisms in SFE. Total microcystins concentration in zooplankton tissue was below the value of 10–18 $\mu\text{g (g dry wt.)}^{-1}$ associated with acute death in *Daphnia* during laboratory feeding studies (Rohrlack et al., 2005). However, even at low concentrations, *Microcystis* can affect zooplankton community structure and function by sublethal toxicity or non-toxin related factors such as feeding inhibition or providing phytoplankton food of poor quality or low digestibility (DeMott & Mueller-Navarra, 1997; Rohrlack et al., 2005). Further, dissolved microcystins released from lysed *Microcystis* cells at the end of the bloom are toxic and can reduce feeding success for zooplankton (Pietsch et al., 2001). Large zooplankton such as *Daphnia* are sensitive to dissolved microcystins and demonstrate reduced growth and fecundity in

the presence of *Microcystis* (Reinikainen et al., 1999). More information on these potential impacts are needed for SFE.

Management strategies

The worldwide impact of *Microcystis* blooms on ecosystem structure and function and human health through drinking water and recreation suggests the potential need for management of *Microcystis* populations in SFE (White et al., 2005). Because the spatial and temporal variability of *Microcystis* cell density and total microcystins concentration is high in SFE, management might require consideration of physical, chemical, and biological factors at both large and small spatial and temporal scales (Donaghay & Osborn, 1997). Although there are many management strategies for control of *Microcystis* and its toxins (Pearl et al., 2001), regulation of streamflow may be the most important for SFE. High streamflow would prevent accumulation of *Microcystis* biomass in stable backwater sloughs or shallow-flooded islands, where residence time is long and vertical mixing is low. High streamflow would also increase vertical mixing which decreases colony viability and the competitive advantage of *Microcystis* colonies to obtain light by floating on the surface of the water column (Huisman et al., 2004). Streamflow could further be managed to influence water quality conditions such as water temperature and salinity that initiate and sustain bloom biomass and affect microcystins concentration (Jacoby et al. 2000). A decline in the density and biomass of fish, zooplankton, mysid shrimp, and diatoms has left the food web in SFE vulnerable to any adverse impact so that even a small change in the impact of *Microcystis* and its associated toxins on the food web may be important for fishery production (Lehman, 2004; Sommer et al. 2007).

Conclusion

Microcystis and its associated toxin microcystin varied spatially and temporally over the bloom season in SFE. Significant differences in cell density and chl *a* concentration were associated with the *Microcystis* bloom among months, rivers and

stations. Differences in *Microcystis* cell density and total microcystins concentration per cell⁻¹ and microcystins concentration chl *a*⁻¹ were correlated with environmental conditions, particularly streamflow and water temperature. These environmental conditions were correlated with differences in areal growth rate within the euphotic zone and probably driven by high P_m^B and α^B during the peak of the bloom. The variation of the bloom and its associated toxin concentration is potentially important ecologically because total microcystins are present in the tissues of the lower food web animals, mesozooplankton, amphipods, worms, jellyfish and clams. Although the bloom contains hepatotoxic microcystins, the present concentrations are low and probably not acutely toxicity to food web animals. However, the higher concentration of total microcystins in some animals and higher total microcystins concentration in animal than algal tissue suggests biomagnification or accumulation could increase the impact of these toxins on the aquatic community.

Abstract The impact of the toxic cyanobacterium *Microcystis aeruginosa* on estuarine food web production in San Francisco Estuary is unknown. It is hypothesized that *Microcystis* contributed to a recent decline in pelagic organisms directly through its toxicity or indirectly through its impact on the food web after 1999. In order to evaluate this hypothesis, phytoplankton, cyanobacteria, zooplankton, and fish were collected biweekly at stations throughout the estuary in 2005. Concentrations of the tumor-promoting *Microcystis* toxin, microcystin, were measured in water, plankton, zooplankton, and fish by a protein phosphatase inhibition assay, and fish health was assessed by histopathology. *Microcystis* abundance

was elevated in the surface layer of the western and central delta and reached a maximum of 32×10^9 cells l^{-1} at Old River in August. Its distribution across the estuary was correlated with a suite of phytoplankton and cyanobacteria species in the surface layer and 1 m depth including *Aphanizomenon* spp., *Aulacoseira granulata*, *Bacillaria paradoxa*, *Rhodomonas* spp., and *Cryptomonas* spp. Shifts in the phytoplankton community composition coincided with a decrease in the percentage of diatom and green algal carbon and increase in the percentage of cryptophyte carbon at 1 m depth. Maximum calanoid and cyclopoid copepod carbon coincided with elevated *Microcystis* abundance, but it was accompanied by a low cladocera to calanoid copepod ratio. Total microcystins were present at all levels of the food web and the greater total microcystins concentration in striped bass than their prey suggested toxins accumulated at higher trophic levels. Histopathology of fish liver tissue suggested the health of two common fish in the estuary, striped bass (*Morone saxatilis*), and Mississippi silversides (*Menidia audens*), was impacted by tumor-promoting substances, particularly at stations where total microcystins concentration was elevated. This study suggests that even at low abundance, *Microcystis* may impact estuarine fishery production through toxic and food web impacts at multiple trophic levels.

Introduction

Microcystis aeruginosa (*Microcystis*) is a cyanobacterium species that can form harmful algal blooms (CHAB) in freshwater water bodies world wide (Chorus, 2005). Its distribution has spread into some estuaries including the Chesapeake Bay, the San Francisco Bay, and the Neuse River in the USA, the Swan River in Australia, and the Guadiana River in Spain and Portugal (Paerl, 1988; Sellner et al., 1988; Rocha et al., 2002; Robson & Hamilton, 2003, 2004; Lehman et al., 2005). *Microcystis* is considered a toxic CHAB because some species contain powerful hepatotoxins called microcystins that initiate cancer and promote tumor formation in the liver of humans and wildlife (Zegura et al., 2003; International Agency for Research on Cancer, 2006; Ibelings & Havens, 2008). It also produces a surface scum that impedes recreation, reduce aesthetics, lower dissolved oxygen concentration, and cause taste and odor problems in drinking water (Paerl et al., 2001). *Microcystis* and other freshwater cyanobacteria blooms are currently a worldwide concern because their frequency and distribution are increasing (Fristachi et al., 2008). Although the potential impact of *Microcystis* blooms on human health is known, its potential impact on the structure and function of aquatic food webs is poorly understood (Ibelings & Havens, 2008).

Microcystis can affect phytoplankton community composition through allelopathy (Legrand et al., 2003). Cyanobacteria produce a large array of metabolites including organic and amino acids, peptides, alkaloids, carbohydrates, and lipopolysaccharides that can affect higher trophic levels (Paerl et al., 2001; Smith et al., 2008). Differential response of phytoplankton and cyanobacteria (plankton) to these allelopathic substances affects plankton community composition and species diversity in laboratory cultures (Sedmak & Kosi, 1998; Suikkanen et al., 2005). In nature, the response of the plankton community is variable and probably depends on environmental conditions (Graneli et al., 2008), but the full impact of *Microcystis* on plankton communities in the field is poorly understood.

Many studies have demonstrated the effect of *Microcystis* or its toxins on zooplankton growth and survival. Microcystins either in zooplankton food or dissolved in the water column affect survival and growth rate of copepods, cladocera, and rotifers (Ghadouani et al., 2006; Federico et al., 2007). Secondary metabolites such as lipopolysaccharides in some non-toxic *Microcystis* strains can also inhibit zooplankton growth (Rohrlack et al., 2001, 2005). The greatest impact of *Microcystis* on natural zooplankton populations may be its poor food quality (Wilson et al., 2006). Low concentrations of polyunsaturated and saturated fatty acids compared with other plankton make *Microcystis* a nutritionally poor quality food (Müller-Navarra et al., 2000). The large diameter of the *Microcystis* colonies also makes them difficult to ingest, may physically clog feeding appendages and increase food rejection rate (Ghadouani et al., 2004). In addition, the presence of *Microcystis* in the water column and associated production of protease inhibitors may inhibit feeding in some zooplankton (Agrawai et al., 2001; Ferrão-Filho et al., 2002). Some or all of these factors may explain field and laboratory research which suggests *Microcystis* alters zooplankton community structure and total biomass by reducing the growth and survival of zooplankton, especially large (>1 mm) cladocerans like *Daphnia* (Ghadouani et al. 2006; Chen et al., 2007). The response of the zooplankton community to *Microcystis* is complex and depends on a variety of factors including season, length of exposure, and the *Microcystis* strain and how these interact with the fitness of each zooplankton species (Gustafsson & Hansson, 2004; Wilson & Hay, 2007).

At higher trophic levels, *Microcystis* blooms affect fish health through impacts on growth rate, histopathology, and behavior (Malbrouck & Kestemont, 2006). Microcystin enters the fish gut passively during swimming or actively through food intake, and accumulates in fish tissue (De Magalhães et al., 2001). Microcystin slows protein synthesis by inhibiting protein phosphatase 1 and 2A and promotes tumor formation and cancer in fish tissue (Fischer & Dietrich, 2000; van der Oost et al., 2003). Microcystin can increase heart rate and produce osmoregulatory imbalance by stimulating drinking in adults which makes fish more susceptible to toxins in the environment, including microcystin (Best et al., 2001, 2003). Recent research suggests microcystins also cause

oxidative stress in fish by reducing the production of antioxidants and increasing lipid peroxidation in liver, kidney, and gill tissue (Bláha et al. 2004; Prieto et al., 2007). The lipopolysaccharides in *Microcystis* cells further decrease antioxidant formation in fish and may be more toxic than microcystin (Best et al., 2002). At a population level, *Microcystis* causes effects such as mortality and delayed hatching in fish embryos or may simply affect feeding rate (Malbrouck & Kestemont, 2006; Palíková et al., 2007).

Microcystis blooms are a fairly recent occurrence in San Francisco Estuary (SFE), and were first observed in the delta region in 1999 (Lehman et al., 2005). The population level during the summer bloom period is relatively low when compared with many *Microcystis* blooms worldwide which form a dense scum on the surface of the water column (Lehman et al., 2008). It is unknown, if this bloom is still in its initial stage of establishment, or has reached maximum abundance. Recent genetic studies indicate the *Microcystis* strain in SFE is genetically different from known strains (Moisander et al., 2009). However, the coincident appearance of *Microcystis* and a decline in a number of fish and zooplankton species of concern including delta smelt (*Hypomesus transpacificus*), striped bass (*Morone saxatilis*), and threadfin shad (*Dorosoma petenense*) and their calanoid copepod prey *Eurytemora affinis* and *Pseudodiaptomus forbesii* in the freshwater regions of the estuary suggest that there is a link between the fishery decline and the presence of *Microcystis* in the estuary since 2000 (Sommer et al., 2007). Research on *Microcystis* in 2003 and 2004 confirmed the presence of toxic microcystins in plankton and zooplankton in SFE (Lehman et al., 2005, 2008). We hypothesize that *Microcystis* directly or indirectly contributed to the decline in fish and zooplankton species of concern through toxicity or impacts on the food web.

The purpose of this study was to utilize a combination of plankton, zooplankton, and fish community composition, tissue microcystins concentration, and histopathology to determine if *Microcystis* may have influenced the production or health of organisms in the estuarine food web in 2005. Such information is invaluable for developing strategies to manage future estuarine food web resources impacted by this toxic cyanobacterium. It may also assist with developing a more comprehensive understanding of the factors that contributed to the decline in pelagic organisms and

increase in *Microcystis* blooms in SFE since 2000 (Lehman et al., 2005; Sommer et al., 2007).

Materials and methods

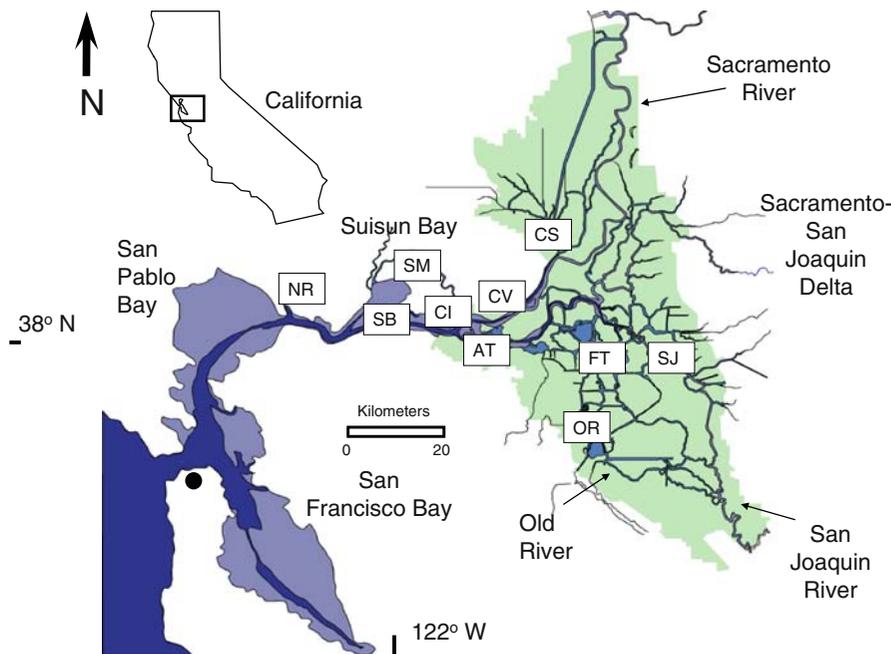

Study area

San Francisco Estuary (SFE) consists of an inland delta that flows into a chain of downstream marine bays—Suisun, San Pablo, and San Francisco—and creates one of the largest estuaries on the west coast of North America (Fig. 1). The Sacramento River on the north and the San Joaquin River on the south converge just east of Suisun Bay to form a delta that contains 200 km² of waterways. The Sacramento River is the largest of the rivers that feed the delta, and has an average discharge of $498 \pm 21 \text{ m}^3 \text{ s}^{-1}$ compared with $70 \pm 7 \text{ m}^3 \text{ s}^{-1}$ for the San Joaquin River over the August and September period of this study. The delta has many kinds of habitats from shallow flooded islands that are 2 m deep to wide and deep river channels that are 13 m deep. Flow in the delta is influenced by tides that reach 2 m in depth, tidal velocities up to 30 cm s^{-1} and tidal excursions of up to 10 km. The delta is largely rural with a population of about 500,000 people within the cities of Sacramento, Stockton, and West Sacramento. Most of the 1,300 km of sloughs and 57 islands in the delta are used for agriculture and wildlife habitat.

Field sampling

Chlorophyll *a* and total microcystins concentration plus a suite of water quality conditions were sampled biweekly at each station between August 1 and September 30, 2005 at 10 stations throughout the freshwater to brackish water reaches of SFE (Fig. 1). Stations were selected that reflected different habitats within the delta including the brackish water habitat in Suisun Bay at Chipps Island (CI) and Middle Ground (SB), saltwater marsh habitat at Montezuma Slough (SM), freshwater habitat in the Sacramento River at Cache Slough (CS), the San Joaquin River at Turner Cut (SJ) and Old River near Ranch del Rio (OR), brackish water habitat in the Sacramento River at Collinsville (CV) and the San Joaquin River at

Fig. 1 Map of San Francisco estuary showing codes for sampling stations for Napa River (NR) at the City of Napa, Suisun Bay at Middle Ground (SB), Suisun Marsh at Montezuma Slough (SM), Chipps Island (CI), Sacramento River at Collinsville (CV) and Cache Slough (CV), Old River at Franks Tract (FT) and Ranch del Rio (OR), and San Joaquin River at Turner Cut (SJ) and Antioch (AT)

Antioch (AT), and flooded island habitat in Old River at Franks Tract (FT). A station was added in the Napa River (NR) outside of the delta which did not have a *Microcystis* bloom for perspective.

Microcystis colonies in the surface layer were sampled by horizontal surface tows of a 0.5 m diameter plankton net with 75 μm mesh netting as described in Lehman et al. (2005). Water samples containing plankton biomass were stored at 4°C and filtered within 2 h onto Millipore APFF glass fiber filters. Filters for microcystins analysis were folded, wrapped in aluminum foil, frozen, and stored at -80°C until laboratory analysis for toxin content. Filters for chlorophyll *a* analysis were preserved with 1 ml of saturated magnesium carbonate solution, immediately frozen and stored at -14°C until analysis for pigment content.

Pigments were extracted from glass fiber filters in 90% acetone and analyzed for chlorophyll *a* (corrected for phaeophytin) and phaeophytin using spectrophotometry (American Public Health Association et al., 1998). Water samples for identification and enumeration of plankton were preserved and stained with Lugol's iodine solution, and phytoplankton were counted at $\times 700$ using an inverted microscope technique (Utermöhl, 1958). This magnification allowed clear identification of plankton cells $>6 \mu\text{m}$ in diameter. Phytoplankton species were identified by taxonomic

descriptions in *Freshwater Algae of North America, Ecology, and Classification* (Wehr & Sheath, 2003) and *Cyanoprokaryota 1, Teil: Chroococcales* (Komárek & Anagnostidis, 2001). *Microcystis aeruginosa* was identified as the only *Microcystis* species in each sample. Plankton cell carbon was calculated from cell volume computed from cell dimensions applied to simple geometrical shapes with correction for the small plasma volume in diatom cells (Menden-Deuer & Lessard, 2000).

Water quality conditions were determined from laboratory analysis of water collected near the surface using a van Dorn bottle sampler. Water samples for chloride, alkalinity, ammonium-N, nitrate-N plus nitrite-N, soluble reactive phosphorus, and silicate concentration were filtered through 0.45 μm pore size Millipore HATF04700 nucleopore filters. Water samples for dissolved organic carbon were filtered through Millipore APFF glass fiber filters. Filtered and raw water samples were either stored at 4°C or -14°C until analysis for nutrients (United States Environmental Protection Agency, 1983; United States Geological Survey, 1985) or dissolved microcystins analysis. Total suspended solids, total and dissolved organic carbon concentration, and alkalinity were determined by standard methods (American Public Health Association et al., 1998). Water temperature, pH, specific conductance, and dissolved oxygen were measured

near the surface using a Yellow Springs Instrument (YSI) 6600 water quality sonde.

Zooplankton were collected at each station by a 3 min diagonal tow of a 0.5 m diameter plankton net fitted with a 150 μm mesh netting. Zooplankton were kept at 4°C and separated by pipette from *Microcystis* in the water sample using a dissecting microscope within 48 h of sampling. Zooplankton tissue was rinsed in distilled water and frozen at -80°C until toxin analysis. Zooplankton for identification and enumeration were dyed and preserved in 10% buffered formalin with rose bengal dye. Species identification and enumeration were conducted using a dissecting scope.

Juvenile striped bass (*Morone saxatilis*) and Mississippi silversides (*Menidia audens*) were collected at beaches near the edge of channels adjacent to the open water sampling station. Juvenile striped bass and Mississippi silversides were selected for this study because they occur throughout the estuary and prey on mesozooplankton and amphipods that may use *Microcystis* as a food source. Fish were sampled using a 30 \times 1.8 m, 3.2 mm mesh beach seine. Sampling consisted of 2–8 hauls per station during flood tide when beaches were covered in water. Fish 30–300 mm were most vulnerable to this beach seine sampling technique (Nobriga et al., 2005). Live striped bass and Mississippi silversides were immediately placed in a cooler with river water, aerated with a stone aerator, and transported to a nearby laboratory boat for dissection. Only live fish were dissected for tissue analysis. Juvenile striped bass were not collected in sufficient quantity for analysis at FT and OR.

Fish were decapitated, and liver and muscle were surgically removed from each fish in less than 1 h after collection. The liver tissue of each fish was partitioned into two samples: one for analysis of total microcystins content and one for histopathology. For total microcystins analysis, tissue was wrapped in aluminum foil, flash frozen with liquid nitrogen and kept frozen at -80°C until analysis. Tissue samples for histopathological analysis were stored at room temperature in 10% neutral buffered formalin. Because the fish were small (typically <100 mm long), liver and muscle tissues from multiple striped bass were combined to get sufficient tissue for microcystins analysis. Mississippi silversides were so small that liver and muscle tissue could not be separated.

Microcystins analysis

Filters with plankton tissue for total microcystins analysis were extracted by sonication with 10 ml of 50% methanol containing 1% acetic acid, clarified by centrifugation, and the extract used for toxic microcystins analysis using the protein phosphatase inhibition assay (PPIA) technique, while anatoxin-a in plankton samples was measured by HPLC as described in Lehman et al. (2005). Dissolved microcystin concentration was computed as the difference between whole water and plankton tissue concentrations.

The toxic microcystins concentration in fish tissue was determined from lyophilized tissue (0.1 g dw liver or 0.6 g dw muscle) that was extracted with 50% methanol (MeOH) containing 1% acetic acid (HOAc) at a ratio of 10 ml solvent: 1 g dw tissue. The tissue was homogenized using a Biospec tissue tearor at 5,000–10,000 rpm for 1 min and then centrifuged at 3,000 rpm for 10 min. The supernatant was transferred to a glass tube, and the particulate material was re-extracted with the same volume of solvent. The pooled supernatants were taken to dryness in vacuo and resuspended in 1 ml of acidified 50% MeOH. PPIA was used to determine the total concentration of free microcystins, expressed as microcystin-LR equivalents, in the fish tissue. The PPIA method used for fish tissue was the same as that used for plankton and zooplankton tissue described above. The recovery of free microcystins in fish tissue was determined using an internal standard, [S-propyl-cys⁷] microcystin-LR, synthesized from microcystin-LR (Smith & Boyer, 2009).

Histopathology

Histopathological analysis was conducted on fish liver tissue following the methods of Teh et al. (2004). After 48 h in 10% neutral buffered formalin, tissues were dehydrated in a graded ethanol series and embedded in a paraffin block. For each tissue block, serial sections (4 μm thick) were cut and stained with hematoxylin and eosin. Tissue sections were examined under a BH-2 Olympus microscope for common and/or significant lesions.

Tissues were screened and scored on an ordinal ranking system for a variety of histopathological features and lesions (0 = none/minimal, 1 = mild, 2 = moderate, and 3 = severe; and 0 = not present or

infrequently observed, 1 = mildly affected in <10% of the tissue, 2 = moderately affected in 10–50% of the tissue, and 3 = severely affected in greater than 50% of the tissue, respectively). Due to the importance of the number of preneoplastic foci and tumors in the progression of fish hepatocarcinogenesis, basophil preneoplastic focus and hepatocellular adenoma lesions were enumerated rather than scored by severity.

Seven characteristics of the liver lesions were scored to identify toxic exposure in fish: glycogen depletion, eosinophilic protein droplets, cytoplasmic inclusions, single cell necrosis, fatty vacuolation, or lipidosis, macrophage aggregates and focal/multifocal parenchymal leukocytes or lymphocytes. Glycogen depletion was characterized by decreased hepatocyte size, loss of the 'lacy', irregular, and poorly demarcated cytoplasmic vacuolation typical of glycogen, and increased cytoplasmic basophilia (i.e., blue coloration). Eosinophilic protein droplets were characterized by the presence of proteins which appeared as refractile, eosinophilic (pink coloration), round, and well-demarcated cytoplasmic vacuoles. Cytoplasmic inclusions were characterized by the accumulation of foreign materials within the cytoplasm of hepatocytes. Single cell necrosis was characterized by cells having eosinophilic cytoplasm with nuclear pyknosis and karyorrhexis. Fatty vacuolation or lipidosis was characterized by excess lipids which appeared as clear, round, and well-demarcated cytoplasmic vacuoles. Macrophage aggregation was characterized as a cluster of macrophages packed with coarsely granular yellow–brown pigment. Focal/multifocal parenchymal leukocytes or lymphocytes were characterized by focal to multifocal aggregates of lymphocytes, occasionally mixed with other inflammatory cells. Cumulative assessment was based on the sum of the mean of individual lesion scores where higher total mean score indicated poorer fish conditions.

Statistical analysis

Due to the lack of normality in the data sets, all statistical analyses were computed using non-parametric statistics. Comparisons of physical, chemical, and biological data were computed using non-parametric statistical techniques for single and multiple comparisons, Wilcoxon and Kruskal–Wallis comparison tests (SAS, 2004). Correlation coefficients were

computed using the non-parametric Spearman rank correlation coefficient (r_s). Data were reported as the mean \pm the standard deviation.

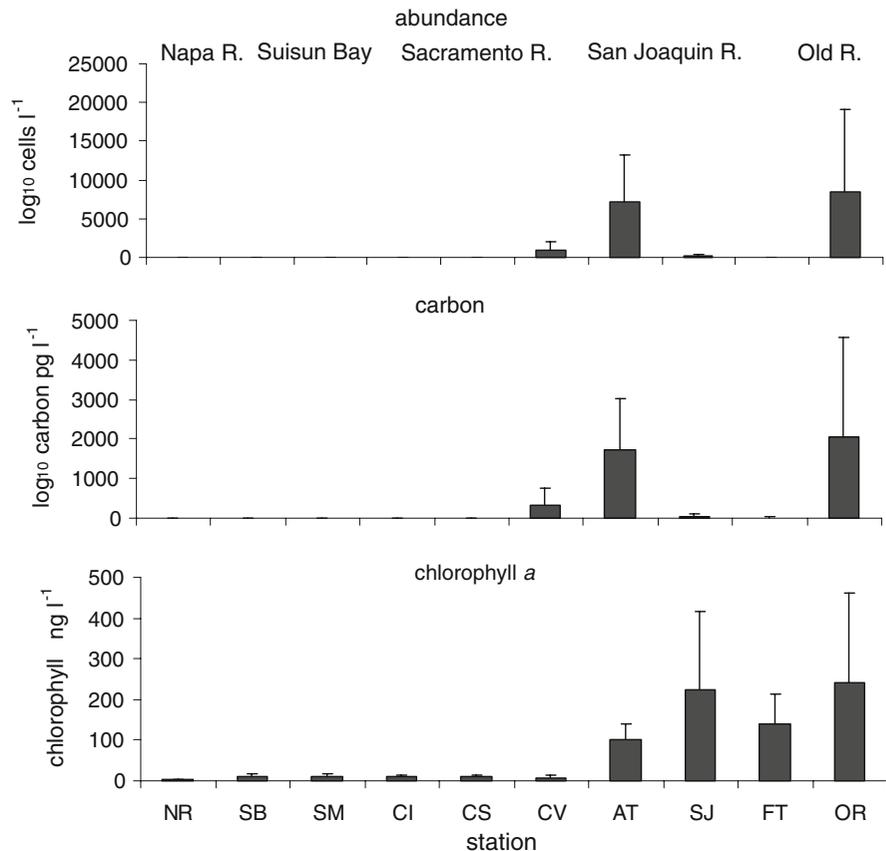

Similar patterns in plankton and zooplankton community composition or carbon and their correlation with environmental factors were evaluated with Primer-e version 6 software (Clarke, 1993; Clarke & Gorley, 2006) using a combination of multidimensional scaling (MDS), analysis of similarities among data (ANOSIM), identification of variables that best explain the data variance (BEST), and multivariate comparisons of data patterns (RELATE). These were applied to patterns in plankton species composition over space or time by visualizing the data patterns using an MDS of the Bray Curtis dissimilarity index computed from the square root of density or carbon data. Similar patterns in plankton or zooplankton community composition and carbon among stations were quantified with ANOSIM, while similarities between patterns in physical (normalized) and plankton and zooplankton community composition or carbon were quantified by Spearman rank correlation coefficients using RELATE. Species which accounted for most of the variation in the plankton, zooplankton, or environmental data were identified by Spearman rank correlation coefficients applied to groups of variables using BEST.

Results

Plankton

Microcystis abundance was greatest ($P < 0.01$, ANOSIM) in the western and central delta (stations CV, AT, FT, SJ, and OR). Average *Microcystis* abundance (9×10^6 cells l^{-1}) at these stations was nearly an order of magnitude greater than at Suisun Bay stations SB and CI (1.0×10^6 cells l^{-1}) or the outlying stations SM, CS, and NR where *Microcystis* did not occur (Fig. 2). In the western and central delta, *Microcystis* abundance was elevated at stations CV, AT, and OR and significantly greater at stations OR and AT ($P < 0.05$). Spatial variability characterized *Microcystis* in the western and central delta where abundance ranged by orders of magnitude from no cells l^{-1} at station CV in early August to 32×10^9 cells l^{-1} at station OR in mid-August.

Fig. 2 *Microcystis* abundance, carbon, and chlorophyll *a* concentration at stations throughout the estuary

Chlorophyll *a* concentration increased with *Microcystis* carbon in the surface layer (Fig. 2). *Microcystis* carbon comprised about 90% of the plankton carbon, and was correlated with both total plankton carbon ($r_s = 0.83$; $P < 0.01$) and chlorophyll *a* concentration ($r = 0.76$, $P < 0.01$) for all stations combined. *Microcystis* carbon was also positively correlated with diatom, green algae, and miscellaneous flagellate carbon ($r_s = 0.43$, $P < 0.01$; $r_s = 0.74$, $P < 0.01$, and $r_s = 0.76$, $P < 0.01$, respectively). Chlorophyll *a* concentration and total plankton carbon were also correlated ($r_s = 0.82$; $P < 0.01$).

Plankton community composition varied with *Microcystis* abundance throughout the water column. In the surface layer, plankton community composition was correlated with *Microcystis* abundance for all stations combined ($P < 0.01$, RELATE). The variation in this plankton community was primarily due to the cyanobacterium *Aphanizomenon* spp., diatoms *Aulacoseira granualata* and *Bacillaria paradoxa*,

green alga *Chlorella* sp., and miscellaneous flagellates ($r_s = 0.94$, BEST; Fig. 3). *Microcystis* comprised 5, 48, 100, 86, 100, and 95% of the total abundance at SB, CV, AT, SJ, FT, and OR, respectively, and less than 1% at the rest of the stations. *Microcystis* abundance was also significantly correlated ($P < 0.05$, RELATE) with the plankton community composition in the western and central delta where *Aphanizomenon* sp., *A. granulata* and *B. paradoxa* accounted for 92% ($r_s = 0.96$, BEST) of the variation. In addition, the abundance of cyanobacteria species including *Aphanizomenon* spp., *Planktolyngbya* spp., *Pseudodanabaena* spp., and *Merismopedia* spp. covaried ($P < 0.01$, RELATE) with *Microcystis* abundance for all stations combined (Fig. 3). The plankton community at 1 m depth was also correlated with *Microcystis* abundance in the surface layer for all stations ($P < 0.05$, RELATE; Fig. 4). About 83% of the variation in the plankton community at 1 m was associated with the abundance of the cryptophytes *Rhodomonas* spp. and *Cryptomonas* spp., the green

Fig. 3 Average percent abundance of phytoplankton and cyanobacteria genera or species among stations. Only genera or species that comprised more than 1% of the abundance for any one station were included

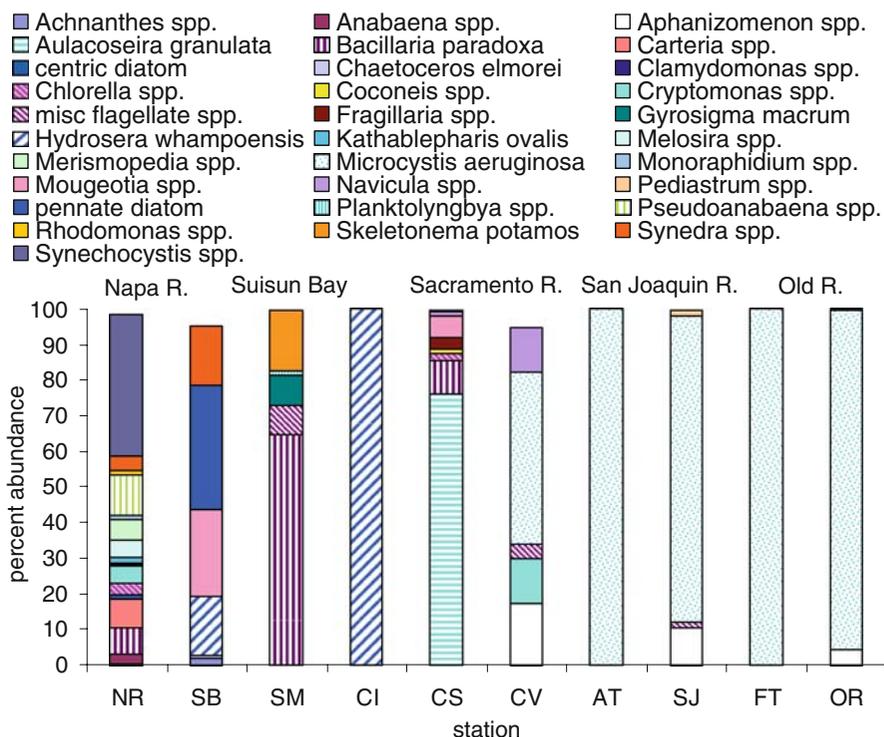

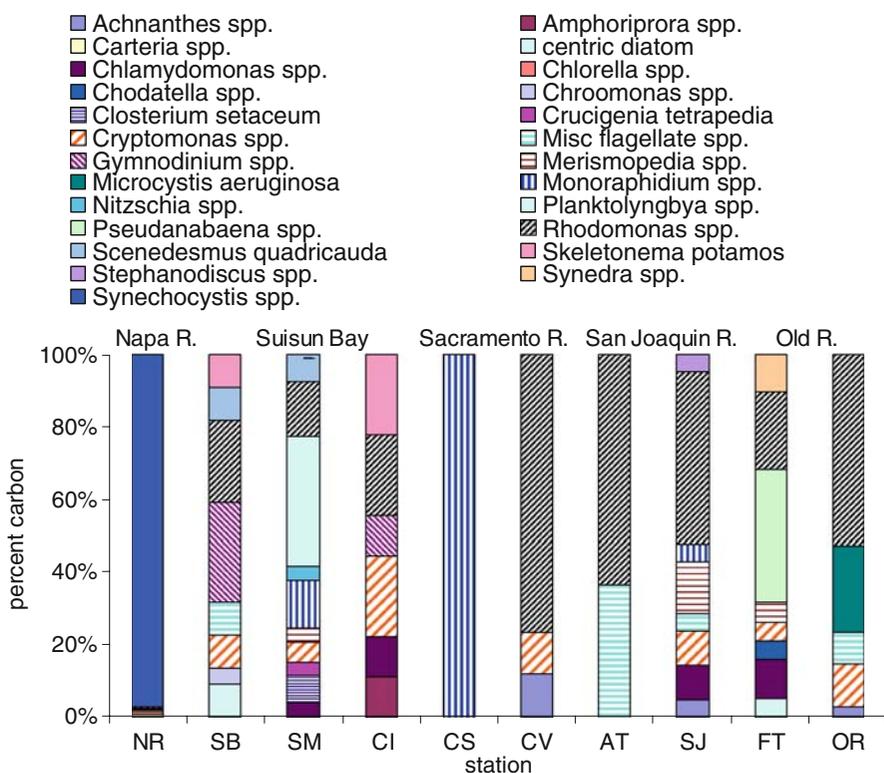

Fig. 4 Percent carbon of phytoplankton and cyanobacteria genera or species at 1 m depth. Only genera or species that composed more than 1% of the abundance for any one station were included

algae *Closterium setaceum* and *Monoraphidium* spp., and the dinoflagellate *Gymnodinium* spp. ($r_s = 0.91$, BEST) which were abundant in the western and central delta; 50% of this variation was due to *Rhodomonas* spp. alone ($r_s = 0.71$, BEST). Plankton community composition at 1 m depth was correlated with *Microcystis* abundance even on a small geographical scale. The cryptophytes *Rhodomonas* spp. and *Cryptomonas* spp., the cyanobacteria *Merismopedia* spp., and *Microcystis* and miscellaneous flagellates ($r_s = 0.86$, BEST) characterized differences in the plankton community at AT, OR, and CV compared with SJ and FT ($P < 0.05$, ANOSIM); most of this variation was due to *Rhodomonas* spp. ($r_s = 0.65$, BEST). *Microcystis* abundance was similarly greater at AT and OR compared with SJ and FT ($P < 0.05$, ANOSIM).

Differences in the plankton community composition affected the plankton carbon among groups. Plankton group carbon differed ($P < 0.05$, ANOSIM) between stations OR, CV, and AT and stations FT and SJ at 1 m (Fig. 5). Most of this difference was associated with diatom, green algae, and cryptophyte carbon ($r_s = 0.89$, BEST), and was characterized by a greater ($P < 0.05$) percentage of cryptophytes and a lower ($P < 0.05$) percentage of diatoms and green algae at stations OR, CV, and AT compared with stations SJ and FT. The difference was most striking for cryptophyte carbon which comprised 70–90% of the total carbon at OR, CV, and AT, but only 35–45% of the total carbon for nearby stations at SJ and FT. Most of the cryptophyte carbon was produced by *Rhodomonas* sp. and *Cryptomonas* sp.

Microcystis abundance was correlated with water quality conditions across regions ($P < 0.01$, RELATE). Water quality conditions differed ($P < 0.01$, ANOSIM) among the western and central delta (CV, AT, SJ, FT, and OR), Suisun Bay (SB, SM, and CI), CS and NR stations or station groups (Table 1). About 72% (BEST) of this variation was correlated with chloride, total organic carbon, and total suspended solids concentration which increased seaward. Among variables, *Microcystis* abundance was negatively correlated with chloride ($P < 0.01$, RELATE), total suspended solids ($P < 0.01$, RELATE), and total organic carbon ($P < 0.01$, RELATE), and positively correlated with nitrate-N ($P < 0.05$, RELATE), soluble phosphorus ($P < 0.05$, RELATE), and total nitrogen (nitrate-N plus ammonium-N; $P < 0.01$, RELATE) concentration.

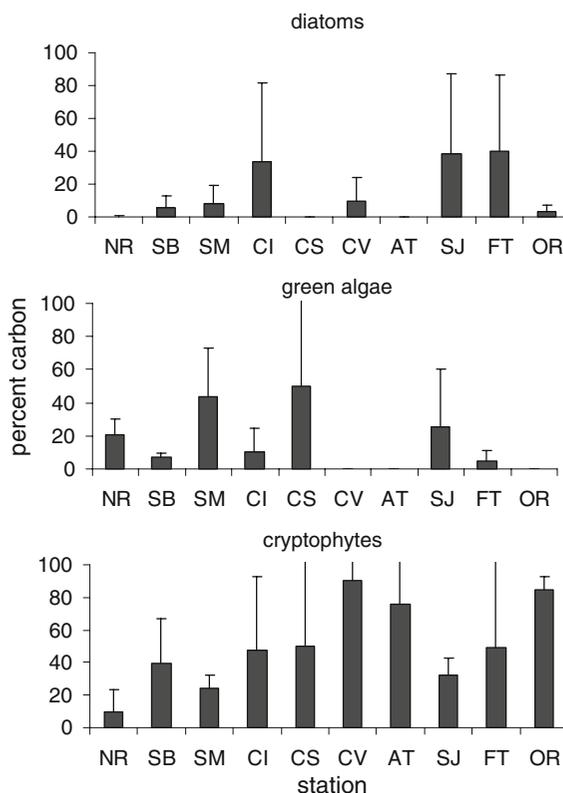

Fig. 5 Percent carbon for diatom, green algae, and cryptophyte carbon at 1 m depth

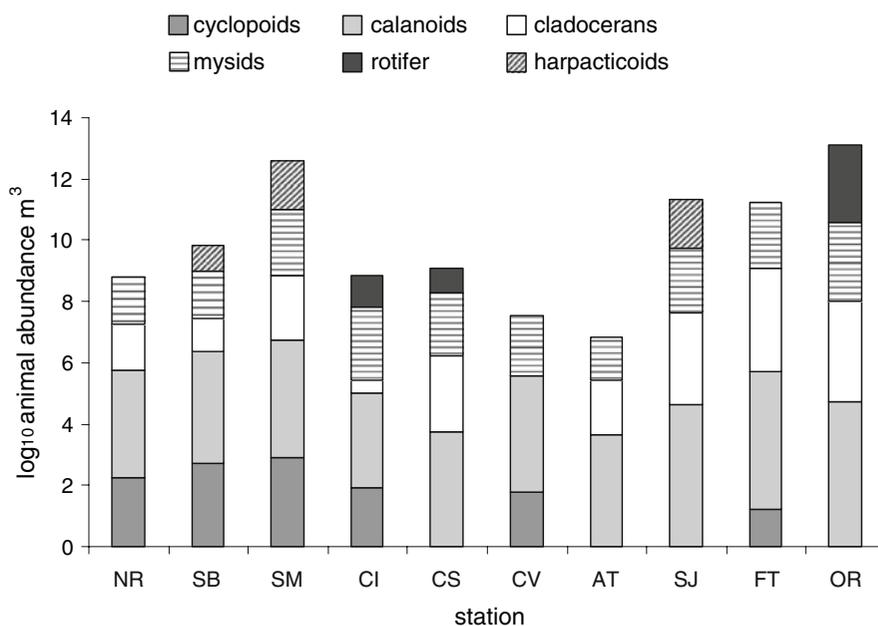

Although ammonium-N concentration was elevated at some stations in the western and central delta and the Sacramento River at stations at CS and CV, neither it nor the total nitrogen (nitrate-N and nitrite-N plus ammonium-N) to soluble phosphorus molar ratio (NP) was significantly correlated with *Microcystis* abundance across all regions or within the western and central delta separately. Plankton group carbon or plankton species abundance at 1 m was not significantly correlated with any of the water quality conditions measured, including the NP ratio.

Zooplankton

Zooplankton community composition differed ($P < 0.01$, ANOSIM) across the delta and was correlated with *Microcystis* abundance in the surface layer ($P < 0.01$, RELATE). Significant differences in the zooplankton community composition in the western and central delta and Suisun Bay ($P < 0.01$, ANOSIM)

Table 1 Average water quality conditions in the surface layer computed from biweekly data for stations sampled in the San Francisco Estuary between August and September 2005

Water quality variable	Stations

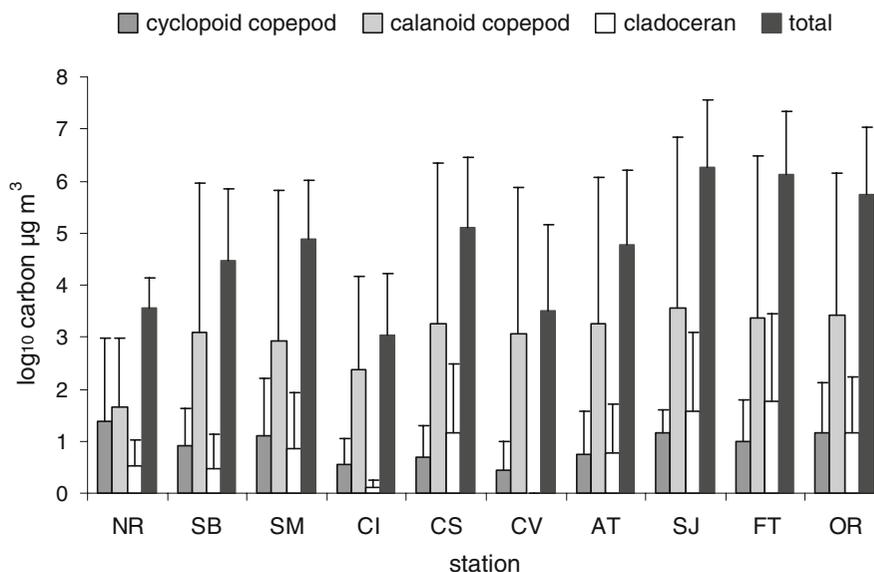

Fig. 6 Mesozooplankton abundance (\log_{10} animals l^{-1}) by taxonomic group among stations determined from diagonal net tow samples

were also correlated with *Microcystis* abundance ($P < 0.01$, RELATE). Most of the variation in the zooplankton community in the western and central delta and Suisun Bay was due to calanoid and cyclopoid copepods and cladocera ($r_s = 0.80$, BEST; Fig. 6). Calanoid copepods in the western and central delta were characterized by nauplii and the freshwater copepod *Pseudodiaptomus* spp., and were significantly

different ($P < 0.05$, ANOSIM) from Suisun Bay, where the brackish water calanoid copepod *Acartiella* spp. was abundant. Both *Pseudodiaptomus* spp. and *Acartiella* spp. accounted for 88% of the variation in the zooplankton community between the western and central delta and Suisun Bay ($r_s = 0.94$, BEST).

Microcystis carbon in the surface layer was significantly correlated with both total zooplankton carbon

Fig. 7 Log₁₀ average total and mesozooplankton group carbon ($\mu\text{g m}^{-3}$) and their standard deviation (*line*) among stations determined from diagonal net tow samples

and zooplankton group carbon for all stations ($P < 0.01$, RELATE) and for Suisun Bay and the western and central delta, separately ($P < 0.01$, RELATE). Calanoid copepod, cyclopoid copepod, rotifer, and cladocera carbon differed ($P < 0.01$, ANOSIM) between Suisun Bay, the western and central delta and the outlying stations NR and CS (Fig. 7). Nearly all of this difference in carbon among stations was due to the high biomass of the calanoid copepod *Pseudodiaptomus* sp. in the central delta ($r_s = 0.99$, BEST). Although the zooplankton group carbon differed between stations CV, SJ, and OR in the western and central delta, it was not associated with *Microcystis* abundance (Fig. 7). In contrast, *Microcystis* carbon was associated with differences in the cladocera to calanoid copepod carbon ratio among stations in the western and central delta ($P < 0.01$, RELATE). The cladocera to calanoid copepod carbon ratio was lower ($P < 0.01$) at stations OR, AT, and CV than FT and SJ (0.003 ± 0.003 and 0.02 ± 0.02 , respectively).

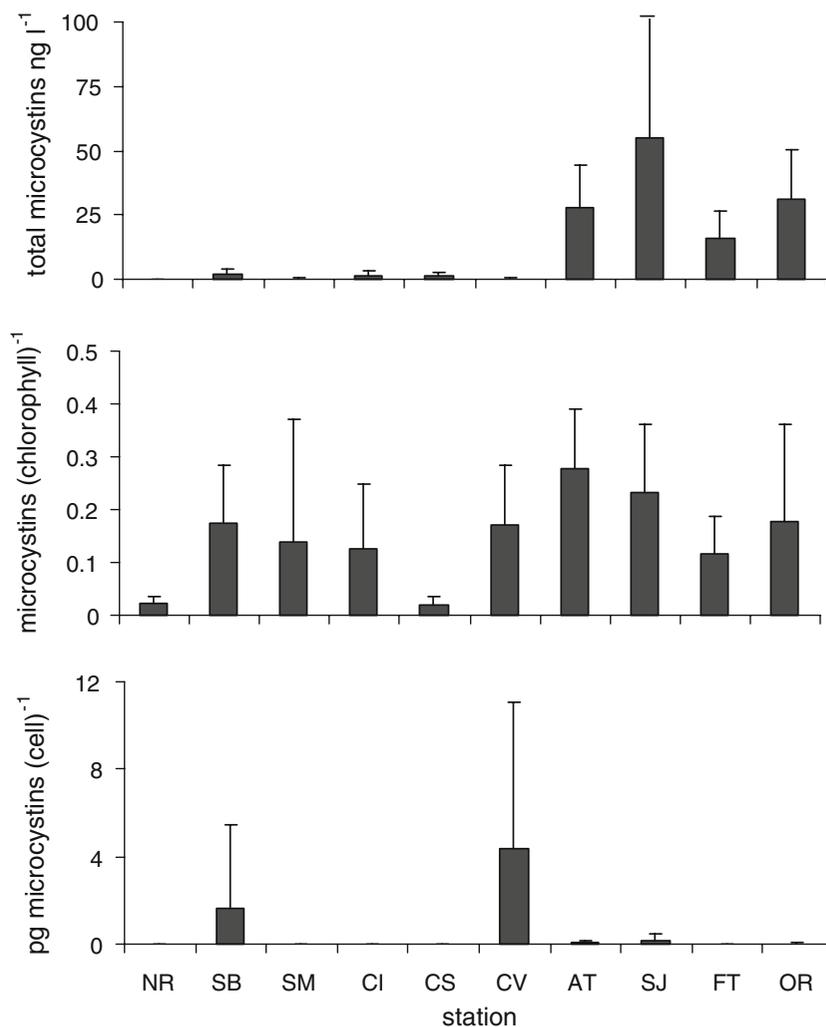

Toxins in plankton and animal tissue

Microcystins were present in the surface plankton samples throughout the estuary where *Microcystis* occurred (Fig. 8). The highest total microcystins concentration in *Microcystis* tissue ($P < 0.05$, ANOSIM) occurred in the San Joaquin and Old rivers at stations AT, SJ, FT, and OR where it reached an average of 60 ng l^{-1} . Total microcystins concentration

was correlated with both chlorophyll *a* concentration and *Microcystis* abundance for all stations ($r_s = 0.89$, $P < 0.01$; $r_s = 0.74$, $P < 0.01$), the Suisun Bay and western and central delta ($r_s = 0.87$, $P < 0.01$; $r_s = 0.68$, $P < 0.01$), and the western and central delta ($r_s = 0.79$, $P < 0.05$; $r_s = 0.45$, $P < 0.05$). The relative toxicity of *Microcystis* appeared to be uniform throughout the estuary because both total microcystins per unit chlorophyll *a* concentration and total microcystins per *Microcystis* cell were not statistically different among stations, despite large differences in average values (Fig. 8). Dissolved total microcystins concentration was above detection limits nine times during the sampling season, three times in August at CI, CS, and OR ($0.05\text{--}3.1 \text{ ng l}^{-1}$), and six times in September at SB, CV, AT, FT, and OR ($0.4\text{--}10.88 \text{ ng l}^{-1}$). Anatoxin-a concentration was low and below detection limits in plankton samples 17 times during the summer; range $2.4\text{--}143 \text{ pg l}^{-1}$.

Total microcystins were present in zooplankton and amphipod tissue throughout the estuary. Total microcystins in zooplankton and amphipod tissue ranged from 0.40 to $1.43 \mu\text{g (g dry wt)}^{-1}$, and was greatest at SJ by a factor of 2 (Table 2). Low biomass precluded absolute measurements of total microcystins in most zooplankton and amphipod tissue samples. However, detection limits suggested average total microcystins concentration in animal tissue was low, and could only have reached as high as $3.99 \mu\text{g (g dry wt)}^{-1}$ in zooplankton and $0.99 \mu\text{g}$

Fig. 8 Average (bar) and standard deviation (line) of total microcystins concentration ($\mu\text{g l}^{-1}$), total microcystins per unit chlorophyll *a* and total microcystins per *Microcystis* cell (within the $>75 \mu\text{m}$ size fraction collected in surface net tows). Total microcystins were measured by protein phosphatase inhibition assay

(g dry wt) $^{-1}$ in amphipod tissue in the central and western delta. A more thorough statistical evaluation of these trends was limited by the small sample size and qualitative nature of some of the data.

Total microcystins were present in the liver, muscle, and whole body tissues of juvenile striped bass and Mississippi silversides at all stations where fish occurred (Table 2). Total microcystins concentration in individual striped bass muscle tissue ranged by a factor of 3 from 1.03 to 3.42 $\mu\text{g (g dry wt)}^{-1}$, but averages among stations were similar (Table 2). Total microcystins concentration in striped bass liver tissue was slightly less than in muscle tissue and varied by a factor of 5 among samples (range 0.34–1.89 $\mu\text{g (g dry wt)}^{-1}$). Tissue concentrations were not statistically different among stations, but were elevated in individual samples at AT in the San Joaquin River and SM in

Suisun Bay. Mississippi silversides contained similar amounts of total microcystins in liver and muscle tissue as striped bass (Table 2). As might be expected, total microcystins concentration in the whole body tissue of Mississippi silversides was more than an order of magnitude lower than for liver and muscle tissue alone. Absolute total microcystins concentrations and differences in concentration among samples were probably lower than the actual values due to the need to composite from 2 to 10 fish tissue samples for toxin analysis from these very small fish; this was particularly true for liver samples.

Histopathology

Histopathological analysis revealed that Mississippi silversides and juvenile striped bass were likely

Table 2 Average absolute and relative total microcystins concentration (μg (g dry weight) $^{-1}$) in mesozooplankton and fish tissue measured between August and September 2005 at stations throughout the estuary

Toxic microcystins were measured by protein phosphatase inhibition assay

exposed to toxic substances including cancer causing substances throughout the estuary. Several types of histological changes were observed in juvenile striped bass liver tissue. Mild to moderate glycogen depletion occurred in liver tissue for all stations (Fig. 9). Mild, but elevated lesion scores for cytoplasmic inclusion, single cell necrosis and lipidosis also suggested the striped bass in the Sacramento River and San Joaquin Rivers were exposed to toxic contaminants and cancer causing substances. Hepatic preneoplastic foci and the presence of tumors in liver tissue further supported the exposure of striped bass at station AT to cancer causing substances in the San Joaquin River. Importantly, elevated lesion scores for cancer causing substances and the presence of tumors in striped bass liver coincided with elevated concentrations of total microcystins at AT. Liver lesion scores for the San Joaquin River differed from those in Suisun Bay where the maximum lesion scores resulted from a different suite of biomarkers, such as eosinophilic protein droplets, macrophage aggregates, and focal parenchymal leukocytes.

The liver tissue of Mississippi silversides also demonstrated histological changes characteristic of exposure to toxic substances throughout the estuary. Like striped bass, glycogen depletion was mild to moderate at most stations (Fig. 10). Liver lesion scores characteristic of exposure to toxic substances, single cell necrosis, and cytoplasmic inclusions, occurred in liver tissue for fish in San Joaquin River and Suisun Bay, while those for hepatic lipidosis were moderately elevated in liver tissue for Suisun Bay and Old River. Maximum lesion scores in liver tissue for glycogen depletion, eosinophilic protein droplets, and cytoplasmic inclusions occurred in Suisun Bay and San Joaquin River, Sacramento River, and the San Joaquin River, respectively. All of the remaining lesion scores were highest for Mississippi silversides in Suisun Bay at station CI.

Discussion

Phytoplankton

Microcystis forms dense surface blooms that may exert a pronounced effect on the surrounding plankton through its effect on the quantity and quality of the light field in the water column in the presence of

Fig. 9 Average liver lesion scores for each biomarker quantified in juvenile striped bass collected at stations throughout the estuary. No fish were present at stations FT and OR

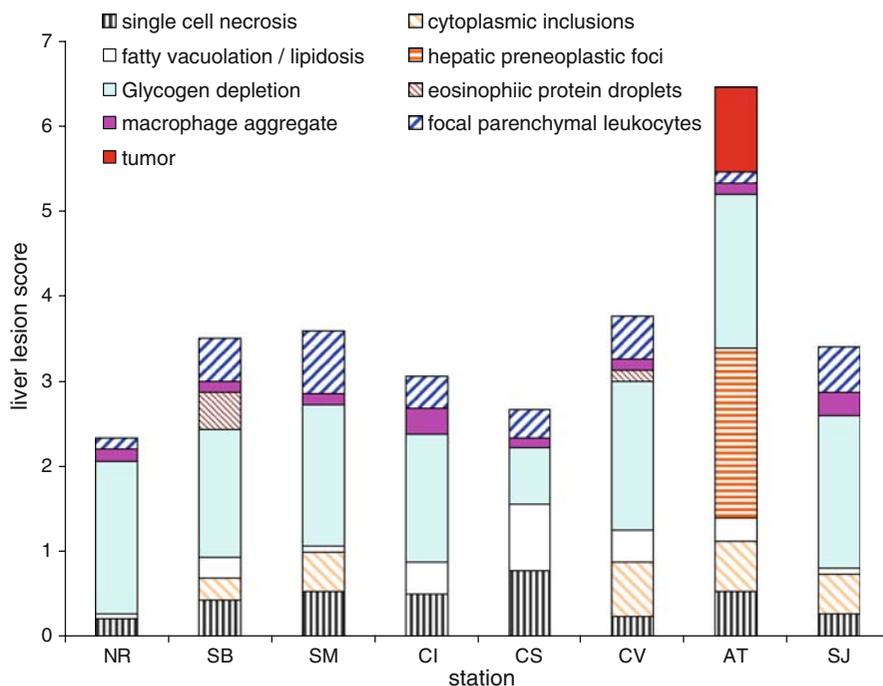

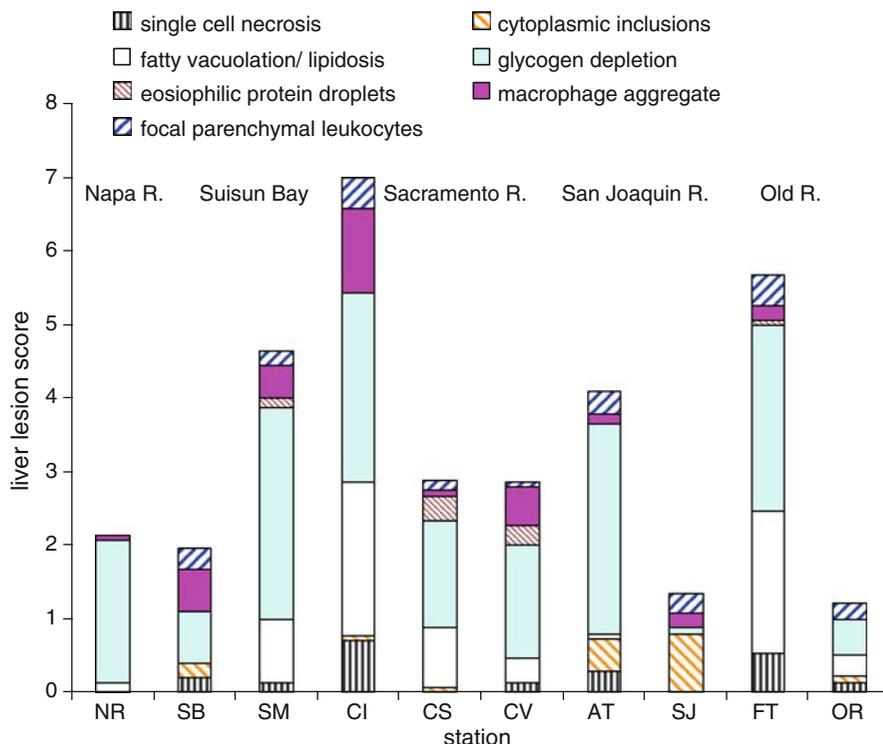

Fig. 10 Average liver lesion scores for each biomarker quantified in Mississippi silversides collected at stations throughout the estuary

carbonate concentrating mechanisms (Giordano et al., 2005) and nutrient uptake (Marinho & Azevedo, 2007). *Microcystis* contain gas vesicles that allow

them to float on the surface of the water column where they can decrease light availability and primary productivity for plankton below the surface.

This may partly explain the decreased density of diatom, green algae, and other cyanobacteria at 1 m depth compared with cryptophytes with flagella that enable them to adjust their light position in the water column. *Microcystis* can alter the pH, and hence inhibit CO₂ uptake, giving preference to cyanobacteria with their enhanced carbonate concentrating capabilities (Giordano et al., 2005). However, the pH among the stations did not differ, suggesting that differences in carbonate concentrating mechanisms were not important in SFE. *Microcystis* co-occurred with *Aphanizomenon* spp. This filamentous cyanobacterium has similar enhanced carbonate and light capturing capabilities through carboxysome and phycobilisomes as *Microcystis*, but because it has heterocysts that produce nitrogen needed for growth, it does not compete with *Microcystis* for nitrogen (Paerl et al., 2001). *Microcystis* is extremely flexible in its ability to use organic nitrogen and phosphorus and alternative forms of nutrients may provide a selective advantage for this species even though nutrients are rarely limiting in SFE (Jassby, 2005). Recent increases in ammonium concentration in the western delta may give a competitive advantage to *Microcystis* which rapidly assimilates ammonium over nitrate (Blomqvist et al., 1994; Jassby, 2005). However, recent reductions in river flow may have had a greater influence on abundance (Kuwata & Miyazaki, 2000; Lehman et al., 2008).

Microcystis may have affected plankton community composition through allelopathy by the production of microcystins or other bioactive peptides. Microcystins were associated with a decrease in diatom density and increase in the growth rate and number of cyanobacteria species in laboratory cultures (Sedmak & Kosi, 1998; Suikkanen et al., 2005). Microcystins may not have affected some phytoplankton, such as the chain diatom *Aulacoseira granulata* or the green alga *Monoraphidium contortum* in SFE, which were common in the surface layer. Laboratory studies suggest these species grow well in the presence of *Microcystis* (Sedmak & Kosi, 1998; Jia et al., 2008). *Microcystis* can inhibit photosynthesis and the growth rate of the cyanobacteria *Nostoc* spp., *Anabaena* spp., and *Synechocystis* spp. (Vassilakaki & Pflugmacher, 2008; Singh et al., 2001) and may contribute to their absence or low density in SFE. The impact of *Microcystis* on algal growth is often species specific. *Microcystis* inhibited

chlorophyll *a* synthesis in *Scenedesmus obliquus*, but increased the growth of *Scenedesmus quadricauda* in laboratory cultures (Sedmak & Kosi, 1998; Jia et al., 2008). Dissolved microcystins can also affect cell aggregation, increase cell volume, and production of photosynthetic pigments in *Scenedesmus quadricauda* (Sedmak & Eleršek, 2006). *Scenedesmus* spp. was not found in the surface or 1 m samples where *Microcystis* was abundant for this study, but has been a common species in the delta over time (www.iep.water.ca.gov). The increased abundance of the cryptophytes *Rhodomonas* spp. and *Cryptomonas* spp. in SFE may also be due to species specific responses to *Microcystis*. Although elevated *Microcystis* abundance was associated with decreased abundance of the cryptophyte *Cryptomonas arosa* (Sedmak & Kosi, 1998), cryptophyte growth varied among species when exposed to filtrates from freshwater and brackish water cyanobacteria including *Nodularia*, *Aphanizomenon*, and *Anabaena* (Suikkanen et al., 2005). The mechanisms associated with the allelopathy of *Microcystis* are poorly understood, but the growth and photosynthesis of *Peridinium gatunense* were decreased by inhibition of carbonic anhydrase activity (Sukenic et al., 2002).

The loss of diatom and green algal carbon and increase in cryptophyte carbon associated with elevated *Microcystis* abundance was sufficient to affect the quantity and quality of the phytoplankton carbon available to the food web in SFE. Diatom and green algae have some of the largest cells by volume in the phytoplankton community within SFE, therefore their loss can remove a large portion of the total carbon available to the food web (Lehman, 1996). Because cryptophytes have a relatively low average biovolume, the increase in their carbon was insufficient to compensate for the loss of diatom and green algal carbon. This was true even though most of the cryptophyte carbon was composed of two relatively large volume species, *Rhodomonas* spp. and *Cryptomonas* spp. A decrease in the diatom and green algal biovolume was also associated with an increase in cyanobacteria and cryptophyte biovolume between 1975 and 1993 in SFE, but it was attributed to long term changes in environmental conditions, particularly flow (Lehman, 2000a). Nutrient concentrations are often thought to be the primary driver of plankton blooms, particularly cyanobacteria blooms (Paerl et al., 2001). Recent research suggested haptophytes,

chlorophytes, and dinoflagellates increase with ammonium-N concentration in the Neuse River estuary (Rothenberger et al., 2009). However, nutrient concentration, including ammonium-N concentration and the NP molar ratio, did not account for the majority of the variation in *Microcystis* abundance in the surface layer or the distribution phytoplankton carbon among classes at 1 m depth for this study.

Zooplankton

Zooplankton carbon was positively correlated with *Microcystis* abundance. Most of the zooplankton carbon occurred in the western and central delta, and was composed of calanoid copepods. Copepods can actively reject toxic strains of *Microcystis*, and, therefore, are less likely to be affected by toxic blooms at low to moderate levels (DeMott & Moxter, 1991). In addition, some zooplankton can effectively use decomposed *Microcystis* as a food source (Hanazato & Yasuno, 1987). Copepod biomass was also not affected by *Microcystis* biomass in Steele Lake, Canada (Ghadouani et al., 2003). It is likely that the gradual seaward decrease in copepod carbon, dominated by the freshwater copepod *P. forbesii*, was due to other factors such as salinity or clam grazing in SFE (Kimmerer, 2004).

However, it is also possible that the presence of *Microcystis* and its toxins in the western and central delta affected the ability of calanoid copepods to reach maximum population levels. *P. forbesii* decreased in the western and central delta after 1999 and coincided with the appearance of *Microcystis* blooms (Lehman et al., 2005; Sommer et al., 2007). Although initial laboratory feeding studies indicated one of the common copepods in SFE, *Eurytemora affinis*, did not consume *Microcystis*, zooplankton tissue in SFE contained microcystins (Lehman et al., 2005, 2008). In Chesapeake Bay, zooplankton can consume some *Microcystis* even though they do not actively feed on this cyanobacterium (Sellner et al., 1993). Recent laboratory feeding studies confirmed that the survival of both *P. forbesii* and *E. affinis* was reduced when *Microcystis* exceeded 10% of the diet, and that *P. forbesii* was three times more sensitive than *E. affinis* (Ger et al., 2009). Dissolved microcystins also affect zooplankton growth and survival and can increase in the presence of zooplankton (Jang et al., 2003).

Dissolved microcystins occurred occasionally and may have contributed to the variability in zooplankton composition and biomass.

Elevated *Microcystis* biomass was associated with a low cladocera to calanoid copepod ratio. *Microcystis* blooms are often associated with low cladocera biomass because large cladocera like *Daphnia* sp. are more sensitive to *Microcystis* than small cladocera (Chen et al., 2007). *Microcystis* is a poor quality food and both toxic and non-toxic *Microcystis* adversely affect cladocera survival, growth rate, reproduction rate, clutch size, feeding rate, and nutrition (Reinikainen et al., 1999; Rohrlack et al., 2001, 2005; Wilson et al., 2006; Abrantes et al., 2006; Federico et al., 2007). *Microcystis* blooms can also affect the growth rate of cladocera by physically inhibiting feeding (Lurling, 2003). The *Microcystis* strain may also be important in SFE where DNA analysis suggested the western delta had different and more toxic *Microcystis* strains than the central delta (Moisander et al., 2009; D. Baxa, personal communication).

Fish

Toxic *Microcystis* may adversely affect fish health in the estuary when hepatotoxic microcystins cause liver damage and tumors (Malbrouck & Kestemont, 2006; Ibelings & Havens, 2008). Five of the lesion types evaluated in this study, single cell necrosis, cytoplasmic inclusions, hepatic lipidosis, hepatic preneoplastic foci, and hepatocellular adenoma (tumor) are likely pathologic responses to toxic exposure in fish (Teh et al., 1997; Malbrouck & Kestemont, 2006). The combined presence of these lesions in juvenile striped bass liver tissue suggests fish in the Sacramento and San Joaquin River were recently exposed to toxins. Low concentrations in fish tissue may indicate the rapid depuration of microcystins or toxin dilution through the food web (Ibelings & Havens, 2008). The presence of hepatic preneoplastic foci and hepatocellular adenoma in these young fish suggests the toxin was carcinogenic and affecting the fish at a very early life stage, which is atypical. We hypothesize that microcystins within the *Microcystis* colonies either contributed to or were the cause of these histopathological changes in striped bass liver tissue in the San Joaquin River, especially at station AT where the combined presence of the five lesion types

coincided with high total microcystins concentration. Ongoing research suggests *Microcystis* populations can be more toxic at AT than other stations in the estuary (D. Baxa, personal communication). Single cell necrosis and cytoplasmic inclusions in the liver tissue of Mississippi silversides further supported the contaminant exposure of fish in the lower San Joaquin River to *Microcystis* toxins. Dissolved microcystins may have contributed to the observed lesion scores, but anatoxin-a concentrations were probably too low.

Food web

Through its impact on multiple trophic levels, *Microcystis* may influence fishery production including the decline in pelagic organisms measured since 2000 in SFE (Sommer et al., 2007). The effects of *Microcystis* on food web organisms suggested by this study include direct impacts through nutrients, light, allelopathy, or toxicity on the growth and survival of phytoplankton, zooplankton, and fish or indirect impacts through the food web. The potential impact of *Microcystis* on phytoplankton group carbon maybe important for fishery production in SFE where the health and survival of key zooplankton food species like *P. forbesii* rely on the abundance of wide diameter diatom and green algae cells that provide good quality food in the optimum size range for filtering feeding (Müller-Navarra et al., 2000; Lehman, 2000b). This was supported by the strong positive correlation between total zooplankton and *Neomysis* shrimp carbon with diatom carbon between 1975 and 1993 in the estuary (Lehman, 2004), particularly after the depletion of diatoms following the invasion of the overbite clam in 1987 (Kimmerer, 2004). Although cladocera carbon was only a small percentage of the total zooplankton carbon compared with copepods, the decrease in the cladocera to calanoid copepod ratio may directly affect food availability for threadfin shad (T. Sommer, personal communication), an important forage species for piscivores in SFE (Nobriga & Feyrer, 2007). Importantly, the impact of *Microcystis* on the aquatic community may be greater than suggested by impacts on copepods and cladocera. Microcystins are commonly present throughout the food web, and in SFE were measured in clams, worms, and jellyfish that also serve as food resources for fish (Ibelings &

Havens, 2008; Lehman et al., 2005, 2008). Identifying the full impact of *Microcystis* on the SFE food web requires further information on high frequency spatial and temporal variability of the aquatic food web and body burdens across a larger suite of species and trophic levels.

Acknowledgments This project was funded by a special study grant from the San Francisco Bay Delta Interagency Ecological Program. Special thanks are due to many including E. Santos, F. Feyrer, and M. Dempsey for assistance with sampling, M. Bettencourt for phytoplankton counts and M. Satchwell (SUNY-ESF) for PPIA toxin analysis.

Abstract

Following the aggressive invasion of the bivalve, *Potamocorbula amurensis*, in the San Francisco Bay-Delta in 1986, selenium contamination in the benthic food web increased. Concentrations in this dominant (exotic) bivalve in North Bay were three times higher in 1995–1997 than in earlier studies, and 1990 concentrations in benthic predators (sturgeon and diving ducks) were also higher than in 1986. The contamination was widespread, varied seasonally and was greater in *P. amurensis* than in co-occurring and transplanted species. Selenium concentrations in the water column of the Bay were enriched relative to the Sacramento River but were not as high as observed in many contaminated aquatic environments. Total Se concentrations in the dissolved phase never exceeded 0.3 µg Se per l in 1995 and 1996; Se concentrations on particulate material ranged from 0.5 to 2.0 µg Se per g dry weight (dw) in the Bay. Nevertheless, concentrations in *P. amurensis* reached as high as 20 µg Se per g dw in October 1996. The enriched concentrations in bivalves (6–20 µg Se per g dw) were widespread throughout North San Francisco Bay in October 1995 and October 1996. Concentrations varied seasonally from 5 to 20 µg Se per g dw, and were highest during the periods of lowest river inflows and lowest after extended high river inflows. Transplanted bivalves (oysters, mussels or clams) were not effective indicators of either the degree of Se contamination in *P. amurensis* or the seasonal increases in contamination in the resident benthos. Se is a potent environmental toxin that threatens higher trophic level species because of its reproductive toxicity and efficient food web transfer. Bivalves concentrate selenium effectively because they bioaccumulate the element strongly and lose it slowly; and they are a direct link in the exposure of predaceous benthivore species. Biological invasions of estuaries are increasing worldwide. Changes in ecological structure and function are well known in response to invasions. This study shows that changes in processes such as cycling and effects of contaminants can accompany such invasions. © 2002 Published by Elsevier Science B.V.

1. Introduction

Selenium is an environmental toxicant that has been responsible for adverse reproductive effects and local extinctions of fish and birds in cooling reservoirs of coal-fired power plants (Lemly, 1985), wetlands receiving agricultural drainage (Presser and Ohlendorf, 1987; Skorupa, 1998) and river ecosystems draining seleniferous agricultural lands (e.g. the Colorado River and its tributaries; Hamilton, 1999). Although selenium is nutritionally essential, the window is narrow between essential concentrations in food and concentrations that cause adverse effects (Hodson and Hilton, 1983). Selenium becomes a reproductive toxin at slightly enriched concentrations because it substitutes for sulfur in the tertiary structures of proteins and thereby causes deformities in embryos or inhibition of the hatchability of eggs (e.g. Stadtman, 1974; Diplock, 1976; Skorupa, 1998).

Assessment of selenium effects in aquatic systems is complicated by the differing bioavailability of its several oxidation states (VI, selenate; IV, selenite; 0, elemental selenium; -II, selenide) and the occurrence of organic or inorganic forms within an oxidation state (Cutter and Bruland, 1984; Cutter, 1989). Biogeochemical conversion of dissolved Se to particulate forms is also complicated. Organic selenide is produced by plants (such as phytoplankton) or other primary producers (Wrench, 1978; Wrench and Measures, 1982) after uptake of selenite or selenate. Particulate elemental selenium is produced via dissimilatory reduction of selenate or selenite by bacteria (Oremland et al., 1990). Particulate selenium is a critically important phase because diet is the primary route of selenium exposure for invertebrates and other animals (Lemly, 1985; Luoma et al., 1992). Bivalves are especially effective bioaccumulators of selenium because they assimilate almost all the selenium they ingest with particulate material (e.g. from phytoplankton; Luoma et al., 1992) and they lose the element slowly (rate constants of loss are 0.01–0.03 per day; Reinfelder et al.,

1997). The selenium bioaccumulated by invertebrate consumers like bivalves is efficiently transferred to their predators upon ingestion and concentrations can be biomagnified in predator tissues. Therefore, selenium most seriously threatens upper trophic level birds and fish (Lemly, 1995).

Although predators are the species of greatest concern with regard to selenium contamination, they are mobile, impractical to sample in large numbers, and generally not especially useful for routine monitoring. Consumer species like bivalves are practical to sample (Phillips and Rainbow, 1993), and they integrate the influences of environmental concentrations, speciation and transformation of selenium. Bioaccumulated selenium in consumers is the critical link in exposure of predators. Monitoring contaminant exposure in a bioindicator is not a substitute for other types of investigations, but it can help focus more complicated studies of fate and effects (Brown and Luoma, 1995).

San Francisco Bay, the largest estuary on the west coast of North America, is formed by the confluence of the Sacramento River and the San Joaquin River. The North Bay extends from the confluence of the two rivers to the Golden Gate, and is comprised of Suisun Bay toward the rivers, an intermediate, large and shallow San Pablo Bay, and Central Bay seaward (Fig. 1). The largest water management system in the world can divert 30% of the Sacramento River during high flows and 60% during the low flow season before it reaches the Bay (for agriculture and drinking water; Nichols et al., 1986). Nearly all of the San Joaquin River is recycled southward for agricultural/urban uses by the water management system, during most months, especially in dry years. Wide seasonal and year-to-year changes in freshwater inflow are linked to precipitation and water management (Nichols et al., 1986). Seasonal and year-to-year differences in river inflows control hydraulic residence times in Suisun Bay, the salinity gradient, and distributions of dissolved and

particulate constituents like selenium (Largier, 1996; Monismith et al., 1996; Nichols et al., 1986).

San Francisco Bay is one of the few estuaries in which selenium contamination has been studied (Cutter, 1989; Johns et al., 1988). In the 1980s concentrations of selenium in birds, fish (White et al., 1988; Urquhart and Regalado, 1991) and invertebrates (Johns et al., 1988) in the Bay were high enough to be of concern (Luoma et al., 1992), despite relatively low concentrations of selenium in water (Cutter, 1989). Refineries were the predominant source of selenium during this period, especially during the season of low river discharge (Cutter and San Diego-McGlone, 1990). Saline soils rich in selenium are common in the western San Joaquin Valley (SJV). Release of selenium is accelerated by irrigation of those soils and disposal of irrigation drainage has contaminated ground water, wetlands and riverine habitats in the SJV (Presser and Ohlendorf, 1987). Selenium contamination in the San Joaquin River is well known (Presser and Ohlendorf, 1987); and San Joaquin River inputs could be a source of selenium when waters from that river reach the Bay. The selenium studies of the 1980s showed little input from this source, but those studies were conducted during a prolonged drought when

little runoff from the San Joaquin River reached the Bay.

The purpose of the present paper is to contrast Se contamination in the water column and in bivalves between the mid-1980s and 1995–1997. Two changes have occurred in the intervening period that could affect Se cycling in the Bay. First, beginning in the mid-1980s, an invading species of bivalve, *Potamocorbula amurensis*, became the predominant benthic macroinvertebrate in the Bay (Carlton et al., 1990). Biological invasions of estuaries have become an increasing problem worldwide and are known to change community structure and function (Cohen and Carlton, 1998; Carlton and Geller, 1993). *P. amurensis* is a voracious feeder that has essentially eliminated the standing stock of phytoplankton from the water column of the Suisun Bay (Cloern, 1996). The result has been an increase in energy available to the benthic food web and a decrease in energy available to the water column food web (J. Thompson, USGS, personal communication). Second, greater than normal precipitation and high river runoff occurred during this study period (May 1995–November 1997), in contrast to the periods of drought that characterized earlier study periods. This could result in more selenium

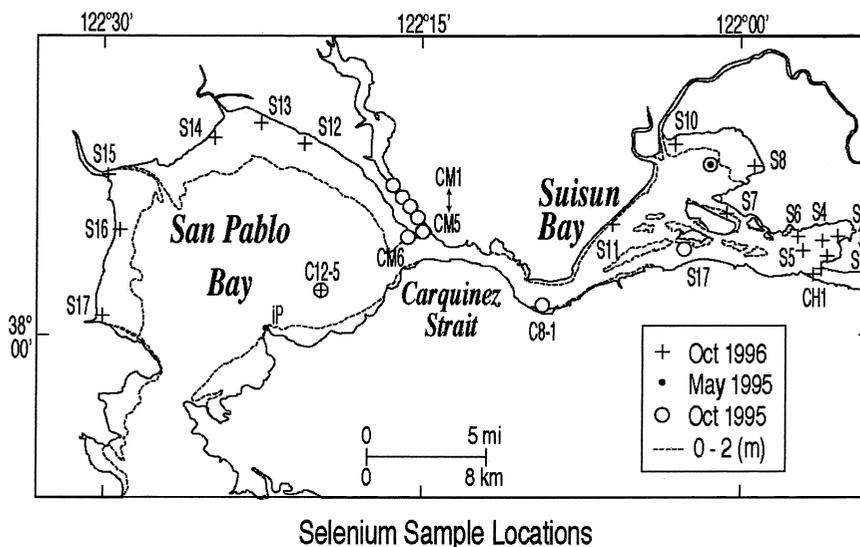

Fig. 1. Shoal (S) and Channel (C) sites sampled in North San Francisco Bay for *P. amurensis* in May 1995, October 1995 and October 1996.

entering the Bay from the agricultural runoff than occurred previously. Our study investigates several questions:

- have selenium concentrations in the predominant benthos changed after the invasion of *P. amurensis*?
- Are the seasonal and spatial patterns of selenium contamination different from those recorded earlier?
- Is selenium contamination focused in specific habitats where the element might be expected to accumulate (shallow waters vs. adjacency to marshes vs. deeper channel waters)?
- Is selenium uptake by *P. amurensis* different than in co-occurring species or experimentally transplanted species?

2. Experimental design

Four experiments were conducted to evaluate the implications of the invasion and the status of selenium contamination. To establish a reliable baseline of Se concentrations in the bivalves and evaluate seasonal variability, samples were collected near monthly from October 1995 through November 1997 at the station nearest Carquinez Strait (USGS 8.1), traditionally the most Se-contaminated reach of the Bay-Delta. Additional sites were added to resolve the spatial distribution of selenium enrichment in the bivalves. In October 1995, *P. amurensis* were collected from five locations in the tidal reaches of the Napa River and one site toward the river mouths from Carquinez Strait (USGS 6.1). The Napa River meets the Bay at Carquinez Strait, where Se concentrations have been highest. In October it is expected that the Napa River and the Bay exchange water in both directions throughout the sampling area (D. Schoelhammer, USGS, personal communication). Twenty-four sites were sampled in October 1996 to compare contamination in San Pablo and Suisun Bays and to compare deeper water sites (four stations) to shallow sites (20 stations) adjacent to different marshes. Finally, to evaluate if transplanted bivalves yielded results typical of the native community, *P. amurensis* were collected in May 1995, October 1995 and October 1996 from

three sites near those used in bivalve transplants by the San Francisco Bay Regional Monitoring Program (RMP; Fig. 1). These sites were in Grizzly Bay, Carquinez Strait (USGS 8.1) and San Pablo Bay-Pinole Point (USGS 12.5).

3. Methods

Resident clams (*P. amurensis*) were collected from the subtidal zone with a Van Veen grab and 1 or 2 mm sieves. Channel depths ranged from 8 to 20 m. The subtidal sites adjacent to marshes in Honker Bay and the Napa River (Fig. 1) were located in the shallows at an average depth of 1–3 m. Clams were also collected intertidally at low tide with a shovel, sieve and bucket. Between 60 and 120 clams of all sizes were collected at each time and each site and placed into containers of water collected at the site. The clams were kept in this ambient water in a constant temperature room at 10 °C to depurate for 48 h, as previous studies showed a residence time of material in the gut of *P. amurensis* to be approximately 24 h (Decho and Luoma, 1991). Clams from each site were separated into size classes of 1 mm difference and similar sized individuals were composited. Samples of larger numbers of individuals were necessary for smaller size classes in order to obtain enough mass for analysis. Soft tissues were dissected from the shell and tissues. Each composite was then lyophilized and homogenized. Mean concentrations characteristic of a site at a particular time were determined from analyses of three replicate composite samples each containing 20–60 individuals (each composite contained at least 250 mg dry weight (dw) soft tissue).

Selenium in the bivalves was determined by hydride atomic absorption spectrophotometry. Selenium subsamples were digested in concentrated nitric and perchloric acids at 200 °C, reconstituted in hydrochloric acid, and then stored until analysis. All glassware and field collection apparatus were acid washed, thoroughly rinsed in ultra-clean deionized water, dried in a dust-free positive pressure environment, sealed and stored in a dust free cabinet. Quality control was maintained by frequent analysis of blanks, analysis of

National Institute of Standards and Technology standard reference materials (tissues and sediments) with each analytical run, and internal comparisons with prepared quality control standards. Analyses of National Institute of Technical Standards (NITS) reference materials (oyster tissue, San Joaquin soils) were within an acceptable range of certified values reported by NITS (data in Luoma and Linville, 1996).

Water and particulate samples were collected in June 1995 and October 1996 using methodologies described earlier (Cutter, 1989). Pre-cleaned teflon Go-Flo sampling bottles were used to obtain water 1 m below the surface. The water was filtered through pre-cleaned and pre-weighed 0.45 μm Nucleopore membrane filters into 1 l linear polyethylene bottles and acidified to pH 1.5 with HCl. Filters were carefully folded, placed in polyethylene vials and immediately frozen. Total dissolved selenium was determined by boiling a 4 M HCl acidified sample with potassium persulfate solution for 1 h; then analyzing as a selenite sample by selective generation of hydrogen selenide, liquid nitrogen-cooled trapping, and atomic absorption detection (0.01 mol l⁻¹ detection limit). The standard additions method of calibration was used to ensure accuracy and all determinations were made in triplicate. Particulate selenium determinations were made using digestion procedures described by Cutter (1985) and procedures for reducing iron concentrations described by Cutter (1989). Filters were dried at 40 °C, re-weighed, then digested using a three step nitric-perchloric acid digestion. After iron removal by passage through an anion exchange resin, the digest was analyzed as a total selenium sample.

4. Results and discussion

4.1. River discharge

River discharges could influence allochthonous inputs of selenium from the San Joaquin River. Probably more important are the inflows from the Sacramento River, which has very low selenium concentrations and dilutes enriched Se inputs to

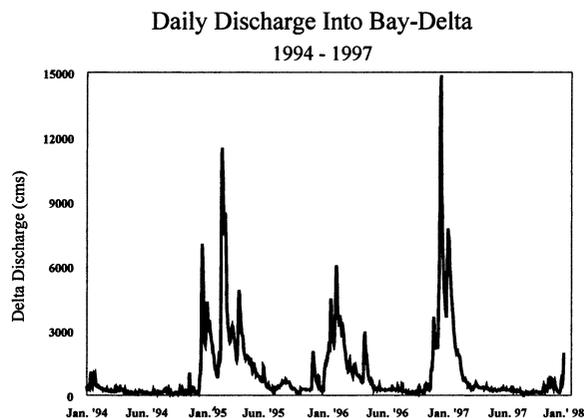

Fig. 2. Daily river discharge into San Francisco Bay, determined as net delta outflow at Chipps Island in Suisun Bay, between 1 January 1994 and 30 November 1997, as m³ s⁻¹.

the Bay (Cutter, 1989). The Mediterranean climate of the area drives a seasonal cycle in river discharge and causes large year-to-year variability in discharge. Nearly all precipitation occurs in the watershed between approximately November and April. The early flow is trapped in dams and snowfall; the highest river flows typically occur from January through approximately June, followed by low river flows through the rest of the year (Fig. 2). Interannual differences also reflect differences in precipitation. The period of record for the present study, 1995–1997, was characterized by high peak river inflows and, especially in 1995, a prolonged period of elevated river discharge. Previous studies of selenium in San Francisco Bay occurred between 1976 and 1977 and 1986 and 1990. Both were periods of prolonged drought, except for a flood in April 1986. Fig. 2 contrasts the patterns of river discharge in 1995–1997 to a typical drought year (1994) when both the magnitude and the period of high river discharges are reduced (also see hydrograph in Johns et al., 1988).

4.2. Selenium in the water column

Fig. 3(a) compares total dissolved selenium concentrations in estuarine transects from June 1995 to October 1996, with concentrations determined by the same methods in September 1986

(Cutter, 1989). All values are plotted as a function of salinity. Arrows depict the location of Carquinez Strait in each transect. Selenium concentrations in the Bay in 1995–1996 exceeded those in the Sacramento River, as in previous studies ($0.065 \pm 0.022 \mu\text{g Se per l}$; Cutter and San Diego-McGlone, 1990). The highest concentration in the Bay was $0.29 \mu\text{g l}^{-1}$. Within the Bay-Delta the concentrations at most stations followed the order June 1995 < October 1996 < September 1986, but the differences among the three transects were small, and appear to fall with the range of variation defined by Cutter and San Diego-McGlone (1990). The shape of the October 1996 transect differed from that in September 1986 because of elevated selenium concentrations at the upstream-most station, perhaps indicating some San Joaquin input. Total dissolved Se concentrations

were low compared with the USEPA water quality standard of $5 \mu\text{g Se per l}$ (Environmental Protection Agency, 1992).

Particulate selenium is the variable most likely to ultimately determine selenium bioavailability (Luoma et al., 1992). Concentrations of selenium on suspended particulate material were determined only in October 1996, during the present study. Particulate selenium was uniformly higher in Oct 1996 than in the estuarine transect conducted in September 1986 (Cutter, 1989; Fig. 3(b)). The highest concentration was observed in the river station in October 1996 (nearly $8 \mu\text{g g}^{-1}$ dw), again indicating particulate selenium inputs from the San Joaquin River were possible (subsequent studies have not found these high values, however; Cutter et al., unpublished data).

4.3. Selenium in *P. amurensis*

4.3.1. Spatial variability

Among the stations that were sampled in May 1995, selenium concentrations in soft tissues of *P. amurensis* ranged from 3.7 ± 0.7 to $7.1 \pm 0.3 \mu\text{g Se per g dw}$ (Table 1). Se concentrations were higher in *P. amurensis* from the Carquinez Strait ($7.1 \mu\text{g Se per g dw}$), than ($P < 0.01$) in the shallows of Suisun Bay ($3.9 \mu\text{g Se per g dw}$) and San Pablo Bay ($3.7 \mu\text{g Se per g dw}$). The latter two sites were not statistically different. Concentrations in October 1995 were higher than in May 1995. Se in *P. amurensis* from Carquinez Strait ($15.4 \mu\text{g Se per g dw}$) and Suisun Bay ($14.5 \mu\text{g Se per g dw}$) were not statistically different; but both were higher than Se concentrations in San Pablo Bay ($11.6 \mu\text{g Se per g dw}$; $P < 0.05$; Table 1). Concentrations were also elevated in the tidal Napa River compared with May concentrations in the North Bay.

Concentrations of Se in *P. amurensis* in October 1996 were similar to October 1995 (Table 1; Fig. 4). The range of mean Se concentrations in *P. amurensis* was 6.9 – $8.7 \mu\text{g Se per g dw}$ in San Pablo Bay, and 5.9 – $20 \mu\text{g Se per g dw}$ in Suisun Bay. The greatest enrichment was observed in the Carquinez Strait ($20.0 \mu\text{g Se per g dw}$). Higher concentrations were observed toward the rivers, at stations S1–S6, compared with other shallow water locations in Suisun Bay or San Pablo Bay

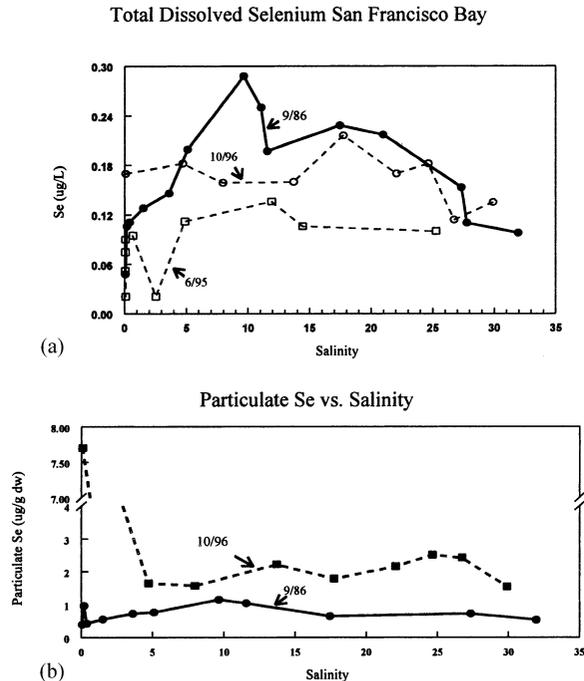

Fig. 3. (a) Dissolved Se concentrations ($\mu\text{g Se per l}$) as a function of salinity, determined in transects across the salinity gradient of North San Francisco Bay in September 1986 (Cutter, 1989), June 1995 and October 1996. (b) Concentrations of particulate Se ($\mu\text{g Se per g dw}$) as a function of salinity determined in transects across the salinity gradient of North San Francisco Bay in September 1986 (Cutter, 1989) and October 1996.

Table 1

S15	6.9	1.2	3
S16	7.5	0.3	3
S17	7.9	0.7	2

Each sample composite included approximately 20–60 individual *P. amurensis*, and >250 mg dw soft tissue. Napa River stations are numbered North-to-South ascending. Stations S1–S17 are in shallow water.

($P < 0.001$; Table 1; Fig. 4). Like dissolved and particulate concentrations in October 1996, the higher concentrations toward the rivers in *P. amurensis* could have reflected inputs from the San Joaquin River.

Thus all three samplings of bivalves indicate that Se concentrations in *P. amurensis* are enriched compared with background concentrations

typical of bivalves (< 3 $\mu\text{g Se per g}$; Johns et al., 1988) and that enrichment is widespread through North San Francisco Bay. Concentrations varied nearly 4-fold among sites. The observation of the highest concentrations near Carquinez Strait is consistent with past studies (Cutter, 1989; Johns et al., 1988) and the previously identified refinery source of Se input. Dilution of contamination (i.e.

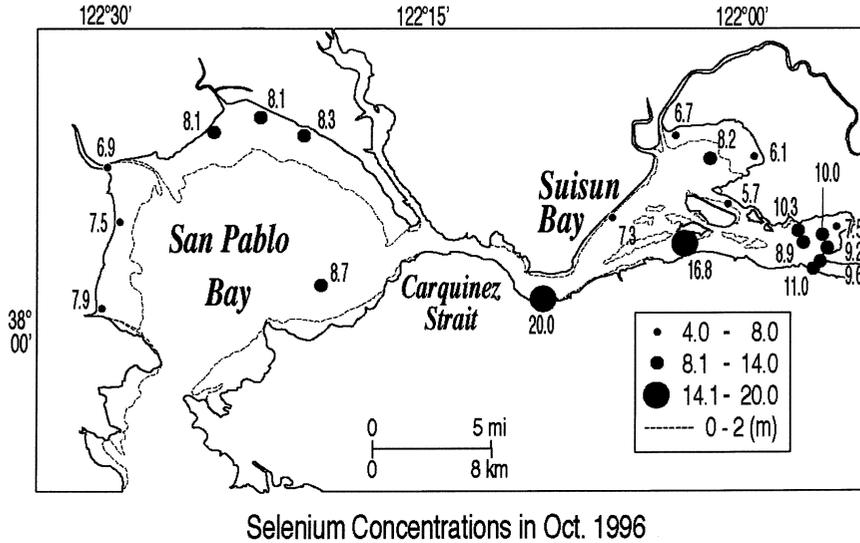

Fig. 4. Map showing distribution of mean Se concentrations in *P. amurensis* ($\mu\text{g Se per g dw}$) at 20 locations in Suisun and San Pablo Bays, in North San Francisco Bay, in October 1996. Standard deviations (S.D.) are shown in Table 1. Site codes are shown in Fig. 1.

the lowest concentrations in *P. amurensis*) near the eastward marshes in Suisun Bay and the western-most shallows of San Pablo Bay are consistent with dilution away from the refineries. Sources and mixing appeared to be more important than shallow versus deep-water habitat, despite the possibility that selenium is trapped in shallow wetlands. Some riverine input is also possible. Long residence times and complicated, tidally driven circulation patterns (Bureau et al., in prep.) probably contribute to the somewhat complicated pattern of the contamination in *P. amurensis* in Suisun and San Pablo Bay during periods of low river inflow.

4.4. Temporal variability

Selenium concentrations in *P. amurensis* from Carquinez St. varied as much as three-fold seasonally between May 1995 and November 1997 (Fig. 5). The lowest concentrations were observed in May 1995 ($7.1 \pm 0.3 \mu\text{g Se per g dw}$) and May 1997 ($6.2 \pm 0.2 \mu\text{g Se per g dw}$). Concentrations were highest in October 1995 to February 1996 ($15.4 \pm 1.0 \mu\text{g g}^{-1}$ – $18.9 \pm 0.4 \mu\text{g Se per g dw}$), October 1996 ($20 \pm 1.4 \mu\text{g Se per g dw}$), and

November 1997 ($15.3 \pm 3.4 \mu\text{g Se per g dw}$). The larger standard deviations in the four samples in late 1997 are probably the result of employing fewer individual animals per composite.

The seasonal pattern of selenium in *P. amurensis* from Carquinez Strait coincided with seasonal changes in river inflows. The lowest concentrations always occurred after episodes of highest river inflows and shortest hydraulic residence

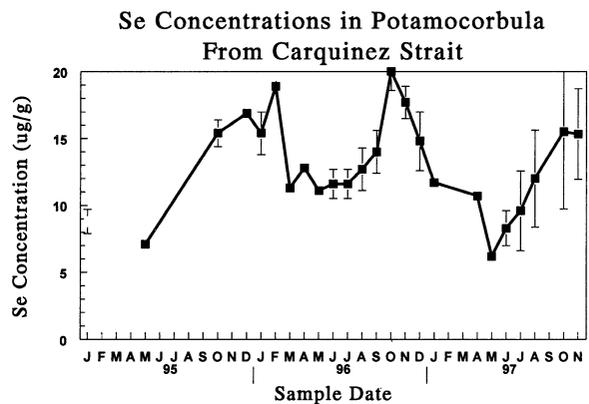

Fig. 5. Mean and S.D. of Se concentrations in *P. amurensis* ($\mu\text{g Se per g dw}$) at site C8.1 as determined at near monthly intervals between May 1995 and November 1997.

times. The greatest increase in Se occurred after prolonged periods of low flow, as hydraulic residence times increased. Increased Se bioaccumulation with increased residence times has been reported in other systems (Lemly, 1998). In contrast, Johns et al. (1988) did not observe strong seasonality in concentrations of Se in *Corbicula fluminea* in Suisun Bay, in the mid-1980s. One important difference was that that study did not include periods of river inflows as high or as prolonged as those occurring in 1995–1997.

4.5. Comparison to historic concentrations in bivalves

The selenium concentrations in *P. amurensis* in Suisun and San Pablo Bay are considerably higher than found in bivalves, in general, in uncontaminated estuaries in Northern California (1.7–3.1 μg Se per g dw, Johns et al., 1988; White et al., 1988). Data from *P. amurensis* itself is not available from uncontaminated estuaries. Concentrations in *P. amurensis* are also higher than in earlier studies from the Bay. Selenium exposures in the bivalves *Mytilus edulis* and *C. fluminea* were studied near Carquinez Strait in 1975 and 1984–1986, respectively (Risebrough, 1977; Johns et al., 1988). Risebrough et al. (1977) reported a mean concentration of 8 ± 3 μg Se per g dw in transplanted *M. edulis* from four sites near Carquinez Strait and concentrations of 10–11.4 μg Se per g dw in bivalves deployed directly in Carquinez Strait. These were some of the highest concentrations in the Bay at that time. Johns et al. (1988) sampled resident *Corbicula amurensis* at near monthly intervals from a station toward the rivers from Carquinez Strait (the most seaward population of *Corbicula* present in Suisun Bay at the time). In 67 samples they found a mean concentration of 6 ± 3 μg Se per g dw in the clams. Mean selenium concentrations in *P. amurensis* among all the samples reported above (15 ± 3 μg Se per g dw) were higher than found previously in either *M. edulis* or *C. fluminea*. The dominant bivalve in Suisun Bay changed from *C. fluminea* in 1985–86 to *P. amurensis* after the invasion of the latter species (Carlton et al., 1990; Nichols et al., 1990), so an increase in the exposure of ben-

thic predators to Se is likely if they consumed the invasive bivalve.

4.6. Comparison to monitoring with co-occurring and transplanted bivalves

Some species possess characteristics that enhance their bioaccumulation of contaminants. High assimilation efficiencies of selenium are typical of most marine organisms (Reinfelder et al., 1997; Wang and Fisher, 1999). But some species (copepods are an example) lose selenium rapidly (~ 0.15 per day) compared with other elements (Wang and Fisher, 1998), whereas loss rates from bivalves are slow (0.01–0.03 per day; Luoma et al., 1992; Reinfelder et al., 1997). Efficient assimilation and slow loss means that bivalves have generally strong capabilities to bioaccumulate selenium in their tissues (Reinfelder et al., 1997). *P. amurensis* is an unusually voracious filter feeder, it has an unusually short gut residence time (Decho and Luoma, 1991) and it utilizes a variety of food sources. All of these traits could enhance its ability to bioaccumulate Se, even compared with other bivalves.

Direct comparisons with co-occurring species are difficult with *P. amurensis*, because it tends to replace other bivalves and consumer organisms (Nichols et al., 1990). In June 1997 we found *P. amurensis* from a Carquinez Strait mudflat had 12.9 ± 1.2 μg Se per g dw and a co-occurring population of *M. balthica* contained 3.7 ± 0.1 μg Se per g dw. But this was only one coincident sampling. A comparison of *P. amurensis* with *C. fluminea* toward the rivers in Suisun Bay found similar concentrations in both species in October 1996, but sample sizes were very small. Conclusive determination of any special bioaccumulative characteristics of *P. amurensis* await further comparisons with co-occurring species and comparative kinetic studies.

An alternative approach is to compare Se bioaccumulation in *P. amurensis* with values in transplanted bivalves used to monitor the Bay. In the RMP of the San Francisco Estuarine Institute (SFEI, 1995, 1996), bivalves are transplanted for 90–100 days then contaminant uptake is compared with concentrations observed before the

Table 2

Comparison of selenium concentrations in transplant and resident species in North Bay in May 1995, October 1995 and October 1996

Site	Species transplant	Change in condition index ($T_F - T_0$)	Se ($\mu\text{g g}^{-1}$ dry) [$T_F - T_0$]	Species: resident	Se ($\mu\text{g g}^{-1}$ dry)
<i>May 1995</i>					
Grizzly Bay	<i>C. fluminea</i>	0.018	1.4 [−0.3]	<i>P. amurensis</i>	3.9 ± 0.8
Napa R. (Carquinez)	<i>C. gigas</i>	−0.022	6.2 [4.6]	<i>P. amurensis</i>	7.1 ± 0.3

<i>October 1995</i>					
Grizzly Bay	<i>C. fluminea</i>	−0.02	4.8 [0.1]	<i>P. amurensis</i>	14.5 ± 1.4
Napa R. (Carquinez)	<i>C. gigas</i>	−1.04	2.9 [−0.2]	<i>P. amurensis</i>	15.4 ± 1.0
San Pablo Bay-Pinole Pt.	<i>M. californianus</i>	−0.02	2.5 [−0.8]	<i>P. amurensis</i>	11.6 ± 1.1
<i>October 1996</i>					
Grizzly Bay	<i>C. fluminea</i>	−0.038	2.9 [1.3]	<i>P. amurensis</i>	8.2 ± 0.7
Napa R. (Carquinez)	<i>C. gigas</i>	−0.089	7.2 [2.9]	<i>P. amurensis</i>	20 ± 1.4
San Pablo Bay-Pinole Pt.	<i>M. californianus</i>	−0.039	2.7 [−2.4]	<i>P. amurensis</i>	8.7 ± 2.1

For transplanted species the final concentration is presented with the level of bioaccumulation of selenium over deployment period ($T_F - T_0$) displayed in brackets. The change in condition index over the period of deployment, a measure of growth (or lack of feeding), is also presented. 'Transplant' data from SFEI, 1995, 1996.

deployment. The RMP employs three different bivalves, due to differing salinities in the Bay, *C. fluminea* is used in Suisun Bay; the oyster *Crassostrea gigas* is used near Carquinez Strait; and the mussel *Mytilus californianus* is used in San Pablo Bay. Three of the sampling locations used for *P. amurensis* were near the above locations used by the RMP, and the 1995–1996 studies with *P. amurensis* were conducted at the same time as an RMP sampling.

Table 2 shows concentrations of Se in the transplants and the level of bioaccumulation, or lack thereof, during deployment in May 1995, October 1995 and October 1996. Changes in condition index over the deployment period are also shown; and these are compared with concentrations in the resident *P. amurensis* at the end of the deployment period of the transplanted species. Absolute concentrations of Se in tissues and patterns of bioaccumulation in time and space are compared. The differences in absolute concentrations were small in May 1995. But substantial differences were

observed between the deployed bivalves and *P. amurensis* in both October 1995 and October 1996. In October 1995, selenium concentrations in *P. amurensis* were 11.6–15.4 $\mu\text{g Se per g dw}$ among the three sites. None of the deployed species bioaccumulated Se during the deployment (concentrations were similar to the original population) and concentrations ranged from only 2.5 to 4.8 $\mu\text{g Se per g dw}$ (Table 2). A similar result occurred in October 1996. In that experiment, bioaccumulation of selenium was observed in *C. gigas* but concentrations were less than half those in *P. amurensis* at a nearby site. No significant bioaccumulation occurred in *C. fluminea*, although the concentration of Se in *P. amurensis* at that site was $8.2 \pm 0.7 \mu\text{g Se per g dw}$. Thus the seasonal pattern of greatly increased bioaccumulation in October compared with May was clear in *P. amurensis* but was not observed in the deployed animals.

The approach used to study bioaccumulation may be the cause of the differences between Se

bioaccumulation in *P. amurensis* and the transplants, *C. fluminea*, *C. gigas* or *M. californianus*. Phytoplankton blooms in Suisun Bay have essentially disappeared since the *P. amurensis* invasion, presumably due to consumption of primary production by the invasive bivalve. It is notable that condition index appeared to decline in all transplants in both October experiments (Table 2). Reduced condition index after deployment suggests that the deployed bivalves were not feeding normally in the fall. Uptake from food is the predominant route of selenium exposure (Luoma et al., 1992; Wang and Fisher, 1999). Therefore, it is possible that non-feeding deployed animals were not exposed to environmental selenium. The deployed animals gave no indication that high selenium concentrations were common in the predominant benthic species in North Bay during the season of low river inflows. Thus, the transplanted animals did not provide an accurate picture of selenium contamination in the estuary, and did not reach the level of selenium contamination found in *P. amurensis*.

4.7. Consequences of high selenium concentrations in *P. amurensis*

Bivalves are a critical link for passing selenium to benthivores because trophic transfer is the primary route of predator exposure (Lemly, 1985). The highest concentrations of Se in *P. amurensis* are especially significant in that they exceed values that other studies have shown reduce growth or cause reproductive damage when ingested in experiments by birds and fish (Hamilton et al., 1990; Heinz et al., 1989). Teratogenicity, effects on hatchability of eggs and reduced growth of young life stages have a threshold of occurrence above 3–10 $\mu\text{g Se per g dw}$ in food in various studies (Lemly, 1998; Hamilton, 1999; Heinz et al., 1989). A high frequency of adverse effects is found when concentrations in food (prey) exceed 10–11 $\mu\text{g Se per g dw}$ (Skorupa, 1998; Adams et al., 1998). The highest concentrations in *P. amurensis* exceed the latter value by two-fold.

Some of the important resource species in the North Bay/Delta eat *P. amurensis* and presumably other bivalves (sturgeon, diving ducks

such as scoter and scaup, dungeness crab; Carlton et al., 1990). Earlier studies (White et al., 1988; Urquhart and Regalado, 1991) showed that these benthivores were the predators with the highest selenium concentrations. Average yearly Se concentrations in the liver of the diving duck, surf scoter, ranged from 75 to 200 $\mu\text{g g}^{-1} \text{ dw}$ in 1986–1990, a 7- and 14-fold increase from a reference site (Humboldt Bay). White sturgeon captured between 1986 and 1990 contained annual average concentrations ranging from about 9–30 $\mu\text{g Se per g dw}$ in liver ($n = 52$); and 7–15 $\mu\text{g Se per g dw}$ in flesh ($n = 99$). In 1986, the Dungeness crab had an average soft tissue concentration of 15 $\mu\text{g Se per g dw}$, which was a three fold increase from the reference site (Humboldt Bay). Predators that fed from the water column (e.g. striped bass) seemed to have lower selenium concentrations than the benthivores.

If the susceptibility of San Francisco Bay to invasion by the exotic species *P. amurensis* (Carlton et al., 1990) caused greater Se contamination in the benthos, this effect could be passed on to benthivores. Little data is available to evaluate selenium concentrations in benthivores after 1990. But the 5-year Se Verification Study extended from 1986 through 1990 (Urquhart and Regalado, 1991). *P. amurensis* was first observed in the Bay in 1986 and became well established by 1988 (Carlton et al., 1990; Nichols et al., 1990). Annual mean selenium concentrations in bivalves and two benthivores, sturgeon and scoter, were collected simultaneously in that study and in several of the years between 1986 and 1990. Bivalve selenium concentrations (not including *P. amurensis*) and benthivore concentrations were strongly correlated in that data set (Figs. 6 and 7). The highest values in benthivores were observed in 1989 and 1990. If the mean concentration of selenium in *P. amurensis* was inserted into Fig. 7 at the 1989–1990 benthivore concentration, the added point is consistent with changing selenium exposures of predators. Thus preliminary analysis indicates that the successful invasion of this new resident of Suisun Bay could have changed the exposure of at least some predators in this system.

5. Conclusions

Invasion of San Francisco Bay by the exotic bivalve, *P. amurensis*, resulted in an increase by threefold of selenium concentrations in the predominant macrobenthic food in the estuary. Se concentrations in bivalve-consuming benthivores in the North Bay appeared to increase between the time *P. amurensis* populations were first observed (1986, Carlton et al., 1990) and when it became established as the predominant benthic species (~1988–1990; Urquhart and Regalado, 1991). This is of concern because Se is a strong reproductive toxin for such species, and Se concentrations in *P. amurensis* in fall 1995 and 1996 were in excess of the toxicologic threshold for adverse effects on such predators. Se-contaminated *P. amurensis* were widespread in Suisun and San Pablo Bays in 1995 and 1996. Seasonal variability is an important feature of selenium contamination in *P. amurensis*, with the highest concentrations occurring in fall during the period of longest hydraulic residence times. Transplanted bivalves were not good surrogate indicators for exposure and contamination of the resident bivalve.

Selenium in Benthos Carquinez Strait

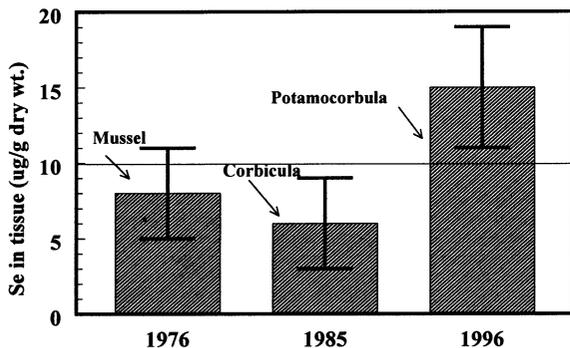

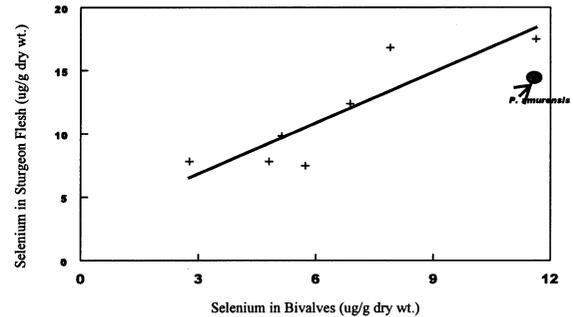

Fig. 6. Mean and S.D. of Se concentrations ($\mu\text{g Se per g dw}$) in three studies of bivalves from in or near Carquinez Strait in three different decades. 'Mussels' were studies of transplanted *M. edulis* in 1976 (Risebrough et al., 1977); 'Corbicula' represents mean of 67 samplings of the clam *C. fluminea* (Johns et al., 1988) and 'Potamocorbula' is the mean of all Carquinez samples in the present study.

Bivalves v. Sturgeon Flesh

Bivalves v. Scoter Flesh

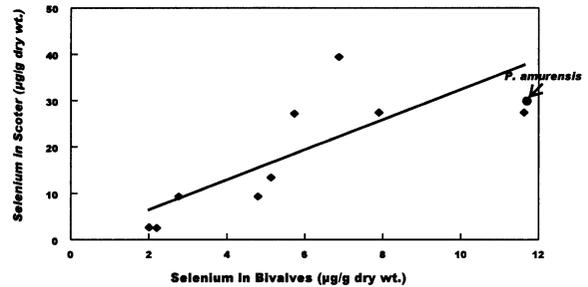

Fig. 7. Relationships between Se concentrations in resident bivalves (data from White et al., 1988; Urquhart and Regalado, 1991; Johns et al., 1988) and either sturgeon flesh or the flesh of the diving ducks (surf scoter) from North San Francisco Bay and Humboldt Bay (data from White et al., 1987, 1988, 1989; Urquhart and Regalado, 1991). Predators and prey were sampled in the same season, year and sub-bay. Mean Se concentration in *P. amurensis* at Carquinez in 1995 is superimposed on each graph to match predator data from 1989–1990, because *P. amurensis* was probably the primary food of these predators in 1989–1990.

We did not fully disprove the hypothesis that the invasive species, *P. amurensis*, is not more efficient at bioaccumulating selenium than other bivalves, although some evidence points in that direction. But this is not the only way an invasive species can affect the fate and effects of a contaminant. The efficient bioaccumulation of Se by bivalves, in general, and the efficient dietary transfer of Se from bivalves to higher trophic levels means that an invasion that shifts the structure of an estuarine community toward dominance by a bivalve-based benthic food web can enhance adverse effects of selenium in the system, by expand-

ing the availability of a contaminated food supply. Whatever the basic mechanism, it seems clear that the invasion of the non-native bivalve *P. amurensis* has resulted in increased bioavailability of a potent environmental toxin to certain benthivores in San Francisco Bay. Changes in contaminant cycling and potential effects are yet another reason to be concerned by the threat of invasive species in our estuarine ecosystems (Cohen and Carlton, 1998; Carlton and Geller, 1993).

eScholarship provides open access, scholarly publishing services to the University of California and delivers a dynamic research platform to scholars worldwide.

Plan (DRERIP) draws both from the current state of knowledge of the Bay–Delta and of environmental Se science. It is an ecosystem-scale methodology that is a conceptual and quantitative tool to (1) evaluate implications of Se contamination; (2) better understand protection for fish and aquatic-dependent wildlife; and (3) help evaluate future restoration actions. The model builds from five basic principles that determine ecological risks from Se in aquatic environments: (1) dissolved Se transformation to particulate material Se, which is partly driven by the chemical species of dissolved Se, sets dynamics at the base of the food web; (2) diet drives bioavailability of Se to animals; (3) bioaccumulation differs widely among invertebrates, but not necessarily among fish; (4) ecological risks differ among food webs and predator species; and (5) risk for each predator is driven by a combination of exposures via their specific food web and the species' inherent sensitivity to Se toxicity. Spatially and temporally matched data sets across media (i.e., water, suspended particulate material, prey, and predator) are needed for initiating modeling and for providing ecologically consistent predictions. The methodology, applied site-specifically to the Bay–Delta, includes use of (1) salinity-specific partitioning factors based on empirical estuary data to quantify the effects of dissolved speciation and phase transformation; (2) species-specific dietary biodynamics to quantify foodweb bioaccumulation; and (3) habitat use and life-cycle data for Bay–Delta predator species to illustrate exposure. Model outcomes show that the north Bay–Delta functions as an efficient biomagnifier of Se in benthic food webs, with the greatest risks to predaceous benthivores occurring under low flow conditions. Improving the characterization of ecological risks from Se in the Bay–Delta will require modernization of the Se database and continuing integration of biogeochemical, ecological, and hydrological dynamics into the model.

Ecosystem-Scale Selenium Model for the San Francisco Bay-Delta Regional Ecosystem Restoration Implementation Plan (DRERIP)

Theresa S. Presser^{1,†} and Samuel N. Luoma^{1,2}

ABSTRACT

Environmental restoration, regulatory protections, and competing interests for water are changing the balance of selenium (Se) discharges to the San Francisco Bay-Delta Estuary (Bay-Delta). The model for Se described here as part of the Delta Regional Ecosystem Restoration Implementation Plan (DRERIP) draws both from the current state of knowledge of the Bay-Delta and of environmental Se science. It is an ecosystem-scale methodology that is a conceptual and quantitative tool to (1) evaluate implications of Se contamination; (2) better understand protection for fish and aquatic-dependent wildlife; and (3) help evaluate future restoration actions. The model builds from five basic principles that determine ecological risks from Se in aquatic environments: (1) dissolved Se transformation to particulate material Se, which is partly driven by the chemical species of dissolved Se, sets dynamics at the base of the food web; (2) diet drives bioavailability of Se to animals; (3) bioaccumulation differs widely among invertebrates, but not necessarily among fish; (4) ecological risks dif-

fer among food webs and predator species; and (5) risk for each predator is driven by a combination of exposures via their specific food web and the species' inherent sensitivity to Se toxicity. Spatially and temporally matched data sets across media (i.e., water, suspended particulate material, prey, and predator) are needed for initiating modeling and for providing ecologically consistent predictions. The methodology, applied site-specifically to the Bay-Delta, includes use of (1) salinity-specific partitioning factors based on empirical estuary data to quantify the effects of dissolved speciation and phase transformation; (2) species-specific dietary biodynamics to quantify foodweb bioaccumulation; and (3) habitat use and life-cycle data for Bay-Delta predator species to illustrate exposure. Model outcomes show that the north Bay-Delta functions as an efficient biomagnifier of Se in benthic food webs, with the greatest risks to predaceous benthivores occurring under low flow conditions. Improving the characterization of ecological risks from Se in the Bay-Delta will require modernization of the Se database and continuing integration of biogeochemical, ecological, and hydrological dynamics into the model.

INTRODUCTION

The Delta Regional Ecosystem Restoration Implementation Plan (DRERIP) process focuses on construction of conceptual models that describe and define the relationships among the processes, habitats, species, and stressors for the Bay-Delta (DiGennaro and others 2012). The models use common elements and are designed to interconnect to achieve the goals of evaluating and informing Bay-Delta restoration actions. Selenium is recognized as an important stressor in aquatic environments because of its potency as a reproductive toxin and its ability to bioaccumulate through food webs (Chapman and others 2010; Presser and Luoma 2010a). Selenium's role is well documented in extirpation (i.e., local extinctions) of fish populations (Lemly 2002) and in occurrences of deformities of aquatic birds in affected habitats (Skorupa 1998). For Se, exposure is specific to a predator species' choice of food web and physiology, making some predators more vulnerable and, thus, more likely than others to disappear from moderately contaminated environments (Lemly 2002; Luoma and Presser 2009; Stewart and others 2004).

Concern about Se as a stressor in the Bay-Delta watershed originates from the damage to avian and fish populations that resulted when an agricultural drain to alleviate subsurface drainage conditions in the western San Joaquin Valley released Se into the Kesterson National Wildlife Refuge in the 1980s (Presser and Ohlendorf 1987). Later it was recognized that (1) some aquatic predators in the Bay-Delta were bioaccumulating sufficient Se to threaten their reproductive capabilities (SWRCB 1987, 1988, 1989, 1991) and; (2) primary Se sources included not only organic enriched sedimentary deposits in the San Joaquin Valley and elsewhere, but also their anthropogenic by-products such as oil (Cutter 1989; Presser 1994; Presser and others 2004). Proposals in 1978 and 2006 to extend an agricultural drain from the western San Joaquin Valley directly to the Bay-Delta as a way of removing Se from the valley were found both times to present substantial and broad ecological risks (e.g., USBR 1978, 2006; Presser and Luoma 2006).

Currently, Se contamination is spatially distributed from the Delta through the North Bay (Suisun Bay, Carquinez Strait, and San Pablo Bay) to the Pacific Ocean, mainly from oil-refining discharges internal to the estuary, and agricultural drainage discharges exported via the San Joaquin River. Regulatory and planning processes have intervened in the cases of both existing Se sources resulting in a decline in contamination since 1986-1992 when concentrations were maximal (SWRCB 1987, 1988, 1989, 1991; Presser and Luoma 2006; USBR 1995, 2001, 2009). However, the North Bay, the Delta, and segments of the San Joaquin River and some of its tributaries and marshes remain designated as impaired by Se (SWRCB 2011). More recently, the State initiated a Se Total Maximum Daily Load (TMDL) process to target both agricultural and oil refinery sources of Se (SFBRWQCB 2007, 2011) in coordination with development and implementation of site-specific water quality Se criteria for the protection of fish and wildlife by the U.S. Environmental Protection Agency (USEPA 2011a). The presence of a major oil-refining industry in the North Bay, and the substantial accumulated reservoir of Se in the soils and aquifers of the western San Joaquin Valley suggest that the potential for ecological risk from Se within the Bay-Delta watershed will continue into the foreseeable future as Se management and mitigation efforts take place (Presser and Luoma 2006; Presser and Schwarzbach 2008; USBR 2008; [Appendix A.1](#)).

Historic and more recent data show that certain predator species are considered most at risk from Se in the Bay-Delta (e.g., white and green sturgeon, scoter, scaup) because of high exposures obtained when they consume the estuary's dominant bivalve, *Corbula amurensis*, an efficient bioaccumulator of this metalloid (Stewart and others 2004; Presser and Luoma 2006). The latest available surveys of Se concentrations in *C. amurensis* and white sturgeon (*Acipenser transmontanus*) that were feeding (based upon isotopic evidence) in Carquinez Strait, Suisun Bay, and San Pablo Bay (Stewart and others 2004; Linares and others 2004; Kleckner and others 2010; Presser and Luoma 2010b; SFEI 2009) continue to show concentrations exceeding U.S. Fish and Wildlife Service (USFWS) dietary and tissue toxicity guide-

lines (Skorupa and others 2004; Presser and Luoma 2010b). Sturgeon contain higher concentrations of Se than any other fish species, reflecting their position as a top benthic predator (Stewart and others 2004). Surveys of surf scoter (*Melanitta perspicillata*) and greater scaup (*Aythya marila*) that feed voraciously on *C. amurensis* as they overwinter in Suisun Bay (SFEI 2005; De La Cruz and others 2008; De La Cruz 2010; Presser and Luoma 2010b) show Se has bioaccumulated to levels in muscle and liver tissue that may affect their ability to successfully migrate and breed (Heinz 1996; USDOJ 1998; Ohlendorf and Heinz 2011).

Endangered Species Act requirements led to a number of species being determined as jeopardized by Se in the Bay-Delta under a proposed chronic aquatic life Se criterion of 5 $\mu\text{g L}^{-1}$ (USFWS and NOAA Fisheries 2000), including delta smelt (*Hypomesus transpacificus*); longfin smelt (*Spirinchus thaleichthys*); Sacramento splittail (*Pogonichthys macrolepidotus*); Sacramento perch (*Archoplites interruptus*); tidewater goby (*Eucyclogobius newberryi*); green sturgeon (*Acipenser medirostris*) and its surrogate white sturgeon (*Acipenser transmontanus*); steelhead trout (*Oncorhynchus mykiss*); Chinook salmon (*Oncorhynchus tshawytscha*); California clapper rail (*Rallus longirostris obsoletus*); California least tern (*Sterna antillarum brownii*); bald eagle (*Haliaeetus leucocephalus*); California brown pelican (*Pelecanus occidentalis californicus*); marbled murrelet (*Brachyramphus marmoratus*); and giant garter snake (*Thamnophis gigas*). Recent analysis by the USFWS (2008a) of 45 species assumed the species most at risk depended on benthic food webs: greater scaup; lesser scaup (*Aythya affinis*); white-winged scoter (*Melanitta fusca*); surf scoter; black scoter (*Melanitta nigra*); California clapper rail; Sacramento splittail; green sturgeon; and white sturgeon. Not enough species-specific information is currently available for consideration of Se exposures for the giant garter snake, an endangered aquatic predator (USFWS 2006, 2009); the Dungeness crab (*Cancer magister*), an invertebrate that consumes *C. amurensis* (Stewart and others 2004); or for species that are within the Dungeness-crab food webs.

Human health advisories currently are posted for the Bay-Delta for the consumption of scoter, greater scaup, and lesser scaup based on elevated Se concentrations in their muscle and liver tissue (CDFG 2012, 2013). Selenium was found to be below the level of human health concern for consumption of edible tissue in certain species of fish, including white sturgeon, from the estuary (OEHHA 2011). White sturgeon contained the highest levels of Se among species of fish surveyed. Some individual white sturgeon sampled from North Bay locations had Se concentrations that exceeded Se advisory levels, based on specific consumption rates (see later detailed discussion under "Human Health" on page 23). Additionally, white sturgeon recreational fishing is limited, based on a decreasing species population (CDFG 2012).

It was recently suggested that the traditional regulatory approach to managing Se contamination is deeply flawed (Reiley and others 2003; Luoma and Presser 2009; Chapman and others 2010), and that a new conceptual model of the processes that control its toxicity is needed for regulatory purposes, especially in estuarine environments like the Bay-Delta. In recognition of the issues with the traditional approach to deriving a criterion for Se, the USEPA is leading a cooperative effort to develop site-specific fish and wildlife Se criteria for habitats affected by Se in California. Specifically for the Bay-Delta, the effort includes protection of Federally listed species and designated critical habitat (USFWS and NOAA Fisheries 2000; USEPA 2011a). Development of Se criteria for the Bay-Delta is proceeding first in this effort because the estuary is considered a sensitive hydrologic system and habitat in terms of Se and it was thought that protection here would elicit regulatory compliance upstream (USEPA 2011a). On the broader scale, Se is considered a general stressor of the estuary, and a constituent that should be analyzed as part of management and restoration planning and implementation (USEPA 2011b; NRC 2010, 2011, 2012).

The cooperative regulatory effort specifically recognizes that the new conceptual model must consider (1) the inaccuracies of deriving toxicity from waterborne Se concentrations; (2) the bioaccumulative nature of Se in aquatic systems; (3) Se's long-term

SAN FRANCISCO ESTUARY & WATERSHED SCIENCE

persistence in aquatic sediments and food webs; and (4) the importance of dietary pathways in determining toxicity (USEPA 1992, 2000a; USFWS and NOAA Fisheries 2000; Luoma and Presser 2009; Presser and Luoma 2006, 2010a, 2010b). Revisions by USEPA also are occurring at the national level to incorporate into the basis for regulation recent advances in the environmental science of Se. For example, a fish tissue Se criterion and implementation plan are being proposed to better integrate dietary exposure pathways into regulatory frameworks, and ensure an adequate link to toxicity (USEPA 2004, 2011b). During this transitional period when species may be jeopardized and while Se criteria are being revised, USEPA has applied the national chronic freshwater Se criterion of $5\mu\text{g L}^{-1}$ to the estuary (USEPA 1992, 2000a).

We present here an ecosystem-scale Se conceptual model for the Bay-Delta that addresses the needs of both the DRERIP process and the USEPA. Quantitative applications of the model are also possible. Quantification provides an opportunity to evaluate site-specific Se risks under different circumstances, using field data combined with a systematic quantification of each of the influential processes that link source inputs of Se to toxicity. The methodology is presented in terms of specified DRERIP components (i.e., drivers, linkages, and outcomes). As an example of how quantitative applications can be used, we calculate the dissolved ambient Se concentrations that would result in compliance with a chosen fish or bird tissue guideline under different assumptions or environmental conditions. Uncertainties and model sensitivities are illustrated by comparing outcomes of different exposure scenarios. The scenario approach could facilitate the model's use by decision-makers for quantitative evaluation of restoration alternatives for ecosystem management and protection.

MODEL OVERVIEW

The DRERIP Ecosystem-Scale Selenium Model for the Bay-Delta (Figure 1) has five interconnected modules that depict drivers (sources and hydrology), linkages (ecosystem-scale processes), concentration outcomes

(Se concentrations in water, particulates, and organisms), and food web exposure outcomes (effects on fish, wildlife, and human health). Model outcomes in Figure 1 are further refined to critical choices for modeling and species-specific risk scenarios for the Bay-Delta. Together the five modules consider the essential aspects of environmental Se exposure: biogeochemistry, food web transfer, and effects. They also take into account the estuary's ecology and hydrology as well as the functional ecology, physiology and ecotoxicology of the most vulnerable predator species. The modules define relationships that are important to conceptualizing and quantifying how Se is processed from water through diet to prey and predators, and the resulting effect on components of the food web. Thus, the DRERIP Ecosystem-Scale Selenium Model combines fundamental knowledge of Se behavior in ecosystems (Se drivers, linkages, and outcomes) with site-specific knowledge of the Bay-Delta (Bay-Delta drivers, linkages, and outcomes) to define site-specific Se risk (Figure 1).

The DRERIP Se submodels provide details for

- Sources and Hydrology (submodel A, Figure 2);
- Ecosystem-Scale Se Modeling (submodel B, Figure 3);
- Exposure: Food Webs, Seasonal Cycles, Habitat Use (submodels C, D; Figures 4, 5);
- Fish and Wildlife Health: Ecotoxicology and Effects (submodels E, F; Figures 6, 7); and
- Human Health (submodel G, Figure 8).

A human health pathway is designated, but emphasis here is on Se pathways to fish and wildlife health. The North Bay and the Delta are emphasized because the important Se sources have the potential to most affect those habitats and ecosystems (submodel A, Figure 2).

The quantitative DRERIP Ecosystem-Scale Selenium Model is based upon concepts and parameters developed elsewhere for a wide variety of aquatic systems and their food webs (submodel B, Figure 3; submodel E, Figure 6) (Luoma and Rainbow 2005; Luoma and Presser 2009; Chapman and others 2010; Presser and Luoma 2010a). To quantitatively apply the rela-

Delta Regional Ecosystem Restoration Implementation Plan Ecosystem-Scale Selenium Model

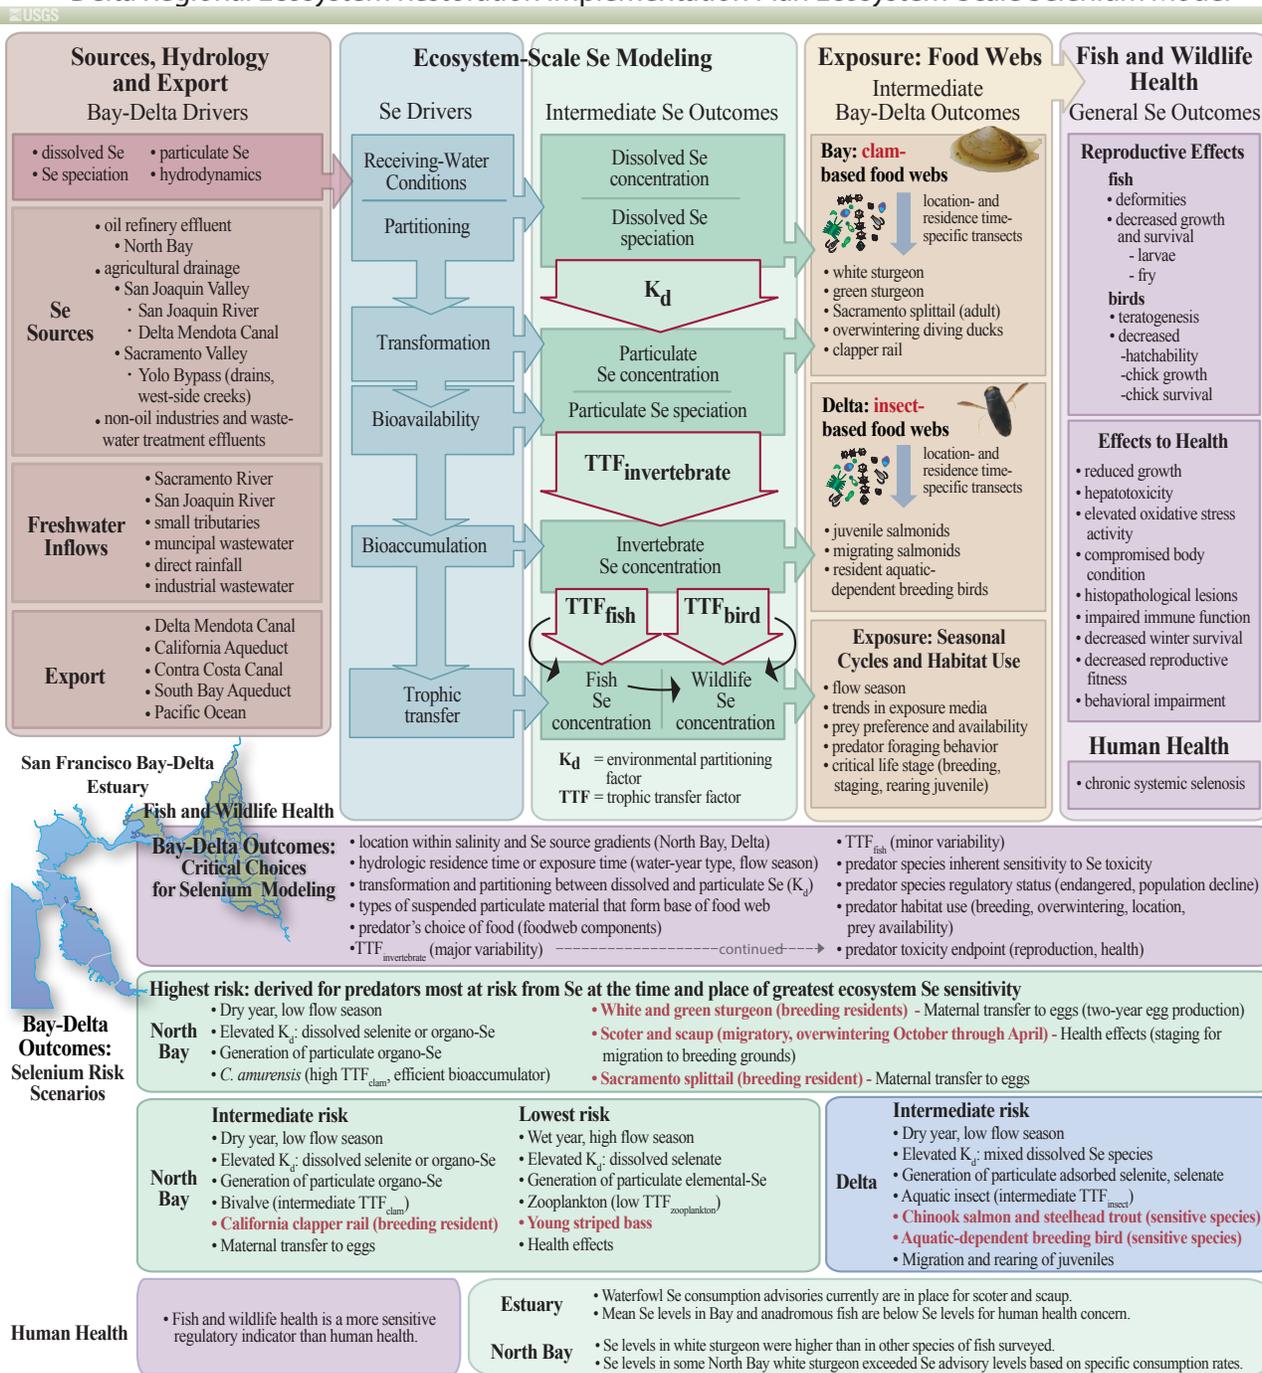

Figure 1 The DRERIP Ecosystem-Scale Selenium Model illustrates five interconnected modules that depict essential aspects of the Bay-Delta's hydrology, biochemistry, and ecology and of the exposure and ecotoxicology of predators at risk from selenium. These modules, and the detailed sub-models that follow, conceptualize (1) how selenium is processed from water through diet to predators and (2) its effects on ecosystems. Critical choices for modeling are summarized, and a quantitative application of the model for the estuary is derived for predators most at risk from Se at the time and place of greatest ecosystem Se sensitivity.

SAN FRANCISCO ESTUARY & WATERSHED SCIENCE

tionships in the conceptual model, we use empirical data from the Bay-Delta (e.g., Cutter and Cutter 2004; Presser and Luoma 2006, 2010b) to (1) help define environmental partitioning factors (K_d s) that quantify transformation of dissolved Se into particulate forms; and (2) help define biodynamic trophic transfer factors (TTFs) that quantify uptake by consumer species and their predators (submodel C, Figure 4; submodel D, Figure 5; submodel F, Figure 7). The broader, ecosystem-scale Se modeling approach was validated by comparing model forecasts with field data, across both a range of common food webs and hydrologic environments (Luoma and Rainbow 2005; Presser and Luoma 2010a) and specifically for the Bay-Delta and Newport Bay (Presser and Luoma 2006, 2009, 2010b).

The organizing principle for quantification is the progressive solution of a set of simple equations, each of which quantifies a process important in Se exposure (submodel B, Figure 3). The interaction of Se loading from different sources, hydrology, and hydrodynamics determine dissolved Se concentrations in the Bay-Delta. Transformation of Se from its dissolved form to a particulate form (represented here operationally as K_d) ultimately determines bioavailability to the food web. In a given environment, Se is taken up much faster from food than from solution by animals. Thus, the entry of Se into the food web can be estimated by a TTF for each trophic level. $TTF_{invertebrate}$ defines dietary uptake by a consumer species, which occurs when invertebrates (or herbivorous fish), feed on primary producers, detritus, microbes, or other types of particulate materials. Selenium bioaccumulation differs widely among invertebrate species because of different physiologies (Luoma and Rainbow 2005). These differences are captured by employing species-specific TTFs (Luoma and Presser 2009). Species-specific TTFs for predaceous fish and birds ($TTF_{predator}$) also are applied to the transfer of Se from invertebrate prey species to their predators (Presser and Luoma 2010a).

For the Bay-Delta, Stewart and others (2004) showed that Se concentrations differ widely among predators that live in the same environment. The main reason for those differences lies in the prey preferences of predators. For example, bass eating from the water-column food web consume invertebrates with much

lower Se concentrations than sturgeon eating benthic invertebrates, especially bivalves (Stewart and others 2004). The differences in Se uptake among predator species ($C_{predator}$) can be captured only if the correct prey species (or class of prey species) is included in the equation (submodel B, Figure 3) and the conceptualization (submodel C, Figure 4). This also means that the choice of predator species is critical in assessing risks from Se contamination.

Selenium concentrations in predators can be predicted with surprisingly strong correlation to observations from nature if particulate Se concentrations are known and an appropriate food web is used for the predator (Luoma and Presser 2009; Presser and Luoma 2010a). One use of these calculations might be to quantify the degree to which different species of birds and fish might be threatened by Se in a specified environment, for example. The correspondence between observed $C_{predator}$ and predictions of $C_{predator}$ from the series of equations that begins with dissolved concentrations (submodel B, Figure 3) depends upon how closely the partitioning between dissolved and particulate Se used in the model matches that occurring in the ecosystem of interest. One use of quantification in this instance is to run the model in the reverse direction to determine the dissolved Se concentration in a specific type of hydrologic environment and food web that would result in a specified Se concentration in the predator. Later, we present a detailed example of how the latter might be applied to real-world issues.

In the final step, effects on the reproduction and health of predaceous fish and birds are determined from bioaccumulated Se concentrations. Selenium is one of the few trace elements for which tissue concentrations have been correlated to these adverse effects in both dietary toxicity tests and field studies. The toxicity data for some of the key species in the Bay-Delta are limited or non-existent. The necessity of establishing effects thresholds from surrogate species adds some uncertainty to assessments of risk. Therefore, in our examples, we use different possible choices for such thresholds.

Additionally, modeling here is within a specified location and flow condition to provide context for

exposure and to help narrow the uncertainties in quantifying the ecological and physiological potential for bioaccumulation (Presser and Luoma 2010b).

MODULES

Sources, Hydrology, and Export

Estuary Mass Balance

The major portion of the estuary from the rivers to the Golden Gate Bridge is termed the Northern Reach, with Suisun Bay near the head of the estuary (submodel A, [Figure 2](#)). Selenium sources and their hydraulic connections within that reach have been documented in a number of publications (Cutter 1989; Cutter and San Diego-McGlone 1990; Cutter and Cutter 2004; Meseck and Cutter 2006; Presser and Luoma 2006, 2010b; SFBRQWCB 2011) ([Figure 1](#); submodel A, [Figure 2](#)). In brief, the most important regulated estuarine sources of Se are (1) internal inputs of oil refinery wastewaters from processing of crude oils at North Bay refineries; and (2) external inputs of irrigation drainage from agricultural lands of the western San Joaquin Valley conveyed mainly through the San Joaquin River. (submodel A, [Figure 2](#)). These and other potential Se sources are described in detail in [Appendix A.1](#). These details reflect the depth of history for Se management within the Bay-Delta watershed and the continuing tradeoffs that accompany their presence.

The Sacramento and San Joaquin rivers are the main sources of freshwater inflow to the Bay-Delta, with the Sacramento River being the dominant inflow under most conditions (Conomos and others 1979; Peterson and others 1985). The rivers provide 92% of the freshwater inflows to the Bay-Delta, with small tributaries and municipal wastewater providing approximately 3% each (McKee and others 2008).

In general, Se concentrations in the Sacramento River (above tidal influence, e.g., at Freeport) are low and relatively constant (1998 to 1999 average: $0.07 \mu\text{g L}^{-1}$; range 0.05 to $0.11 \mu\text{g L}^{-1}$) (Cutter and Cutter 2004). Dissolved Se concentrations in the San Joaquin River (above tidal influence, e.g., at Vernalis) were about an order-of-magnitude higher than those in the Sacramento River in 1999 (1998 to 1999 aver-

age: $0.71 \mu\text{g L}^{-1}$; range 0.4 to $1.07 \mu\text{g L}^{-1}$) (Cutter and Cutter 2004) and are much more variable. In the late 1980s and early 1990s concentrations above $5 \mu\text{g L}^{-1}$ were observed occasionally in the San Joaquin River (Presser and Luoma 2006), but in-valley source control efforts have reduced Se loads and concentrations ([Appendix A.1](#)).

In the present configuration of the Bay-Delta, the San Joaquin River is predominantly re-routed and exported back to the San Joaquin Valley (submodel A, [Figure 2](#); [Appendix A.1](#)). Hence, for the purposes of evaluating Se contamination sources, the simplest assumption is that the “baseline” Se concentrations (undisturbed by human activities) in the Delta would be close to the Se concentrations in the Sacramento River. The pre-disturbance baseline Se concentrations in the Bay or tidal reaches of the rivers would be concentrations in the Sacramento River mixed with concentrations in coastal waters, as reflected by the salinity of the sampling location. Deviations from that baseline reflect inputs of Se internal to the Bay (industrial or local streams) (Cutter and San Diego-McGlone 1990; Cutter and Cutter 2004) or input of Se to the Bay from the San Joaquin River.

The current San Joaquin River contributions to the Bay, thought to be minimal during most flow conditions, are especially difficult to measure ([Appendix A.1](#)). However, that could change. Under some proposals for modifications in water infrastructure, increased diversion of the Sacramento River through tunnels or canals would be accompanied by greater inflows from the San Joaquin River to the Delta and the Bay. In simulations available of the implications of such a change, Meseck and Cutter (2006) found that Se concentrations doubled in particulate material in the Bay.

The conceptual model described above suggests that parameters critical in determining the mass balance model for Se inputs for the Bay-Delta are (1) total river discharge (Sacramento River and San Joaquin River); (2) water diversions or exports (i.e., pumping at Tracy and Clifton Court Forebay south to the Delta-Mendota Canal and the California Aqueduct); (3) proportion of the San Joaquin River directly

Sources and Hydrology

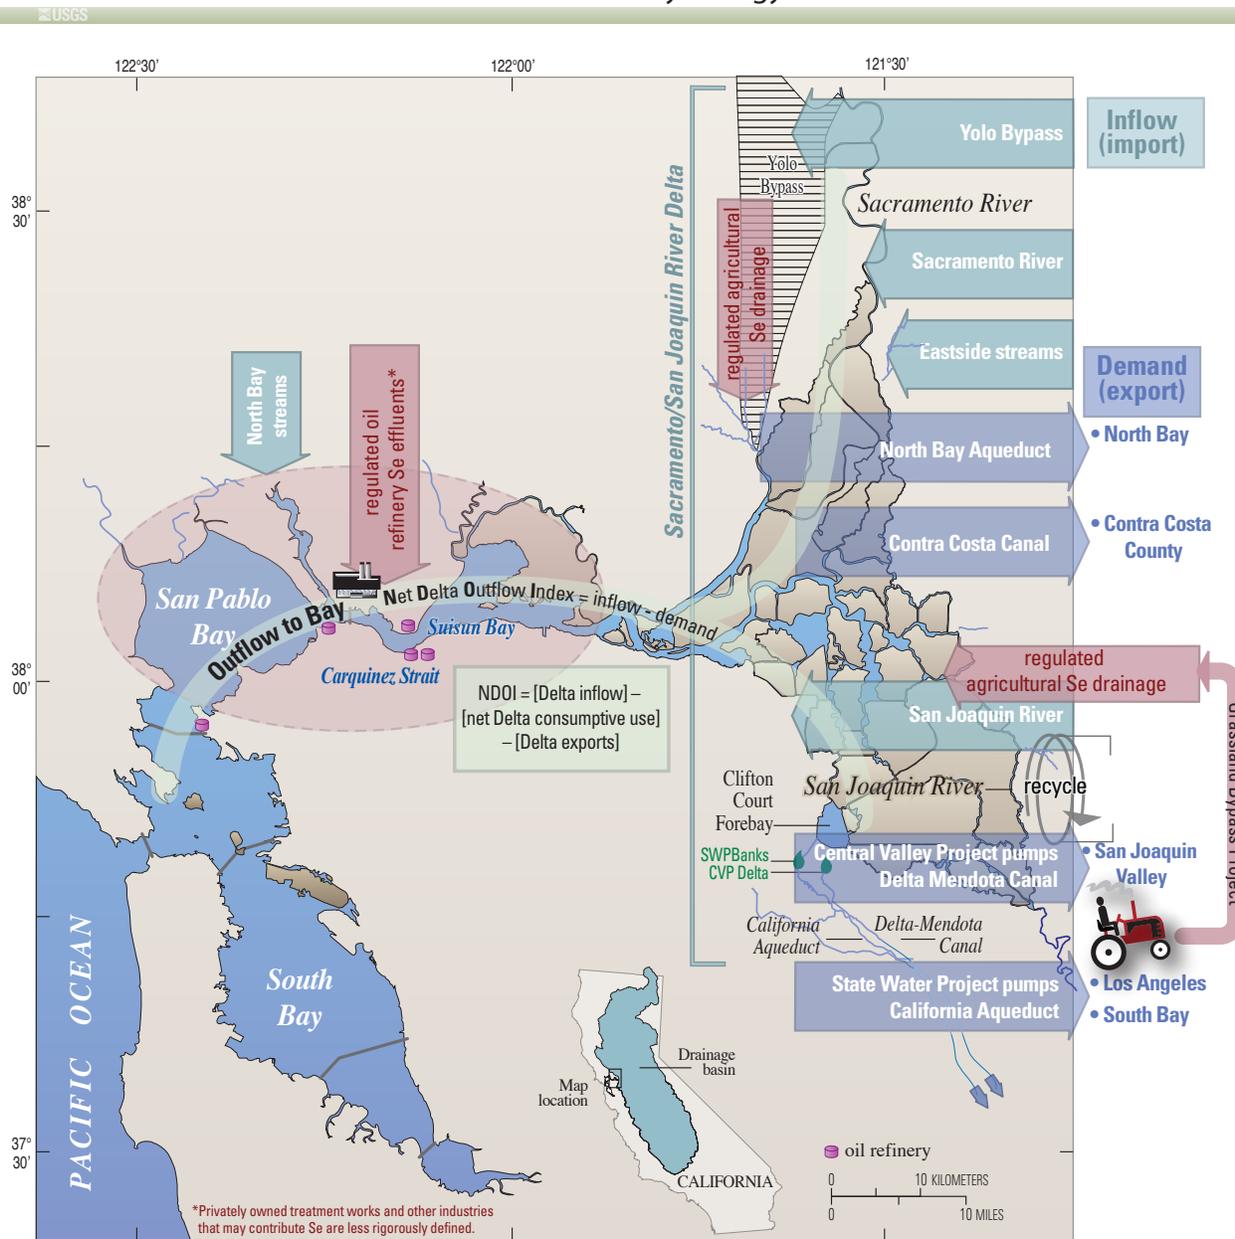

Figure 2 Submodel A. Sources and Hydrology

recycled south before it enters the Bay; 4) Se concentrations in each of the internal and external sources; and 5) total outflow of the rivers to the Bay or Net Delta Outflow Index (NDOI).

There are several uncertainties in quantification of the Se mass balance. One is the difficulty of precisely defining the contribution of the San Joaquin River to the NDOI, and hence the agricultural component of Se inputs to the Bay. Diversions and Delta hydrodynamics are sufficiently complex that every method available to determine that contribution has serious uncertainties (e.g., subtracting Sacramento River flow at Rio Vista from NDOI). Simple water accounting suggests minimal potential for flow from the San Joaquin River to enter the Bay (i.e., as measured by the percent by which river flow at Vernalis exceeds total export) during many months of the year (USBR 2012). Inputs are possible during spring months (April and May), wet and above normal years, and times of low capture efficiency (e.g., when river barriers are in-place) or when the ratio of the Sacramento River and San Joaquin River discharges is lowest in the fall.

A second uncertainty is that the strong tidal circulation in the Bay and the Delta mixes dissolved and particulate Se through the entire tidal reach, distorting spatial patterns that might otherwise help identify important sources of Se input (Ganju and others 2004). The three-dimensional nature of tidally driven hydrodynamics dissociates distributions of dissolved and particulate Se as well, adding complexity. One important outcome of this is that particulates contaminated with Se from industrial sources in Suisun Bay could feasibly be found throughout the full tidal range in both rivers, including otherwise uncontaminated segments of the Sacramento River. Riverine endmember concentrations of particulate Se, therefore, must be defined from landward of the reach of the tides, although river discharge at those locations does not necessarily represent riverine outflow to the Bay. Collecting an adequate mass of suspended particulate material for Se analysis in non-tidal freshwaters is challenging; therefore, few such data exist for the Sacramento River and even for some of the areas possibly affected by agricultural drainage. Hydrodynamic models of varying complexity are

available that can approximate water movements in this complex situation (e.g., Delta Simulation Model II). But modeling the distribution of particulate material (crucial for understanding implications of Se) is much more difficult (Ganju and others 2004).

Links Between Source Inputs and Water Inflows

Both Sacramento River and San Joaquin River discharges vary dramatically during the year depending on runoff, water management, and diversions. Residence (or retention) time is affected by river discharges (e.g., Cutter and Cutter 2004), but the strong tidal influences make that difficult to precisely define. Nevertheless, even a coarse differentiation of seasonal periods (low flow and high flow) and classification by water year (critically dry, dry, below normal, normal, above normal and wet) can be useful in evaluating influences on processes important to the fate and bioavailability of Se (Presser and Luoma 2006). Empirical data suggest processes such as dilution of local inputs and phase transformations that incorporate Se into organic particulate material appear to be affected by changes in retention time in the estuary, at least to some extent (Cutter and Cutter 2004; Doblin and others 2006; Presser and Luoma 2006, 2010a, 2010b). For example, Cutter and San Diego-McGlone (1990) found that a peak in selenite concentrations was centered around the area of inputs from oil refineries during low riverine inflows to the Bay in the 1980s; but that peak disappeared during periods of high riverine discharge. They used a one-dimensional model of the water and a Se mass balance to show that the mass of Se discharged by the refineries was the dominant source of selenite during low flows, but that it was insignificant compared to the mass of Se input from the Sacramento River during high flows. The selenite peak was reduced and replaced by a different pattern of dissolved Se speciation when Se discharges from the refineries were reduced by about half in 1999 (Cutter and Cutter 2004). Similarly, high Se concentrations in the southernmost Delta (Stockton) reflect San Joaquin River inputs, but concentrations seaward of this location decline as they are diluted by the large volumes of Se-poor Sacramento River water channeled into the Delta for export (Lucas and Stewart 2007). Local

SAN FRANCISCO ESTUARY & WATERSHED SCIENCE

tributaries could be an internal source of Se to the Bay, but these inputs occur almost entirely during high riverine inflow periods when their Se loads are insignificant compared to the large mass of Se carried into the Bay by high discharge from the Se-poor Sacramento River.

The NDOI, essentially inflow minus demand, is often used to indicate hydrologic influences on Se concentrations, including differences in retention time of a parcel of water in the Bay and Delta (Cutter and Cutter 2004). Increased exposure time (i.e., the cumulative amount of time a particle spends within a domain, taking into consideration repeated visits over multiple tidal cycles; L. Doyle, W. Fleenor, and J. Lund, University of California, Davis, pers. comms.; 2012) at the lowest inflows may explain why NDOI is a relevant indicator of the effect of flow on processes such as conversion of Se from dissolved to particulate forms.

Exports

The Delta–Mendota Canal, California Aqueduct, Contra Costa Canal, and South Bay Aqueduct all export water from the Delta. Thus, all are secondary recipients of the Se sources considered here (submodel A, Figure 2). The Delta–Mendota Canal also receives agricultural drainage directly, with that source proposed to be under regulatory control (USFWS 2009; USBR 2011). In general, however, few data are available to assess a mass balance for Se through the State Water Project, Central Valley Project, and other water-delivery systems.

In terms of export of Se to the Pacific Ocean from the Bay, some data are available for seaward locations in the Bay. Dissolved concentrations at these locations are among the lowest observed in the system when not under flood flows (Cutter 1989; Cutter and San Diego–McGlone 1990; Cutter and Cutter 2004); particulate concentrations are occasionally high, however. Under shorter residence times during high flows, increased dissolved concentrations near the Golden Gate Bridge (Cutter and Cutter 2004) suggest sources internal to the Bay affect ocean-dissolved Se concentrations. Outflows to the sea have been estimated in simple mass balance models (Cutter and San Diego–

McGlone 1990) although there are some uncertainties in such estimates. Ocean disposal was considered as one of the alternatives for comprehensive agricultural drainage management from the western San Joaquin Valley (USBR 2006). However, efficient Se recycling within productive ocean ecosystems and the opportunities for Se biomagnification in complex marine food webs suggest serious risks are likely (Cutter and Bruland 1984); hence, there are reasons for careful study before such options are considered.

Ecosystem-Scale Selenium Modeling

Dissolved Selenium Concentrations, Speciation, and Transformation

Total dissolved Se concentrations within the Bay range from 0.070 to 0.303 $\mu\text{g L}^{-1}$, with a mean of $0.128 \pm 0.035 \mu\text{g L}^{-1}$ and a median of 0.125 $\mu\text{g L}^{-1}$ across 128 samples collected since 1997 (Doblin and others 2006; Lucas and Stewart 2007). The mean concentration is only approximately two times higher than Se concentrations in the dominant freshwater endmember (the Sacramento River). In all surveys since the 1980s, Se concentrations in the tidal Bay and Delta are highest in Suisun Bay, with a downward spatial trend from Carquinez Strait toward the ocean. The latter suggests that dissolved concentrations in the ocean endmember are about the same as those in the Sacramento River.

The dissolved gradients of Se concentration are not necessarily the best indicators of the distribution of Se effects. Ecological implications depend upon the biogeochemical transformation from dissolved to particulate Se. Phase transformation of Se is of toxicological significance because particulate Se is the primary form by which Se enters food webs (Figures 1, 3 and 4) (Luoma and others 1992). Speciation of dissolved Se into its three dominant oxidation states is an important component in many conceptual models. In the Bay-Delta, speciation of dissolved Se is important because it influences the type and rate of phase transformation reaction that creates particulate Se. Examples of phase transformation reactions include (1) uptake by plants and phytoplankton of selenate, selenite, or dissolved organo-Se and transformation to particulate organo-Se by

Submodel B

Ecosystem-Scale Se Modeling

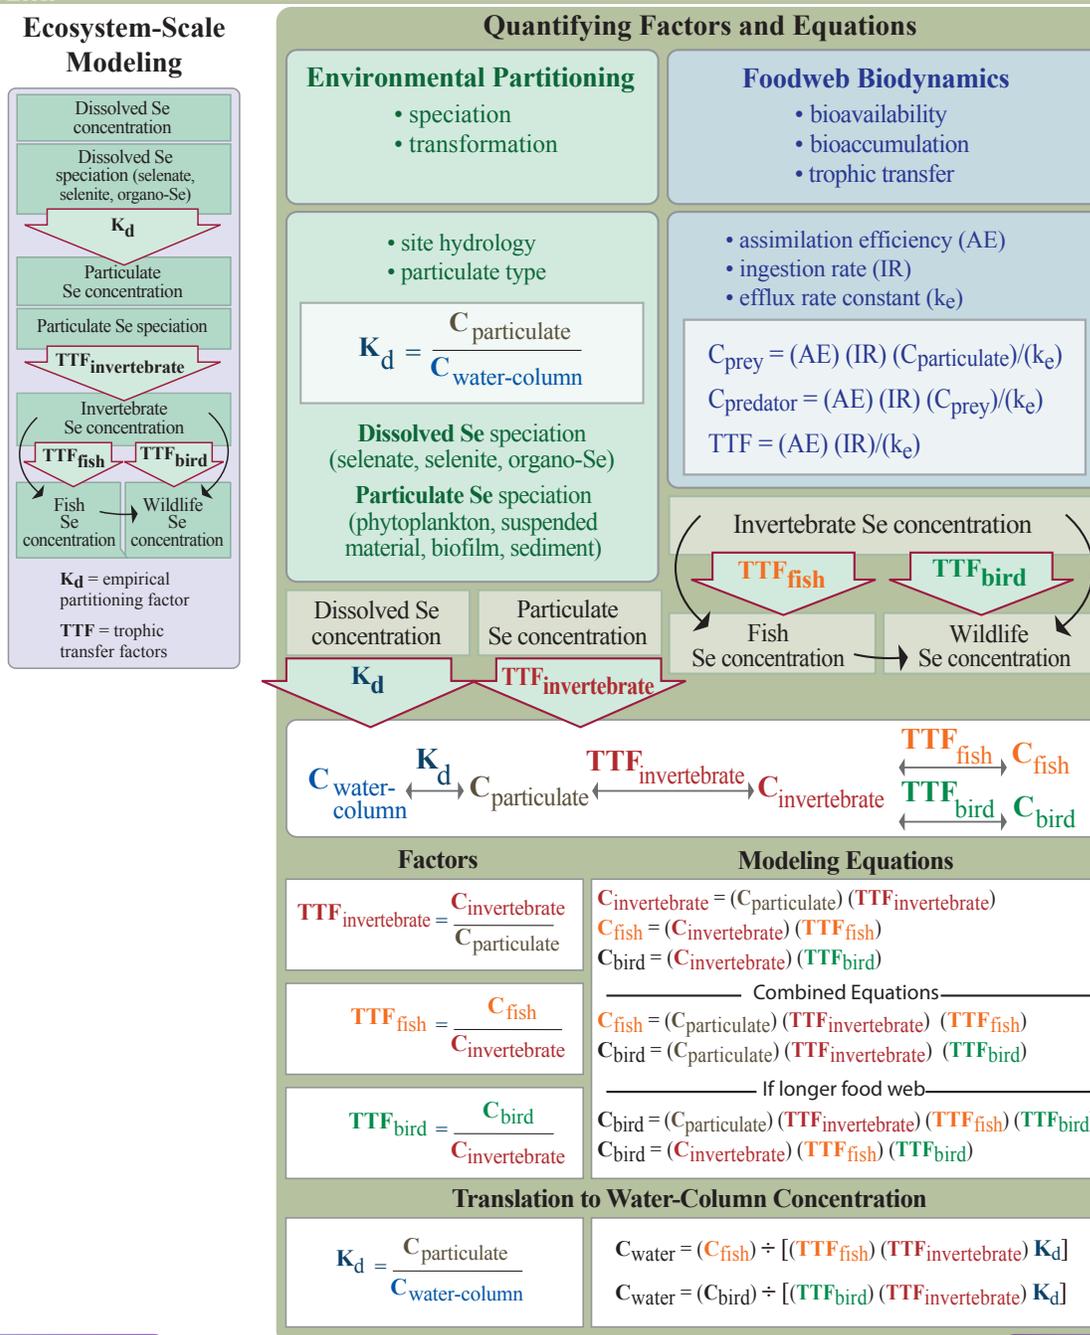

Figure 3 Submodel B. Ecosystem-Scale Se Modeling

SAN FRANCISCO ESTUARY & WATERSHED SCIENCE

assimilatory reduction, where uptake of selenate is considerably slower than uptake of the other two forms (e.g., Sandholm and others 1973; Riedel and others 1996; Wang and Dei 1999; Fournier and others 2006); (2) sequestration of selenate into sediments as particulate elemental Se by dissimilatory biogeochemical reduction (e.g., Oremland and others 1989); (3) adsorption as co-precipitated selenite through reactions with particle surfaces; and (4) recycling of particulate phases back into water as detritus or as dissolved organo-Se, after organisms die and decay (e.g., Velinsky and Cutter 1991; Reinfelder and Fisher 1991; Zhang and Moore 1996).

These different biogeochemical transformation reactions result in different forms of Se in particulate material: organo-Se, adsorbed Se, or elemental Se. Although only a few studies have determined speciation of particulate Se (e.g., Doblin and others 2006), such data can greatly aid in understanding bioavailability. Experimental studies show that particulate organo-Se is the most bioavailable form when it is eaten by a consumer species (Luoma and others 1992). Detrital or adsorbed Se is also bioavailable when ingested by animals, although to a lesser extent than organo-Se (Wang and others 1996). Non-particle associated elemental Se is not bioavailable (Schlekat and others 2000).

Concentrations of Se in particulate materials (per unit mass material) within the Bay and tidal freshwaters range widely from 0.1 to 2.2 $\mu\text{g g}^{-1}$ dry weight (dw), with a mean of $0.56 \pm 0.32 \mu\text{g g}^{-1}$ dw and a median of $0.45 \mu\text{g g}^{-1}$ dw ($n = 128$) since 1997 (Doblin and others 2006; Lucas and Stewart 2007). The 15-fold range in particulate concentrations contrasts sharply with the 4-fold range in dissolved concentrations, as do the contrasts in standard deviations. Not only are particulate concentrations much more dynamic than dissolved concentrations, but they also are about four times higher if expressed in common units. Both reflect biogeochemical transformation processes and, perhaps, inorganic adsorption. The latter is probably more important in soils than in the aquatic environment. Given the different dynamics and the variability of dissolved and particulate Se, it is not surprising that the ratio of the two also is quite variable.

Geochemical models that attempt to capture phase transformations of Se under different conditions are problematic. In fact, no models are available that can predict particulate Se concentrations based solely upon dissolved concentrations and biogeochemical conditions. One reason is that conventional thermodynamic equilibrium-partitioning models are inadequate for Se. Critical Se transformation processes are biological, and not predictable from thermodynamics. Some model approaches predict the particulate Se added on to a pre-existing particulate concentration, using a combination of phytoplankton productivity and re-suspension (Meseck and Cutter 2006; SWRCB 2011; Tetra Tech, Inc. 2010). While such models provide interesting estimates of temporal and spatial distributions of particulate Se, their major limitations lie in the basis upon which the pre-existing concentration is chosen and their inability to comprehensively account for all the processes involved in transformation.

The choice of the (pre-existing) baseline particulate Se concentration is critical to the questions models can address. Local data can be used for choosing pre-existing Se concentrations at the seaward and landward boundaries in the Bay-Delta. But the data used to date are from tidally affected reaches of the river, and are likely to be biased by redistribution of already contaminated particles from tidal pumping. As noted above, few data exist for particulate Se concentrations above the tidal reach of the Sacramento River; nor are there adequate determinations of Se concentrations on particulates from the coastal zone. In such a case, answers to questions about changing the internal Se inputs to the Bay are biased in that the boundary condition already includes such inputs (SWRCB 2011; Tetra Tech, Inc. 2010). On the other hand, this modeling approach appears to be well suited to test the influence of changing inputs from one boundary or from primary production alone (Meseck and Cutter 2006; Tetra Tech, Inc. 2010).

Observations of environmental partitioning of Se between dissolved and particulate phases can be employed to estimate transformation efficiencies in lieu of a comprehensive approach to modeling biogeochemical phase transformation for Se. Presser and Luoma (2006) first used field observations to

quantify partitioning, which they described by the somewhat controversial term K_d . Luoma and Presser (2009) were careful to emphasize that their K_d s represented conditional observations from the Bay-Delta at a specific time and place; and were not meant to be equilibrium constants. Thermodynamic equilibrium constants would be inappropriate to describe an inorganic to organic transformation. They pointed out that no single constant could be expected to apply to all environmental conditions either in the Bay-Delta or elsewhere. Site hydrology, dissolved speciation, and the type of particulate material are all influential, although specific influences were not necessarily predictable in quantitative terms. An operational approach was therefore chosen to try to estimate influences of such processes.

They defined K_d as the ratio of particulate material Se concentration (in dw) to the dissolved Se concentration observed at any instant in simultaneously collected samples. The specific equation is

$$K_d = (C_{\text{particulate material}}, \mu\text{g kg}^{-1} \text{ dw}) \div (C_{\text{water}}, \mu\text{g L}^{-1}) \quad (1)$$

Of interest here is the particulate matter at the base of the food web. As sampled in the environment that can include suspended particulate Se (which is a physically inseparable mix of phytoplankton, periphyton, detritus and inorganic suspended material), biofilm, sediment and/or attached vascular plants. Feeding characteristics of the organisms in question and data availability dictate the best choice among these. For example, for a filter-feeding bivalve in the Bay-Delta, Se concentrations determined in suspended particulate material (in $\mu\text{g g}^{-1} \text{ dw}$) are the preferred parameter for modeling because these animals filter their food from the water-column.

Some broad generalizations are possible about K_d s for Se (Presser and Luoma 2010a). For example, if all other conditions are the same, K_d will increase as selenite and dissolved organo-Se concentrations increase relative to selenate. Calculations using data from laboratory microcosms and experimental ponds show speciation-specific K_d s of 140 to 493 where selenate is the dominant form; 720 to 2,800 when an elevated proportion of selenite exists; and 12,197 to 36,300 for 100% dissolved seleno-methionine uptake

into algae or periphyton (Besser and others 1989; Graham and others 1992; Kiffney and Knight 1990). Compilations of K_d s also show different general ranges for rivers, streams, lakes, ponds, wetlands, and estuaries that are affected by Se inputs (Presser and Luoma 2010a), although with some overlap. Exposure time for phase transformation is probably an important factor driving differences among such systems. Estuaries are among the sites with the highest values (range of medians from 4,000 to 21,500) indicating efficient conversion of dissolved Se to particulate Se. Finally, although the influence of exposure time for a particle within an estuary is challenging to understand precisely, especially in the Bay-Delta because of the dominance of tidally driven circulation, K_d s seem to be higher during conditions where more time is available for transformation reactions to occur (Presser and Luoma 2010b).

The most recent transects of the Bay that provide spatially and temporally matched data for derivation of K_d s from dissolved and particulate Se concentrations were from June 1998 to November 1999 (Cutter and Cutter 2004; Doblin and others 2006). In these studies, samples were collected at 1 meter below the surface, and included dissolved Se concentrations, suspended particulate material Se concentrations, dissolved Se speciation, suspended particulate Se speciation, salinity, and total suspended material. These data were collected in four different transects across the salinity gradient in the Northern Reach under a variety of river discharge and presumed residence time conditions. The full range of dissolved Se concentrations in these transects was 0.070 to 0.303 $\mu\text{g L}^{-1}$. The suspended particulate material Se concentrations were more variable: 0.15 to 2.2 $\mu\text{g g}^{-1} \text{ dw}$. Calculated K_d s ranged from 712 to 26,912. The degree of variability across this whole data set is large. However, the largest part of the variability was driven by very high values in the landward-most and seaward-most samples, where dissolved concentrations were very low. Such ratios can be artificially inflated when values become very low in the denominator, if the numerator does not decline as rapidly. Tidal pumping of contaminated particles from the Bay upstream into the less contaminated Sacramento River water is a possible cause of such an effect.

SAN FRANCISCO ESTUARY & WATERSHED SCIENCE

Downstream transport of highly contaminated particles from the San Joaquin River into Bay or Delta water could also be a cause. Finally, seaward, where residence times are elevated in Central and San Pablo bays, biological transformation could enrich Se in particles while depleting it from the water column. If the goal is to find conditions where there is sufficient linkage between dissolved and particulate Se to be useful in forecasts of one from the other, none of these conditions would apply. Presser and Luoma (2010b) avoided such biases and thereby constrained variability by restricting K_{ds} geographically to the middle range of the salinity zone in Suisun Bay. This also focused the modeling on the most contaminated segment of the estuary.

If location is restricted to Carquinez Strait–Suisun Bay—eliminating freshwater and ocean interfaces—then the range of dissolved Se concentrations is narrowed to 0.076 to $0.215 \mu\text{g L}^{-1}$ and the range of suspended particulate material Se concentrations is narrowed to 0.15 to $1.0 \mu\text{g g}^{-1}$ dw. The variation of K_d is narrowed to a range of means of $1,180$ to $5,986$ (or of individual measurements, 712 to $7,725$). Because this data set is still large, median or mean concentrations, or a given percentile, can be used as viable indicators of partitioning in modeling scenarios.

Seasonality also is important, and restrictions to specific flow regimes also can be used to constrain variability. For example, the highest mean K_{ds} occur during periods of the lowest river inflows (and highest residence times). Constrained to Suisun Bay, the mean K_d was $1,180 \pm 936$ in June 1998. This was a high flow season wherein Cutter and Cutter (2004) estimated a residence time of 11 days. The mean K_d was $5,986 \pm 1,353$ in November 1999. This was a low flow season with an estimated residence time of 70 days. The mean K_d among all constrained samples was $3,317$, and the mean for low flow seasons was $4,710$.

Transects in the Delta were also conducted between 1998 and 2004 in different flow regimes (Doblin and others 2006; Lucas and Stewart 2007). Dissolved Se concentrations among all these samplings ranged from 0.083 to $1.0 \mu\text{g L}^{-1}$, with a mean of 0.25 ± 0.24 ($n = 72$). Particulate concentrations ranged from

0.27 to $6.3 \mu\text{g g}^{-1}$ dw, with a mean of 0.98 ± 0.94 ($n = 71$). As in the Bay transects, the range in particulate concentrations (23-fold) exceeds the range in dissolved concentrations (12-fold). Concentrations and variability, thus, were even greater in the Delta, overall, than in the Bay. In the Delta, K_{ds} ranged from 554 to $38,194$, with the range of means from $1,886 \pm 1,081$ in January 2003 (a high flow season) to $7,712 \pm 3,282$ in July 2000 (a low flow season). Sets of dissolved and particulate Se concentrations determined as part of focused research for the Delta in September 2001, the low flow season of a dry year, yielded some especially elevated K_{ds} ($>10,000$) (Lucas and Stewart 2007). In general, these elevated K_{ds} may reflect tidal pumping, or represent times and areas where Se is concentrating in particulate material because of differing hydrologic environments (e.g., slow-moving backwaters with high productivity). Constraining variability is more difficult in the Delta, hence, quantifying phase transformation from empirical data is more uncertain in this system.

Given the degree of variability in both the Bay and the Delta, modeling that requires linking dissolved Se to particulate Se should include several scenarios using different K_{ds} that are within a range of values constrained, as described above.

Uptake Into Food Webs

Kinetic bioaccumulation models (i.e., biodynamic models, Luoma and Fisher 1997; Luoma and Rainbow 2005, 2008) account for the now well-established principle that Se bioaccumulates in food webs principally through dietary exposure. Uptake attributable to dissolved exposure makes up less than 5% of bioaccumulated Se in almost all circumstances (Fowler and Benayoun 1976; Luoma and others 1992; Roditi and Fisher 1999; Wang and Fisher 1999; Wang 2002; Schlekat and others 2004; Lee and others 2006). Biodynamic modeling (submodels B and C, Figures 3 and 4) shows that Se bioaccumulation (the concentration achieved by the organism) is driven by physiological processes specific to each species (Reinfelder and others 1998; Wang 2002; Baines and others 2002; Stewart and others 2004). Biodynamic models have the further advantage of providing a basis for

deriving a simplified measure of the linkage between trophic levels: TTFs. For each species, a TTF can be derived from either experimental studies or field observations.

Experimental derivation of TTFs is based on the capability of a species to accumulate Se from dietary exposure as expressed in the biodynamic equation (Luoma and Rainbow 2005):

$$dC_{\text{species}}/dt = (AE) (IR) (C_{\text{food}}) - (k_e + k_g) (C_{\text{species}}) \quad (2)$$

where C_{species} is the contaminant concentration in the animals ($\mu\text{g g}^{-1} \text{ dw}$), t is the time of exposure in days (d), AE is the assimilation efficiency from ingested particles (%), IR is the ingestion rate of particles ($\text{g g}^{-1} \text{ d}^{-1}$), C_{food} is the contaminant concentration in ingested particles ($\mu\text{g g}^{-1} \text{ dw}$), k_e is the efflux rate constant (d^{-1}) that describes Se excretion or loss from the animal, and k_g is the growth rate constant (d^{-1}). Key determinants of Se bioaccumulation are the ingestion rate of the animal, the efficiency with which Se is assimilated from food, and the rate constant that describe Se turnover or loss from the tissues of the animal (Luoma and Rainbow 2005; Presser and Luoma 2010a). Experimental protocols for measuring such parameters as AE, IR, and k_e are now well developed for aquatic animals (Luoma and others 1992; Wang and others 1996; Luoma and Rainbow 2005). The rate constant of growth is significant only when it is comparable in magnitude to the rate constant of Se loss from the organism. Consideration of the complications of growth can usually be eliminated if the model is restricted to a long-term, averaged accumulation in adult animals (Wang and others 1996).

In the absence of rapid growth, a simplified, resolved biodynamic exposure equation for calculating a Se concentration in an invertebrate (submodel B, Figure 3) is

$$C_{\text{invertebrate}} = [(AE)(IR)(C_{\text{particulate}})] \div [k_e] \quad (3)$$

For modeling, these physiological parameters can be combined to calculate a $\text{TTF}_{\text{invertebrate}}$, which characterizes the potential for each invertebrate species to bioaccumulate Se. $\text{TTF}_{\text{invertebrate}}$ is defined as

$$\text{TTF}_{\text{invertebrate}} = [(AE)(IR)] \div k_e \quad (4)$$

Similarly, foodweb biodynamic equations for fish or birds are

$$C_{\text{fish or bird}} = [(AE) (IR) (C_{\text{invertebrate}})] \div k_e \quad (5)$$

and

$$\text{TTF}_{\text{fish or bird}} = [(AE) (IR)] \div k_e \quad (6)$$

Where laboratory data are not available, TTFs can be defined from field data, where the TTF defines the relationship between Se concentrations in an animal and in its food in dw. The field $\text{TTF}_{\text{invertebrate}}$ must be defined from spatially and temporally matched data sets (in dw or converted to dw) of particulate and invertebrate Se concentrations (submodel B, Figure 3) as

$$\text{TTF}_{\text{invertebrate}} = C_{\text{invertebrate}} \div C_{\text{particulate}} \quad (7)$$

A field derived species-specific TTF_{fish} is defined as

$$\text{TTF}_{\text{fish}} = C_{\text{fish}} \div C_{\text{invertebrate}} \quad (8)$$

where $C_{\text{invertebrate}}$ is for a known prey species, C_{fish} is reported as muscle or whole-body tissue, and both Se concentrations are reported in $\mu\text{g g}^{-1} \text{ dw}$ (submodel B, Figure 3).

Whether the TTFs are determined from the laboratory or the field, the modeling approach is sufficiently flexible to represent complexities such as mixed diets. For example, a diet that includes a mixed proportion of prey in the diet can be addressed using the equation

$$C_{\text{fish}} = (\text{TTF}_{\text{fish}}) [(C_{\text{invertebrate a}}) (\text{prey fraction}) + (C_{\text{invertebrate b}}) (\text{prey fraction}) + (C_{\text{invertebrate c}}) (\text{prey fraction})] \quad (9)$$

Equations are combined to represent step-wise bioaccumulation from particulate material through invertebrates to fish (submodel B, Figure 3) as

$$C_{\text{fish}} = (\text{TTF}_{\text{invertebrate}}) (C_{\text{particulate}}) (\text{TTF}_{\text{fish}}) \quad (10)$$

Similarly, for birds, the combined equation is

$$C_{\text{bird}} = (\text{TTF}_{\text{invertebrate}}) (C_{\text{particulate}}) (\text{TTF}_{\text{bird}}) \quad (11)$$

Modeling can accommodate longer food webs that contain more than one higher trophic level consumer (e.g., forage fish being eaten by predatory fish) by

SAN FRANCISCO ESTUARY & WATERSHED SCIENCE

incorporating additional TTFs. One equation for this type of example (submodel B, Figure 3) is

$$C_{\text{predator fish}} = \frac{(TTF_{\text{invertebrate}}) (C_{\text{particulate}})}{(TTF_{\text{forage fish}}) (TTF_{\text{predator fish}})} \quad (12)$$

Modeling for bird tissue also can represent Se transfer through longer or more complex food webs (e.g., TTFs for invertebrate to fish and fish to birds) as

$$C_{\text{bird}} = (TTF_{\text{invertebrate}}) (C_{\text{particulate}}) (TTF_{\text{fish}}) (TTF_{\text{bird}}) \quad (13)$$

Variability or uncertainty in processes that determine AEs or IRs can be directly accounted for in sensitivity analysis (Wang and others 1996). This is accomplished by considering the range in the experimental observations for the specific animal in the model. Field-derived factors require some knowledge of feeding habits, and depend on available data for that species. Laboratory and field factors for a species can be compared and refined to reduce uncertainties in modeling (Presser and Luoma 2010a).

A substantial number of species-specific TTFs are available (Luoma and Presser 2009; Presser and Luoma 2010a). These are enough data at least to begin to model important food webs. Across invertebrate species, TTFs range from 0.6 to 23. Of the 29 species studied, 27 species have TTFs > 1. Thus, most invertebrate species bioaccumulate as much as or more Se than concentrated in the trophic level below them. In other words, the concentration of Se biogeochemically transformed into algae, microbes, seston, or sediments is preserved and/or (bio)magnified as Se passes up food webs. In general, TTFs for bivalves (clams, mussels, oysters) and for barnacles are the highest among species of invertebrates (i.e., an experimentally determined TTF range of approximately 4 to 23) (Presser and Luoma 2010a).

Trophic transfer factors from the available data for fish have a median of approximately one, and vary much less than among invertebrates: from 0.5 to 1.8 (Presser and Luoma 2010a). Compilations show that TTFs derived from laboratory biodynamic experiments range from 0.51 to 1.8; TTFs for different fish species derived from field studies are similar, ranging from 0.6 to 1.7.

Trophic transfer factors for aquatic birds (diet to bird egg) are less well developed, and laboratory data are limited (Presser and Luoma 2010a). The most robust data from the laboratory relate Se concentrations in the diet (as seleno-methionine) to egg Se concentrations from controlled feeding of captive mallards (*Anas platyrhynchos*). The range of $TTF_{\text{bird egg}}$ calculated from the compilation of nominal experimental diet Se concentrations and mean egg Se data given in Ohlendorf (2003) for mallards is 1.5 to 4.5. Using the detailed data from Heinz and others (1989) narrows this range to 2.0 to 3.9, with a mean of 2.6. Field data could be used to refine $TTF_{\text{bird egg}}$ on a site-specific basis, but variability in food sources and habitat use may add uncertainty to such data, and limits applications among habitats.

Exposure: Food Webs, Seasonal Cycles, and Habitat Use

Selenium is at least conserved and usually biomagnified at every step in a food web (Presser and Luoma 2010a). Selenium toxicity is generally assumed to be observed first in specific predator species as differences in food web exposure are propagated up trophic pathways (Luoma and Rainbow 2005; Stewart and others 2004). Some invertebrate species also may be susceptible to environmentally relevant Se concentrations (Conley and others 2009, 2011). Selenium is usually not detoxified in animal tissues by conjugation with metal-specific proteins or association with non-toxic inclusions (Luoma and Rainbow 2008). Hence, general mechanisms that semi-permanently sequester metals in non-toxic forms and lead to progressive accumulation with size or age probably are less applicable to the metalloid Se than to metals in general (Luoma and Presser 2009).

Predator population distribution, feeding preference, prey availability, life stage, gender, physiology, and species sensitivity are all variables that influence how a predator is affected by Se. Field factors such as varying weather, water depth, human disturbance, and food dispersion also affect foraging energetics, and accessibility of contaminants in foods on a localized level. Despite these complexities, some generalizations are possible at the present state of

understanding. Predator species for the Bay-Delta, their food webs, and potential exposure are shown in submodels C and D (Figures 4 and 5), with further supporting information compiled in Appendix A.2 and A.3.

Based upon studies of invertebrate bioaccumulation the greatest exposures to Se will occur in predators that ingest bivalves in the Bay-Delta (Stewart and others 2004; Presser and Luoma 2006, 2010b). The estimated maximum percentages of diet that are clam-based for various benthic predators were estimated by the USFWS (2008a) (submodel C, Figure 4): lesser scaup 96%; surf scoter 86%; greater scaup 81%; black scoter 80%; white-winged scoter 75%; California clapper rail 64%; bald eagle 23%; white sturgeon (and assumed for green sturgeon) 41%; and Sacramento splittail (2-year olds) 34%. Dietary estimates are not specific to *C. amurensis*, but a bivalve component to diet in general. Bald eagles are an example of a predator with a diet wherein 23% are those waterfowl (scaups and scoters) that primarily feed on benthic mollusks (USFWS 2008a). Clapper rails feed on benthic food webs, but are littoral feeders that usually do not eat *C. amurensis*, which is mostly subtidal. Figure 4 (submodel C) also shows potential food webs for Dungeness crab. Diet component data and kinetic loss rates are not documented for life stages of this crustacean, but isotopic data indicate that clams such as *C. amurensis* would be expected to be an important food for this species (Stewart and others 2004). Selenium concentration data, in turn, indicate that predators of this crab would be subjected to elevated dietary Se concentrations (submodel C, Figure 4).

Food webs illustrated for Delta inhabitants include aquatic insects to salmonids (submodel C, Figure 4). The diets of salmon and steelhead trout are dominated by species with TTFs lower than bivalves. These species thereby incur less dietary Se exposure than molluscivores. Field data for Se concentrations are limited to 1986 to 1987 for Chinook salmon (Saiki and others 1991) and absent for steelhead trout that inhabit the estuary and migration corridors. Although their exposures are not exceptionally high, these species may be vulnerable because of their toxicological sensitivity to Se (USFWS 2008a, 2008b; Janz

2012). Delta smelt are endemic to the estuary and are included here because population numbers for the Delta smelt are alarmingly low. Thus, the USFWS (2008a) concluded that this species is particularly vulnerable to any adverse effect. It should be noted, however, that the feeding habits of Delta smelt would not suggest high exposures compared to other species, and sensitivity or bioaccumulation data are not available.

Not all predators reside in the estuary throughout their lives. When a predator is present across flow seasons and during critical life stages may influence Se exposure and effects. Predator seasonal cycle diagrams are shown for migratory birds (scoter and scaup); breeding birds (California clapper rail, bald eagle); migrating/rearing juveniles (Chinook salmon, steelhead trout); and breeding fish (green sturgeon, white sturgeon, and Sacramento splittail) (submodel D, Figure 5). The North Bay is part of the migration corridor and feeding ground for anadromous fish such as white sturgeon, Chinook salmon, and striped bass. The estuary also serves seasonally as a nursery area for species that spawn either in freshwater (e.g., Sacramento splittail) or in the ocean (e.g., Dungeness crab). Migrating diving ducks on the Pacific flyway winter and feed in the estuary as they stage for breeding in the freshwater ecosystems of the boreal forests of Canada and Alaska (De La Cruz and others 2009). As migratory waterfowl move north to breed in the spring, there is the potential for depuration of Se (USFWS 2008a; Appendix A.2 and A.3).

Some of the highest *C. amurensis* Se concentrations of the annual cycle occur when overwintering scoter and scaup actively feed in Suisun Bay and San Pablo Bay during the fall and early winter, (Linville and others 2002; Kleckner and others 2010) (submodel D, Figure 5). Long-lived white sturgeon feed predominantly on *C. amurensis* and have a two-year internal egg maturation that makes them particularly vulnerable to loading of Se in eggs and reproductive effects (Linville 2006). As an indication of this potential, Linares and others (2004) found Se concentrations as high as $47 \mu\text{g g}^{-1} \text{ dw}$ in immature gonads of 39 white sturgeon captured in the estuary. In earlier studies, Kroll and Doroshov (1991) reported that Se concentrations in developing ovaries

Submodel D

Exposure: Seasonal Cycles and Habitat Use

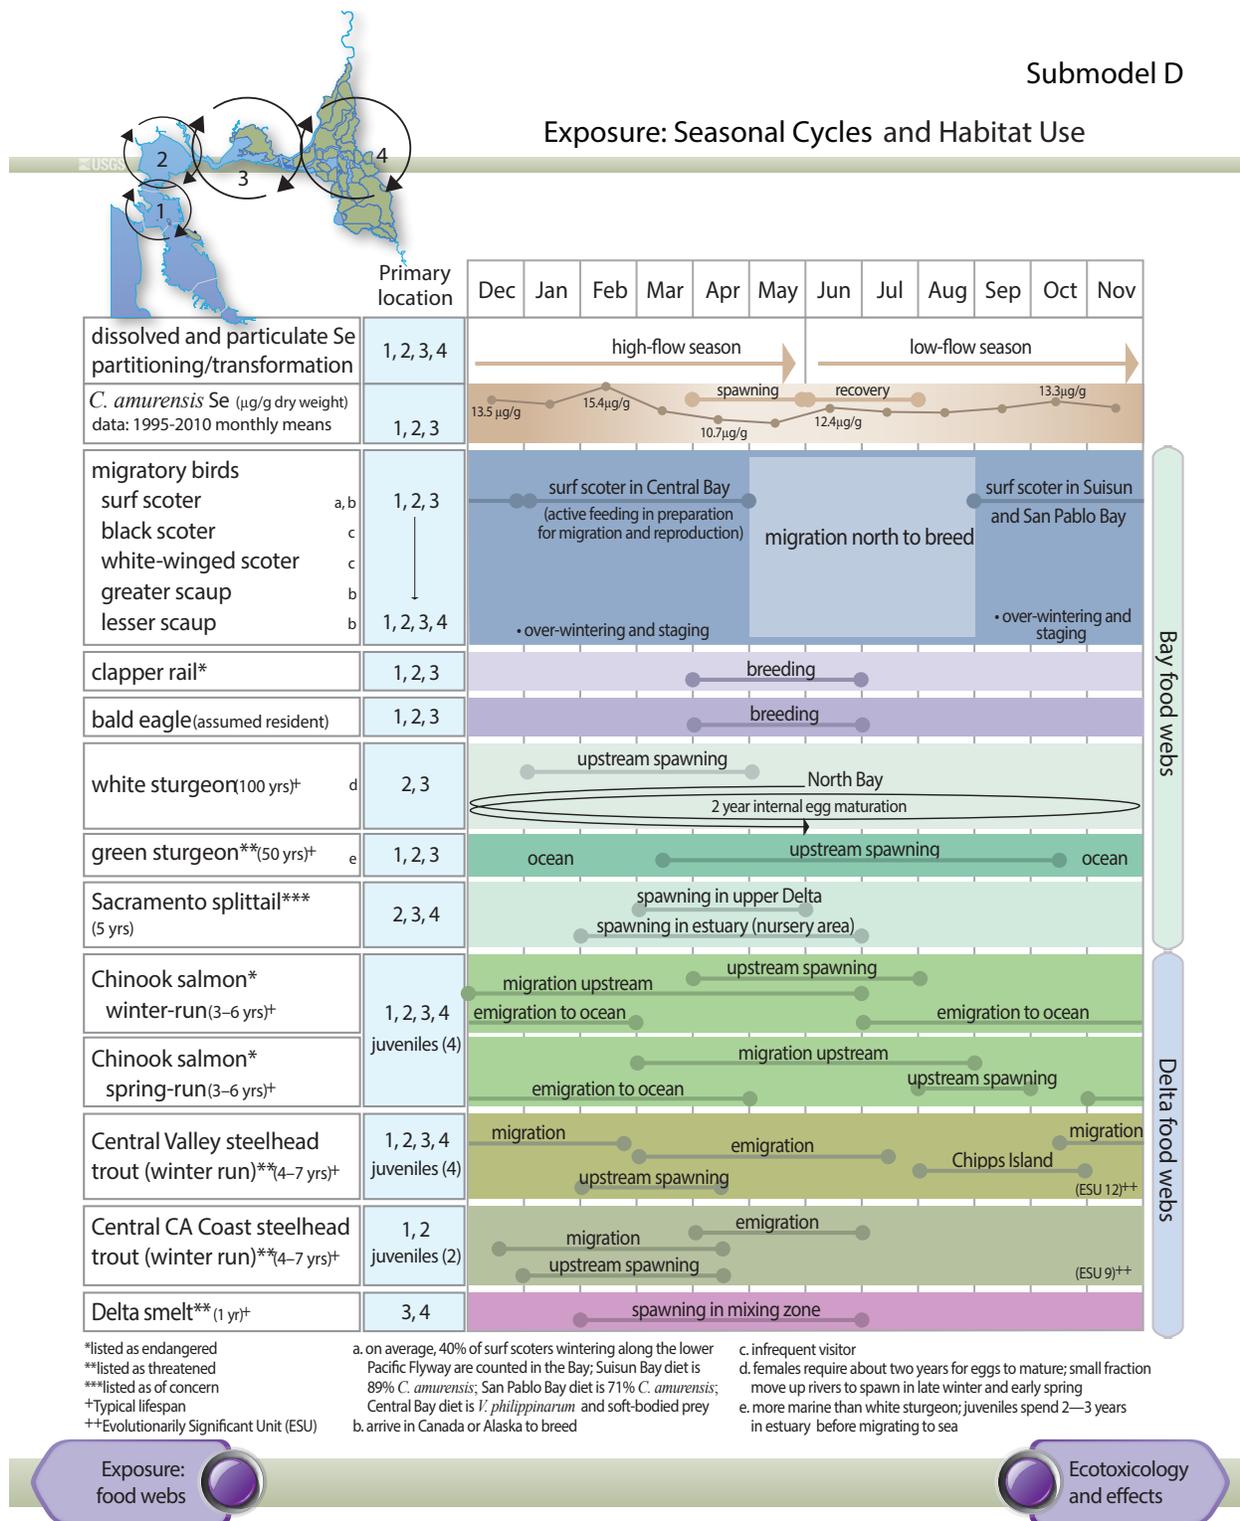

Figure 5 Submodel D. Exposure: Seasonal Cycles and Habitat Use

SAN FRANCISCO ESTUARY & WATERSHED SCIENCE

of white sturgeon from the Bay contained maxima of $72 \mu\text{g g}^{-1}$ and $29 \mu\text{g g}^{-1}$. This range of wild white sturgeon reproductive tissue Se concentrations approach or exceed levels that cause severe deformities and mortalities in newly hatched larvae (Lemly 2002; Linville 2006). Larger, older Sacramento split-tail also feed on *C. amurensis* and they are known to spawn both in the upper Delta and estuary (Stewart and others 2004). Modeling for species such as clapper rail would need specifics of diet composition (i.e., which species of clam, mussel, or crab is consumed), and whether prey species are efficient bioaccumulators of Se. Formalized, detailed knowledge such as this (submodel D, Figure 5), in turn, helps set choices in comparative modeling scenarios.

Fish and Wildlife Health: Ecotoxicology and Effects

Toxicity arises when dissolved Se is transformed to organic-Se by bacteria, algae, fungi, and plants (i.e., synthesis of Se-containing amino acids *de novo*) and then passed through food webs. It is generally thought that animals are unable to biochemically distinguish Se from sulfur, and therefore excess Se is substituted into proteins and alters their structure and function (Stadtman 1974). Other biochemical reactions also can determine and mediate toxicity (Chapman and others 2010). The effect of these reactions is recorded, most importantly in birds and fish, as failures in hatching or proper development (teratogenesis or larval deformities) (submodel E, Figure 6). Other toxicity endpoints include growth, winter survival, maintenance of body condition, reproductive fitness, and susceptibility to disease (submodel E, Figure 6; Appendix A.3). Specifically, Se can alter hepatic glutathione metabolism to cause oxidative stress (Hoffman and others 1998, 2002; Hoffman 2002) and diminished immune system function (Hoffman 2002).

Details of general ecotoxicological pathways of Se for fish and birds and effects of concern for Se are shown in submodel E (Figure 6). As represented here, birds and fish differ in how Se taken up from diet distributes among tissues (submodel E, Figure 6). Physiological pathways shown here for birds emphasize an exogenous dietary pathway and for fish an

endogenous liver pathway. Species-specific Se effect models for the Bay-Delta are shown for breeding clapper rail; migratory scoter and scaup; white sturgeon; downstream-migrating juvenile salmonids; and upstream-migrating adult salmonids (submodel F, Figure 7). Details of Se-specific toxicological information for predator species considered here are compiled in Appendix A.3.

Such health effects are important to the overall ability of birds and fish to thrive and reproduce. But the consequences of Se transfer from the mother to her progeny via each reproductive stage are the most direct and sensitive predictors of the effects on birds and fish (Heinz 1996; Lemly 2002; Chapman and others 2010). Ultimately, it would be expected that effects on reproduction, especially in slowly reproducing, demographically vulnerable species (e.g., sturgeon), could lead to effects on populations and community changes.

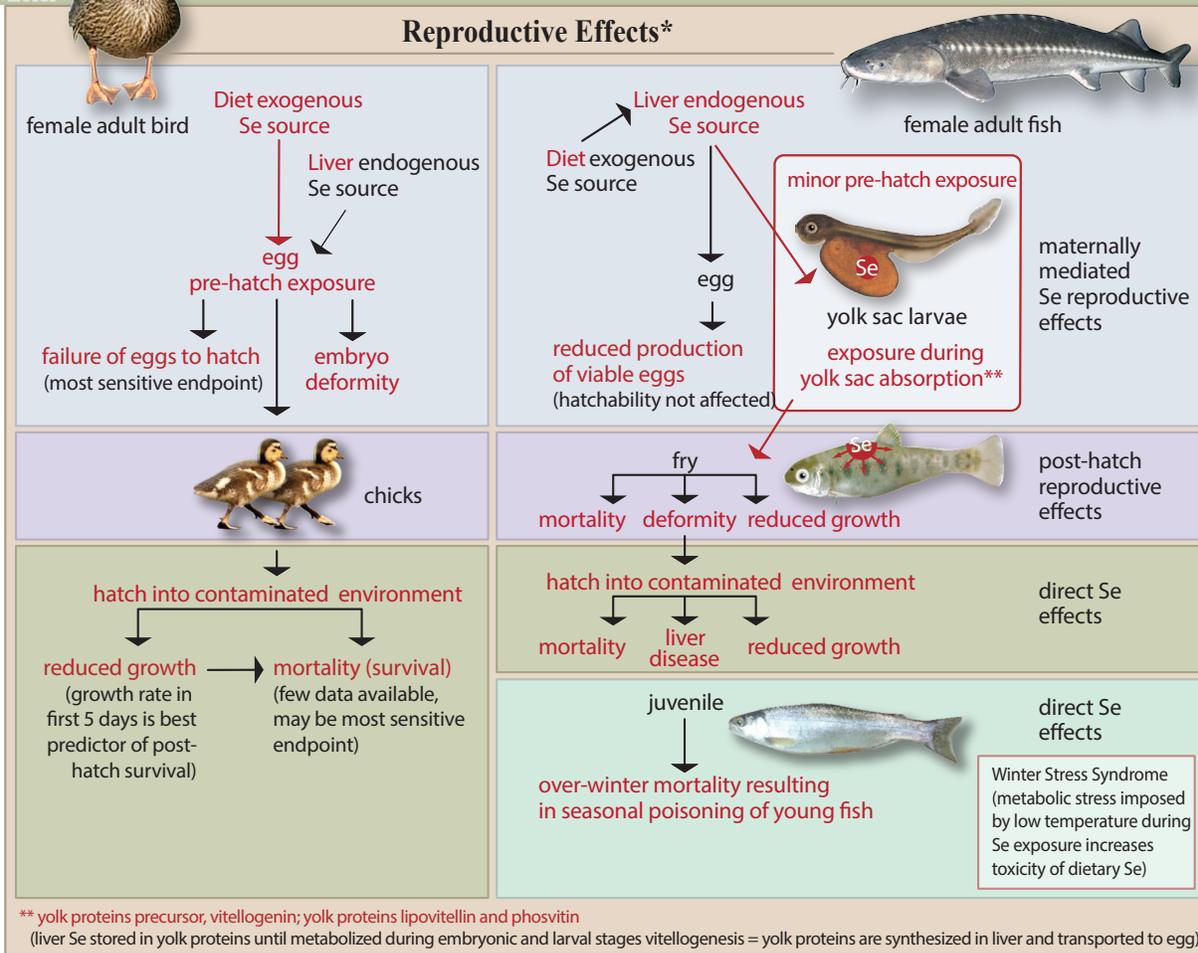

To translate exposure into toxicity, effects levels are needed for predator species. Traditionally, guidelines relate Se concentrations in water to effects. But it is increasingly recognized that the concentrations of Se bioaccumulated in fish and bird tissues are more strongly related to signs of toxicity in nature, and would provide less ambiguous guidelines (Chapman and others 2010). The best correlations occur between Se in reproductive tissue and effects on reproductive processes. To assess implications of Se contamination in water from such relationships a bioaccumulation model is, then, necessary.

Experimental determination of tissue Se concentrations at which adverse effects occur is influenced by choice of endpoint, life-stage, dietary form, route of transfer, and choice of effect concentration. Another consideration in determining the guideline is the steepness of the Se dose-response curves and the choice of mathematical models to describe the curve (Skorupa 1998; Ohlendorf 2003; Lemly 2002; Environment Canada 2005; Beckon and others 2008; Chapman and others 2010). Effect guidelines that focus on a combination of the most sensitive assessment measures might include, for example, a selenomethionine diet, parental exposure, and embryonic or larval life-stage effect (Presser and Luoma 2006).

Submodel E

Ecotoxicology and Effects

USGS

Effects to Health*

- reduced growth
- hepatotoxicity
- elevated oxidative stress activity (altered hepatic enzyme function)
- compromised body condition (edema; low body mass; low protein and fat content; loss of feathers)
- histopathological lesions
- impaired immune function
- decreased winter survival
- decreased reproductive fitness (decreased breeding propensity; reduced recruitment)
- behavioral impairment (missed breeding window, delayed timing of departure)
- lowered saline tolerance and gill effects in fish

*Reproductive endpoints measure or are related to direct effects to reproduction. Health endpoints are considered to indirectly relate to reproduction.

Food webs and seasonal cycles

Species-specific effects

Species-Specific Effects

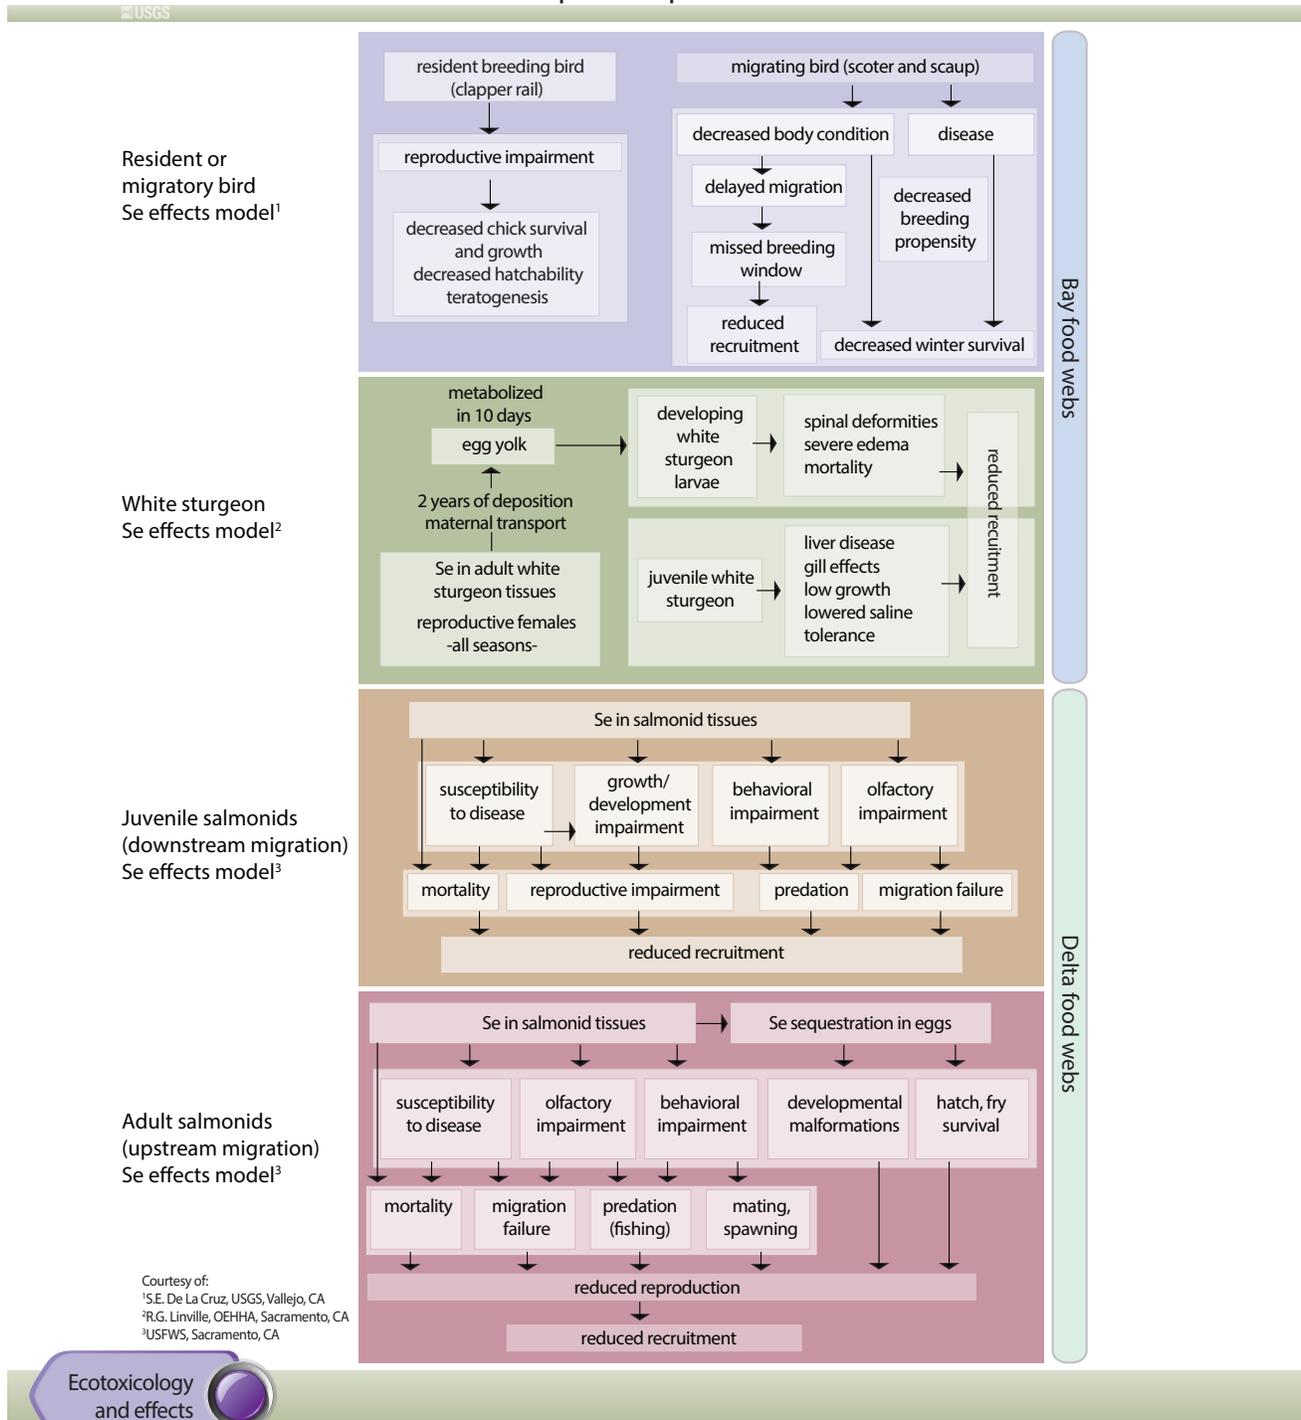

Figure 7 Submodel F. Species-Specific Effects

Even then the choice of statistical analysis and effect level can lead to disagreement about effect guidelines.

Human Health

A number of species from the Bay-Delta are consumed by humans (submodel G, [Figure 8](#)). Human health advisories against consumption of greater scaup, lesser scaup, and scoter because of elevated Se levels have been in effect since 1986 (Presser and Luoma 2006) for Suisun Bay, San Pablo Bay, Central Bay, and South Bay (CDFG 2012, 2013). The health warning states that no one should eat more than four ounces of scaup meat per week or more than four ounces of scoter meat in any two week period. Further, no one should eat the livers of ducks from these areas.

Fish consumption advisories, including for white sturgeon, exist for the Bay because of the effect of mercury and PCBs (OEHHA 2011, 2012). Pesticides, flame retardants, and Se also were tested, but a mean concentration calculated for each fish species collected from locations throughout the Bay-Delta over a range of years was found to be below that chemical's advisory tissue level (OEHHA 2011, 2012). Specifically for Se, concentrations in white sturgeon ($n = 56$ during 1997 to 2009, or 4.3 fish per year) were higher than other species of fish tested; and some Se concentrations for white sturgeon collected in North Bay locations (maximum $18.1 \mu\text{g g}^{-1} \text{ dw}$) exceeded Se advisory levels (e.g., $10.4 \mu\text{g g}^{-1} \text{ dw}$ or $2.5 \mu\text{g g}^{-1}$ wet weight based on consumption of three 8-ounce meals per week (OEHHA 2011, 2012). Length restrictions (117 to 168 cm) and a bag limit of one fish per day are in effect for legal fishing of white sturgeon in the Bay, with a mean of 134 cm measured in fish collected for advisories.

A median per angler consumption rate of 16 g d^{-1} was determined specifically for Bay fish during 1998 and 1999 (SFEI 2000). This site-specific rate can be compared to a national recreational fisher consumption rate of 17.5 g d^{-1} and a national per capita rate of 7.5 g d^{-1} (USEPA 2000b).

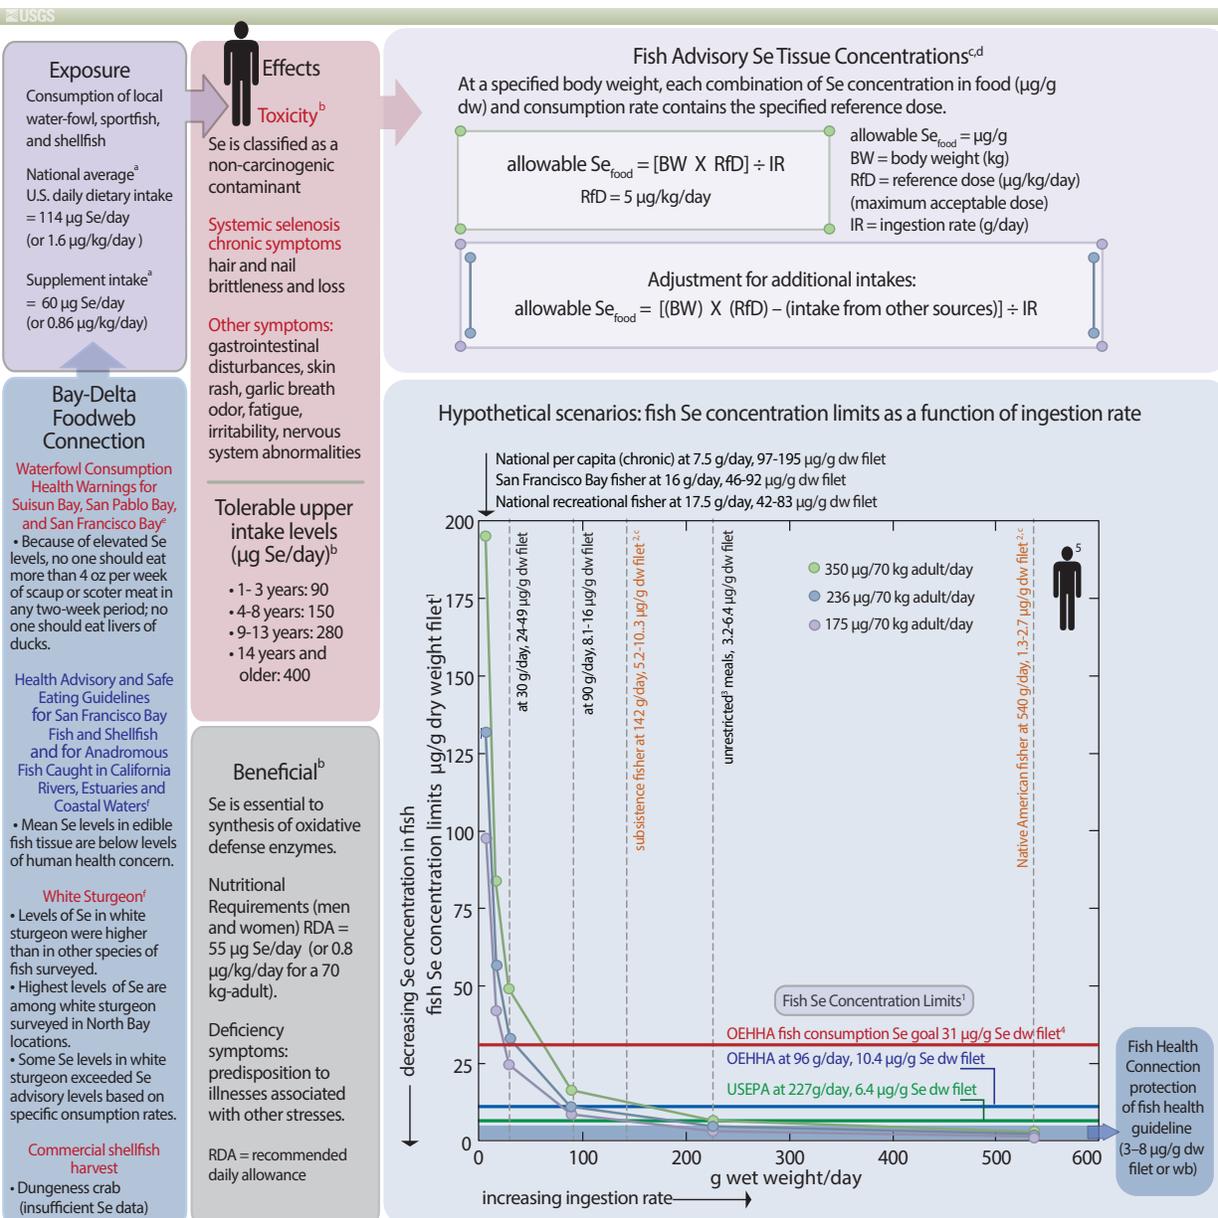

Nutritional guidelines, toxicity symptoms, and national guidance concerning human health risk for consumption of fish are shown in submodel G ([Figure 8](#)). The details of how guidelines shown in [Figure 8](#) were determined and how they might be linked to regulation of Se in wildlife and to fish health are presented in [Appendix A.4](#).

QUANTITATIVE MODELING

This section presents an example of an application of the quantitative DRERIP Ecosystem-Scale Selenium Model. The questions addressed in this example are: What are the implications for ecosystem concentrations of Se if a fish tissue and/or wildlife Se guideline is implemented (a guideline based upon Se concentrations in a predator)? More specifically, what changes in dissolved or particulate Se concentration in the Bay-Delta would be necessary to achieve the selected tissue concentrations in predators? Agencies have traditionally regulated contaminants on the basis of dissolved concentrations, and managed inputs from different sources based upon their implications for dissolved concentrations (e.g., total mass daily loadings). This example shows a methodology that ties the new concept of tissue guidelines to the traditional concept of dissolved-concentration-based management. Inherent in every regulatory guideline are assumptions about the environment being regulated. The model allows an explicit evaluation of the implications of different assumptions.

The generalized equations for prediction of a dissolved Se concentration from a tissue Se concentration are given in submodel B ([Figure 3](#)). [Table 1](#) gives the specific combinations of choices for food web, guideline, location, hydrologic condition, K_d , and TTFs used for the Bay-Delta application. In this example, several alternatives for a tissue guideline were chosen from among those that have been discussed in the regulatory context. Then, the invertebrate, particulate, and dissolved Se concentrations were calculated that would be expected if the tissue concentrations were in compliance with each choice of a guideline. Calculations also were conducted under different assumptions about K_d , food web, and TTFs. Finally, the calculated dissolved, particulate,

and invertebrate Se concentrations were compared with observations of those values from the Bay-Delta to assess how much existing conditions would be need to change to achieve compliance with the chosen guidelines (Table 2). Implicitly, comparisons of outcomes with data from nature tests how well model predictions match reality (Luoma and Rainbow 2005). Comparisons under different assumed conditions test the sensitivity of the model to changes within a few critical parameters.

The method, as indicated in the conceptual model (Figures 3 and 4, especially) includes the following steps: (1) selection of tissue guidelines to test; (2) selection of places and times of interest; (3) derivation of K_d using spatially and temporally matched dissolved and particulate Se concentrations constrained within the selected place and time; (4) selection of a food web of interest to each locality; (5)

determination of species-specific TTFs for invertebrates and their specific predators that are relevant to the place and food web; (6) prediction of invertebrate, particulate and dissolved Se concentrations; (7) comparison of predicted values to field observations of Se concentrations in these media in the Bay-Delta; and (8) conclusions about implications for compliance.

Modeling Parameters and Variables

Guidelines

The effect guidelines chosen for evaluation were 5 and 8 $\mu\text{g g}^{-1}$ dw fish whole-body; as well as 7.7, 12.5, and 16.5 $\mu\text{g g}^{-1}$ dw for bird eggs (Presser and Luoma 2010b) (Table 1). The regulatory community is debating appropriate critical tissue values that relate bioaccumulated Se concentrations and toxicity in predators (see previous discussion). We are not

	July 2000 – 8.0	7.3	2.6	No data	2.1	3%

suggesting these are the best choices for guidelines; but they are within the range of those that are being discussed. In particular, the fish whole-body target of $5 \mu\text{g g}^{-1}$ and a bird egg target of $7.7 \mu\text{g g}^{-1}$ have been derived to provide additional protection for endangered species (Skorupa and others 2004; Skorupa 2008). The illustrated scenarios also considered the differences in the changes required if a bird egg-based guideline were used instead of a whole-body fish-based guideline.

Place and Time

The modeling scenarios compared two locations: a brackish-water Bay environment and a tidal freshwater Delta environment. For the Bay, we constrained

consideration to the geographic area of Carquinez Strait and Suisun Bay (Presser and Luoma 2010b) (Table 1). In terms of drivers, this location is affected by oil-refinery effluents that contain Se, and also could be influenced by inputs from the San Joaquin Valley. As noted previously, Se concentrations in at least some predators (sturgeon and diving ducks) at this location now exceed USFWS Se guidelines (Presser and Luoma 2010b). For the Delta, the area considered was from Stockton westward through the Delta, and was constrained to the freshwater environment. We also compared scenarios for average conditions across the year(s) in the Bay, to a specific example of conditions for one low flow season

(November 1999). An average condition for the Delta was modeled.

Partitioning and K_d s

The approach of Presser and Luoma (2006, 2010b) was used to select two K_d s for the scenarios from the Bay and one for the Delta (Table 1). The data for the Bay were narrowed to a Carquinez Strait–Suisun Bay location (Cutter and Cutter 2004; Doblin and others 2006; Presser and Luoma 2010b) to focus on the most contaminated area in the estuary, and to exclude the extreme K_d s at the ocean and freshwater interfaces. We selected the mean of co-collected dissolved and particulate Se concentrations from a transect for November 1999 ($K_d = 5,986$) to represent low flow conditions. Average conditions in the Bay across all seasons and several years were represented by the grand mean of all transects through the Carquinez Strait–Suisun Bay area during 1998–1999 ($K_d = 3,317$) and the freshwater Delta during 2003–2004 ($K_d = 3,680$). For comparison, the Delta grand mean K_d for low flow transects was 2,613 and for high flow transects 5,283. As discussed earlier, the value that describes transformation, even when constrained, is the most variable of any of the model parameters. The uncertainty associated with the choice of this value could be avoided if environmental guideline were based upon empirically determined particulate Se, but cannot be avoided if it is necessary to relate tissue Se to dissolved Se.

Food Webs and TTFs

For the Bay, the food web used was for suspended particulate material to *C. amurensis* to clam-eating fish or aquatic-dependent clam-eating bird (submodel C, Figure 4 and Table 1). The diet for both predators was assumed to be 50% clam and 50% benthic crustaceans. The bivalve food web is the most efficient at accumulating Se in the system, in both the field and in the quantitative model; therefore, it is the most environmentally protective to use in evaluating a tissue guideline. Different assumptions, of course, could be used for the percentage of diet that is clam-based (e.g., 75% to 96% for scoter and scaup, submodel C, Figure 4). Data on variability of benthic

assemblages with time, Bay location, and hydrologic condition also can be used to adjust dietary considerations (Peterson and Vayssieres 2010). If migrating scoter and scaup were modeled, a guideline based on body-condition endpoint, rather than a direct reproductive guideline, would be appropriate. To test the sensitivity of the choice of predator, one comparative simulation was calculated for a pelagic food web in the Bay: suspended material to zooplankton to young striped bass. The food web for the Delta was suspended particulate material to aquatic insects to juvenile salmon or steelhead trout.

Only a few recent data sets from the Bay-Delta are available that analyze Se concentrations across a reasonably complete food web (e.g., Stewart and others 2004). Some important food webs have not been assessed at all (e.g., aquatic insects and Chinook salmon or steelhead trout) (Presser and Luoma 2010b). However, studies of Se concentrations in enough individual predator and prey species are available to assess the predictions from the model and to derive, in a few instances, some critical trophic transfer relationships (e.g., Linville and others 2002; Stewart and others 2004; Schwarzbach and others 2006; Lucas and Stewart 2007; De La Cruz and others 2008; De La Cruz 2010). For the Bay, the dominant bivalve in the Carquinez Strait–Suisun Bay area is *C. amurensis*. This species strongly bioaccumulates Se (Linville and others 2002). A species-specific $TTF_{C. amurensis}$ of 17 (a range of 14 to 26 over different estuary conditions) was used here based on the field calibration that Presser and Luoma (2010b) describe. Benthic crustaceans, like amphipods and isopods, are much less efficient than clams in bioaccumulating Se; TTFs can range from 0.8 for amphipods to 2.0 for other crustaceans (Presser and Luoma 2010a). Under the assumption of a mixed diet of *C. amurensis* ($TTF_{C. amurensis} = 17$) and benthic crustaceans ($TTF_{\text{benthic crustacean}} = 0.8$ and 2.0), the combined diet TTF used here is 9.2.

An important benthic predator, white sturgeon, was chosen for the example, because the Se biomagnifier *C. amurensis* is an important food source for this species in the Bay. White sturgeon accumulate higher concentrations of Se than any other fish in the Bay (Stewart and others 2004; OEHHA 2011), making it

SAN FRANCISCO ESTUARY & WATERSHED SCIENCE

the environmentally conservative choice for evaluating a guideline. From studies in the late 1980s, field TTFs derived specifically for white sturgeon from the Bay that used bivalves as prey, showed a range from 0.6 to 1.7, with a mean of 1.3 (Presser and Luoma 2006); similar to the value of 1.1, which is the mean among all fish species studied. Calculations from more recent data sets for *C. amurensis* at Carquinez Strait, and seaward white sturgeon, showed a somewhat lower TTF of 0.8 (Presser and Luoma 2010b).

For the Delta food web, Se TTFs for freshwater aquatic insects were selected from data from literature sources (submodel C, Figure 4). For example, Presser and Luoma (2010a) derived a mean Se TTF_{insect} of 2.8 (range 2.3 to 3.2) based on matched field data sets for particulate and insect Se concentrations in freshwater environments for several species of aquatic insect larvae including mayfly, caddisfly, dragonfly, midge, and waterboatman. These values generally compare well to laboratory-derived TTFs for aquatic insect larvae (Conley and others 2009). TTFs for other potential invertebrates in Delta food webs (range 0.6 to 2.8) also are shown in submodel C, Figure 4 (Presser and Luoma 2010a).

Much less data are available to evaluate bioaccumulation in avian food webs. Data from the study of toxicity in mallards (Heinz and others 1989, 1990) are the most comprehensive studies available to use for modeling dietary exposure. From these studies, the laboratory-derived TTF_{bird egg} of 2.6 was assumed for transfer of Se from prey to bird eggs (which correlate best with toxicity). For the model, this choice of TTF for bird species was lowered to 2.0 to illustrate the possible effect of field variables on exposure factors that encompass habitat use and feeding behavior. A diet of 50% clams and 50% crustaceans was assumed for a clam-eating bird.

Implications of Model Choices and Estuary Conditions

Details of the calculations to evaluate implications of different guidelines, under different conditions, are summarized in Table 2. To compare the implications of these choices, we determined the percentage Se concentrations in dissolved and particulate form that

exceeded the value predicted to be necessary to meet the tissue guideline. All published dissolved ($n = 168$) and particulate Se ($n = 168$) data from the Bay and from the Delta, collected after 1997, are employed in this estimate. Together, the scenarios depict a Bay for which there is ecological risk from Se contamination, but the degree of risk, judged by the degree of compliance with the guidelines, depends heavily upon assumptions about toxicity (the guideline), transformation, and choice of food web.

The occurrence of $8 \mu\text{g g}^{-1}$ dw Se in sturgeon muscle from the contaminated area of San Francisco Bay (Linares and others 2004) is one of several lines of evidence that ecological risks from Se are occurring in the Bay. When this concentration was used for a predator guideline (Table 2), the model predicted Se concentrations in invertebrates and suspended particulate material and a dissolved Se concentration that were within the range typical of the Bay-Delta (Table 2). Thus, the model results appear to successfully capture the links between Se concentrations in different ecosystem components of the Bay, in general [also see Presser and Luoma (2010b) for further validation details]. This also suggests that the use of calibrated mean K_{ds} to reduce uncertainties about transformation adequately captures and constrains the variability in these processes. The agreement between ecosystem observations and the predicted Se concentrations in invertebrates and predators similarly points to the validity of the TTFs.

The most remarkable conclusion from the calculations is that fish tissue Se concentrations typical of risks to reproductive toxicity (the selected guideline examples) occur in the Bay at dissolved Se concentrations more than ten times less than the traditional water quality regulatory guideline of $5 \mu\text{g L}^{-1}$ (Table 2). At least some food webs in the Bay and the Delta are particularly vulnerable to small changes in bioavailable Se concentrations. The very high K_{ds} consistently observed in both the Bay and the Delta, compared to many other ecosystems (Presser and Luoma 2010a), may be one reason for this sensitivity. Also influential is the strong ability of invertebrates such as *C. amurensis* to bioaccumulate Se when compared to other prey species. It appears that ecosys-

tems wherein dissolved Se is efficiently transformed to particulate Se, and in which particulate Se is propagated up a food web to predators, will amplify relatively small changes in concentrations of dissolved Se concentrations to levels that could affect predators.

Under low flow conditions, 23 to 66% of dissolved Se determinations in the Bay exceeded the value predicted to be necessary to meet the higher sturgeon-based guideline or the higher bird-based guidelines (Table 2). Under guidelines chosen to protect endangered species, 100% exceedance occurs at low flow conditions. Clearly, low flow conditions, like those in November 1999, are the time of greatest ecosystem sensitivity to Se inputs (as suggested by Presser and Luoma 2006). It is notable that the example presented here does not represent the most extreme condition of a low flow season of a dry year or critically dry year.

If annual average conditions are assumed (the mean of spatially constrained K_{ds}), compliance is much more sensitive to the choice of guideline. Few if any exceedances (1 to 3%) are observed if the higher fish or bird egg guidelines are implemented under that assumption. For endangered species protection under an average condition, exceedance is approximately 47% for both the fish and bird guidelines. Of course, regulations based upon average conditions run the risk of under-protecting species sensitive to Se exposure during the protracted time in every year (especially drier years) when Se is most bioavailable.

Considering the choice of different guidelines, if a $5 \mu\text{g g}^{-1}$ guideline is implemented that uses sturgeon as the target organism, the entire Bay would be out of compliance. The model calculation suggests nearly all anthropogenic Se would have to be removed to drive sturgeon tissues to concentrations as low as $5 \mu\text{g g}^{-1}$, especially during a low flow condition. The projected dissolved Se concentration necessary to reach that level in sturgeon tissue is approximately the value for the Sacramento River, and hence the pre-disturbance baseline condition for the Bay. The modeling results suggest that if it is assumed that $5 \mu\text{g g}^{-1}$ represents the toxicity threshold for sturgeon, and if it were applied using concentrations in sturgeon from the field, then there is no room for any deviation from concentrations in the Sacramento River without risk

to the species. It is important to remember, however, that this toxicity guideline was derived for the most sensitive fish species. So, the use of the most sensitive surrogate in the toxicity guideline combined with field determinations from the fish with the greatest exposure results in an ultra-sensitive outcome.

These model results also illustrate how sensitive the implementation of a tissue guideline can be to the choice of predator. For example, many of the differences between sturgeon-based guidelines and bird egg-based guidelines are relatively small. Both appear to be sensitive indicators of ecological risks. However, the outcomes of guidance based upon striped bass, a water-column predator, are quite different from outcomes based upon bird eggs or sturgeon. The model showed that while aquatic birds and sturgeon are at risk under most assumptions, few or no exceedances of Se concentrations occur if the choice of regulatory indicator is based upon striped bass tissues. The differences are the result of the different invertebrate prey of the two species. Sturgeon eat a diet that includes strong Se bioaccumulator species (bivalves); striped bass eat from prey that live in the water-column and do not strongly bioaccumulate Se.

Selenium concentrations in the water column or particulate material of the Delta are higher and more variable than in the Bay. Average K_{ds} are similar between the Delta and the Bay. Nevertheless, few exceedances of dissolved and particulate Se concentrations (3% to 19%) are predicted in the Delta, even when the most sensitive fish guideline is used. This is consistent with the observation of low Se concentrations in the few fish that have been sampled from the Delta (e.g., Foe 2010). Use of the local food web is extremely influential in this outcome. Bioaccumulation of Se in the aquatic insect larvae (and other arthropods) that are the primary prey species of most Delta fish and birds is much lower than bioaccumulation by bivalves. As a result, it appears that the Delta food webs are easier to protect from adverse effects of Se than benthic food webs in the Bay, even if it is assumed that the most sensitive fish guideline applies. Nevertheless, the actual concentrations of dissolved Se predicted to be

SAN FRANCISCO ESTUARY & WATERSHED SCIENCE

necessary to meet the tissue guidelines range from 0.37 to 0.80 $\mu\text{g L}^{-1}$, far below the Se concentrations typical of most existing dissolved guidelines for Se (Luoma and Presser 2009). This reflects the unusually high K_d s consistently observed in this freshwater environment.

Few determinations of Se concentrations in particulate material in the incoming rivers to the Bay are available outside the tidal range. Lucas and Stewart (2007) reported matched dissolved and particulate Se concentrations from which one K_d could be calculated (a value of 1,212) for the San Joaquin River during transect sampling in 2000. The example in Table 2 shows that if that were typical of the river, and the food web was mainly based upon arthropods, then compliance with a tissue guideline could occur at dissolved Se concentrations ten times higher than would be the case in the Bay. This river simulation is based on very limited data; it is given here for comparative purposes to show the sensitivity of the model to the choice of hydrologic setting. Comprehensive modeling of the San Joaquin River system would require data collection and analysis specific to the river's settings, predator species, food webs, and habitats. Percentage exceedance (Table 2) is based on weekly sampling of total Se for the river at Vernalis from water year 1995 through water year 2010 (SWRCB 2012)

CONCLUSIONS

The DRERIP Ecosystem-Scale Selenium Model outcomes for the Bay-Delta show critical choices for Se modeling, and derived risk scenarios that illustrate varying degrees of risk, depending on those choices (Figure 1; Tables 1 and 2). In general, the conceptual model for Se shows that the focus of concern for this contaminant is the top of the food web. Quantitative model calculations show that enough is known to adequately characterize the distribution of Se through the Bay-Delta ecosystem, although the available data from which to validate the outcomes is dated and does not include conditions within a low flow season of a dry year or critically dry year. Presser and Luoma (2010b) give additional specifics for updated data collection and model refinements.

Selenium concentrations in fish or bird tissues alone appear to be good indicators of ecological risks from Se. Key invertebrates (e.g., the bivalve *C. amurensis* in the Bay) may be a more pragmatic indicator for frequent monitoring. Given that (1) suspended particulate material Se concentrations are key to accurate prediction of prey and predator Se concentrations; and (2) dissolved Se concentrations are constrained to a narrow dynamic range within the estuary, a suspended particulate material Se concentration also may be a sensitive parameter on which to assess change. Dissolved Se concentrations appear to be the variable of choice for regulatory agencies, however, because of links to total maximum daily loads.

The ability to quantitatively characterize distributions among all these ecosystem components from field determination of only one component allows great flexibility in future monitoring whatever the choice of indicator. The detailed site-specific conceptual model, and the ability to quantitatively apply that model, also provide perspective on the processes that are most influential in determining Se contamination in the predators of this Se-sensitive environment (Figure 1).

The quantitative example (Tables 1 and 2) provides some lessons for implementing regulations to manage Se in this system. First, it is notable that extremely small changes in dissolved Se concentrations, in absolute terms, have strong implications for compliance with the tissue guidelines. A regulatory program that focuses on dissolved Se would require an extremely rich data set to reliably detect the differences between compliance and non-compliance, based upon the translation from tissue to dissolved Se. This is another reason why regulation of suspended particulate material Se concentration may be a more sensitive parameter on which to assess change.

Second, if compliance is determined from tissue concentrations in a predator, the choice of that predator is crucial. Predators of bivalves in benthic food webs are much more at risk than predators from pelagic food webs. The former should be the basis of tissue monitoring in the Bay.

Third, any decision as to whether reductions in ambient concentrations of Se would be required to comply with the tissue guidelines depends upon the choice

of guideline and assumed environmental conditions. For example, the modeling suggests that a fish tissue guideline of $5 \mu\text{g g}^{-1}$ would ultimately require essentially all enriched Se inputs to the Bay to be eliminated if the guideline were applied using Se concentrations in sturgeon. According to the calculations, dissolved Se concentrations in the Bay would have to decline to nearly those in the Sacramento River to comply with such a guideline. If a guideline of $8 \mu\text{g g}^{-1}$ was used, the Bay would be near compliance under average conditions; but 66% out of compliance in a situation like November 1999 (i.e., low flow). Calculating in the opposite direction from a traditional dissolved Se concentration guideline, allowing dissolved concentrations of Se in the Bay to reach $5 \mu\text{g L}^{-1}$ (the current regulatory guideline) or even $2 \mu\text{g L}^{-1}$ would result in tissue concentrations (potentially greater than $100 \mu\text{g g}^{-1}$ in *C. amurensis*) that could threaten many of the predators in the Bay, if other conditions stay as they are.

Fourth, the current food webs in the Delta are less at risk from Se than the benthic food webs of the Bay, because of the differences in food webs. The differences between the Delta and the Bay are not the result of the freshwater versus brackish water nature of the systems of interest because, on average, transformation efficiencies are similar in the two. Where transformation processes are greatly different between two ecosystems, then a different outcome from implementing the same tissue guideline might be expected. The San Joaquin River example shows how a less efficient transformation of dissolved Se to particulate Se in the river can result in less sensitivity of the ecosystem to changes in Se concentrations.

Finally, the more specificity added to the model, the less uncertainty in predictions. If, for example, the geographic range is narrowed by using data only from Carquinez Strait–Suisun Bay, then freshwater and ocean interfaces are avoided. If the temporal range is narrowed to low flow seasons of dry years (i.e., high residence time or high exposure time), then focus can be on times when the transformative nature of the estuary is elevated. Juxtaposition of times when suspended particulate material or prey species achieve maximum Se concentrations with critical life stages of species at risk being present allows regulatory consid-

erations to focus on times that govern Se's ecological effects (i.e., ecological bottlenecks) (Figure 1).

The greatest strength of the analytical and modeling processes is that it is an orderly, ecologically consistent approach for assessing different aspects of the fate and effects of Se. Assessments such as the examples shown here can represent a starting point for initiating management decisions. Application of the DRERIP Ecosystem-Scale Selenium Model shows that management of Se requires incorporation of the complexity of dietary exposures and the systematic consideration of critical aspects of hydrology, biogeochemistry, physiology, ecology, and ecotoxicology to define ecosystem protection. Although this is complex, scenarios can be developed from specific questions that arise in the planning and implementation of restoration actions for the Bay-Delta. Quantitative evaluation of those scenarios is feasible. However, the Se database and monitoring program need to be modernized (e.g., refocused and expanded). Specifically, monitoring should include (1) representation of conditions in dry and critically dry years; and (2) collection of spatially and temporally matched data sets across media (i.e., water, suspended particulate material, prey, and predator) to ensure that derived site-specific factors are current for the ecological and hydrological dynamics of the Bay-Delta. Only then will predictions from the model remain relevant and realistic to a constantly evolving estuary.

ACKNOWLEDGEMENTS

This work was supported by CALFED (in the project's earlier phases), the U.S. Geological Survey National Research and Toxics Substances Hydrology Programs, and the U.S. Environmental Protection Agency (San Francisco, California, Region 9). Jeanne DiLeo (U.S. Geological Survey, Menlo Park Publishing Service Center) prepared the outstanding graphics. We thank William Beckon and Thomas Maurer (U.S. Fish and Wildlife Service, Sacramento, California) for provision of species at risk for the Bay-Delta. We also thank William Beckon, Susan De La Cruz (U.S. Geological Survey, Vallejo, California) and Regina Linville (Office of Environmental Health Hazard Assessment,

SAN FRANCISCO ESTUARY & WATERSHED SCIENCE

Sacramento, California) for assistance with species-specific effects models and human health considerations. Thanks also go to Mark Huebner (U.S Geological Survey, Menlo Park, California) for exceptional assistance with manuscript preparation.

Chinook salmon outmigration survival in wet and dry years in California's Sacramento River

Cyril J. Michel, Arnold J. Ammann, Steven T. Lindley, Philip T. Sandstrom, Eric D. Chapman, Michael J. Thomas, Gabriel P. Singer, A. Peter Klimley, and R. Bruce MacFarlane

Abstract: Outmigration survival of acoustic-tagged, hatchery-origin, late-fall-run Chinook salmon (*Oncorhynchus tshawytscha*) smolts from the Sacramento River was estimated for 5 years (2007–2011) using a receiver array spanning the entire outmigration corridor, from the upper river, through the estuary, and into the coastal ocean. The first 4 years of releases occurred during below-average river flows, while the fifth year (2011) occurred during above-average flows. In 2011, overall outmigration survival was two to five times higher than survival in the other 4 years. Regional survival estimates indicate that most of the improved survival seen in 2011 occurred in the riverine reaches of the outmigration corridor, while survival in the brackish portions of the estuary did not significantly differ among the 5 years. For the 4 low-flow years combined, survival rate in the river was lower in the less anthropogenically modified upper reaches; however, across all regions, survival rate was lowest in the brackish portion of the estuary. Even in the high-flow year, outmigration survival was substantially lower than yearling Chinook salmon populations in other large rivers. Potential drivers of these patterns are discussed, including channelization, water flow, and predation. Finally, management strategies are suggested to best exploit survival advantages described in this study.

Résumé : La survie durant la dévalaison de la fin de l'automne de saumoneaux quinnat (*Oncorhynchus tshawytscha*) du fleuve Sacramento issus d'écloseries et munis d'émetteurs acoustiques a été estimée sur une période de 5 ans (2007–2011) à l'aide d'un réseau de récepteurs couvrant tout le corridor de dévalaison, du cours supérieur du fleuve jusqu'au littoral océanique, en passant par l'estuaire. Les lâchers des 4 premières années ont eu lieu pendant des périodes de débits du fleuve sous la moyenne, alors que les débits étaient supérieurs à la moyenne pour les lâchers de la cinquième année (2011). En 2011, la survie globale durant la dévalaison était de deux à cinq fois supérieure à la survie durant les 4 autres années. Les estimations régionales de la survie indiquent que les meilleurs taux de survie observés en 2011 se sont produits dans des tronçons fluviaux du corridor de dévalaison, alors que la survie dans les portions saumâtres de l'estuaire n'a pas varié de manière significative durant ces 5 années. Pour les 4 années combinées de faibles débits, le taux de survie dans le fleuve était plus faible dans les tronçons supérieurs moins modifiés par l'activité humaine; cela dit, pour toutes les régions, le taux de survie était le plus faible dans la portion saumâtre de l'estuaire. Même durant l'année de débits élevés, la survie durant la dévalaison était considérablement plus faible que celle de populations de saumons quinnat d'un an dans d'autres grands cours d'eau. Les causes possibles de ces motifs, dont la canalisation, l'écoulement de l'eau et la prédation, sont abordées. Enfin, des stratégies de gestion sont suggérées pour l'exploitation optimale des avantages liés à la survie décrits dans l'étude. [Traduit par la Rédaction]

Introduction

Knowing where excessive mortality is occurring is crucial to designing effective conservation measures for salmon populations. Salmon utilize many different habitats during the different stages of their life cycle, but it is the degradation of freshwater or estuarine habitats that is commonly cited as the cause of population declines (Nehlsen et al. 1991). Of particular concern is the high mortality often experienced in these habitats during one of the most vulnerable stages in the salmon life cycle: the downstream migration of juveniles (smolts) heading to the ocean from their riverine birthplace (Healey 1991).

There has been extensive research on juvenile salmonid smolt survival in large rivers of the west coast of North America, most notably in the Columbia and Fraser rivers (McMichael et al. 2010;

Muir et al. 2001; Rechisky et al. 2013; Skalski et al. 1998; Welch et al. 2008, 2009). These studies have indicated that outmigration survival can vary widely from year to year and population to population, and further research in these rivers has shown that survival rates often correlate with environmental variables such as flow, turbidity, and temperature (Giorgi et al. 1997; Gregory and Levings 1998; Smith et al. 2003). This information has proved crucial for improving salmon survival in the Columbia River, through improvements in fish passage structures and changes in dam operations (Connor et al. 2003).

California's Sacramento River, in contrast, is critically lacking in smolt outmigration survival information. The Sacramento River, compared with the Columbia and Fraser rivers, has an order of magnitude lower discharge, exists in a warm and dry Med-

iterranean climate, and yet is the primary source of water to the state's industrial, domestic, and agricultural sectors. The Sacramento River and its estuary are currently the objects of intense conservation concern owing to the poor status of some of its salmon and steelhead (sea-run rainbow trout, *Oncorhynchus mykiss*) populations (among other native species) and habitats. In spite of these problems, the Sacramento River is still an important contributor to west coast Chinook salmon (*Oncorhynchus tshawytscha*) fisheries, largely because of extensive hatchery propagation efforts (O'Farrell et al. 2013). Several very large water and habitat management projects are under consideration that are expected by their proponents to contribute to the restoration of Chinook salmon populations, yet survival rates across the life cycle of these populations are poorly known. Several coded-wire and acoustic tagging studies have assessed Chinook salmon smolt survival in the Sacramento – San Joaquin Delta (the freshwater portion of the estuary), which is the hub of water infrastructure for the majority of southern California and a location where anthropogenic modifications are extensive and salmonid losses are great (Baker and Morhardt 2001; Brandes and McLain 2001; Perry et al. 2010). However, no study has assessed smolt survival through the entirety of the outmigration corridor, from the upper limit of anadromy to the Pacific Ocean.

In this study, we quantify the spatial and temporal patterns of hatchery late-fall-run Chinook salmon smolt survival in the Sacramento River system. Utilizing an extensive network of acoustic receivers, we estimated survival through the river and estuary over 5 years at a fine-scale spatial resolution previously not possible. This resolution allowed us to discern regional and temporal differences in survival that cannot be obtained using traditional tagging methods.

Methods

Study area

The Sacramento River is the longest and largest (measured by flow discharge) river that is fully contained within the state of California and is the third largest river that flows into the Pacific Ocean in the contiguous United States (Fig. 1). The headwaters are located just south of Mount Shasta in the lower Cascade Range, and the river enters the ocean through the San Francisco Estuary at the Golden Gate. The total catchment area spans approximately 70 000 km². The Sacramento River and its tributaries have been heavily dammed and otherwise impacted by human activities; it is estimated that 47% of the historic spawning, migration, and (or) rearing area is no longer accessible to Chinook salmon (Yoshiyama et al. 2001).

The Sacramento River watershed includes diverse habitats, from relatively pristine run-riffle reaches in the north, to a heavily channelized and impacted waterway further south, and finally to the San Francisco Estuary, the largest and most modified estuary on the west coast of North America (Nichols et al. 1986). The San Francisco Estuary is composed of an expansive tidally influenced freshwater delta upstream of its confluence with the San Joaquin River and a series of increasingly saline bays. The sheer size and physical differences between these two sections of the estuary merit separate consideration with respects to their influence on salmon survival; therefore, we use the terms “delta” and “bays” to differentiate between the two.

The annual mean daily discharge for the Sacramento River from 1956 to 2008 was 668 m³·s⁻¹ (California Department of Water Resources 2007). However, this water does not continue downstream unimpeded; owing to one of the world's largest water storage and water transportation infrastructures, replete with abundant dams, reservoirs, diversions, and aqueducts, it is estimated that current discharge of the Sacramento and San Joaquin rivers combined is less than 40% of the predevelopment discharge (Nichols et al. 1986). The damming and water diversions of the

Sacramento River and its tributaries have also homogenized river flows throughout the year, reducing winter high flows and flooding while increasing flows in the summer and fall (Buer et al. 1989).

The study area included approximately 92% of the current outmigration corridor of late-fall-run Chinook salmon, from release to ocean entry. Specifically, the study area's furthest upstream release site at Jelly's Ferry (518 km upstream from the Golden Gate Bridge) is only 47 km downstream from Keswick Dam, the first impassable barrier to adult salmon returning to spawn on the Sacramento River.

Central Valley late-fall-run Chinook salmon

The late-fall-run is one of the four Chinook salmon runs occurring in the Sacramento River drainage and is the only run to exhibit a predominately yearling migrant life history (Moyle 2002). Following emergence from the gravel, wild late-fall-run juveniles exhibit a river residency of 7 to 13 months, after which smolts (juvenile salmon that are actively migrating to the ocean) will migrate to the ocean between the months of October and May at a fork length of 90 to 170 mm (Fisher 1994; Snider and Titus 2000a, 2000b). In contrast, the subyearling life history demonstrated by a 4- to 7-month freshwater residency is the more common life history strategy used by the other salmon populations in the Sacramento River. Moyle et al. (1995) outlined six major threats to the late-fall-run Chinook salmon population, one of which was mortality during outmigration, potentially due to water diversions and increased predation in bank-altered areas. In 2004, the fall-late-fall-run Chinook salmon evolutionarily significant unit (ESU) was designated a “species of concern” by the United States Endangered Species Act.

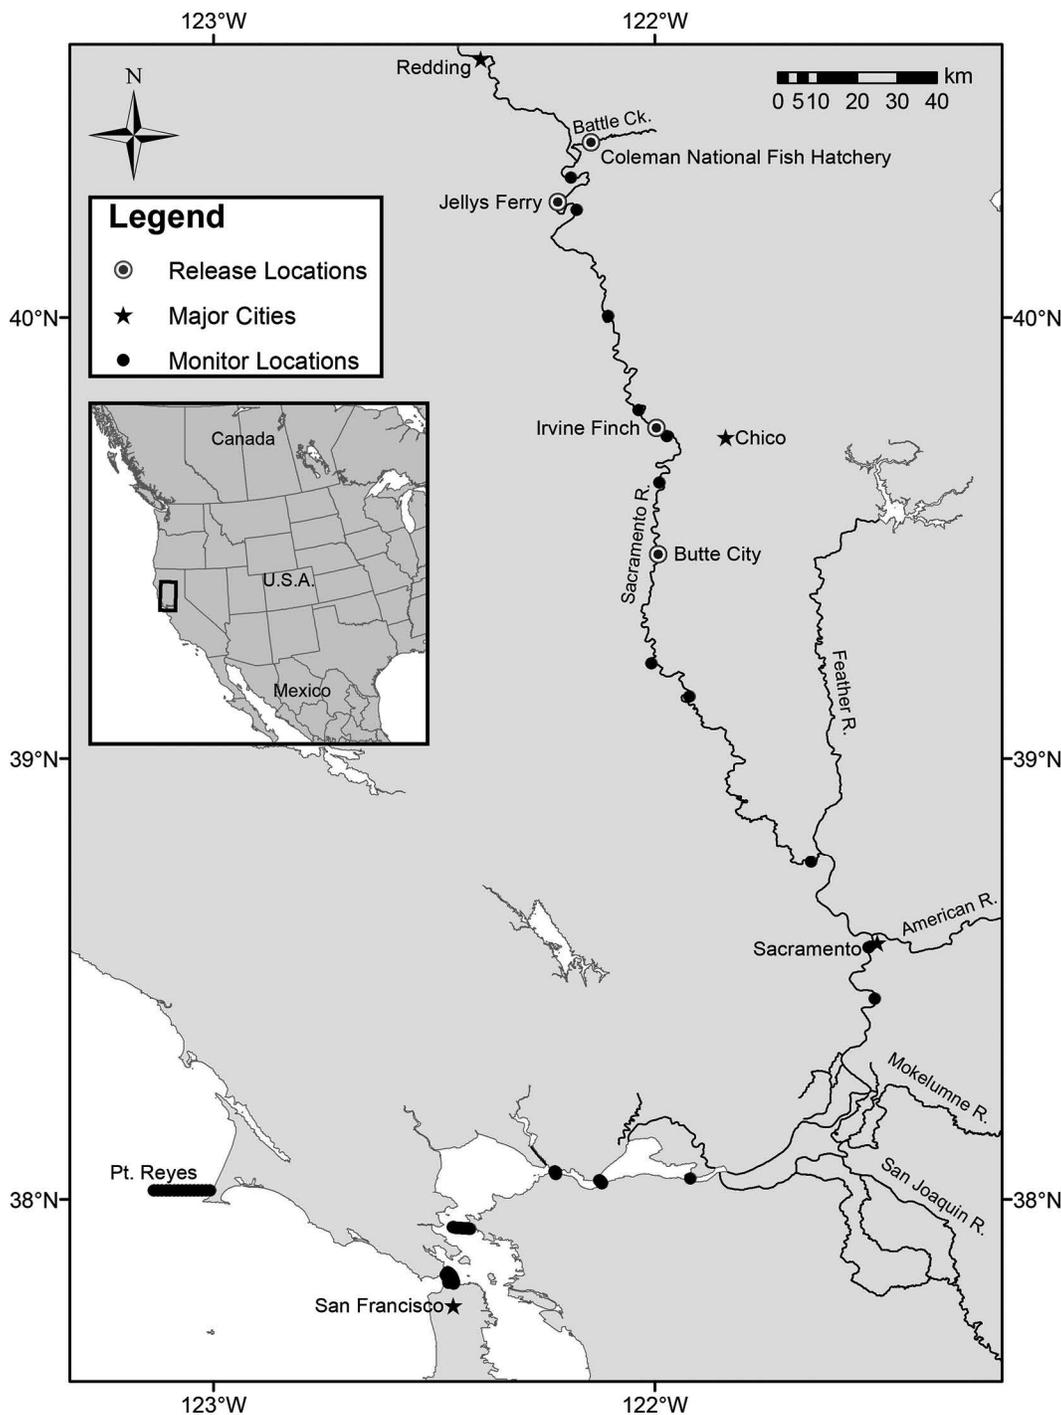

The United States Fish and Wildlife Service's (USFWS) Coleman National Fish Hatchery (Anderson, California) is the only hatchery to produce late-fall-run Chinook salmon, releasing approximately one million smolts a year between mid-December and mid-January. Annual escapement for this population can vary from just several hundred to 42 000; the mean annual escapement from the winter of 1973–1974 to the winter of 2007–2008 is 12 386 individuals (Azat 2015). Little information exists regarding what proportion of the late-fall-run adult population is of hatchery origin versus wild origin. Palmer-Zwahlen and Kormos (2013) estimated that in 2011, 100% of late-fall-run adults returning to Coleman National Fish Hatchery were hatchery fish, while 44% of late-fall adults recovered during carcass surveys on the Sacramento River were hatchery origin.

Fish tagging and releases

For five consecutive winters, from January 2007 to December 2010 – January 2011 (henceforth referred to as 2007, 2008, 2009, 2010, and 2011 seasons, based on the year during which January tagging occurred), 200 to 304 late-fall-run Chinook salmon smolts from Coleman National Fish Hatchery were implanted with acoustic tags and released into the Sacramento River. Release times were scheduled to be within a few days of the release times of the general production of hatchery fish. Only smolts 140 mm or larger were tagged to keep the tag mass to less than 6% of the fish mass. Therefore, tagged smolts were representative of the larger hatchery individuals; specifically, from 2007 to 2011, smolts at or above the 140 mm cutoff represented 23.5%, 38.4%, 50.2%, 29.6%, and 50.9%, respectively, of the total hatchery production. In the rare instance that a smolt had severe descaling, fin erosion, or other obvious injuries, the smolt was discarded and not tagged.

Acoustic tags were surgically implanted into the peritoneal cavity of anesthetized fish. The tag was inserted through a 12 mm incision anterior to the pelvic girdle and 3 mm to the side of the linea alba. The incision was then closed with two simple interrupted stitches tied with square knots of nonabsorbable nylon cable-type suture. All fish were allowed to recover for a minimum

Fig. 1. Study area map including the Sacramento River, Sacramento – San Joaquin River Delta, Suisun – San Pablo – San Francisco bays and Pacific Ocean. Bull's-eye icons signify a release location, stars symbolize a major city, and black dots symbolize a receiver location.

of 24 h before release. Additional surgery details can be found in Ammann et al. (2013). In study years 2008 and 2009, an additional group of smolts from the same hatchery were tagged with dummy acoustic transmitters to monitor tag effects and tag retention in laboratory trials. No fish shed their tags over 221 and 160 days (the entire length of the trial in both years, respectively), and tagged fish growth and survival was not significantly different than untagged fish (Ammann et al. 2013). Since fish in the field and captive studies had similar tag burdens (1.6% to 6.3% for field study, 2.6% to 5.6% for captive study), we assumed that mortality in the field study was not tag-related.

In the first year (2007), a total of 200 fish were released in small batches (13–14 fish each) every weekday afternoon for the third, fourth, and fifth weeks of January 2007 at the Coleman National Fish Hatchery into Battle Creek (river kilometre 534 — “rkm” is distance from ocean), a tributary to the Sacramento River (Table 1). In the following 4 years, fish were released in two groups. In 2008–2010, a total of approximately 300 fish were released; ~50 fish were simultaneously released at dusk at three release sites in the upper 150 km of the mainstem Sacramento River (rkm 518, 412, 363) in mid-December and early January, allowing the lower release groups to reach the lower river and estuary in larger numbers,

Table 1. Means and standard deviations (SD) for mass and fork length of acoustically tagged smolts by year and for all years combined.

Year	Sample size	Fork length \pm SD (mm)	Mass \pm SD (g)
All	1350	158.8 \pm 12.4	43.9 \pm 11.2
2007	200	164.6 \pm 10.7a	46.6 \pm 9.8a
2008	304	168.7 \pm 13.3b	52.6 \pm 13.8b
2009	300	152.1 \pm 8.5c	38.9 \pm 7.9c
2010	306	152.5 \pm 10.2c	39.3 \pm 8.8c
2011	240	158.1 \pm 7.8d	42.9 \pm 6.8d

Note: Size distributions with different letters are significantly different ($P < 0.05$).

which improved statistical precision of the survival estimation. In 2011, 240 fish were released; 120 fish were released in mid-December and early January at dusk at Jelly's Ferry (rkm 518), a site on the mainstem Sacramento River, only 7.3 km downstream of the confluence with Battle Creek. Fish were transported to the release sites by truck at low densities (~ 10 g·L⁻¹) in coolers with aerators. In years with multiple release sites, transport times were extended for closer sites to keep potential transport stress equal among all release groups.

Acoustic telemetry

Acoustic tagging technology was used to acquire high-resolution movement data and survival estimates. Uniquely coded Vemco 69 kHz V7-2L acoustic tags (mean \pm SD: 1.58 \pm 0.03 g in air, 7 mm diameter by 20 mm long; Amirix Systems, Inc., Halifax, Nova Scotia, Canada) and Vemco VR2/VR2W receivers were used to tag and track fish. The tags transmitted every 30 to 90 s (with a mean of 60 s) in the first year of the study, then transmitted every 15 to 60 s (with a mean of 45 s) in the following 4 years. Battery life tests were conducted in 2007, 2010, and 2011 with a subset of tags from the same batch used for tagging smolts. In 2007, tag life of 11 test tags ranged from 138 to 749 days, with a mean of 513 days; in 2010, tag life of 20 test tags ranged from 127 to 297 days, with a mean of 194 days; in 2011, tag life of 25 test tags ranged from 98 to 214 days, with a mean of 172 days. For the purposes of verifying that tag life was sufficient to last the entire migration of all smolts, the time elapsed from release to last known detection was calculated for each smolt for all 5 years of the study. Last known detection for smolts was either last known detection before disappearance or time of arrival to the Golden Gate receiver location (considered the end of the outmigration in this study). The longest outmigrating individual per year took 32, 89, 67, 97, and 79 days, respectively, for the years 2007–2011, with 99.2% of smolts successfully outmigrating or disappearing within the first 60 days after release. Therefore, we believe the battery life for our tags were sufficient to last the entire outmigration period of our tagged smolts.

The receiver array spanned 550 km of the Sacramento River watershed from below Keswick Dam to the entrance to the ocean (Golden Gate) and beyond to Point Reyes. This network of approximately 300 receivers at 210 receiver locations was maintained by the California Fish Tracking Consortium (<http://californiafishtracking.ucdavis.edu>), a group of academic, federal, and state institutions and private consulting firms. We selected a subset of these receiver locations for the final survival analyses, as per the selection criteria described in the Data analysis section of the Methods (see below).

The acoustic receivers automatically process all detection data and drop most false detections or incomplete codes from the detection file. All detections were then subject to standardized quality control procedures to remove any remaining false detections (see Michel et al. 2013).

Data analysis

Survival in each reach

Juvenile Chinook salmon express obligate anadromy, meaning that they will travel toward the ocean once the emigration has begun with scarce exceptions (Healey 1991). Therefore, in a linear system such as the Sacramento River, if receiver locations were capable of detecting every passing tag, then if a fish is detected at one receiver location but is never detected thereafter, we could assume that the fish has died somewhere in the reach between the receiver location where it was last detected and the next downstream receiver location.

However, receiver locations rarely operate perfectly, necessitating the estimation of detection and survival probabilities at each receiver location. We used the Cormack–Jolly–Seber (CJS) model for live recaptures (Cormack 1964; Jolly 1965; Seber 1965) within program MARK (White and Burnham 1999) using the RMark package (Laake and Rexstad 2008) within program R (version 3.0.1; R Core Team 2013). The CJS model was originally conceived to calculate survival of tagged animals over time, by resampling (recapturing) individuals and estimating survival and recapture probabilities using maximum likelihood. For species that express an obligate migratory behavior, a spatial form of the CJS model can be used, in which recaptures (i.e., tagged fish detected acoustically downstream from release) occur along a migratory corridor (Burnham 1987). The model determines if fish not detected at certain receivers were ever detected at any receiver downstream of that specific receiver, thus enabling calculation of maximum-likelihood estimates for detection probability of all receiver locations (p), survival (Φ), and 95% confidence intervals for both (Lebreton et al. 1992).

An initial run of the model with all possible river receiver locations together with the major estuary receiver locations was performed for each individual year separately, after which a subset of the river receiver locations that had consistently high tag detection probabilities through the years and that were strategically located were chosen to delimit the river reaches that were used in the spatial survival analysis. Additionally, because survival between the Battle Creek release site and Jelly's Ferry receiver location was only estimated in 2007, and because Jelly's Ferry was the furthest upstream release site for all following years, only fish known to have reached the Jelly's Ferry receiver location in 2007 were included in all survival analyses, and Jelly's Ferry was considered to be their release location. In total, 145 of the 200 smolts released in 2007 were known to have reached the Jelly's Ferry release location and were included in survival analyses. A total of 19 receiver locations were chosen, extending from just below the most upstream release site, Jelly's Ferry, to the Golden Gate (Fig. 1; Table 2). Between them, we delineated 17 reaches in which mortality can be accurately estimated (the detection probability and survival of the 18th and last reach can only be estimated jointly, as there is no detection information beyond this point in which to assess the final receiver location).

Parallel receiver lines were installed at the Golden Gate approximately 1 km apart to estimate detection probability and survival at the inner (East) Golden Gate receiver line by using the western line to assess performance of the eastern line. After the 2008 outmigration season, a coastal ocean receiver line was deployed across the continental shelf at Point Reyes, approximately 60 km north of the Golden Gate. Detections from this receiver line were included in the encounter history for the Golden Gate West line to improve accuracy in the estimation of survival and detection probability to the Golden Gate East line. However, because the Point Reyes receiver location did not exist in the 2007 or 2008 season, and few fish were detected there in subsequent years, it was not formally included as a receiver location in the survival analyses.

Survival per 10 km, regional survival, and overall survival

For each year, we used the 18 receiver locations to estimate reach survival (Φ_R) for 17 reaches, using the fully time-varying CJS

Table 2. Locations of acoustic receivers and tagged smolt release locations.

Location	rkm	Description
Battle Creek	534	Release site 2007
Jelly's Ferry	518	Receiver location and release site 2008–2011
Bend Bridge	504	Receiver location
China Rapids	492	Receiver location

model, which in this case actually varies over space; specifically, each reach has a parameter (reach model). Detection probabilities were also allowed to vary by reach. These survival estimates were then standardized by reach lengths l (giving survival per 10 km, Φ_{10}) to allow inter-reach survival comparisons. This was done by setting the time intervals (in reality, space intervals for this application) in the `process.data()` function of RMark package to a vector of reach lengths (in units of 10 km). The per 10 km survival estimates are calculated by RMark according to the following formula (eq. 1):

$$(1) \quad \Phi_{10} = \sqrt[l]{\Phi_R}$$

To account for the propagation of error, standard errors for n th root parameter estimates were calculated by the RMark package using the `delta` method (Powell 2007; Seber 1982).

Regional (river, delta, and bays) and overall (from the release site to the Golden Gate) survival was then assessed for each year. We did this by taking the product of the reach survival estimates that fall inside the spatial extent of interest, and we present this as percent survival. To account for the propagation of error, standard errors of the cumulative products of survival estimates were also calculated using the RMark package, using the `deltamethod.special()` function. When using the `delta` method for estimating the variance of the product of survival estimates, the variance-covariance matrix for the survival estimates must be included in the estimation. Confidence intervals for the product of survival estimates must be calculated on the logit scale, then back-transformed to the real probability scale. Therefore, to estimate 95% confidence intervals, we used our product of survival estimates ($\hat{\Phi}$) along with its respective standard error of the beta estimate ($\widehat{SE}_{\text{logit}(\hat{\Phi})}$) by using the following formula (eq. 2):

$$(2) \quad \text{expit}[\text{logit}(\hat{\Phi}) \pm 1.96 \times \widehat{SE}_{\text{logit}(\hat{\Phi})}]$$

The influences of different spatial and temporal factors on survival rates were assessed by modeling Φ_R as a function of the factor in question. Specifically, the influence of these factors was assessed by allowing each release group (e.g., five groups for the release year model: 2007, 2008, 2009, 2010, and 2011) within each model to have its own set of survival parameters. Each factor-specific survival model was compared with one another and with a base model (a model with no factor-specific parameters) using Akaike's information criterion corrected for small sample sizes (AIC_c). Goodness-of-fit was assessed by estimating the \hat{c} variance inflator factor of the base model. For this we used two different methods and adopted the more conservative estimate. First, we simulated \hat{c} and deviance from 100 simulations using the bootstrap procedure. Then, we estimated \hat{c} in two ways, first by dividing the deviance estimate from the original data by the mean of simulated deviances, giving a \hat{c} of 1.309, then by dividing the \hat{c} from the original data by the mean \hat{c} from the bootstraps, giving a \hat{c} of 1.494. We therefore adopted the more conservative \hat{c} of 1.494 and used it to adjust all AIC values for overdispersion (hereinafter called $QAIC_c$). As a rule of thumb, if a test model lowered $QAIC_c$ relative to the base model by a difference of more than seven, the test model was deemed substantially more parsimonious and therefore was supported over the base model.

The effects of reach ($n = 17$), release year ($n = 5$), release site ($n = 3$), and all interactions of those factors were tested (see Table 3 for models). This was done by comparing the $QAIC_c$ score of each model with the $QAIC_c$ score of a version of the "reach model" that combines data from all 5 years, which henceforth will be considering the "base model". We used the reach model as our base model under the assumption that survival must vary through space given the spatial heterogeneity of the study system. To test this assumption, a "null model" was also included for comparison. This model only allowed one parameter for survival (representing the null hypothesis: constant survival through space and time). An initial run of several models that allowed for a different parameterization of the detection probability terms while keeping the survival terms the same indicated that the model allowing for detection probability to vary by reach and year was the best supported model. Therefore, all survival models presented in Table 3 allow detection probability to vary by reach and year: $p(\text{reach} \times \text{year})$.

To better understand whether annual fluctuations in survival occurred on a regional scale, we also included three models that allowed survival to vary per reach and per year (reach \times year) in only the river, the delta (the delta being the freshwater portion of the estuary), or the bays (Suisun, San Pablo, and San Francisco bays, i.e., the brackish portion of the estuary). These models allowed survival to vary by reach in the remaining regions and are therefore also comparable with the base model.

Finally, the influence of individual covariates (fork length (mm) and mass (g)) on survival was assessed. The model selected a priori to include these covariates was the base model. The individual covariates were added both as an additive factor (different intercept per reach, but common slope) and as a factor including the interaction term (different intercept and different slope). These models were then compared using $QAIC_c$ with the base model without any individual covariates to determine whether fish size and mass affects survival.

For the purpose of considering migration rate as a potential driver for survival rates, mean successful migration movement rate (MSMMR, $\text{km}\cdot\text{day}^{-1}$; Michel et al. 2013) was calculated per year. Migration movement rate from release site to the West Golden Gate receiver line (i.e., entry to the Pacific Ocean) was calculated for every fish that was detected (i.e., successfully reached the ocean) at either of the Golden Gate receiver lines. These values were then averaged per year and compared with the overall survival for that year in Table 4.

Table 3. Survival models for different spatial and temporal factors, as well as individual covariates, ordered from lowest to highest QAIC_c, omitting 2011 data.

Survival (ϕ) treatment	Δ QAIC _c	No. of parameters
(River survival \times year) \times reach	0.0	126
(Delta survival \times year) \times reach	25.3	93
Base model (reach)	26.6	90
Reach + length	26.6	91
Reach \times year	27.9	144
Reach \times length	40.0	108
(Bays survival \times year) \times reach	49.0	105
Reach \times mass	50.0	108
Reach \times release	53.8	126
Reach \times year \times release	270.8	288
Null model (constant survival)	308.4	73

Note: The Δ QAIC_c statistic represents the QAIC_c distance from the most parsimonious model. The number of parameters includes the parameters for estimation of detection probabilities (reach- and year-specific).

Results

Overall survival of late-fall-run Chinook salmon through the entire migration corridor (rkm 518–2) per year ranged from 2.8% to 15.7%, with 2011 having the highest survival (Table 4). The MSMMR values indicate that the first 4 years of the study had relatively similar migration rates, ranging from 17.5 to 23.5 km per day, whereas 2011 had a faster migration rate of 36 km per day.

Survival rate on a reach-by-reach basis was quite variable. During the first 4 years of the study, the upper river reaches (reaches 1 through 8; rkm 518–325) had some of the lowest survival per 10 km, and the lower reaches of the river (reaches 9–12; rkm 325–169) had the highest. The delta was comparable to the upper river, and the San Francisco and Suisun bays (reaches 13–17; rkm 169–2) had the lowest survival rates (Fig. 2). During these same 4 years, detection probabilities per year and per receiver location throughout the watershed ranged from 4% to 100%, with 90% of all detection probabilities being larger than 50%. In the fifth year, river flows at the time of release were much higher than in the previous 4 years (Fig. 3), and as a result detection rates were much lower in the river, with only three of the twelve river receiver locations having a detection probability higher than 1%. Therefore, 2011 reach-specific survival in the river was not estimable.

Region-specific survival estimates were calculated using the product of all reach-specific survival estimates within the region of interest (Fig. 4; Table 4). Although reach-specific survival parameters could not be estimated for the river region in 2011, detection probability improved downstream as water velocity decreased, allowing the estimation of reach-specific and region-specific survival estimates downstream of the river region. To estimate river region survival in 2011 and to further investigate differences in survival between 2011 and the previous years, the detection data was simplified for a post hoc CJS modeling exercise that would allow the inclusion of 2011. We simplified the detection data by only including detections from four receiver locations separating the major watershed regions: Freeport at the downstream end of the river region, Chipps Island at the downstream end of the delta region, and the two parallel Golden Gate receiver lines at the downstream end of the bays region. Additionally, only fish released at the Jelly's Ferry site were included for all years, since the other release locations did not have associated receiver locations. A preliminary model that allowed survival and detection probability to vary by region and by year (region \times year) allowed us to estimate survival in the river region in 2011 (Fig. 4; Table 4). This estimate revealed that survival in the river in 2011 was much higher than in all previous years, while survival in the delta and bays was similar among all 5 years. We also constructed

Table 4. Percent overall survival to Golden Gate East receiver line (rkm 2) per year, including standard error (SE), and mean successful migration movement rate (MSMMR) with SE.

Release group	% Survival	SE	MSMMR \pm SE (km-day ⁻¹)

*Estimated from post hoc survival model.

a set of similar models where 1 year was given its own set of region-specific survival parameters, while the remaining 4 years shared the same region-specific survival parameters. These models allowed detection probability to vary by region and by year. Five models were constructed, each one allowing a different year to have its own survival parameters. The model allowing 2011 to have its own region-specific survival parameters while the other 4 years shared the same region-specific parameters was substantially better supported (Δ QAIC_c > 7) than all the other models of the same type, as well as the preliminary model (permitting all years to have different region-specific survival parameters).

In the analysis of the effect of different spatial and temporal factors on survival, 2011 data was omitted because of the lack of detection data available in the river portions of the watershed. The influence of reach on survival rates (base model) was found to have substantially better support (Δ QAIC_c \gg 7) than the null model (constant survival through space and time; Table 3). The reach models that included release site or year (reach \times release and reach \times year, respectively), as well as the interaction model (reach \times year \times release), did not improve their support over the base model. The year model was better supported than the release model. The only model that had substantially better support than the base model was the model that allowed for river survival to have a year effect, while delta and bays survival was held constant through time ((river survival \times year) \times reach). The model allowing only the delta reach to have a year effect ((delta survival \times year) \times reach) was marginally better supported than the base model (Δ QAIC_c < 2).

Tagged fish mass and fork length varied significantly among years ($P < 0.001$), and pairwise hypothesis testing using Bonferroni and Tukey's honestly significant difference tests both indicate that fish sizes were statistically different among all years (with the exception of the 2009–2010 pair; Table 1). However, the addition of individual covariates (mass, length) as factors to the base model did not improve parsimony in any circumstance, although the length model did fit the data better than the mass model. A model adding length as an additive factor had more support than the other covariate models and had approximately equal support with the base model (Δ QAIC_c < 0.1; Table 3). Therefore, the significant

Fig. 2. Percent survival per 10 km per reach for the 2007–2010 study years combined. Figure and map are delimited based on the regions (from upstream to downstream): upper Sacramento River, lower Sacramento River, Sacramento – San Joaquin River Delta, and Suisun – San Pablo – San Francisco bays. The Sacramento River was delimited into an upper and lower section to highlight the shift in survival rates. Error bars represent 95% confidence intervals. 2011 data was omitted owing to poor detection probabilities.

differences in mass and fork length among years did not appear to affect survival.

Discussion

This study used high resolution fish tracking and environmental data to provide the first reach-specific survival estimates of Chinook salmon smolts in the Sacramento River over the entire migration corridor. Survival was relatively high in the lower river compared with other areas, a somewhat unexpected finding given that this reach is channelized and rip-rapped. Also, and in contrast with the commonly held belief that mortality during the Central Valley smolt outmigration is greatest in the delta (Williams 2006), we observed relatively high mortality in the upper river and especially in the bays downstream of the delta. We found that survival over the entire migration route was much lower in 4 low-discharge years (2.8%–5.9%) than in 1 high-discharge year (15.9%; Fig. 3); higher survival in the high-discharge year was due mainly to increased survival in the river region. This suggests that riverine survival dynamics may be playing an underappreciated role in determining annual salmon stock abundance, as shown with Cheakamus River steelhead stock in British Columbia (Melnychuk et al. 2014).

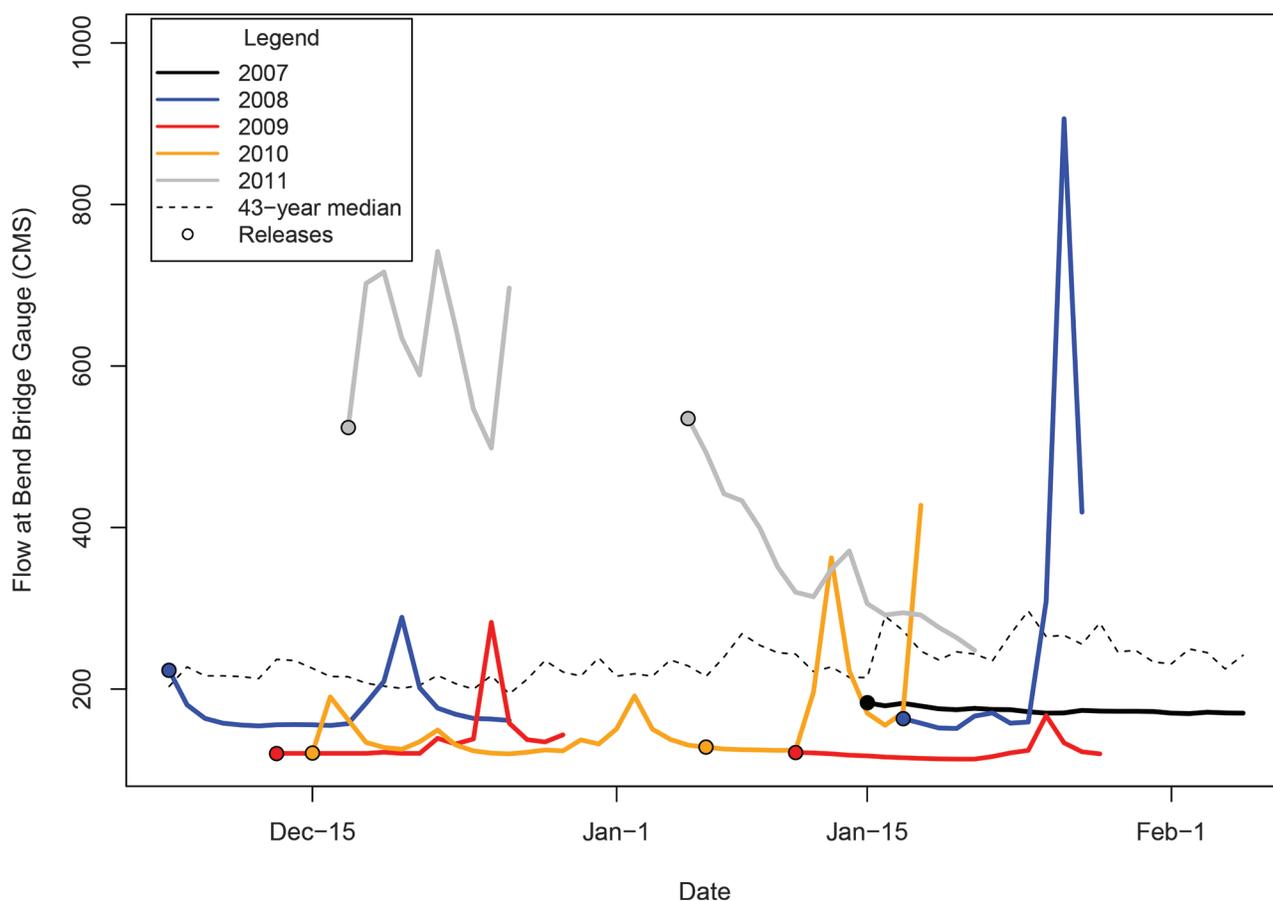

One potential reason why the lower Sacramento River had higher survival than expected may be due to channelization. Levees, riprap, and channelization have been considered detrimental for salmon populations owing to their degradation of spawning grounds (reduced input of gravel), the paucity of prey to feed upon, and an absence of cover that results in a greater frequency of predation on juveniles (Buer et al. 1989; Chapman and Knudsen 1980; Garland et al. 2002; Schmetterling et al. 2001). However, Michel (2010) found a strong positive correlation between channelized reaches and smolt survival. Given limited rearing potential, smolts likely migrate through channelized reaches, reducing the period of exposure to sources of mortality. The majority of potential predator species in the watershed are typically found associated with submerged structure and vegetation, which in the lower Sacramento River are mostly limited to the rip-rapped lit-

toral zone. A smolt travelling downstream in the lower Sacramento River only needs to avoid the channel margins to minimize exposure to predators. Outmigrating Chinook salmon smolts in the Sacramento River travel disproportionately more in the center of the channel (Sandstrom et al. 2013). Similarly, smolt survival was higher in deep impoundments compared with shallower undammed reaches of the Columbia River (Welch et al. 2008).

Previous studies of salmon survival in the Sacramento River and estuary, based primarily on coded-wire tags, suggested significantly lower mortality in the bays, but higher mortality in the river. Brandes and McLain (2001) found survival of subyearling fall-run Chinook salmon smolts from Port Chicago to the Golden Gate (roughly equal to our bays region) during the 1984–1986 years to vary between 76% and 84%, compared with a range of 26% to 43% in this study. California Department of Fish and Wildlife monitored survival rates of late-fall Chinook salmon from Battle Creek to rkm 239 (within the river region) during the 1996–2000 years using coded-wire tag recoveries at rotary screw traps. They estimated survival rates to vary between 1.1% and 2.7% (Snider and Titus 1998, 2000a, 2000b, 2000c; Vincik et al. 2006) compared with a range of 15.5% to 63.2% over a longer distance in this study. Reasons for these discrepancies could lie in the conditions during the years compared or could have to do with the difference in sampling protocol and survival estimation.

Overall survival of outmigrating late-fall-run Chinook salmon smolts in the Sacramento River is low in comparison with the Columbia and Fraser rivers, in spite of those rivers having substantially longer migration corridors. Welch et al. (2008) found that yearling Chinook salmon smolts from the Snake River (a tributary to the Columbia River) had an overall survival of 27.5% ($\pm 6.9\%$ SE) to the ocean over a distance of 910 km in 2006. That study also found that overall survival for yearling Chinook salmon smolts from various tributaries of the Fraser River to the ocean over distances ranging from 330.8 to 395.2 km had an overall survival varying from 2.0% ($\pm 3.6\%$ SE) to 32.2% ($\pm 20.7\%$ SE), with the majority of the tributary- and year-specific survival estimates

Fig. 3. Hydrograph at the Bend Bridge gauging station, 14 rkm downstream from the furthest upstream release site (Jelly's Ferry), for each of the 5 years of the study. The median daily flow values over a 43-year period (including the study years) are represented with a dotted line. Solid dots represent release date for tagged smolts in relation to the respective year's hydrograph. Hydrographs are only depicted as long as 90% of released smolts are still actively migrating in the river region; in some years, December-released fish have all died or outmigrated before January release, and therefore some yearly hydrographs are not continuous.

above 15%. Rechisky et al. (2009) found that outmigrating yearling Chinook salmon from the Yakima River (a tributary to the Columbia River) had an overall survival of 28% ($\pm 5\%$ SE) to the ocean over a distance of 655 km.

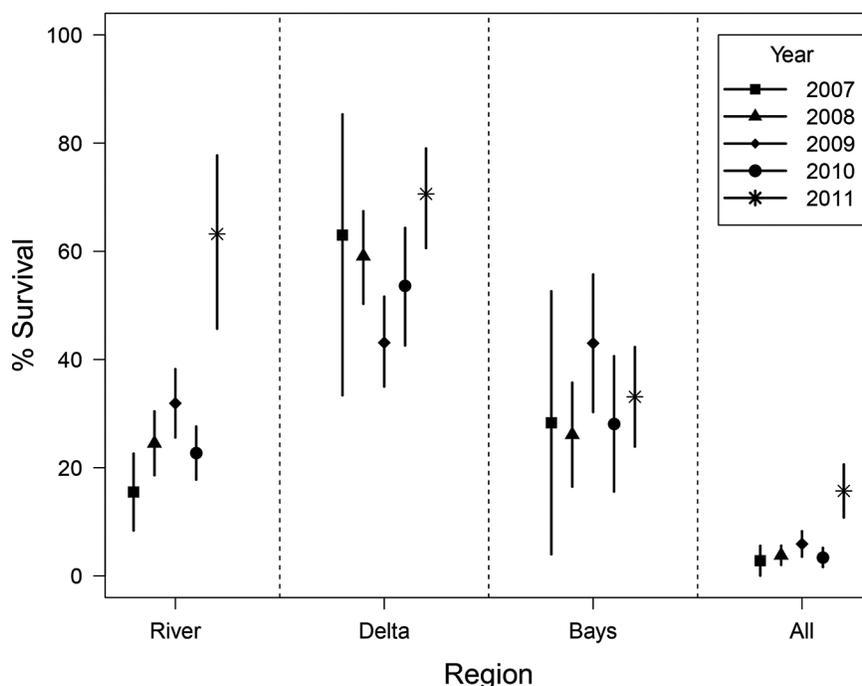

There are also striking differences in the spatial patterns of survival between the Sacramento River and the Columbia and Fraser rivers. Columbia River tagging studies have found survival for yearling Chinook salmon through the lower river and estuary to vary between 82% and 100% (or between 98.3% and 100% per 10 km), depending on the year and population (Harnish et al. 2012; Rechisky et al. 2013). Similarly sized sockeye salmon (*Oncorhynchus nerka*) smolts experienced little to no mortality during outmigration through the mainstem Fraser River (including the estuary) during the years 2010–2013 (Rechisky et al. 2014). In our study, survival through the estuary (delta and bays region combined) ranged from 15.1% to 23.4% (89.3%–91.7% per 10 km).

There are a number of possible explanations for why the survival of Chinook smolts in the Sacramento River is generally lower than that in other west coast rivers. Flows in the Sacramento River are highly regulated by large water storage dams, and peak discharge is typically much reduced in the outmigration period (Buer et al. 1989; Brown and Bauer 2010). In contrast, no dams exist on the mainstem Fraser River, and the dams on the Columbia River are used for hydropower and do not reduce or homogenize flows to the same extent as water storage dams. It is only in wet years such as 2011 that water flows are high enough for water managers to allow substantial dam releases in the Sacramento River. We

observed much higher in-river survival during 2011, and other studies have shown positive relationships between survival and river flow (Connor et al. 2003; Smith et al. 2003). Higher flows correspond to higher velocities and faster travel times, reducing the time smolts are exposed to predators (Høgåsen 1998). High flows may also be correlated to higher turbidities, which can reduce the effectiveness of visual predators (Ferrari et al. 2014; Gregory and Levings 1998).

Differences in the condition of estuaries offer another explanation. Magnusson and Hilborn (2003) found that in comparing the survival of subyearling Chinook salmon smolts in 27 different small- to medium-sized estuaries in the US Pacific Northwest, there was a significant positive relationship between survival and the percentage of the estuary that was in pristine condition. They also note that according to MacFarlane and Norton (2002), estuary use by subyearling Chinook salmon smolts was less in the brackish portion of San Francisco Estuary than other estuaries in the Pacific Northwest, potentially owing to the poor condition of the estuary. Nichols et al. (1986) posited that the San Francisco Estuary is the most modified estuary on the west coast of the United States, which suggests that the low survival estimates seen in this study are consistent with Magnusson and Hilborn's (2003) findings. Cohen and Carlton (1998) suggested that the extensive modification of the San Francisco Estuary contributes to it being perhaps the most invaded estuary in the world. Invaders include a number of piscivorous fish species that likely prey on migrating juvenile salmon. The role of predation clearly warrants study.

Fig. 4. Percent survival per major region for all 5 study years. Regions include river, delta, bays, and the percent survival for the entire watershed (All). Error bars represent 95% confidence intervals.

Survival rates during drought years observed in this study, if applicable to natural populations, suggest that populations are likely contracting. Bradford's (1995) review of Pacific salmon mortality rates suggested that typical fished Chinook salmon populations have a total mortality rate of 6.76 (based on fecundity) and a mean observed egg-to-smolt mortality rate of 2.56. Mean smolt mortality rate ($-\log_e(\text{survival})$) during the first 4 years of our study was 3.23. A stable population subject to these mortality rates would require total mortality to be no more than 0.97 (or no less than 38% survival) for the period between ocean entry and reproduction, a period of 2–4 years for late-fall Chinook subject to major ocean harvest rates.

Our results have implications for the management of Central Valley salmon hatcheries. Much of the hatchery production in the Central Valley is transported by tanker truck to the bays to avoid mortality incurred during the migration through the river and delta. Offsite release leads to undesirable levels of straying, and a recent independent review of California salmon hatchery practices recommends on-site release of hatchery production (CHSRG 2012). Salmon smolts have long been known to migrate during peak flows (Healey 1991; Høgåsen 1998; Kjelson et al. 1981). Our study has shown that fish migrating during high flows have higher survival. Hatcheries could employ a “release window” strategy during which they wait for a peak flow or coordinate their operations with releases from upstream reservoirs that could create artificial pulse flows. Reservoir releases have been shown to improve subyearling Chinook salmon smolt survival (Zeug et al. 2014), although evidence for improved yearling survival is not as clear (Giorgi et al. 1997; Young et al. 2011). The efficacy of reservoir release will depend on the degree to which survival benefits of migrating during freshets are due to decreased travel time versus higher turbidity, which may not be easily manipulated through reservoir operations.

Our study has demonstrated remarkably low survival rates for acoustically tagged hatchery-origin late-fall-run Chinook salmon smolts in the Sacramento River. The Sacramento River is also home to three other runs of Chinook salmon that migrate at smaller sizes and later in the season (Fisher 1994), when water

temperatures are higher and predators may be more active. These other runs may therefore be experiencing even lower survival. Furthermore, most mortality in this study occurred in a 1- to 2-week period for hatchery fish. This has disconcerting implications for wild fish that must spend several months to a year rearing in the watershed. As tags become smaller, the study design utilized here can be applied to document spatial and temporal patterns of survival in these other runs that are of important conservation and fishery concerns, providing resource managers with valuable information on where and when survival problems are occurring — information necessary to effective mitigation of survival problems.

Acknowledgements

Funding for the project was provided by a CALFED Bay Delta program grant, project U-05-SC-047 (A.P.K. and R.B.M. principle investigators). We are grateful for the help from many technicians and volunteers, including (but not limited to) Ian Cole, Alison Collins, Nicholas Delaney, Heidi Fish, Alex Hearn, Andrew Jones, and Ian Ralston. Special thanks are extended to Kevin Niemela, Kurtis Brown, and Scott Hamelburg of US Fish and Wildlife Service (USFWS) and the helpful staff of the Coleman National Fish Hatchery for providing late-fall-run Chinook salmon smolts and logistical support for this study. The California Fish Tracking Consortium allowed the realization of this project through the collaboration and data-sharing of several academic, federal, and state institutions. Sean Hayes, Ann-Marie Osterback, and anonymous reviewers provided valuable comments that improved the manuscript.

Abstract

“Super-blooms” of cyanobacteria that produce potent and environmentally persistent biotoxins (microcystins) are an emerging global health issue in freshwater habitats. Monitoring of the marine environment for secondary impacts has been minimal, although microcystin-contaminated freshwater is known to be entering marine ecosystems. Here we confirm deaths of marine mammals from microcystin intoxication and provide evidence implicating land-sea flow with trophic transfer through marine invertebrates as the most likely route of exposure. This hypothesis was evaluated through environmental detection of potential freshwater and marine microcystin sources, sea otter necropsy with biochemical analysis of tissues and evaluation of bioaccumulation of freshwater microcystins by marine invertebrates. Ocean discharge of freshwater microcystins was confirmed for three nutrient-impaired rivers flowing into the Monterey Bay National Marine Sanctuary, and microcystin concentrations up to 2,900 ppm (2.9 million ppb) were detected in a freshwater lake and downstream tributaries to within 1 km of the ocean. Deaths of 21 southern sea otters, a federally listed threatened species, were linked to microcystin intoxication. Finally, farmed and free-living marine clams, mussels and oysters of species that are often consumed by sea otters and humans exhibited significant biomagnification (to 107 times ambient water levels) and slow depuration of freshwater cyanotoxins, suggesting a potentially serious environmental and public health threat that extends from the lowest trophic levels of nutrient-impaired freshwater habitat to apex marine predators. Microcystin-poisoned sea otters were commonly recovered near river mouths and harbors and contaminated marine bivalves were implicated as the most likely source of this potent hepatotoxin for wild otters. This is the first report of deaths of marine mammals due to cyanotoxins and confirms the existence of a novel class of marine “harmful algal bloom” in the Pacific coastal environment; that of hepatotoxic shellfish poisoning (HSP), suggesting that animals and humans are at risk from microcystin poisoning when consuming shellfish harvested at the land-sea interface.

Introduction

During 2007, 11 dead and dying southern sea otters were recovered along the shore of Monterey Bay in central California with lesions suggestive of acute liver failure. Some animals were diffusely icteric and their livers were enlarged, bloody and friable. Expected causes for this condition, such as systemic bacterial infection were excluded via microscopic examination and diagnostic testing. Livers from affected animals tested positive for cyanotoxins (microcystins) via liquid chromatography-tandem

mass spectrophotometry (LC-MS/MS) and hepatic lesions consistent with microcystin intoxication were observed microscopically. Environmental surveillance revealed that some local freshwater lakes and rivers supported *Microcystis* blooms during late summer and autumn, triggering the investigation reported here.

Cyanobacteria (formerly called “blue-green algae”) have a worldwide distribution and can form extensive blooms in freshwater and estuarine habitat. Toxin production by the cyanobacterium *Microcystis aeruginosa* was first reported in 1946 [1] and additional toxic species have been described. Exposure to environmentally

stable microcystins in food, drinking water, nutritional supplements and during medical dialysis can cause significant and sometimes fatal hepatotoxicity and possible tumor induction in humans and animals [2-6]. Microcystins are fast becoming a global health concern and recurrent blooms with toxin elaboration have been reported throughout Europe [7,8], Asia [9,10], Africa [11,12], Australia [13,14] and North and South America [15-17]. Factors that contribute to bloom formation and toxin production include warm water [18,19], nutrient enrichment [19,20] and seasonal increases in light intensity [2,21]. Rising global temperatures and eutrophication may contribute to more frequent events and cyanobacterial “super-blooms”, with enhanced risks to human health [23].

Until recently, microcystin intoxication was considered a public health issue mainly of freshwater habitat, reflected by the vast body of published literature on potential human health risks due to microcystin exposure in rivers, lakes, reservoirs and freshwater aquaculture [4,13,16,24,25,26]. In contrast, monitoring of marine water and seafood for similar risks has been limited, despite confirmation of outflows of microcystin-contaminated freshwater to the ocean [14,17,27,28], detection of impacts by microcystins on copepods, corals and fish [29-31] and identification of proteins with protein phosphatase inhibitory activity in seawater, suggesting the existence of an additional class of marine “Harmful Algal Blooms” (HAB); hepatotoxic shellfish poisoning (HSP) [15].

The ability of potent and environmentally stable cyanotoxins to magnify trophically poses additional risks: Microcystin accumulation has been demonstrated in fresh and saltwater mussels [7,32], farmed crustaceans [33,34], fish [30] and possibly humans [26]. In addition, exposure of estuarine and marine biota to microcystins may trigger behavioral adaptations, such as decreased feeding on co-occurring nutritious species, that facilitate trophic transfer [9,35-38]. Despite these concerns, worldwide shellfish sanitation and water safety programs do not typically include microcystin testing.

Along the Pacific coast of the United States, large-scale *Microcystis* blooms with toxin production occur each year in lakes and rivers throughout Washington [39], Oregon [4] and California [40,41]. In California, *Microcystis*-contaminated runoff has been documented at the marine interfaces of the Klamath River [42] and San Francisco Bay [17]. Here we extend areas of concern to include the central California coast and document numerous marine mammal deaths due to microcystin intoxication.

The potential for cyanotoxins to flow to the ocean, resulting in deaths of marine species is a newly recognized problem. Demonstration of bioaccumulation in marine invertebrates and deaths of threatened southern sea otters due to microcystin intoxication provides strong evidence for significant and recurrent marine pollution by freshwater-derived microcystins within North America’s largest national marine sanctuary. Because sea otters and humans utilize the same coastal habitat and share the same marine foods, our findings in sea otters are also likely to have important human health implications.

Materials and Methods

Performance of this research was approved by the California Department of Fish and Game, Office of Spill Prevention and Response and the University of California.

1.) Environmental testing

Chemical confirmation of microcystin exposure in tissues from southern sea otters stranding during 2007 prompted investigation of local freshwater sources flowing into Monterey Bay for any prior

history of cyanobacterial blooms. This investigation revealed that Pinto Lake, located approximately 8.5 km inland from Monterey Bay had a history of severe and recurrent *Microcystis* blooms with microcystin production. Visual examination of Pinto Lake, light microscopy and liquid chromatography-mass spectrophotometry/mass spectrophotometry (LC-MS/MS) testing in fall, 2007, confirmed the occurrence of an extensive *Microcystis* bloom with high toxin production, leading authorities to post warning signs at this location for several weeks. Stepwise sampling of water and surface bloom from Pinto Lake, its drainage into Corralitos Creek, and the Pajaro River that carries water from this region to Monterey Bay was performed during the bloom event.

Because bloom events are often ephemeral and patchy, sensitive methods are required to facilitate source tracking efforts. We investigated use of resin-based, Solid Phase Adsorption Toxin Tracking (SPATT) samplers to passively monitor fresh and salt water for microcystin contamination. SPATT was first proposed for HAB monitoring in 2004 to circumvent disadvantages associated with invertebrate bioassays [43]. To evaluate their performance under laboratory conditions, SPATT bags were placed into subsamples of concentrated water/*Microcystis* mixtures from Pinto Lake that were used for laboratory-based invertebrate exposures (section 3). Replicate SPATT samplers were also placed in each exposure tank during the invertebrate studies to assess consistency and repeatability of microcystin adsorption, and additional SPATT bags were deployed in the local marine environment and at the freshwater outflows of selected local rivers.

SPATT bags were constructed from 100 micron Nitex bolting cloth filled with 3 g (dry weight) HP20 (Diaion) resin. For activation, bags were soaked in 100% HPLC-grade methanol (MeOH) for 48 hours, rinsed thoroughly, transferred into a fresh volume of Milli-Q for MeOH residue removal by sonication and stored in Milli-Q at 4-6°C prior to use. Plastic embroidery hoops were used to fasten the bags in place during field deployment. After exposure, SPATT bags were evaluated using LC-MS for adsorption of domoic acid and microcystins as described below. In the laboratory, adsorption of environmentally-relevant concentrations of microcystins (hundreds of ppb) was observed in <24 h, following an exponential decay (adsorption) curve in a closed volume of filtered Pinto Lake water. In prior studies, 100% recovery of microcystin was achieved with simple extraction procedures (sequential 50% MeOH column extractions) (data not shown).

2.) Sea otter necropsy and microcystin testing

Sea otter carcasses were recovered by stranding network members, chilled with ice and transported to CDFG for necropsy as previously described [44]. Detailed postmortem examinations were performed by a veterinary pathologist and all major tissues were fixed in 10% neutral buffered formalin, trimmed, paraffin-embedded and 5 µm-thick, hematoxylin and eosin (H&E)-stained sections prepared and examined on a light microscope. Supplementary diagnostic testing included bacterial and fungal culture, immunofluorescence and PCR for common serovars of *Leptospira interrogans* and LC-MS/MS analysis of urine, gastrointestinal content, feces and urine for the presence of microcystin, domoic acid, okadaic acid, nodularin, yessotoxin and anatoxin-A. The primary and contributing cause(s) of death were determined based on gross lesions, histopathology and diagnostic results. Tissues, urine, serum and gastrointestinal contents were also cryoarchived at -80 C.

Analysis of water, tissue and digesta for microcystins was performed at the California Department of Fish and Game (CDFG) Water Pollution Control Laboratory or at the University

of California, Santa Cruz. The preferred method of analysis post-extraction was high performance liquid chromatography tandem mass spectrometry (LC-MS/MS), following the protocols of Mekebri et al. [45]. Prior to testing, tissue samples were first homogenized using a Buchi B-400 mixer equipped with a titanium knife assembly. Pre-weighed samples were mixed with methanol: water (90:10) using a Polytron® homogenizer for four minutes, followed by sonication for one hour. The target analytes were microcystin (MCY)-RR, -Desmethyl RR, -LR, -Desmethyl LR, -LA, -LF, -LW, -LY and -YR, domoic acid, nodularin and okadaic acid. Certified calibration solution standards purchased from Sigma Aldrich and NRC-CNRC (Certified Reference Materials Program, Institute for Marine Biosciences, National Research Council of Canada) were used for method development, analyte identification and quantitation. HPLC-grade solvents (acetonitrile, methanol, water), glass fiber filters (Type A/E, 90 mm, 1 µm), Gelman Acrodisc® CR PTFE syringe filters (13 mm, 0.45 µm), and mobile phase additives, ACS grade formic acid (98%) and trifluoroacetic acid (99%) were also used. A combined intermediate MCY standard working solution was made in methanol and used to prepare a matrix spiking solution (20 ppb), which was serially diluted to develop a seven level calibration curve ranging from 0.2 to 200 ppb.

To determine total microcystin concentration and congener type(s) in water, the cyanobacterial cell walls were ruptured by repeated freeze-thawing and sonication and a 100 ml aliquot was filtered under vacuum through a glass fiber filter. Water and filters were extracted separately and filters containing planktonic material were extracted twice with 15 mL of methanol-acidified water (90:10, v/v) by homogenizing for 1–2 minutes using a Polytron®, followed by 10 minutes of sonication in an ultrasonic bath.

For SPATT detection systems, only dissolved toxins were measured, so cell disruption was not required. Samples were analyzed using an Agilent 1200 liquid chromatograph (LC) connected to a 6130 quadrupole MS, using Selected Ion Monitoring (SIM). For all other samples, an Agilent 6410 triple quadrupole (QqQ) LC-MS was used for LC-MS/MS analysis. The following microcystin ions (m/z) were monitored: 519.8 -RR and 512.8 -desmethyl RR are both [M+2H]²⁺; 105.6 -YR, 995.7 -LR, 981.7 -desmethyl LR, 910.6 -LA, 1026.6 -LW, 987.6 -LF and 825.5 NOD-R were monitored using [M+H]⁺ using multiple reaction monitoring (MRM) mode. Full scan was also collected over the range 100–1100 amu. The MRM windows were established for microcystins using the MSMS product ions, which are the Adda fragments of m/z 135.2 and m/z 213 produced by the transition of the protonated parent ions. Agilent Mass Hunter software was used to collect and process data. The estimated method detection limits (MDL) and reporting limits (RL) for water samples were 0.02 µg/L (ppb) and 0.05 µg/L (ppb) for MCY and DA respectively, and 0.01 µg/L (ppb) and 0.02 µg/L (ppb) respectively for OA. The estimated method detection limit and reporting limit for tissues were 0.500 ng/g and 1.00 ng/g wet weight, respectively, for all toxins.

3.) Laboratory exposure of marine invertebrates

To assess microcystin uptake and retention by marine invertebrates consumed by humans and sea otters, freshwater/cyanobacterial mixtures were collected during a summer, 2009 *Microcystis* bloom at Pinto Lake. Dominance of *Microcystis* was confirmed microscopically and total microcystin concentrations were determined via LC-MS/MS. Live marine invertebrates were collected from Monterey Bay or purchased from commercial vendors, including species that are commonly farmed or harvested, such as Pacific oysters (*Crassostrea gigas*), manila clams (*Tapes semidecussatus*),

mussels (*Mytilus edulis*), snails (*Tegula* spp.), red rock crabs (*Cancer productus*) and dungeness crabs (*Cancer magister*).

Three 1,022 L, temperature-controlled seawater tanks were used to complete the invertebrate exposure studies. The tanks were designed to permit water sampling at the top, middle and bottom of each tank, so that microcystin distributions could be followed through time and compared with results from invertebrate testing. Invertebrates were divided randomly between control (Tank 1), low exposure (Tank 2) and high exposure (Tank 3) tanks and allowed to acclimatize for 3 to 7 d. Bivalves and snails were placed in wire cages or plastic mesh bags and suspended at least 20 cm below the water surface. Large crabs were placed in plastic mesh enclosures that allowed them to range from just below the tank surface to just above the bottom. Snails were fed fresh *Macrocystis* kelp fronds and crabs were provided with chopped capelin (*Mallotus villosus*) every other day. Filter-feeders were exposed to plankton in continually flowing seawater from Monterey Bay until initiation of the microcystin exposure, and then from day 4 to day 21 of the experiment. Starting 4 days post-exposure, all tanks were continually flushed with clean seawater and water and invertebrate sampling continued for 21 days to determine post-exposure depuration characteristics for freshwater microcystins.

At the start of the exposures, a less concentrated *Microcystis* mixture collected from Pinto Lake during a bloom event (2.2 ppm [2,195 ppb] aqueous microcystin-LR mixed with suspended *Microcystis*) was added to the low exposure tank (Tank 2). A more concentrated mixture (10.6 ppm [10,600 ppb] aqueous microcystin-LR mixed with suspended *Microcystis*) was added to the high exposure tank (Tank 3) at the same time, while Tank 1 (the negative control) contained only seawater. Microcystin LR concentrations were measured in invertebrates and seawater sampled from the top, middle and bottom of each tank at regular intervals (24 H, 48 H, 72 H, 7 D, 14 D, and 21 D postexposure). During the first 96 H postexposure, invertebrates in tanks 2 and 3 were continually exposed to the microcystin-contaminated inoculum, while Tank 1 contained only recirculating, clean seawater and served as a negative control. Positive controls consisted of non-exposed water and invertebrate tissues spiked with known concentrations of a commercial preparation of microcystin-LR prior to LC-MS/MS testing.

Following 96 H of continuous microcystin exposure, all 3 tanks were flushed with clean seawater and sampling continued through 21d post-exposure. Prior to seawater flushing, water was collected from tanks 2 and 3, refrigerated and sub-sampled at the same intervals as invertebrates to determine persistence of microcystin toxin in seawater. Invertebrates were washed in tapwater prior to dissection to remove any surface contamination by *Microcystis* or microcystin. Invertebrate sub-sampling techniques reflected patterns of consumption by humans or otters: For snails, the entire body and shell was homogenized and tested whole, while the soft parts of bivalves and crabs were removed and the shells and carapace were discarded. The gastrointestinal tract and/or hepatopancreas was collected and screened for the presence of microcystin-LR in addition to archiving whole bodies and muscle tissue for evaluation as funds permit. All samples were refrigerated or frozen at -80 C prior to LC-MS/MS testing.

Results

1.) Environmental testing

Analysis (LC-MS/MS) of water from Pinto Lake in fall, 2007 confirmed the occurrence of an extensive *Microcystis* bloom with high toxin production (Fig. 1). During this period, microcystin concentrations in scum from the surface of Pinto Lake exceeded

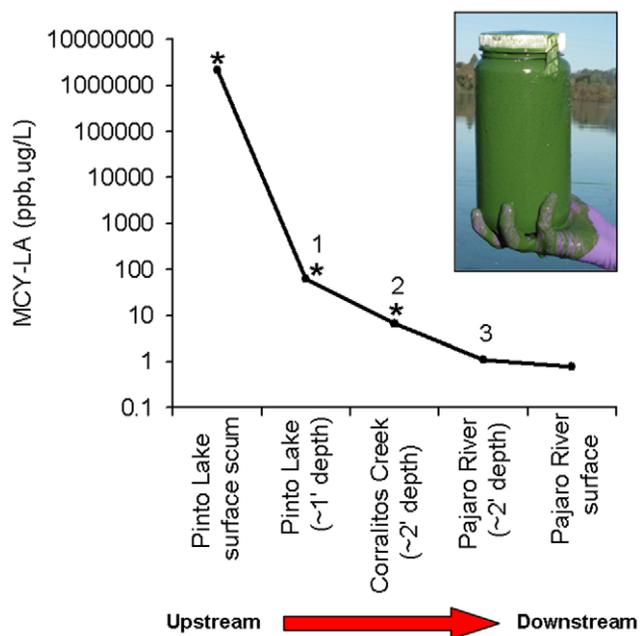

Figure 1. Tracing freshwater contamination by microcystins from land-to-sea. Inset: Sample of surface water collected during a “super-bloom” of *Microcystis* in Pinto Lake in fall, 2007 (Caution: Nitrile gloves and other appropriate personal protective equipment should be used to prevent dermal contact when collecting environmental samples of *Microcystis* and microcystins). Main figure: Time-matched microcystin-LA concentrations (ppb) in samples from Pinto Lake, just downstream in Corralitos Creek and the receiving waters of the Pajaro River within 1 km of Monterey Bay. Asterisks (*) indicate sampling locations where *Microcystis* was detected microscopically. doi:10.1371/journal.pone.0012576.g001

2,100 ppm (2.1 million ppb) MCY-LA, or approximately 2,900 ppm (2.9 million ppb) total microcystins, which is one of the highest microcystin concentrations ever reported from an environmental sample. During this same period, stepwise sampling of water and surface bloom from Pinto Lake, its drainage through Corralitos Creek and the Pajaro River confirmed the presence of *Microcystis* and microcystins from Pinto Lake to the river channel within 1 km of the ocean (Fig. 1). Recurrent *Microcystis* blooms with toxin production were also confirmed microscopically and via chemical analysis in samples from Pinto Lake and surrounding waters in 2008 and 2009 (data not shown). The most common microcystin congener that was detected in samples from Pinto Lake and the adjoining watershed during the 2007 event was MYC-LA, but MCY-RR, MCY-LR, MCY-Desmethyl-LR, MCY-LF and MCY-YR were also detected, and MCY-LR was repeatedly detected in Pinto Lake using SPATT between 2009 and 2010. No other biotoxins were detected in freshwater samples. Deployment of SPATT into microcystin/water mixtures collected from Pinto Lake demonstrated 100% adsorption of free MCY in <24 h (Fig. 2). In addition, higher sensitivity of SPATT for microcystin detection in water, when compared to intermittent “grab” samples, was also demonstrated (Fig. 3). During laboratory invertebrate studies, good agreement between duplicate SPATT bags suspended in each tank was noted for Tanks 2 and 3 (low and high microcystin exposure, respectively), while SPATT bags hung in Tank 1 (negative control) tested negative for microcystin (data not shown).

Using field-deployed SPATT, ocean water and the marine interfaces of selected coastal rivers flowing into Monterey Bay

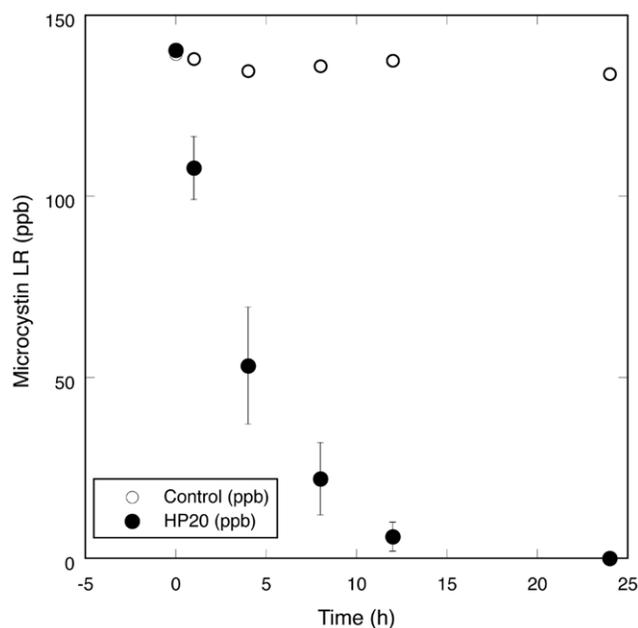

Figure 2. Evaluation of Solid Phase Adsorption Toxin Tracking (SPATT) sampler adsorption characteristics for freshwater microcystins. SPATT adsorption characteristics for microcystin were tested in the laboratory using Pinto Lake water amended with a known quantity of microcystin-LR. A control sample (open symbols) showed no change in microcystin concentration over time; In contrast, SPATT HP20 resin-based samplers (solid symbols: error bars represent standard deviation of 3 replicates) show rapid microcystin adsorption, with near-total depletion of microcystins from a controlled volume of water within <24 hours.

doi:10.1371/journal.pone.0012576.g002

tested negative for microcystins during the dry season in summer and early fall of 2009, when freshwater runoff was minimal. However, at the onset of the fall rainy season (October-November, 2009), SPATT deployed at the marine outfalls of the Pajaro and Salinas Rivers tested positive for microcystins via LC-MS (data not shown). SPATT samplers deployed weekly in the ocean at the Santa Cruz Municipal Pier (Figure 4) during 2008 and 2009 routinely tested negative for microcystins, suggesting that the main source of these toxins for sea otters was not marine in origin. However, low levels of MCY-LR were detected at the pier (located near the mouth of the San Lorenzo River), after the first major storm event of Fall, 2009. Limited testing of fresh- and seawater and invertebrates from other regions of Monterey Bay did not reveal additional sources of microcystin-contamination (data not shown). Sea otter stranding patterns suggest that similar pollution events occurred in other coastal areas, but were not detected.

2.) Sea otter necropsy and microcystin testing

Between 1999 and 2008, livers from 21 southern sea otters with gross and/or microscopic evidence of liver disease (Figs. 5 and 6) tested positive for microcystins via LC-MS/MS (Table 1). On the microscope, livers of microcystin-positive sea otters exhibited hepatocellular vacuolation, apoptosis, necrosis and hemorrhage (Fig. 6) consistent with previous descriptions of microcystin intoxication in humans and animals [1,12,13,46,13,47]. In contrast, livers from 2 captive sea otters (Table 1) and 19 wild otters without evidence of primary liver disease (data not shown) tested negative for microcystin. Carcasses of otters dying due to microcystin intoxication appeared to cluster near river mouths,

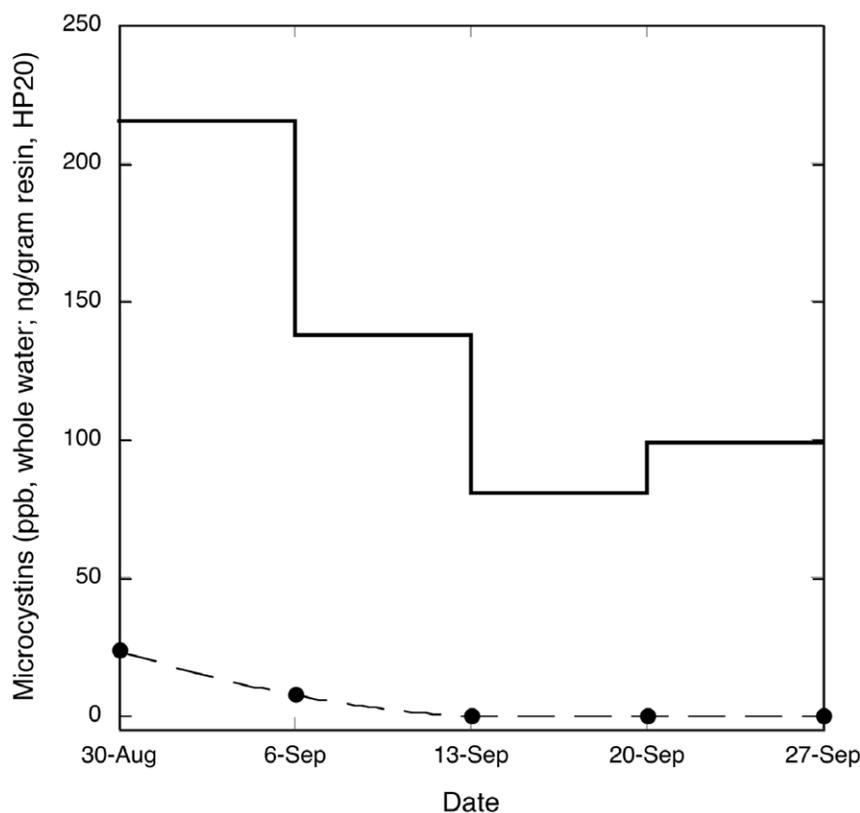

Figure 3. Variation in microcystin detection between conventional “grab” samples and Solid Phase Adsorption Toxin Tracking (SPATT). Comparison of microcystin (MCY-LR) detection in fresh water using intermittent “grab” sampling (sample periods indicated by black circles) and SPATT (solid line indicating weekly averaged toxin values) in Pinto Lake, demonstrating the higher sensitivity of SPATT for microcystin detection. Grab samples were collected at the beginning of each weekly SPATT deployment, and from the same sample location, so each 7-day integrated SPATT deployment is bracketed by two grab samples. doi:10.1371/journal.pone.0012576.g003

coastal ponds, embayments and harbors, all areas with significant potential to receive and retain plumes of contaminated fresh water (Fig. 4).

The earliest confirmed case was in 1999 (Table 1). The greatest number of cases detected/year was in 2007, with 11 LC-MS/MS-confirmed sea otter deaths due to microcystin intoxication. Based on preliminary test results, 71% of known, microcystin-associated sea otter deaths have occurred since 2005 and 81% of affected animals stranded within Monterey Bay, California. However, additional cases were detected along the Big Sur and South-central California coastline, suggesting that multiple point-sources for microcystin exposure exist along the central California coast. One additional case was suspected based on lesions observed on histopathology, but the liver tested microcystin-negative, perhaps due to near-total loss of hepatocyte mass in the liver of this animal. Pathology associated with microcystin intoxication in sea otters will be described in greater detail in a subsequent manuscript.

Hepatic microcystin concentrations varied from 1.36 to 348 ppb wet weight (ww; Table 1). Various forms of microcystin (MCY-RR, -LR and -desmethyl LR) were detected in sea otter livers, with the majority of otters (19/21) testing positive for MCY-RR, compared to 2/21 and 1/21 for MCY-LR and MCY-desmethyl-LR, respectively. One liver tested positive for both MCY-RR and -LR. Feces of one otter recovered during necropsy also tested positive for microcystin, but it is unclear whether this represents ingestion of contaminated prey or enterohepatic toxin circulation. The microcystin congener that was detected at the

highest concentration in a sea otter liver was MCY-LR (348 ppb ww). All water and tissue samples tested negative for okadaic acid, nodularin, yessotoxin and anatoxin-A. Urine from some otters with microcystin-positive livers also tested low-positive for domoic acid on LC-MS/MS; this biotoxin is widely distributed in sediments within Monterey Bay [48] and low levels of domoic acid are commonly detected in sea otter urine at necropsy (M. Miller, pers. commun.).

Four microcystin-positive otters had been previously captured and fitted with intraperitoneal VHF transmitters as part of long-term studies on habitat use, prey selection, and environmental exposure to biological pollutants. The home ranges of all four otters overlapped at the same point in south Monterey Bay (Fig. 7), suggesting a common source of microcystin exposure. Based on the spatial distribution of home ranges for radio-tagged southern sea otters [49], the likelihood of any four animals having overlapping home ranges by chance is <5.8%. Moreover, bivalve mollusks were the first or second most frequently consumed prey type for three of the four otters (for the fourth otter, no foraging data were available). This trait was shared with just 27% of all tagged animals; the majority preferentially fed on non-bivalve prey such as crabs, abalone or urchins [50]. Similar stranding clusters were identified for other microcystin-poisoned otters, leading to identification of several high-risk sites for microcystin intoxication along the shores of Monterey Bay (Fig. 4). Collectively these findings raised suspicion of bivalve prey as a possible vehicle for microcystin poisoning of sea otters.

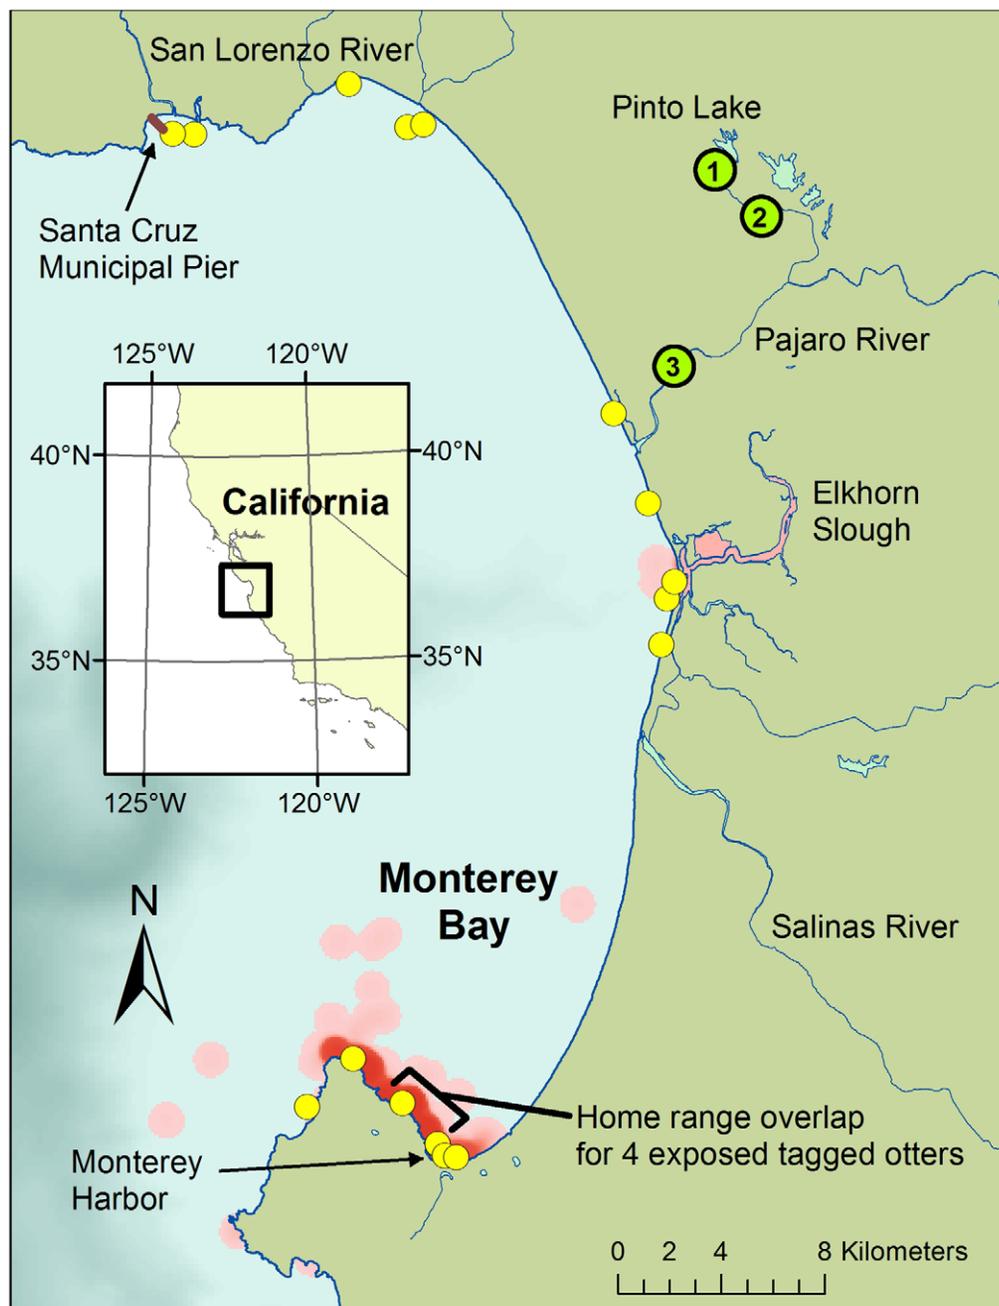

Figure 4. Map of Monterey Bay showing distribution of sea otters dying due to microcystin intoxication (yellow circles). Note spatial association of sea otter strandings with coastal locations of river mouths, harbors, coastal ponds and embayments. Habitat utilization distributions for 4 radio-tagged, microcystin-poisoned otters are plotted as kernel density distributions fit to daily re-sighting locations (red shading, with regions of most intense shading corresponding to the habitats most frequently utilized by affected animals). Locations of freshwater samples collected during a “Super-bloom” of *Microcystis* in 2007 are indicated by green circles, with numbers that correspond with the microcystin concentrations listed in Figure 1. doi:10.1371/journal.pone.0012576.g004

3.) Laboratory exposure of marine invertebrates

Intact *Microcystis* cyanobacteria initially accumulated at the top of the seawater tanks, but were almost completely lysed after 48 hours. Microcystin-LR was detectable in seawater for the duration of the study (21 days) and microcystin concentrations in refrigerated seawater had declined only 44–71% from mean one hour post-exposure levels after 3 weeks (Table 2).

Significant bioconcentration of microcystin by marine bivalves (clams, mussels and oysters) and snails, but not large marine crabs,

was documented (Table 3), with tissue concentrations of microcystin-LR up to 107 times higher in invertebrate tissues than in adjacent seawater. Microcystin concentrations in gastrointestinal tissues ranged from negative to 1,324 ppb wet weight (ww) in invertebrates, with the highest concentrations observed in clams, mussels and oysters sampled between 24 and 48 hours post-exposure.

Marine bivalves were also slow to depurate ingested microcystin; despite continuous seawater flushing beginning at 96 hours post-exposure, gastrointestinal microcystin concentrations at 14 days

post-exposure were at 120%, 14% and 6.5% of 24 hour post-exposure concentrations for oysters, clams and mussels, respectively (Table 3). Mussel digestive tract remained microcystin-positive (30.5 ppb ww) 21 days after the initial exposure period and

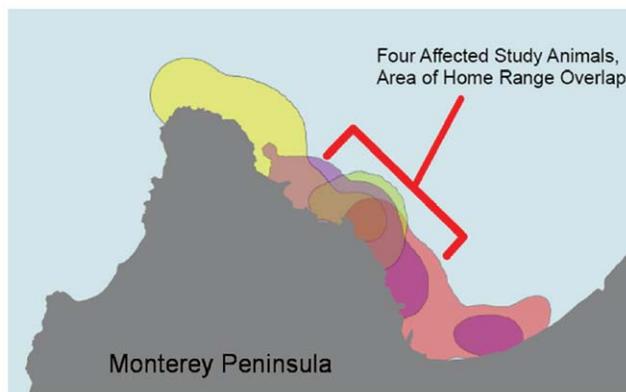

Figure 7. Overlapping home ranges of 4 tagged southern sea otters that died due to microcystin intoxication. Note the spatial overlap of all 4 home ranges on the north central Monterey Peninsula near Monterey Harbor (bracket): This harbor appears to be one of several high-risk locations for microcystin poisoning of sea otters, possibly due to prolonged retention of microcystin-contaminated water.
doi:10.1371/journal.pone.0012576.g007

following 17 days of continuous exposure to clean seawater, which was the longest post-exposure timepoint evaluated during this study

Some variation in microcystin concentration between sample periods was attributed to differences in toxin uptake by individual bivalves, similar to the approximately 4-fold individual variability noted for bioaccumulation of domoic acid and saxitoxin in individual mussels from California coastal waters (R. Kudela, pers. commun.). All non-exposed controls (ambient seawater and invertebrates) tested negative for microcystin throughout the study (data not shown), which is consistent with a proposed freshwater (not marine) source of cyanotoxin exposure for sea otters.

Discussion

Here we provide the first documentation of microcystin intoxication in a marine mammal. Our research confirms deaths of threatened southern sea otters from microcystin intoxication and incorporates 3 distinct, but interconnected lines of scientific inquiry to address the hypothesis that land-sea flow of microcystins with trophic transfer through marine invertebrates is the most likely route of sea otter exposure: 1) Time-integrative passive samplers were deployed in fresh and marine systems along the central California coast, confirming the presence of microcystins; 2) Necropsy, histopathology and chemical analysis of tissues from stranded southern sea otters and 3) Determining dynamics and persistence of freshwater microcystin uptake from contaminated seawater by marine invertebrates using controlled laboratory experiments. Although trophic transfer of biotoxins from plank-

doi:10.1371/journal.pone.0012576.t002

tonic species to higher vertebrates has been demonstrated for marine biotoxins like brevetoxin and domoic acid within estuarine and marine systems [51,52], here we provide the first documentation of putative biotoxin transfer from the lowest trophic levels of nutrient-impaired freshwater habitat to top marine predators at the land-sea interface. Our findings provide the first hint of a serious environmental and public health threat that could negatively impact marine wildlife and humans.

We confirmed that Pinto Lake, a recreational water body located just inland from Monterey Bay exhibits substantial and recurrent *Microcystis* blooms. Biochemical testing of samples from Pinto lake during fall, 2007 revealed total microcystin concentrations of almost 2,900 ppm (2.9 million ppb), one of the highest microcystin concentrations ever reported from an environmental sample; the World Health Organization limit for microcystin contamination of finished drinking water is 1 ppb (0.001 ppm) [53]. Stepwise sampling of downstream tributaries during the late dry season confirmed the presence of *Microcystis* and microcystins throughout the lower Pajaro watershed to within 1 km of the ocean. Factors that facilitate development of cyanobacterial “super-blooms” in fresh water include

elevated nutrient concentrations and salinity, warm temperatures, enhanced vertical stratification of lakes, summer droughts and increased light intensity; all factors that are exacerbated by global climate change [19,22,23,54]. Cyanobacteria can exploit these conditions by developing intracellular gas vesicles and accumulating in dense surface blooms that “shade out” nontoxic phytoplankton like diatoms and green algae. They can also increase local water temperatures through light absorption, creating a positive feedback loop that helps ensure local dominance [23]. Once formed, these biotoxins can exert their effects in areas that are remote from sites of toxin production and can bioaccumulate in invertebrates and fish, suggesting a biologically plausible route for marine mammal (and human) exposure to freshwater toxins at the land-sea interface [32,51,52].

We demonstrated the excellent adsorption characteristics of SPATT resin-based systems for microcystin detection in both fresh and salt water. These passive samplers were more sensitive than periodic grab samples for field detection of microcystins and the ability to evaluate samples for the presence of multiple biotoxins simultaneously is an additional bonus. Preliminary environmental

surveillance using SPATT revealed no detectable microcystin in nearshore marine waters of Monterey Bay until the fall rainy season, when the marine outfalls of the 3 most nutrient-impaired local waterways; the Salinas, the Pajaro and the San Lorenzo Rivers all tested microcystin-positive.

Because of their high metabolic rate, small home ranges and heavy reliance on nearshore-dwelling marine invertebrates as food, sea otters provide an upper trophic-level compliment to the SPATT resin for environmental detection of microcystins. Deaths due to cyanobacterial intoxication were first recognized in 2007, when 11 microcystin-poisoned sea otters were recovered along the shoreline of Monterey Bay. Microcystin intoxication appears to be an emerging health problem for southern sea otters. To date, at least 21 southern sea otters have died due to microcystin intoxication and the frequency of deaths may be increasing over time. Most microcystin-positive sea otters were recovered near embayments, harbors or river mouths. Sea otters generally do not venture into rivers to feed, so upstream exposure to microcystins is unlikely.

For radio-tagged otters that died due to microcystin intoxication, marine bivalves constituted a major portion of their diet. Sea otters routinely consume 25 to 30% of their body weight in clams, mussels, snails, crabs and other marine invertebrates daily [50,55]. Marine bivalves are highly efficient biological filters for polluted water and can bioaccumulate a wide range of terrestrial-origin pollutants, including protozoa, enteric bacteria, viruses, biotoxins and anthropogenic chemicals [32,56–58]. Embayments, harbors and river mouths are favored foraging sites, placing otters directly in the path of concentrated plumes of polluted water at the land-sea interface. A higher risk of exposure to terrestrial-origin pathogens and chemicals has been reported for sea otters residing near impaired habitats and those that feed preferentially on filter-feeding invertebrates [44,49,57,59].

Microcystin accumulation has been demonstrated in fresh- and saltwater mussels, crustaceans, corals, fish and possibly humans [7,30,31,32]. Our hypothesis that sea otters were most likely to be exposed to lethal levels of microcystins through consumption of contaminated invertebrate prey was evaluated through laboratory experiments where bioconcentration and depuration of freshwater microcystins by marine invertebrates could be assessed under defined conditions. We documented significant bioaccumulation and slow depuration of freshwater microcystins by marine oysters, clams, snails and mussels, with gastrointestinal tissue concentrations up to 107 times greater than adjacent seawater. Marine invertebrates were also slow to depurate ingested toxins, with high microcystin concentrations detected at 2 weeks post-exposure (Table 3). Freshwater microcystins were also relatively stable in seawater, with concentrations remaining at 29 to 56% of 1 hour postexposure concentrations, even after 21 days.

Collectively these data provide compelling evidence implicating land-sea flow with trophic transfer through marine invertebrates as the most likely route of biotoxin exposure. Detection of this problem initially in southern sea otters is not surprising, given the high level of scientific scrutiny of this federally-listed threatened species. Due to several unique aspects of their biology, including a

high metabolic rate, a preference to feed near the shoreline and strong reliance on filter-feeding invertebrates as prey, southern sea otters have proven to be highly sensitive indicators of health of nearshore marine ecosystems [44,49,55,60]. Southern sea otters are also a keystone species [61]; by foraging on kelp-feeding invertebrates like urchins, sea otters help maintain the complex 3 dimensional structure of the kelp forest that provides critical habitat for other marine wildlife [62].

Our data appear to strongly support the following hypotheses relevant to microcystin pollution and toxicity: H1: Significant concentrations of freshwater-derived microcystins are intermittently polluting the land-sea interface of central California. H2: These microcystins are causing mortality of threatened southern sea otters, possibly through trophic transfer to marine invertebrates feeding in contaminated freshwater plumes and H3: Wild and farmed marine bivalves consumed by sea otters and humans exhibit high microcystin uptake and slow depuration under conditions that mimic natural exposure. Monterey Bay, the region where the majority of microcystin-poisoned sea otters were recovered, forms the heart of the nation's largest marine sanctuary and is heavily utilized by humans for water contact recreation, tourism, fishing and wildlife viewing. No formal surveillance or regulatory system exists for microcystin detection in water or shellfish in most countries, including the United States. Because sea otters and humans consume many of the same marine foods, our research findings may reveal unrecognized health risks for humans when consuming invertebrates harvested at the land-sea interface.

Acknowledgments

Population dynamics of Longfin Smelt in the San Francisco Estuary II: disaggregating forces driving long-term decline of an estuarine forage fish

Journal:	<i>Transactions of the American Fisheries Society</i>
Manuscript ID:	TAFS-2015-0141
Manuscript Type:	Article
Keywords:	Estuarine < Ecology, Fisheries Oceanography and Recruitment, Population Dynamics
Abstract:	<p>Forage fish production has become a central concern of fisheries and ecosystem managers because populations of small fish are a critical energetic pathway between primary producers and predator populations. Management of forage fish often focuses on controlling exploitation rates, but it is also possible to manage productivity of these species in coastal ecosystems, and estuaries in particular. Like several forage fish species native to the San Francisco Estuary (California, USA), Longfin smelt <i>Spirinchus thaleichthys</i> have experienced dramatic population declines over the past few decades. Trends in the relative abundance of this population, which is not fished commercially or recreationally, have been described statistically but the mechanisms that drive population dynamics are still poorly understood. The objective of this study was to evaluate alternative conceptual models of this species' population dynamics to better understand the forces that may constrain its productivity during different phases of its life cycle. We created contrasting variants of a generalizable population model (the Ricker model) and parameterized those variants using empirical data from a long-term sampling program in this estuary. Predictions from alternative models were compared to empirical results from a second, independent data series of Longfin Smelt relative abundance to determine which population model variants best captured the empirical trend. The results indicated that freshwater flow has a positive association with recruits-per-spawner and that both recruits-per-spawner, and spawners-per-recruit, appear to be density-dependent life stage transitions. Juvenile survival may have declined to some extent, but we could not conclusively demonstrate this. By constraining the possible timing and location of mechanisms that modulate productivity in different life stages, these results improve our understanding of production for a key native forage fish in the San Francisco Estuary.</p>

21 **Abstract:** Forage fish production has become a central concern of fisheries and
22 ecosystem managers because populations of small fish are a critical energetic pathway between
23 primary producers and predator populations. Management of forage fish often focuses on
24 controlling exploitation rates, but it is also possible to manage productivity of these species in
25 coastal ecosystems, and estuaries in particular. Like several forage fish species native to the San
26 Francisco Estuary (California, USA), Longfin smelt *Spirinchus thaleichthys* have experienced
27 dramatic population declines over the past few decades. Trends in the relative abundance of this
28 population, which is not fished commercially or recreationally, have been described statistically
29 but the mechanisms that drive population dynamics are still poorly understood. The objective of
30 this study was to evaluate alternative conceptual models of this species' population dynamics to
31 better understand the forces that may constrain its productivity during different phases of its life
32 cycle. We created contrasting variants of a generalizable population model (the Ricker model)
33 and parameterized those variants using empirical data from a long-term sampling program in this
34 estuary. Predictions from alternative models were compared to empirical results from a second,
35 independent data series of Longfin Smelt relative abundance to determine which population
36 model variants best captured the empirical trend. The results indicated that freshwater flow has a
37 positive association with recruits-per-spawner and that both recruits-per-spawner, and spawners-
38 per-recruit, appear to be density-dependent life stage transitions. Juvenile survival may have
39 declined to some extent, but we could not conclusively demonstrate this. By constraining the
40 possible timing and location of mechanisms that modulate productivity in different life stages,
41 these results improve our understanding of production for a key native forage fish in the San
42 Francisco Estuary.

43

44 Introduction

45 Forage fishes serve as energy conduits between zooplankton and higher trophic-level
46 predators (Pikitch et al. 2014). This central role in aquatic food webs means that forage fish
47 production is critical to sustainable fisheries management (Alder et al. 2008), desired ecosystem
48 functions (Hall et al. 2012), and in some cases the maintenance of biodiversity (Trathan et al.
49 2015). For instance, seabirds around the world display reduced and more variable productivity
50 when forage fish biomass drops below one-third of the maximum observed in long-term studies
51 (Cury et al. 2011). Thus, marine fisheries and ecosystem management are increasingly focusing
52 on protecting forage fishes from over-exploitation. Management may also be directed toward
53 maintaining or restoring the habitats and processes that support production of forage fish,
54 especially in estuarine ecosystems (Kennish 2002; Hughes et al. 2014).

55 A general conceptual model of forage fish productivity in coastal ecosystems, including
56 estuaries, is that recruitment is strongly influenced by the interplay of zooplankton production
57 and predation rates sustained by the forage fishes (Walters and Juanes 1993; Essington and
58 Hansson 2004). The matches and mismatches of forage fishes and their prey can be affected by
59 physical conditions such as ocean currents (Genin 2004) and upwelling (Reum et al. 2011). For
60 species that rely on low-salinity environments to complete their life-cycle, variation in
61 freshwater flow rates can also play an important role in aligning young fish with their prey and
62 protecting them from predators (Turner and Chadwick 1972; North and Houde 2003). Fish
63 behavior and physiological capacities can influence the details of this conceptual model,
64 particularly in euryhaline fishes (Kimmerer 2006; Peebles et al. 2007).

65 However, the protection of forage fish habitats can be very difficult in developed rivers
66 and their receiving estuaries because of strong competition for freshwater with human economic

67 systems (Vörösmarty et al. 2010; Cloern and Jassby 2012). Many estuarine forage fishes that are
68 tolerant of, or dependent on, low-salinity and freshwater habitats, and their supporting food
69 webs, are influenced by the timing, duration, and magnitude of freshwater flow and its effects on
70 estuarine hydrodynamics (Jassby et al. 1995; North and Houde 2003; Gillson 2011). The
71 biological productivity and accessibility of fresh water historically provided by river-estuary
72 systems have attracted considerable human settlement and exploitation that has in turn led to
73 intensive changes, including large-scale reclamation of estuarine landscapes, water pollution,
74 species introductions, modification of estuarine hydrodynamics, and declines in native biota
75 (Kennish 2002; Lotze et al. 2006; Shan et al. 2013). California's San Francisco Estuary
76 (hereafter SFE; Figure 1) is a well-known example of an estuary that has undergone tremendous
77 physical, chemical, and biological transformation (Kimmerer 2002a; Cloern and Jassby 2012).
78 The declines of once productive fisheries and the potential ongoing loss of native fish
79 biodiversity are key aquatic resource concerns in the SFE and its watershed (Moyle 2002;
80 Sommer et al. 2007; Katz et al. 2012).

81 One formerly abundant forage fish of the SFE that has undergone a substantial decline is
82 Longfin Smelt *Spirinchus thaleichthys* (Rosenfield and Baxter 2007). Longfin Smelt is a small,
83 facultatively anadromous, pelagic fish that typically reaches adult sizes of 80-150 mm in fork
84 length (Moyle 2002). Longfin Smelt inhabits lakes, coastal river estuaries, and nearshore marine
85 environments from Alaska to central California; the SFE is the southern limit of the species'
86 inland distribution along the Pacific Coast of North America. Most Longfin Smelt live for two
87 years and are semelparous. In the SFE, Longfin Smelt spawn in tidally-influenced freshwater
88 habitats, but low-salinity habitats may also provide suitable spawning areas (the microhabitat
89 requirements for Longfin Smelt spawning are not known). Spawning typically peaks in the

90 winter (December-February), when water temperatures range from about 7.0°C to 14.5°C
91 (Moyle 2002). Larvae and small juveniles aggregate in low-salinity waters during the late winter
92 through spring (Dege and Brown 2004) then move seaward into mesohaline to marine waters of
93 Central San Francisco Bay and the coastal ocean during the summer (Rosenfield and Baxter
94 2007). Juveniles and adults begin to move landward again during the fall (September-
95 December).

96 Longfin Smelt was once one of the most abundant and widespread fishes in the SFE
97 (Moyle 2002; Sommer et al. 2007). Their former abundance and broad distribution strongly
98 suggest that it once played an important role in the SFE food web; however, given an abundance
99 decline of circa 99.9%, it is likely that Longfin Smelt is currently too rare to serve as an
100 important prey to piscine, avian, or mammalian predators foraging in the estuary. Longfin Smelt
101 is one of several fish populations that play a central role in California water management because
102 in 2009 it was listed as threatened under the California Endangered Species Act (CESA), and
103 regulations developed as part of the CESA listing can limit diversions of fresh water from the
104 estuary. The United States Fish and Wildlife Service has also recently determined that the SFE
105 population of Longfin Smelt warranted protection under the U.S. Endangered Species Act
106 (Federal Register, 77 FR 19755).

107 Many details of Longfin Smelt ecology in the SFE are virtually unknown because it has
108 not been targeted by a sport or commercial fishery for many decades (Moyle 2002), though it is a
109 bycatch species in a limited bait fishery for Bay Shrimp *Crangon franciscorum*. Although
110 CDFW (2009) considered this a factor limiting Longfin Smelt recovery, we know of no evidence
111 that bycatch rates have increased substantially in recent times and until its recent listing under
112 CESA, it did not factor directly into decisions about water diversions. As a result, current

113 scientific understanding of the SFE population is largely derived from correlation-based analyses
114 of abundance indices (Stevens and Miller 1983; Jassby et al. 1995; Kimmerer 2002b),
115 evaluations of the catch data that underlie those indices (Rosenfield and Baxter 2007; Kimmerer
116 et al. 2009; La Tour 2015), and the presumption (e.g., Moyle 2002) that the SFE population is
117 fundamentally similar to the better-researched, but landlocked, population in Lake Washington,
118 Washington, USA (Chigbu 2000).

119 Longfin Smelt is also one of several fishes of the SFE that have shown a strong and
120 persistent association between juvenile production and freshwater flow variation experienced
121 early in their life cycle (Stevens and Miller 1983; Jassby et al. 1995; Kimmerer 2002b;
122 Rosenfield and Baxter 2007; Thomson et al. 2010; Maunder et al. 2015), but little attention has
123 been given to whether and how freshwater flow rates might affect Longfin Smelt production
124 beyond their first year of life. It is also well established that Longfin Smelt production per unit
125 of flow has declined (Kimmerer 2002b; Rosenfield and Baxter 2007; Thomson et al. 2010), but
126 with only one very recent exception (Maunder et al. 2015), researchers have not attempted to
127 evaluate SFE Longfin Smelt population dynamics in a classical spawner-recruit framework.

128 Food web alteration has been considered a primary factor contributing to the decline of
129 SFE Longfin Smelt, but the details of when and where prey production may limit recruitment
130 have not been determined and predation on SFE Longfin Smelt has not been studied so the role
131 of predators as a population driver can only be speculated on. The zooplankton assemblages that
132 Longfin Smelt likely prey upon began changing dramatically following the 1986 invasion of the
133 estuary by overbite clam, *Potamocorbula amurensis*. Changes included abrupt declines in
134 chlorophyll (Alpine and Cloern 1992), several crustaceans including mysid and decapod shrimps
135 (Kimmerer 2002b), and changes in the distribution (Kimmerer 2006; Sommer et al. 2011) and

136 diet composition (Feyrer et al. 2003; Nobriga and Feyrer 2008) of several fishes. In addition,
137 waste water ammonium limits the growth rate of diatoms in the SFE (Wilkerson et al. 2006),
138 which may be another, more gradually changing factor suppressing production of Longfin
139 Smelt's zooplankton prey.

140 Here we explore the population ecology of Longfin Smelt in the SFE in an attempt to
141 identify when during the life cycle (and by extension where) productivity has changed and how
142 changes through time in these productivity parameters may explain the long-term decline of this
143 Longfin Smelt population. To do this, we employ conceptually different variants of a standard
144 population modeling framework (the Ricker Model) to see which formulations of the model best
145 explain empirical trends. We did not attempt to develop a model that recreates Longfin Smelt
146 population dynamics precisely; rather, the objective of this study was to evaluate alternative
147 conceptual models of this species' population dynamics to better understand the forces that may
148 constrain its productivity during different phases of its life cycle. Specifically, we sought to (i)
149 identify factors that are correlated with productivity parameters in different life stages in order to
150 disaggregate the effect of changes in productivity at different life stages, so that (ii) future
151 research and management actions can focus on the Longfin Smelt life stages that have
152 experienced declines in productivity and the environmental variables that can be manipulated to
153 increase the production of those life stages.

154

155 Study Area

156 The SFE is formed by the confluence of two major California river systems, the
157 Sacramento and San Joaquin (Figure 1). These rivers meet in the Sacramento-San Joaquin Delta
158 (hereafter, Delta) and begin to mix with Pacific Ocean waters. This estuarine mixing intensifies

159 in a westward direction in the several embayments that comprise San Francisco Bay (Figure 1;
160 Jassby et al. 1995; Kimmerer et al. 2013). Some portion of Central San Francisco Bay, nearest
161 to the Bay's outlet to the Pacific Ocean, is usually close to marine salinity (≥ 30 psu). In the
162 northern reach of the SFE from San Pablo Bay through the Delta, average salinity decreases from
163 west to east due to the influence of the freshwater flowing from the Central Valley's rivers
164 through the Delta. The Delta is a network of tidal fresh water channels from which large
165 quantities of water are exported to more arid parts of California for agricultural and municipal
166 use. The U.S. Central Valley Project has been exporting water to the San Joaquin Valley since
167 1951 and the State Water Project has been exporting water to the San Joaquin Valley and
168 municipalities in southern California since 1968. The historical changes associated with the
169 development of California's surface water supplies and the diversion of water from the Delta
170 have been reviewed extensively (Arthur et al. 1996; Enright and Culberson 2010; Cloern and
171 Jassby 2012).

172

173

Methods

174 Overview: Fisheries population-dynamic stock assessments have long relied on spawner-recruit
175 models (e.g., Ricker 1954). These mathematical tools link the production of new cohorts of fish
176 (recruits) to the available spawning stock, and often also attempt to explain residual variation in
177 recruitment using environmental covariates (Myers 1998). Fisheries stock assessments are
178 usually applied to harvested fishes, particularly in marine ecosystems. Although Longfin Smelt
179 is not targeted for harvest in the SFE, it is nonetheless useful to construct explicit spawner-recruit
180 relationships to evaluate different conceptual models of Longfin Smelt recruitment (*see also*
181 Maunder et al. 2015).

182 Our analysis was based on alternative formulations of the Ricker (1954) model.

183

$$184 \quad R = aSe^{-BS} \quad (1)$$

185

186 In this general formulation, R is the number (or biomass) of fish recruiting to a population, S is
187 the number (or biomass) of spawners, and a and B are parameters that are solved for; a is the
188 recruits-per-spawner, in essence, the slope of the spawner-recruit relationship near the origin,
189 and B interacts with a to adjust the intensity of density dependence between generations. We
190 developed alternative conceptual models of how SFE Longfin Smelt recruitment might best be
191 modeled using the Ricker model. We used a long-term and age-specific data series of Longfin
192 Smelt relative abundance in the SFE to parameterize alternative Ricker models by (i) screening
193 variables to predict a , (ii) screening variables to predict survival from Age-0 to Age-2 in order to
194 predict S , and (iii) finding values of B that constrained predictions of R to create a contrast with
195 model variants in which we did not apply this constraint. Then we simulated time series of
196 Longfin Smelt relative abundance using each alternative Ricker model, and compared the
197 simulations to a different empirical time series of Longfin Smelt relative abundance that was
198 measured independently of the one used to parameterize the models.

199

200 Alternative Conceptual Models of Longfin Smelt Recruitment: Five alternative conceptual models
201 of Longfin Smelt recruitment were evaluated (Table 1). All models had a recruits-per-spawner
202 term (a , or “a” in the alphanumeric codes that differentiate models in Table 1). One model (1abc)
203 compared Age-0 abundance from one generation to the next (i.e., a estimated recruits-per-
204 recruit) to evaluate whether Age-0 indices were sufficient to model long-term population

205 dynamics, a hypothesis that could be inferred from the numerous published analyses of Age-0
206 Longfin Smelt abundance indices (e.g., Stevens and Miller 1983; Jassby et al. 1995; Kimmerer
207 2002b; Thomson et al. 2010). If this one-stage model performed as well as models with two-life
208 stages (the four models with “2” in their alphanumeric code in Table 1), it would indicate that
209 Age-2 Longfin Smelt abundance is more or less determined by Age-0 production (i.e., that
210 survival from Age-0 to Age-2 was relatively invariant through the data series) and that the use of
211 a traditional two life-stage spawner-recruit model is not necessary to model Longfin Smelt
212 population dynamics in the SFE.

213 The four model variants that used two life-stages incorporated a term to estimate survival
214 between Age-0 and Age-2 to estimate S from predictions of R . These models differed in their
215 combination of an explicit density-dependent term for the spawner-to-recruit life–history
216 transition (indicated by a “b” in the model alphanumeric codes in Table 1) and in whether model
217 parameters were allowed to change through time (indicated by a “c” in model alphanumeric
218 codes). The relative importance of these terms in describing empirical patterns in Longfin Smelt
219 population abundance has ecological and management implications as they suggest different
220 mechanisms constraining population dynamics.

221
222 Data sources: The California Department of Fish and Wildlife (CDFW) conducts several trawl-
223 based surveys of fisheries resources in the SFE (<https://www.wildlife.ca.gov/Regions/3>).
224 Longfin Smelt has been commonly collected in most of these surveys and CDFW generates
225 indices of Longfin Smelt relative abundance from some of the surveys (Stevens and Miller 1983;
226 Rosenfield and Baxter 2007). Here, we use data from the San Francisco Bay Study (SFBS),
227 which has been sampling since 1980, to generate spawner-recruit parameters. Then we

228 compared predictions made with these data to an estimate of Longfin Smelt relative abundance
229 from an independent data series, the Fall Midwater Trawl (FMWT). With the exceptions of
230 1974 and 1979, CDFW has generated unitless abundance indices of Longfin Smelt from the
231 FMWT data since 1967. The methodologies of these sampling programs have been reported
232 elsewhere (e.g., Stevens and Miller 1983; Rosenfield and Baxter 2007) and are not repeated here.
233 The key differences pertinent to this study are: (i) the SFBS and FMWT sampling grids overlap,
234 but the former samples further seaward and the latter samples further landward, (ii) SFBS
235 sampling occurs during all months of the year, but FMWT sampling occurs only during
236 September-December, (iii) the number of stations sampled in a month by the FMWT is
237 considerably higher than the SFBS (~ 100 versus ~ 35), (iv) the SFBS deploys both a bottom-
238 oriented otter trawl and a midwater trawl at each sampling station, whereas the FMWT uses only
239 a midwater trawl, and (v) CDFW calculates age-specific indices of Longfin Smelt relative
240 abundance from the SFBS, but only one index from the FMWT that is essentially an Age-0 index
241 (Table 2).

242 The CDFW uses February-May catch data to generate an index of Age-2 Longfin Smelt
243 relative abundance for each of the sampling gears employed by the SFBS; May-October catch
244 data are used to generate abundance indices for Age-0 Longfin Smelt. For each age-class of
245 Longfin Smelt, we averaged the midwater and otter trawl indices generated from the SFBS to
246 produce unitless annual indices for each age-class (hereafter Bay Age-0 and Bay Age-2; Table
247 2). We combined indices from the two sampling gears because the SFBS midwater trawl was
248 not deployed in some years (Rosenfield and Baxter 2007), so the Bay Age-0 and Bay Age-2
249 provided us with continuous time series of Longfin Smelt relative abundance for 1980-2013. We
250 did not attempt to estimate missing data (missing values were replaced with a zero before taking

251 the average) because it was possible that estimating missing values would be no more accurate
252 than simply treating missing data as zeroes. These choices reflect a trade-off between long-term
253 data availability and the timing of peak Longfin Smelt catches (Rosenfield and Baxter 2007).

254
255 *Selection of Environmental Covariates:* We developed one freshwater flow variable and three
256 water quality variables to use as candidate predictors of Longfin Smelt's life stage transitions.
257 Following Rosenfield and Baxter (2007), we used monthly means of the Net Delta Outflow
258 Index (hereafter Delta outflow; <http://www.water.ca.gov/dayflow/>) to represent the commonly
259 reported influence of freshwater flow on Longfin Smelt. Delta outflow is the estimated net
260 tidally-filtered river flow passing Chipps Island (Figure 1) and the freshwater flow variable that
261 most directly influences salinity distribution in the SFE's river channels and embayments (Jassby
262 et al. 1995; Kimmerer et al. 2013). These open-water habitats comprise the major larval rearing
263 areas for Longfin Smelt (Dege and Brown 2004; Hobbs et al. 2006). We calculated the monthly
264 mean outflow for December-May because these months fully overlap the spawning and larval
265 rearing phases of Longfin Smelt's life cycle in the SFE (CDFW unpublished data) and outflow in
266 these months is typically greater and more variable than in other months. As a result, outflow
267 during these months is most likely to influence the fate of Longfin Smelt (Jassby et al. 1995;
268 Kimmerer et al. 2013). Estuarine hydrodynamics are also influenced greatly during droughts,
269 which also influence the fate of Longfin Smelt (Rosenfield and Baxter 2007). The Delta outflow
270 data were available for 1956-2013 and we converted monthly means into metric units, $\text{m}^3 \cdot \text{s}^{-1}$.

271 We also used monthly means of water temperature ($^{\circ}\text{C}$) and water transparency (Secchi
272 disk depth in cm) from all available data collected by the SFBS. The water temperature data
273 provided to us by CDFW were available from 1980-2011, while the water transparency data

274 were available from 1980-2013. We calculated monthly means of these two water quality
275 variables for February-May (the indexing period for Age-2 Longfin Smelt). During February
276 through May, Age-0 Longfin Smelt are primarily in larval stages with a center of distribution
277 near the estuary's 2 psu isohaline (Dege and Brown 2004).

278 We summarized the Delta outflow, water temperature, and water transparency data
279 separately using Principal Components Analyses (PCA) on the z-scored monthly means. We
280 used PCA because sequential monthly means of flow and water quality variables can be closely
281 correlated due to California's seasonal climate and high year to year variation in precipitation.
282 This covariation makes it difficult to determine what averaging periods best reflect mechanistic
283 linkages between environmental conditions and Longfin Smelt production. We used the first
284 principal component scores from each PCA (Table 2) as candidate predictors of Longfin Smelt
285 recruits-per-spawner in the regression analyses described below.

286
287 Derivation of recruits-per-spawner (a): We represented a using either the ln-transformed ratio
288 Bay Age-0_{t=0}/Bay Age-0_{t=2} (for the one life-stage model; 1abc), or the ln-transformed ratio Bay
289 Age-0_{t=0}/Bay Age-2_{t=0} (for all four of the two life-stage models). We performed multiple linear
290 regression analyses to screen candidate predictors of a in an information-theoretic framework
291 and evaluated predictors using the corrected Akaike Information Criterion (AIC_c) to develop a
292 smaller set of statistically defensible covariates. Regression analyses were conducted separately
293 for each version of the response variable and had to be conducted separately for tests involving
294 water temperature variables due to the smaller data set mentioned above. The candidate
295 predictors and their assumed mechanistic meanings are provided in Table 3.

296 During our analyses, we discovered that the relationship between our Delta outflow
297 variable and the two life-stage version of $\ln(a)$ was not linear. We used LOESS regression to
298 depict the empirical shape of the relationship between these variables and found the LOESS
299 prediction to be very similar to a second order polynomial fit. We used AIC_c to confirm a
300 polynomial fit was better supported than a linear fit and then used the polynomial regression to
301 predict a in our model variants with two life-stages because that equation was far simpler to
302 implement than the LOESS equation.

303
304 Derivation of spawners-per-recruit (S): In models 2a, 2ab, 2ac, and 2abc, we estimated a relative
305 abundance of Age-2 Longfin Smelt to predict the relative abundance of the next generation of
306 Age-0 fish. We did this by deriving an estimator of survival from Age-0 to Age-2 ($S_{0 \rightarrow 2}$) and
307 multiplying estimates of R by this survival term to estimate the next generation of spawners (S).
308 We estimated $S_{0 \rightarrow 2}$ as the ln-transformed ratio Bay Age-2_{t=0}/Bay Age-0_{t-2} (i.e., the two SFBS
309 indices for the same cohort of fish) and tested a set of candidate predictor variables of this ratio,
310 following the same analytical approach used to predict a . For this analysis, we also included the
311 birth year FMWT index as a candidate predictor (Table 3) to evaluate whether juvenile survival
312 might be density-dependent given similar findings for several other SFE fishes (Kimmerer et al.
313 2000; Moyle et al. 2004; Bennett 2005).

314
315 Derivation of the exponent term (e^{-BS}): In order to evaluate whether density-dependence may also
316 affect R , we imposed a carrying capacity on the models identified with a “b” in their
317 alphanumeric codes (Table 1). Inclusion or exclusion of the e^{-BS} term allowed us to investigate
318 whether interannual variation in environmental conditions was sufficient to produce a natural

319 limit on the production of Age-0 Longfin Smelt (models 2a and 2ac), or conversely whether an
320 explicit carrying capacity provides for better fitting models (models 1abc, 2ab, 2abc). To do this,
321 we found values for B that reflected empirical relative abundance maxima given our estimates of
322 a . The maximum FMWT index for Longfin Smelt was 81,737 in 1967. The maximum a ,
323 indexed as Bay Age-0_{t=0}/Bay Age-0_{t=2} was 59 in 1995. We rounded these values up slightly and
324 found a value of B that, when multiplied by hypothetically increasing numbers of spawners
325 would limit the ability for our one life-stage model (model 1abc) to predict FMWT indices
326 greater than 82,000 when a was 60. Similarly for the two life-stage models, the maximum
327 observed a (indexed as Bay Age-0_{t=0}/Bay Age-2_{t=0}) for the ten years with highest Age-2
328 abundance was 168 in 1982. We rounded these values up slightly to calculate a value of B that
329 would limit the ability of simulations from these two life-stage models to predict FMWT indices
330 greater than 82,000 when a was 170.

331

332 *Evaluating changes in population model parameters assumed to result from changes in the SFE*
333 *food web*: The feeding habits of juvenile Longfin Smelt are basically undescribed in the SFE,
334 particularly for individuals foraging in mesohaline to marine waters (but see Hobbs et al. 2006
335 for data on larvae inhabiting the low-salinity zone). Hypothesized changes in Longfin Smelt
336 foraging success are either abrupt (e.g., due to the invasion of the overbite clam) or gradual and
337 continuous (e.g., due to altered nutrient concentrations or changes in water transparency). We
338 explored the predictive power of several temporal variables as surrogates for food web changes
339 in the regression analyses (Table 3). Specifically, Kimmerer (2002b) used 1987 as a change
340 point associated with invasion of the overbite clam; we used a step-decline in that year as a
341 predictor variable for a in model 1abc because fish spawned in 1987 would have been the first

342 ones to be impacted by the high density of clams detected in that year and thereafter. However,
343 Thomson et al. (2010) found that evidence for a step-decline in Longfin Smelt relative
344 abundance was strongest between 1989 and 1991. In our two-life stage models, we tested step-
345 declines in survival in 1989 and 1991; fish spawned in 1987 would have reached adulthood in
346 1989 and that is when one would first expect to see an effect of the clam on $S_{0 \rightarrow 2}$. We also
347 screened “year” as a predictor variable to test for the possibility that trends in survival were not
348 well represented as step-declines (Table 3).

349
350 Spawner-recruit simulations: Using each of the five alternative spawner-recruit models, we
351 generated 58-year time series of predicted Longfin Smelt FMWT indices (1958-2013). We
352 started each simulation by seeding 1956 and 1957 with the median observed FMWT index for
353 Longfin Smelt (798). After 1957, the simulations predicted all Longfin Smelt abundance indices
354 on their own through water year 2013. The simulations were stochastic; each year of each
355 simulation was iterated 1,000 times, using randomly drawn values of every regression parameter,
356 in which the parameter estimate was assumed to be the mean and the standard error was used to
357 scale the random variability. We restricted the simulations such that juvenile survival had to
358 remain ≤ 1 (i.e., $\leq 100\%$). This is an extremely high upper limit on survival, but it is not greatly
359 beyond the observed data; the index ratio we used to represent survival had a maximum
360 empirical value of 0.98 in 2012.

361 We evaluated model variants based on their ability to predict the empirical FMWT time
362 series and by the frequency with which they produced results that were clearly spurious. Each of
363 the resulting 5,000 simulations was compared to the empirical FMWT indices by calculating its
364 mean square error (MSE). Recall that FMWT data were available 1967-1973, 1975-1978, and

1980-2013, so we extracted those years from our simulations for this comparison. The central 95% of MSE estimates (i.e., 950 of the 1,000 iterations) were summarized using boxplots. We also evaluated the relative performance of model variants with the lowest MSEs by summarizing how frequently they had predicted Longfin Smelt quasi-extinction, which we define here as a FMWT index < 1 (the lowest empirical FMWT index was 13 in 2007). Lastly, we summarized the time series predictions from the best-performing models graphically to show more explicitly how they had performed relative to the observed FMWT abundance index time series.

Results

The first principal components (PC1s) for Delta outflow, water transparency, and water temperature had eigenvalues of 3.5, 2.0, and 1.5, respectively, and explained 58%, 50%, and 37% of the variance in the time trends of these variables. The PC1s for Delta outflow and water transparency were highly concordant with multi-month means of each year (Delta outflow Pearson $r = 0.99$, and water transparency Pearson $r = 0.98$). In contrast, the PC1 for water temperature was not correlated with mean water temperature (Pearson $r = 0.17$) and instead reflected variation within years; PC1 of temperature segregated years with relatively large temperature changes between winter and spring (i.e., cool February-March, warm April-May) from years with less seasonal variation. Therefore, we tested both the PC1 of water temperature and mean water temperature as candidate predictor variables for a and $S_{0.5}$.

Recruits-per-spawner: The linear regression analyses used to screen candidate predictor variables indicated positive effects of Delta outflow PC1 and the binary step change at 1987 as predictors of a for use in model 1abc (Table 4). The step change variable was only marginally

388 significant ($P = 0.07$) and opposite in sign to our expectation (i.e., a was predicted to increase
389 after 1987). The final model selected was $\ln(a) = 0.596 \pm 0.146(\text{Delta outflow PC1}) +$
390 $1.54 \pm 0.829(\text{Step-decline}_{1987}) - 1.39 \pm 0.748$. The analogous analyses for models 2a, 2ab, 2ac, and
391 2abc supported only the use of Delta outflow PC1 as a predictor of a ; in this case a nonlinear fit
392 was better supported than a linear fit (Table 4). The final model selected was $\ln(a) = -$
393 $0.148 \pm 0.049(\text{Delta outflow PC1})^2 + 0.954 \pm 0.152(\text{Delta outflow PC1}) + 2.94 \pm 0.303$; neither
394 linear nor nonlinear fits showed evidence of a monotonic residual time trend (Figure 2).

395
396 *Juvenile Survival:* The linear regression analyses used to screen candidate predictor variables of
397 $S_{0 \rightarrow 2}$ strongly supported the use of the birth year FMWT index (Table 5), suggesting that juvenile
398 survival is density-dependent. All of the temporal variables we tested were also statistically
399 significant (or nearly so). Interestingly, the 1989 step-decline performed poorly ($\text{AIC}_c = 103$)
400 compared to “year” ($\text{AIC}_c = 99.6$) and the 1991 step-decline ($\text{AIC}_c = 95.4$). The final model
401 selected was $\ln(S_{0 \rightarrow 2}) = -0.630 \pm 0.114(\ln\text{FMWT}) - 1.68 \pm 0.474(\text{Step-decline}_{1991}) + 3.19 \pm 1.03$.

402
403 *Model Evaluation:* The MSEs of most models overlapped at least somewhat, but two of the five
404 (models 2a and 2ac) had notably poorer fits to the FMWT data, producing higher MSEs 63% to
405 100% of the time (Figure 3). Thus, it appears that an explicit carrying capacity on R is a useful
406 model construct. The MSEs of models 1abc, 2ab, and 2abc were strongly overlapping (Figure 4)
407 suggesting that each provided a similar fit to the FMWT data. Compared to models 2ab and
408 2abc, model 1abc showed comparatively low variation in MSE among model iterations (Figure
409 4), but that low variability reflected this model’s rapid predictions of quasi-extirpation in 100%
410 of the iterations (Figure 5). Thus, although it appeared to have a comparatively good fit to the

411 FMWT data, model 1abc was clearly unreliable. By design, models 2ab and 2abc are equivalent
412 until the 1991 step-decline implemented in the latter. Thus, FMWT predictions using these
413 models were nearly equivalent from 1967-1990 (Figure 6). Median FMWT predictions using
414 model 2ab were closer to the empirical data from 1991-1994; thereafter, the median predictions
415 using model 2ab systematically overestimated the observed FMWT time series and the median
416 predictions from model 2abc were closer to the empirical data (Figure 6). As a result, the
417 median predictions of model 2abc provided a better overall representation of the empirical
418 FMWT indices (compare Figure 6D to Figure 6B); however, predictions from both models
419 strongly overlapped in each year of the simulation (Figure 6A and Figure 6C), making it
420 impossible to conclude that one outperformed the other. In addition, both models 2ab and 2abc
421 considerably underpredicted the FMWT indices and were non-linearly related to them (Figure
422 6B,D), suggesting that our e^{-BS} term was too strongly density-dependent.

423

424

425

Discussion

426

427

428

429

430

431

432

Relying on a few well-supported assumptions about Longfin Smelt life-history and ecology in the SFE, our two best-supported Ricker models both incorporated two life-stages in which productivity was density-dependent in each of the life stage transitions, and recruits-per-spawner was related to freshwater flow rates. Apparently, despite differences in geographic extent, timing, and sampling gears, the SFBS and FMWT sampling programs detect the same general patterns in Longfin Smelt population dynamics, and our Ricker model-based analyses indicated there are (at least) two important, but temporally distinct population dynamic effects;

433 an influence of fresh water flow on the production of Age-0 fish, and density-dependent and
434 possibly declining juvenile survival.

435

436 *Implications of spawner-recruit dynamics:* The influence of freshwater flow on the production
437 of Age-0 Longfin Smelt has been recognized for several decades (Stevens and Miller 1983;
438 Jassby et al. 1995; Rosenfield and Baxter 2007) albeit not with the nonlinearities that we found
439 evidence for (Table 4; Figure 2). Depending on its timing and magnitude, freshwater flow can
440 have both positive and negative effects on the recruitment of Age-0 Longfin Smelt in Lake
441 Washington (Chigbu 2000). We found no evidence that the ratio we used to depict recruits-per-
442 spawner has declined over time and thus, it does not appear that food web changes have
443 impacted this life stage transition. However, there is some suggestion of a cyclical pattern
444 among the residuals (Figure 2), which might be evidence for an ocean influence on Longfin
445 Smelt recruitment in the SFE (sensu Feyrer et al. 2015). This possibility warrants further
446 research. Improving scientific understanding of when freshwater flow modulates Longfin Smelt
447 production may help to reveal the flow-related mechanisms at work and the area where these
448 mechanisms function. Focusing on the time and place where freshwater flow is likely to have its
449 effect on recruitment may assist managers of the Central Valley hydro-system to optimize
450 freshwater flow rates to benefit Longfin Smelt production.

451

452 *Implications of Juvenile Survival:* We found no indication that freshwater flow moderated
453 the survival of Longfin Smelt between Age-0 and Age-2, a result that is consistent with
454 Kimmerer et al. (2009), but we did find evidence that survival in this life stage transition is
455 density-dependent (Table 5). In contrast to the production of Age-0 fish, there was some

456 evidence for continuous and step-declines in the survival of juvenile Longfin Smelt, which may
457 reflect food web-related impacts on this older life stage. Several other studies have detected one
458 or more step declines in overall Longfin Smelt production (Kimmerer 2002b; Thomson et al.
459 2010) and Rosenfield and Baxter (2007) noted an age-specific decline in production between
460 Age-0 and spawning-aged Longfin Smelt, which occurred sometime during the severe drought of
461 1987-1994. However, based on our spawner-recruit modeling, it was not possible to statistically
462 distinguish between the model that allowed survival rates to change (model 2abc) from one in
463 which survival did not change directionally (Model 2ab; Figures 4 and 6).

464 Constraining the timing and location of density-dependence and declining Longfin Smelt
465 survival may help to identify mechanisms controlling these parameters. The forces creating
466 density-dependent survival and possible declines in that survival are most likely to operate
467 between the timing of sampling that produces indices of Age-0 abundance (May-October in year
468 0) and Age-2 abundance (February-May). Most SFE Longfin Smelt spend most of this part of
469 their life-cycle in mesohaline or marine waters (Rosenfield and Baxter 2007), so it is more likely
470 that the mechanisms affecting juvenile survival also operate in mesohaline or marine
471 environments than mechanisms operating in fresh to low-salinity zone waters.

472
473 Implications for Forage Fish Management in the SFE: Our results support some emerging
474 generalizations about fish recruitment in the SFE. The results of the present study suggest that
475 the general life cycle model for Longfin Smelt is very similar to what has been reported for
476 Striped Bass (Kimmerer et al. 2000) and Sacramento Splittail *Pogonichthys macrolepidotus*
477 (Moyle et al. 2004). In each of these species, freshwater flow variation has been linked to
478 productivity early in the life-cycle, an effect subsequently tempered by density-dependent

479 survival in the juvenile life-stage. Density-dependent survival may seem paradoxical in a
480 declining fish species like Longfin Smelt, but fisheries recruitment theory has demonstrated how
481 density-dependent 'looking' spawner-recruit relationships can arise from food web-related
482 mechanisms that are not reflective of populations limiting their own resource base (Walters and
483 Juanes 1993).

484 The SFE population of Longfin Smelt is in the queue to potentially be listed under the
485 U.S. Endangered Species Act (Federal Register, 77 FR 19755). By disaggregating life-stage
486 specific constraints on population dynamics, this study can help inform a future ESA listing
487 decision for Longfin Smelt and development of the accompanying recovery plan if the
488 population is listed. Perhaps more importantly, this study helps to identify where in the life-
489 cycle fish productivity is limited and may be changing over time, potentially informing research
490 and monitoring efforts into Longfin Smelt recruitment limitation. The persistence of Longfin
491 Smelt and several other native forage fish species in the SFE, and potentially the predators that
492 historically relied on these populations (e.g., Striped Bass and Pacific Halibut *Paralichthys*
493 *californicus*), depends on taking steps to improve the productivity of these fishes.

687 Table 1. Summary of five alternative Ricker models of Longfin Smelt recruitment in the San
 688 Francisco Estuary. The alphanumeric model codes are shorthand for the embedded hypotheses;
 689 the number represents the number of life stages explicitly modeled, “a” denotes that all five
 690 models include a recruits per spawner term, “b” denotes that a model has an explicit density
 691 dependent exponent (e^{-BS}), and “c” denotes that the model employs a time-dependent change in
 692 one or more parameters.

Model	Embedded Hypotheses
1abc	The trend in Age-0 relative abundance is sufficient to model long-term population dynamics; the production of Age-0 fish is density-dependent; survival has changed through time (e.g., due to changes in the estuary’s food web)
2a	Understanding the trend in Age-0 relative abundance requires explicit modeling of spawner and recruit relative abundance; the production of Age-0 fish is density independent; survival has not changed through time
2ab	Understanding the trend in Age-0 relative abundance requires explicit modeling of spawner and recruit relative abundance; the production of Age-0 fish is density dependent; survival has not changed through time
2ac	Understanding the trend in Age-0 relative abundance requires explicit modeling of spawner and recruit relative abundance; the production of Age-0 fish is density independent; survival has changed through time
2abc	Understanding the trend in Age-0 relative abundance requires explicit modeling of spawner and recruit relative abundance; the production of Age-0 fish is density dependent; survival has changed through time

693

694 Table 2. Time series of the first principal component (PC1) of principal components analyses (PCA) of available water quantity and
 695 quality variables, and Longfin Smelt indices of relative abundance used in this study. The PCAs on Delta outflow, water temperature,
 696 and water transparency were conducted on data for December-May, February-May, and February-May respectively. All abundance
 697 indices are unitless metrics of Longfin Smelt's relative abundance in the San Francisco Estuary. The Fall Midwater Trawl index is
 698 based on data collected during September-December. Bay indices are average results from the San Francisco Bay Study's two
 699 sampling gears; the Bay Age-0 index is based on data collected during May-October, and the Bay Age-2 index is based on data
 700 collected during February-May.

		fish.	
Fall Midwater Trawl	Fall Midwater Trawl survey	Not applicable	The abundance of Age-0 fish
index			affects subsequent survival

708 ^aThis hypothesis was tested by determining if survival from Age-0 to Age-2 could be better predicted by including flows occurring
709 during spawning, e.g., the ratio of Age-2 index in 1982/Age-0 fish in 1980 tested for an influence of the flow during 1982. The
710 influence of freshwater flow on the year in between birth and spawning was also tested, but not found to be statistically significant and
711 is not reported in this paper, for brevity.

712

713 Table 4. Results of linear regression analyses exploring candidate predictors of two versions of the Longfin Smelt recruits-per-
 714 spawner parameter in the San Francisco Estuary. In model 1abc, the response variable was the natural log of Bay-0_{t=0}/Bay-0_{t=2}. In the
 715 other models, the response variable was the natural log of Bay-0_{t=0}/Bay-2_{t=0}. The cells for each candidate predictor variable report if
 716 the variable was tested in each model step, its *p*-value when it was tested, and then whether it was dropped in subsequent steps based
 717 on its *p*-value. Note that the AIC_c from steps 1 and 2 cannot be compared to steps 3-5 due to the increase in sample size in the latter
 718 three steps.

RE: Protest and Objections to the TUCP filed on March 24, 2015 by the Bureau of Reclamation and Department of Water Resources

Dear Mr. Satkowski:

On behalf of the Natural Resources Defense Council and the Bay Institute, we are writing to protest and object to the Temporary Urgency Change Petition filed on March 24, 2015 by the Bureau of Reclamation and Department of Water Resources (“TUCP”).¹ The drought is causing significant hardship to rural communities, farms, and fish and wildlife across the State, and we recognize the need to conserve scarce water resources during the drought and ensure that health and safety needs for water are met. For these reasons we do not object to maintaining minimum 1,500 cfs CVP/SWP exports for health and safety purposes when the projects are otherwise failing to comply with existing water quality standards. Nor do we object to the very limited use of the midstep export exception solely for critical public health and safety purposes, consistent with the Executive Director’s prior TUCP order.

However, continued drought conditions – and the State’s management responses to the drought – are significantly increasing the risk of driving several of California’s native fisheries extinct, and of doing lasting damage to the health of the Bay-Delta estuary. As discussed in our prior protests and objections over the past year and a half, the best available science shows that continued waiver of D-1641 standards during drought conditions is likely to lead to further population declines for several species whose abundance is at some of the lowest levels ever recorded. The reduction in Delta outflow, in particular, is causing significant adverse effects on numerous fish species and the long term health of the estuary. Moreover, the water temperature modeling

¹ The petition was filed for Permits 16478, 16479, 16481, 16482 and 16483 (Applications 5630, 14443, 14445A, 17512 and 17514A, respectively) of the Department of Water Resources for the State Water Project and License 1986 and Permits 11315, 11316, 11885, 11886, 11887, 11967, 11968, 11969, 11970, 11971, 11972, 11973, 12364, 12721, 12722, 12723, 12725, 12726, 12727, 12860, 15735, 16597, 20245, and 16600 (Applications 23, 234, 1465, 5638, 13370, 13371, 5628, 15374, 15375, 15376, 16767, 16768, 17374, 17376, 5626, 9363, 9364, 9366, 9367, 9368, 15764, 22316, 14858A, 14858B, and 19304, respectively) of the United States Bureau of Reclamation for the Central Valley Project.

*NRDC and the Bay Institute Objections to and Protest of TUCP dated March 24, 2015
March 30, 2015*

recently submitted by the Bureau of Reclamation indicates that water diversions for senior contractors and other operations this year will reduce the coldwater pool in Shasta dam, and that operators are likely to again lose temperature control at Shasta Dam, which last year resulted in greater than 95% mortality of endangered winter run Chinook salmon. TUCP, Attachment A at 36 (acknowledging that temperature modeling forecasts “suggest similar impacts as described during the late summer of WY 2014”); *see* Bureau of Reclamation submittal to SWRCB related to Condition 6b of the March 5, 2015 TUCP Order (“Condition 6b Submittal”).

For these reasons, and as discussed further below, we object to and protest the following modifications of D-1641 standards proposed in the TUCP:

1. Modification of the export limit to permit exports greater than 1,500 cfs when D-1641 standards are not being met (except to meet health and safety needs);
2. Modification of the Vernalis pulse flow standard from 3,100 cfs to 710 cfs;
3. Failure to achieve reasonable temperature control to protect endangered winter run Chinook salmon below Shasta Dam in light of proposed operations, including operations for upstream deliveries in April and May.

We urge the SWRCB to deny these elements of the TUCP and to condition approval of the TUCP upon compliance with an operational plan that adequately protects endangered winter run Chinook salmon.²

1. **The SWRCB Should Deny Modification of the Export Limit to Permit Exports Greater than 1,500 cfs When D-1641 Standards are not being met (Except for Health and Safety Purposes) because the Reduction in Delta Outflow Will Cause Unreasonable Effects on Fish and Wildlife:**

The Executive Director has already concluded that approval of increased exports as proposed in the TUCP would cause unreasonable impacts to fish and wildlife. *See* Revised Order dated March 5, 2015 at 6, 27; Order dated February 3, 2015; Executive Director’s Presentation to the SWRCB on February 18, 2015. We agree with the SWRCB’s conclusion in the March 5, 2015 Order that increased exports, except as strictly necessary for health and safety uses, cause unreasonable effects on fish and wildlife.³

Not only would approval of increased exports as proposed in the TUCP increase the risk of entrainment, as discussed in that order, but more importantly, it substantially reduces Delta outflow. We renew our protests and objections filed January 27, 2015 and February 13, 2015. Further reducing Delta outflow, when the minimum D-1641 outflow and X2 standards are not being met, will cause unreasonable effects on fish and wildlife. The TUCP documents that drought conditions, including significantly reduced outflow, in the past few years are already

² In addition, TBI protests and objects to the continuing relaxation of D-1641 objectives for Delta outflow given the dire consequences for numerous resident and migratory estuarine species described in our protest of the 1/23 TUCP and objections to the 2/3 SWRCB Executive Director’s Order.

³ As the SWRCB’s prior orders explain, the fishery agencies’ concurrences under the ESA does not address the SWRCB’s legal obligations under the Water Code, and despite those agency concurrences, the SWRCB appropriately concluded that increased exports would cause unreasonable effects on fish and wildlife. *See* Revised Order dated March 5, 2015 at 5-6, 24-27.

*NRDC and the Bay Institute Objections to and Protest of TUCP dated March 24, 2015
March 30, 2015*

causing higher abundance of nonnative predators like black bass and expansion of *Corbicula* (an invasive clam species whose grazing of plankton substantially reduces important parts of the food chain for native fisheries), as well as promoting harmful algal blooms, reduced reproductive success for native fisheries, and parasitic outbreaks. TUCP, Attachment A at 69. These are many of the same concerns that we have raised in our prior protests.

Yet inexplicably, the biological analysis included in the TUCP largely ignores the impact of reduced outflow on Delta Smelt (focusing instead on entrainment) and it wholly fails to consider analysis in the recent MAST Report showing that reduced spring outflow has a significant adverse effect on delta smelt recruitment and subsequent abundance. With respect to longfin smelt, the TUCP acknowledges that because “increased outflow is one of the best predictors of Longfin Smelt year class strength, ... it is likely the proposed action will exacerbate poor Longfin Smelt recruitment and survival already expected in 2015 due to the severity of the drought.” TUCP, Attachment A at 80. The TUCP acknowledges that reduced outflow will likely reduce survival of threatened and endangered salmon and steelhead as well. *Id.* at 38-40, 46, 48. In addition, the TUCP wholly ignores the impacts of reduced Delta outflow on other species whose survival and abundance is significantly and adversely affected by reduced Delta outflow, including fall run Chinook salmon, Starry Flounder, and Crangon Shrimp. Delta outflow is one of the most dominant drivers of the health of the estuary, and the TUCP (including the proposal for increased exports) will dramatically reduce Delta outflow below the requirements of D-1641. And of course, independent scientists, the SWRCB, California Department of Fish and Wildlife, and other agencies have concluded that the existing outflow and X2 standards of D-1641 are inadequate to fully protect public trust fishery resources. *See* SWRCB 2010; CDFW 2010, 2012.

The best available science shows that the reduction in Delta outflow proposed in the TUCP will cause reduced survival and abundance of numerous fish and wildlife in the Bay-Delta estuary and upstream. This is not something that can be addressed with real time operations, but instead is a function of increased exports at the expense of Delta outflow. The TUCP unreasonably reduces Delta outflow, particularly the proposal to increase exports when D-1641 outflow and X2 standards are not being met. As in our prior protests and objections, we urge the SWRCB to maintain the existing prohibition on CVP/SWP exports in excess of 1,500 cfs when D-1641 water quality standards are not being met, except as necessary for human health and safety, and deny this element of the TUCP.

2. The SWRCB Should Deny Modification of the Vernalis Pulse Flow Standard from 3,100 cfs to 710 cfs Because it will Cause Unreasonable Effects on Fish and Wildlife:

In this TUCP, the agencies propose to reduce the Vernalis pulse flow standard from 3,100 cfs, which is the minimum pulse flow standard that applies only in Critically Dry water year types, to 710 cfs, which is the minimum base flow that applies only in Critically Dry water year types. This effectively eliminates the pulse flow and dramatically worsens conditions for salmon and steelhead in the Lower San Joaquin River and its tributaries as compared to operations approved 2014, which required 15 days of 3,300 cfs and 15 days of 1,500 cfs during the pulse flow period. *See* TUCP Order dated April 11, 2014. As the SWRCB has noted, what constitutes unreasonable effects on fish and wildlife must be considered in the context of other beneficial uses. *See* Revised Order dated March 5, 2015 at 3, 22, 24. And in contrast to Reclamation’s proposal to largely eliminate the Vernalis pulse flow, media reports indicate that the Bureau of Reclamation

*NRDC and the Bay Institute Objections to and Protest of TUCP dated March 24, 2015
March 30, 2015*

will deliver 450,000 acre feet of water to senior water rights holders on the Stanislaus River. See Steve Knell and Jeff Shields, *Irrigation Districts: State could derail delicate Stanislaus water deal*, Modesto Bee, March 28, 2015. In light of the likely impacts to salmon and other fish and wildlife by reducing the Vernalis pulse flow while delivering 450,000 acre feet of water for agricultural beneficial uses, the SWRCB should reject this element of the TUCP because it will cause unreasonable effects on fish and wildlife.

First, the dramatically reduced Vernalis pulse flow proposed in the TUCP will cause unreasonable effects on San Joaquin basin salmon and steelhead. The TUCP acknowledges that reduced flows will reduce survival of migrating steelhead in the San Joaquin River. TUCP, Attachment A at 66. However, the TUCP wholly ignores the effects on fall run Chinook salmon. As the SWRCB is well aware, the best available science demonstrates that lower flows at Vernalis are very likely to cause substantially reduced survival and subsequent abundance of salmon. *See* SWRCB 2010, 2012; CDFW 2012; NMFS 2012; NRDC and the Bay Institute 2013. The low levels are likely to have devastating effects on survival and subsequent abundance of San Joaquin basin salmon and steelhead.

Second, waiver of the Vernalis pulse flow also reduces Delta outflow by several thousand cubic feet per second during the month of April. As discussed above, and in more detail in our prior protests and objections, reduced Delta outflow significantly harms native fish and wildlife. Rejection of this element of the TUCP would likely reduce or avoid unreasonable effects on salmon and steelhead upstream, and the increased outflow benefitting salmon and pelagic species in the Delta would reduce or avoid the effects downstream. It could also result in additional conserved storage at Shasta Dam, if Keswick releases are reduced in light of increased San Joaquin inflow. For all of these reasons, the SWRCB should reject the TUCP proposal to reduce Vernalis pulse flows to 710 cfs.

3. The SWRCB Should Impose Additional Conditions on CVP/SWP to Provide Reasonable Temperature Control to Protect Endangered Winter Run Chinook Salmon Below Shasta Dam in light of Proposed Operations, Including Operations to make Upstream Deliveries in April:

We request that the SWRCB impose additional conditions on CVP/SWP operations that adequately protect winter run Chinook salmon, which likely will need to include reductions in deliveries to senior contractors. The TUCP states that the intent of the proposed modifications to D-1641 water quality standards protecting fish and wildlife is to conserve upstream storage. TUCP at 2. However, the TUCP itself acknowledges that temperature forecasts suggest a repeat of 2014's disastrous conditions for winter run Chinook salmon, *see* TUCP, Attachment A at 36, which resulted in more than 95% mortality of juvenile winter run Chinook salmon. More recent temperature and operational modeling submitted by the Bureau of Reclamation to the SWRCB indicates that operators are unlikely to maintain temperature control this year. *See* Condition 6b Submittal. It is important to recall that Reclamation's temperature model is biased and likely underestimates the resulting water temperatures this fall. *See* NMFS 2014; March 5, 2015 TUCP order at 17, 26, 32; NMFS letter to Reclamation dated January 29, 2015 at 4. The resulting water temperatures this year are likely to cause unreasonable effects to fish and wildlife, including winter run Chinook salmon and other salmon runs spawning below Keswick dam.

*NRDC and the Bay Institute Objections to and Protest of TUCP dated March 24, 2015
March 30, 2015*

That modeling also indicates that Shasta operations, including operations in April and May, are likely to result in reservoir releases that are substantially higher than that needed for temperature control, impacting end of September reservoir storage and the size of the coldwater pool for winter run and other salmonids. *See* Condition 6b Submittal. Contrary to assertions made at prior SWRCB hearings, it is clear from this modeling that reservoir releases are greater than what are necessary to meet temperature compliance. For instance, in April, the Bureau of Reclamation proposes that reservoir releases would 5,600 cfs (Scenario 6b(1) and Scenario 6b(4)), whereas the water temperature focused Scenario 6b(2) and Scenario 6b(3) would result in releases of 3,250 cfs. *Id.* at 4. Reclamation's proposed operations for April 2015 would result in substantially higher reservoir releases than in April 2014 and indicate that reservoir releases to meet senior water rights are greater than necessary to meet temperature control. The same appears to be true with respect to meeting the outdated Wilkins Slough standard under Reclamation's proposed operations, as well as the magnitude of releases in the summer months. *Id.* As a result, it is clear that CVP/SWP deliveries, including water deliveries to senior contractors, are substantially contributing to unreasonable effects on fish and wildlife below Shasta Dam. We note in this regard that the Bureau of Reclamation proposes to deliver more than 2.6 million acre feet of water to senior agricultural contractors,⁴ in addition to DWR's 20% State Water Project allocation and deliveries to DWR settlement contractors on the Feather River.

The SWRCB has a continuing obligation to protect winter run Chinook salmon and other species spawning below Shasta Dam, and the prior TUCP Order directs Reclamation "to ensure that temperature control on the Sacramento River for salmonids is maintained throughout the year and that issues encountered last year with temperature control are factored into that planning." *See* March 5, 2015 TUCP Order at 22. That TUCP Order also explicitly reserves authority of the SWRCB to require modifications to the order to protect fish and wildlife. *Id.*; *see id.* at 25-26 (acknowledging that Order WR-95 requires Reclamation to operate its facilities on the Sacramento River to achieve temperature control for salmon). In light of the temperature modeling that has been provided, the SWRCB should immediately order Reclamation to modify proposed Shasta Dam operations to ensure adequate temperature control later in the year, including the following measures:

- Limit Shasta Dam releases in April and May to minimum reservoir releases (3,250 cfs) unless necessary for temperature control or health and safety purposes;
- Reduce flows at Wilkins Slough below 3,800 cfs unless necessary for temperature control or for health and safety purposes;
- Reduce releases from Shasta in the summer months unless necessary for temperature control or for health and safety purposes, and consider increased reliance on reservoir releases from Oroville.

The SWRCB should not approve the TUCP without imposition of additional conditions that ensure Shasta operations adequately protect winter run Chinook salmon and other salmon runs spawning below Shasta Dam.

⁴ *See* Bureau of Reclamation, Central Valley Project (CVP) Water Quantities with 2015 Allocation, available online at: http://www.usbr.gov/mp/PA/water/docs/1_CVP_Water_Quantities_Allocation.pdf (last visited March 30, 2015).

*NRDC and the Bay Institute Objections to and Protest of TUCP dated March 24, 2015
March 30, 2015*

Conclusion:

California's drought, currently in its fourth year, continues to cause significant hardship and impacts to rural communities, agriculture, and the State's fish and wildlife. However, if granted in its current form, implementing the TUCP will exacerbate the impacts of four years of drought to a level that causes unreasonable effects on fish and wildlife. The SWRCB should reject those elements noted above and impose additional conditions to ensure that temperature control below Shasta Dam can be maintained.

We greatly appreciate the SWRCB's consideration of our views.

Sincerely,

Doug Obegi

Green and white sturgeon

ABSTRACT

A comparative examination of potential differences in selenium (Se) sensitivity was conducted on two sturgeon species indigenous to the San Francisco Bay-Delta. Juvenile green (*Acipenser medirostris*), recently given a federally threatened status, and white sturgeon (*Acipenser transmontanus*) were exposed to one of four nominal concentrations of dietary L-selenomethionine (SeMet) (0 (control), 50, 100, or 200 mg SeMet/kg diet) for 8 weeks. Mortality, growth performance, whole body composition, histopathology, and Se burdens of the whole body, liver, kidneys, gills, heart, and white muscle were determined every 2 to 4 weeks. Significant ($p < 0.05$) mortality was observed in green sturgeon fed the highest SeMet diet after 2 weeks, whereas no mortality was observed in white sturgeon. Growth rates were significantly reduced in both species; however, green sturgeon was more adversely affected by the treatment. Dietary SeMet significantly affected whole body composition and most noticeably, in the decline of lipid contents in green sturgeon. Selenium accumulated significantly in all tissues relative to the control groups. After 4 and 8 weeks of exposure, marked abnormalities were observed in the kidneys and liver of both sturgeon species; however, green sturgeon was more susceptible to SeMet than white sturgeon at all dietary SeMet levels. Our results showed that a dietary Se concentration at 19.7 ± 0.6 mg Se/kg, which is in range with the reported Se concentrations of the benthic macro-vertebrate community of the San Francisco Bay, had adverse effects on both sturgeon species. However, the exposure had a more severe pathological effect on green sturgeon, suggesting that when implementing conservation measures, this federally listed threatened species should be monitored and managed independently from white sturgeon.

1. Introduction

Green (*Acipenser medirostris*) and white sturgeon (*Acipenser transmontanus*) are two sturgeon species native to the San Francisco Bay Delta (SFBD) and both have exceptional biological, commercial, and ecological values (Moyle, 2002). Their populations, however, have been in steady decline since the nineteenth century (Billard and Leconte, 2001). Recently, green sturgeon was listed as a species of special concern by the State of California and a threatened species by the United States Federal Government (California Natural Diversity Database (CNDDB), 2006). Elevated concentrations of chemical contaminants found in their diets are

considered one of the primary causes of their decline (National Marine Fisheries Service, 2006).

Selenium (Se) is a major water contaminant in SFBD. It is an essential micronutrient for all vertebrates (NRC, 2005), as it is a major component of glutathione peroxidase, an enzyme that protects lipid membranes from oxidative damages at the cellular and subcellular levels (Arteel and Sies, 2001). However, at a slightly higher concentration, dietary Se is toxic to many aquatic animals (Lemly, 2002, 1985; Skorupa, 1998; Steward et al., 2004). In SFBD, major Se inputs include waste discharges originating from petrochemical and industrial manufacturing operations. The most significant source, however, is from irrigated agricultural practices on the seleniferous soils of the Central Valley (Lemly, 2004).

Most field surveys on SFBD sturgeon populations have been conducted on white sturgeon due to their larger natural population. Several such reports have noted elevated tissue Se concentrations [Se]s (up to 30 $\mu\text{g/g}$ dry weight (dw) in the liver and 15 $\mu\text{g/g}$ dw in the muscle; Urquhart and Regalado, 1991; Linville et al., 2002) in these animals. Similar tissue Se levels have been reported to cause toxic effects in freshwater and anadromous fish (Lemly, 2002).

³ These authors contributed equally to this work.

In contrast, very little is known about Se toxicity and tissue burden in green sturgeon. Although the two species are closely related, they exhibit different responses to environmental contaminants. Recent studies have demonstrated a higher sensitivity to dietary methylmercury (MeHg) in green sturgeon compared with white sturgeon (Lee et al., 2011, 2012). Therefore, information with regards to the physiological responses of green sturgeon to environmental contaminants, in general, should not be simply extrapolated from that of white sturgeon. The objective of our current study was to determine and compare the effects of elevated concentrations of dietary L-selenomethionine (SeMet) on the growth performance, tissue burden, and histopathology of juvenile green and white sturgeon.

2. Materials and methods

2.1. Diet preparation

Four isoenergetic and isonitrogenous purified diets were prepared according to Tashjian et al. (2006) and Lee et al. (2011). Different concentrations of L-selenomethionine (Fisher Scientific, Pittsburgh, PA) were added to a basal diet mixture to constitute the four nominal levels of 0 (control), 50, 100, and 200 mg SeMet/kg diet. These SeMet concentrations were chosen to span the range of projected dietary [Se]s in SFB (Luoma and Presser, 2000) and the selenocompound was chosen as it is the predominant Se form found in natural diets of white sturgeon (Fan et al., 2002). Furthermore, previous studies have indicated that toxic responses in animals fed SeMet were similar to those fed diets containing naturally incorporated Se compounds (Hamilton, 2004).

2.2. Animal acquisition, experimental design, and animal maintenance

The acquisition, maintenance, handling, and sampling of animals were approved by the Campus Animal Care and Use Committee at the University of California, Davis and are as described by Lee et al. (2011). Due to the different spawning and hatching times of the two sturgeon species, the two experiments were conducted consecutively, with the green sturgeon experiment conducted between June 20th and August 8th, 2007, and the white sturgeon experiment between August 29th and October 17th, 2007. In brief, 300 juvenile sturgeon (mean weight of 30 ± 2 g) were used in each of the two experiments and they were randomly distributed into twelve 90-L tanks, resulting in 4 dietary groups with 3 replicate tanks per treatment. Daily rations of 3% body weight/day (BW/d) for the first 4 weeks and 2% BW/d for the second 4 weeks (Cui and Hung, 1995) were placed in an automatic feeder (Cui et al., 1996; Hung and Lutes, 1987) which dispensed feed continuously over 24 h. Water temperature, pH, and dissolved oxygen were maintained at 18–19 °C, 7–8, and 7–9 mg/L, respectively. The effluent water was sampled weekly and [Se] was determined by a certified laboratory (BSK Analytical Laboratory, Fresno, CA, using EPA 200.8 method) and ranged from undetectable to 4.2 µg/L.

2.3. Growth performance, tissue sampling, proximate composition and selenium analysis

Fish were batch weighed on a weekly basis and feed rations were adjusted accordingly. Growth performance, tissue sampling, and diet and tissue [Se]s were determined as previously described by Lee et al. (2011) and Huang et al. (2012). For [Se] analysis, each sample was analyzed in triplicates with one replicate spiked with a sodium selenate standard to verify Se recovery. Dolt-4 (National Research Council Canada) was analyzed simultaneously

with the experimental samples and the observed concentration (6.89 mg Se/kg dw) was within the certified standard range (7.06 ± 0.48 mg Se/kg dw). The [Se]s determined in the 0, 50, 100, and 200 mg SeMet/kg diet were 2.2 ± 0.2 , 19.7 ± 0.6 , 40.1 ± 1.5 , and 77.7 ± 3.6 mg Se/kg dw, respectively. Whole body samples were lyophilized and pulverized prior to proximate composition and energy content determinations, which were determined according to AOAC, 1984, 1995, respectively.

2.4. Tissue processing and light microscopy procedures

After 4 and 8 weeks of exposure, three fish from each tank were randomly captured and euthanized with an over-dose of tricaine methanesulfonate solution (1 g/L, Argent Chemical Laboratories, Redmond, WA). Gills, heart, liver, trunk kidneys, and skeletal muscle were surgically removed, fixed, sectioned, stained, examined, and photographed according to Lee et al. (2012).

2.5. Statistical analysis

Statistical analyses were conducted using JMP 7.0 statistical software program (SAS Institute, Cary, NC). A two-way analysis of variance with interactions was used to test for significant differences among the four dietary SeMet concentrations and between the two sturgeon species. The Tukey's honestly significant difference test was used for multiple comparisons among dietary SeMet concentrations and between the two species at each time point. Statistical significance was tested at the 0.05 probability level, and all values are presented as the mean \pm standard error unless noted otherwise.

3. Results

3.1. Mortality and growth performance

Significant mortality was observed in green sturgeon fed the 200 mg SeMet/kg diet from week 2 and by week 8, mortality was also seen in the 100 SeMet/kg diet group (Table 1). At the end of the study, green sturgeon exhibited a mortality of 7.7% and 23% at the 100 and 200 mg SeMet/kg diet treatments, respectively. In contrast, no mortality was observed in the white sturgeon.

Growth rates (% BW/d) were reduced significantly in both species. After 8 weeks, green sturgeon showed depressed growth rates in all the treatment groups, when compared with the control. In contrast, white sturgeon showed depressed growth rates only at the 100 and 200 mg SeMet/kg diet treatment groups. Although growth rate was significantly higher in the control green sturgeon group, compared with that of the white sturgeon, green sturgeon was more sensitive to SeMet than white sturgeon, at all dietary SeMet levels.

Similarly, by week 8, hepatosomatic index (HSI) of green sturgeon exposed to the two upper SeMet treatments was significantly decreased compared with the control. In contrast, dietary SeMet had no significant effect on the HSI in white sturgeon.

3.2. Whole body proximate composition

Significant increases in moisture content were observed in green sturgeon fed the two highest SeMet diets. Similarly, whole body crude protein, lipid and energy contents were also significantly reduced in these treatment groups (Table 2). In white sturgeon, significant increase, compared with the control, was observed in whole body moisture content in the 200 mg SeMet/kg diet group. Significant decreases were observed in lipid contents at the 100 and 200 mg SeMet/kg diet groups. Similar decrease in energy content was also observed at the 200 mg SeMet/kg diet group.

Values represent the mean ± SE ($n = 3$), and different letters denote significant differences ($p < 0.05$) among treatments and species within the exposure period. Initial body composition (%): Moisture 83.0 ± 0.6 and 80.2 ± 0.8 , crude protein 10.5 ± 0.3 and 9.9 ± 0.4 , lipid 1.8 ± 0.2 and 5.3 ± 0.2 , energy (kcal/g) 5.1 ± 0.1 and 6.3 ± 0.1 in green sturgeon and white sturgeon, respectively. Initial whole body Se concentrations in green and white sturgeon were 7.2 ± 0.3 and 4.8 ± 0.5 mg Se/kg dry weight (dw), respectively.

Moisture, lipid, and energy contents of green sturgeon were significantly different from those of white sturgeon at all levels of dietary SeMet. Noticeably, crude protein contents of green sturgeon fed the 100 and 200 mg SeMet/kg diets were significantly lower than those of white sturgeon in the same treatment groups. However, the most significant differences were observed in crude lipid contents between the two species.

3.3. Se burden

Different patterns in whole body Se burden were also observed between the two species (Table 2). White sturgeon accumulated Se in a dose and duration-dependent manner. In contrast, whole body Se in green sturgeon did not increase much after week 4 and there was no obvious dose-dependent Se accumulation. Pattern of Se accumulation among tissues were also different between the two species (Tables 3a and 3b). Selenium levels in the gills and kidneys of green sturgeon showed little increase after week

2 and week 4, respectively. In the white muscle, however, [Se] was found to have increased in a dose dependent manner up to the 100 mg SeMet/kg diet level. Liver [Se] increased continuously throughout the 8 weeks, except in those fed the 200 mg SeMet/kg diet, where [Se] decreased after reaching a concentration asymptote at week 6. Similarly in the heart, [Se] plateaued after reaching a maximum concentration at week 4. In contrast, tissue Se burden of white sturgeon generally increased with increasing exposure duration. In the 200 mg SeMet/kg diet group, the highest Se levels were observed at week 6. The highest tissue Se levels in green sturgeon were observed in the liver, whereas the highest Se levels in white sturgeon were seen in the kidneys.

3.4. Histopathological alteration

Histological examination showed progressions of marked lesions in the kidneys and liver of both species after each sampling period (Tables 4 and 5 and Figs. 1 and 2). Mild histological changes

were noted in the skeletal and heart muscles (results not shown). However, no prominent histological changes were observed in the gills of either species at all times.

3.4.1. Trunk kidney

After exposure to dietary SeMet, the kidneys of both sturgeon species exhibited marked histological changes, compared with the controls. These changes included increased tubular epithelium degeneration (TED), renal corpuscular disintegration (CD), and interstitial tissue degeneration (ITD) (Table 4 and Fig. 1c–h). Tubular epithelium degeneration was mainly characterized by hydropic degeneration, pyknosis, and cell necrosis (Fig. 1c, e, and h). Characterization of CD included the collapse of glomerular capillary loop,

hypertrophy of mesangial cells, thickening of Bowman's capsule layers, and collapse or enlargement of Bowman's space (Fig. 1c, e, and h). Lastly, ITD was identified by necrotic area and loss of tissue (Fig. 1g and h). In general, pathological alterations of the kidneys were proportional to the dose and duration of SeMet exposure.

Compared with week 4, both species displayed a more severe and higher frequency of TED, CD, and ITD in the kidneys at week 8 (Table 4). The most serious damage occurred in the tubular epithelium as TED for both species (Table 4 and Fig. 1). Although some of the lesion scores were the same between the two species, green sturgeon exhibited more severe kidney pathology in all of the SeMet treatment groups (Table 4).

Table 4
Kidney histopathological alterations of green and white sturgeon exposed to a graded levels of dietary selenomethionine (SeMet) for 4 and 8 wk.

	mg SeMet/kg diet							
	Control		50		100		200	
	Green sturgeon	White sturgeon	Green sturgeon	White sturgeon	Green sturgeon	White sturgeon	Green sturgeon	White sturgeon

	Histopathology at 8 wk							
GD	0	0	++	0	+++	+	+++	++
VD	0	0	++	+	++	++	+++	++

Lesion severity scoring: 0 = absent or rarely observed, + = mild (affected less than 10%), ++ = moderate (affected greater than 10% but less than 50%), +++ = severe (affected greater than 50%). GD, glycogen depletion; VD, vacuolar degeneration including single cell necrosis. N=9.

3.4.2. Liver

After 4 weeks, the livers of both species showed marked histological alterations, including glycogen depletion (GD) and vacuolar degeneration (VD) (Table 5 and Fig. 2). In both species, the progression of the aforementioned alterations was generally proportional to the dose and duration of exposure. However, between the two species, the green sturgeon livers exhibited more severe GD and VD (Table 5 and Fig. 2c–h).

4. Discussion

4.1. Mortality and growth depression

In the current study, green sturgeon exhibited significant higher mortalities at the highest SeMet treatment, which is equivalent to a 78 mg Se/kg diet. However, similar to Tashjian et al. (2006), who reported a mean survival rate of $99 \pm 4\%$ in white sturgeon exposed to diets containing up to 191 mg Se/kg for an 8 week period, no significant mortalities were observed among white sturgeon in the current study. Although green sturgeon appeared to be more sensitive to dietary Se, the mortality rate was still lower than that of other fish species. A mean mortality of 37.5% was observed in Chinook salmon parr (*Oncorhynchus tshawytscha*) after an 8.6-week exposure to a 35.4 mg Se/kg diet (Hamilton et al., 1990). Arshad et al. (2011) reported a mean mortality of 25% in juveniles of beluga sturgeon (*Huso huso*) exposed to dietary Se at levels between 1.26 and 20.26 mg/kg for 8 weeks.

Compared with white sturgeon, the significantly higher mortality in the green sturgeon may be a consequence of their higher initial growth. Deng et al. (2002) reported faster growth rates in juvenile green sturgeon when compared with white sturgeon of similar age. As faster growth rate reflects a higher energy demand,

the green sturgeon may have been in an overall lower energy state, especially since the diets were provided in a fixed daily ration and adjusted on a weekly basis. The low HSI, whole body lipid and energy content, and glycogen storage in the hepatocytes are all indicative of the low energy reserves in the green sturgeon.

Compared with other fish species from similar studies, green sturgeon exhibited a more severe growth rate depression. At 8 weeks, green sturgeon fed the 50 and 100 mg SeMet/kg diets (equivalent to 19.7 and 40.1 mg Se/kg diet, respectively) had their average growth rates reduced to 39% and 12% of that of the controls, respectively. In contrast, growth rates of Chinook salmon parr were only reduced to 77.9% and 37.3%, when given an 18.2 and 35.4 mg Se/kg diet in the form of SeMet for 60 days (Hamilton et al., 1990). Interestingly, juvenile beluga sturgeon fed a 20.26 mg Se/kg diet, in the form of SeMet, for 8 weeks, exhibited increased growth rates (Arshad et al., 2011). The observed reduction in growth among the green sturgeon may be a combined physiological response to: (1) the higher energy demand during the rapid initial growth phase and (2) energy relocation/adaptation to chronic Se toxicity. Thus, reduced growth is likely a physiological tradeoff for achieving a comparatively lower Se-induced mortality, as to what were seen in the aforementioned studies.

4.2. Whole body proximate composition

Proximate analysis is a good indicator of the overall physiological condition of a fish (Ali et al., 2005). In the present study, changes in proximate composition, most notably the significant decreases in protein, lipid, and energy contents, indicated that both species were experiencing physiological stress induced by dietary SeMet exposure. However, the treatment effect was more severe on green sturgeon, as the white sturgeon seemed to be in an overall better

All scale bars = 50 μ m.

physiological condition, given the higher lipid and energy contents of their control group.

Chemical contaminants have been shown to induce physiological stress in teleosts. [Beyers et al. \(1999\)](#) reported that largemouth bass (*Micropterus salmoides*) utilize energy relocation to compensate for the additional energetic costs associated with toxic exposures. As described in Selye's general adaptation syndrome ([Selye, 1955](#)), the authors observed a two stage energy relocation in the largemouth bass: first, an allocation of resources from somatic and reproductive growth, which have little effect on the

overall energy status of the animal; and second, the allocation of body reserves such as somatic lipid and protein, which can put the animal in an energy-deficient state. Furthermore, when the stressor persists for sufficient length of time and magnitude, the animal would inevitably enter exhaustion, the third and final stage of stress adaptation ([Selye, 1955](#)).

At the two highest dietary SeMet levels, physiological assessments indicated that green sturgeon were in the exhaustion stage. Characteristics such as glycogen depletion of hepatocytes, increased histopathology in the liver and kidneys, depressed

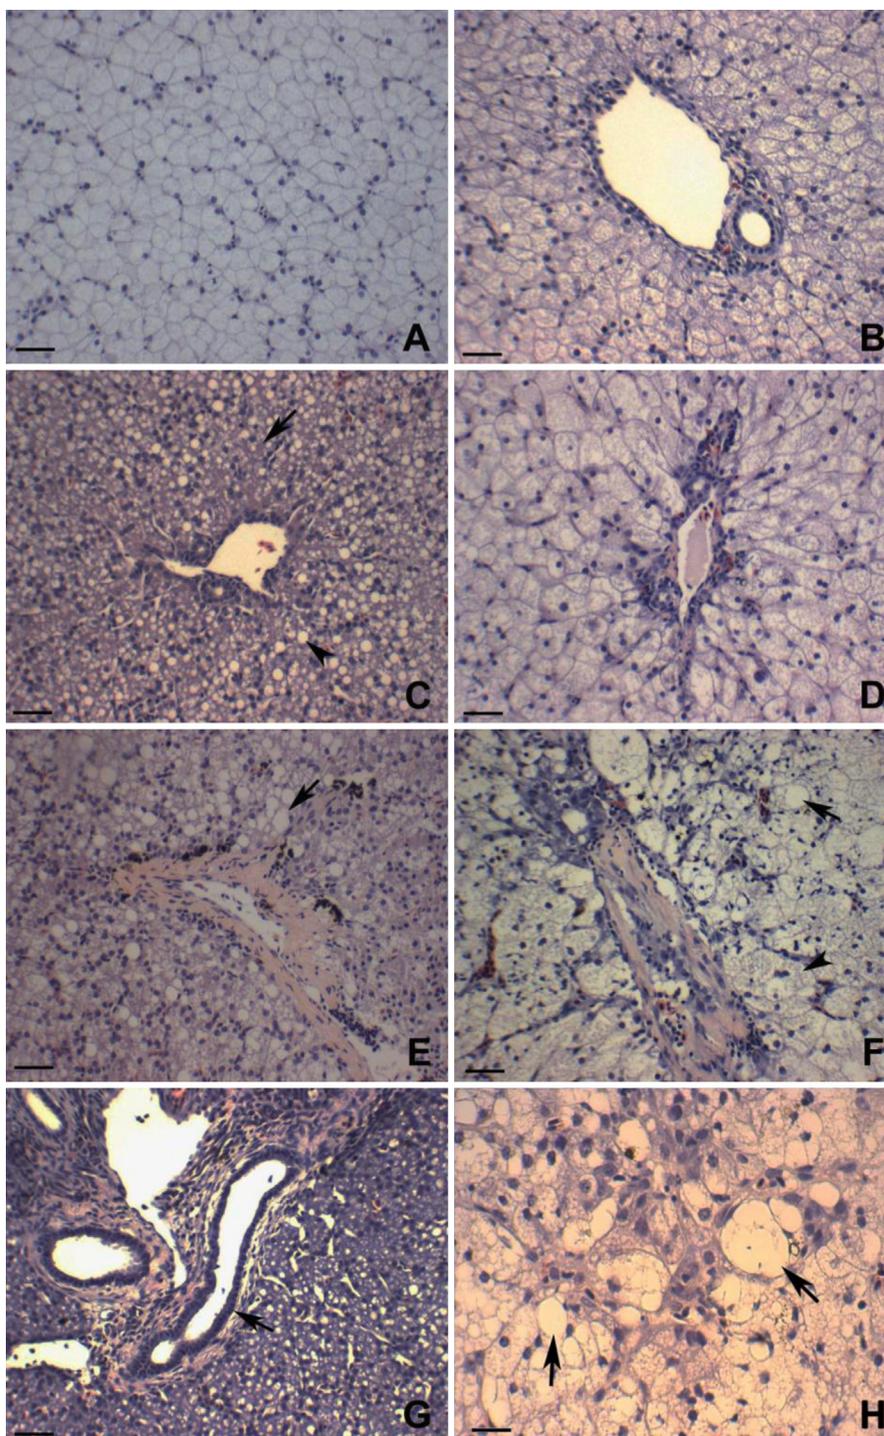

Fig. 2. The liver of *Acipenser medirostris* (left) and *A. transmontanus* (right) stained with hematoxylin/eosin: (A) and (B): Livers of individuals from control groups. growth rates, and increased mortality were observed in these animals. By week 4, the animals have entered the second stage of energy mobilization, as seen in the largemouth bass (Beyers et al., 1999), in which more body constituents, such as lipid and protein, were utilized to meet the additional energy cost associated with Se toxicity. In comparison, the white sturgeon seemed to remain in the resistance state, given that their protein levels remained unaffected by SeMet. Furthermore, their body lipid contents were also

significantly higher. The species difference, again, may be due to the rapid initial growth phase of juvenile green sturgeon, in which the associated high metabolic cost led to a comparatively more energetically vulnerable status. The exact cause of the observed reduction in body lipid is unknown, however, as multiple factors such as reduced food intake due to unpalatability of SeMet enriched feed and increased energy demand for Se detoxification may be involved.

4.3. Se burden

In general, whole body Se burden increased with dietary Se level and exposure duration; however, by week 4, the extent of Se bioaccumulation have slowed down in green sturgeon (Table 2). Avoidance to Se-contaminated food has been reported in waterfowl (Heinz and Sanderson, 1990) and teleost species (Hilton et al., 1980). Unpalatability of foods containing high concentrations of Se was suggested as a factor leading to food avoidances observed in birds and fish species (Ogle and Knight, 1989). In the current study, decreased feeding was noted in green sturgeon, from week 4 onwards, in the two highest SeMet groups. However, similar observation was not made during the first 4 weeks of exposure. Other Se toxicity mechanisms, such as musculature dysfunction may have also contributed to decreased food consumption in this study. Substitution of methionine (Met) by SeMet, in the disulfide bond of muscle actin filament, can generate radical oxygen species (ROS) leading to mechanical malfunction of the organ (Dalle-Donne et al., 2001; Palace et al., 2004). Histological changes observed in the white muscle of both sturgeon species (results not shown) in this study support possible musculature malfunctioning. Similarly, SeMet substitution may have also occurred in the heart muscle, as indicated by mild histological changes in the heart tissues (results not shown), and may have compromised the cardiovascular function of these animals. Thus, it is more likely that the decrease in feeding observed in the latter 4 weeks, the starvation effect, was a secondary effect of Se toxicity, such as locomotor dysfunction, rather than unpalatability relating to the high SeMet content.

The highest Se burden was observed in the green sturgeon livers, at 6 weeks. However, the high liver [Se] may be a combined effect of decreased HSI (half the size of that of the controls), negative growth rates (%BW/d), and decreased food consumption. Lee et al. (2011) reported similar findings in juvenile green sturgeon fed various levels of dietary MeHg for 8 weeks. Regardless of the mechanisms leading to the high organ Se accumulation, extensive liver damages were observed and likely were important factors contributing to the significant growth rate decline observed in green sturgeon and their subsequent high mortality.

Urine is the primary excretion route for Se. Although mammals can also excrete excess Se via feces and exhalation, the urine plays a quantitatively greater role in whole body Se homeostasis (Ellis et al., 1997; Ivancic and Weiss, 2001). Similarly, urine is also the primary Se excretory pathway in white sturgeon (Huang et al., 2012). In the current study, the significantly higher Se burden observed in white sturgeon kidneys suggests a more active depuration of Se (compounds) relatively to that of green sturgeon. However, study on both species using oral intubation and intravenous injection methods demonstrated similar SeMet assimilation and metabolism among the sturgeon (Silas S.O. Hung, University of California at Davis, unpublished date). Thus, the Se concentration plateau observed in the green sturgeon kidneys at post week 4 was likely due to decreased feed consumption rather than decreased urinary Se.

4.4. The trunk kidney

Histological changes in the kidneys in fish have been previously studied and are reliable and sensitive biomarkers for a wide variety of chemical exposures, including SeMet (Sorensen et al., 1984; Handy and Penrice, 1993; Thophon et al., 2003). In this study, the kidneys of sturgeon exposed to SeMet showed marked abnormalities, including TED, CD, and ITD. Collapsed glomerular capillaries, mesangial cell hypertrophy, abnormally abundant matrixes, thickened Bowman's capsule layers, and collapsed or enlarged Bowman's space were also observed in the renal corpuscles of SeMet exposed sturgeon. Similar damages were reported

in green sunfish (*Lepomis cyanellus*) from Se-contaminated lakes (Sorensen et al., 1982, 1984) and in striped bass (*Morone saxatilis*) fed Se-contaminated live feed (Coughlan and Velte, 1989).

The extensive kidney lesions seen in both sturgeon species can be attributed to the primary excretory role of Se compounds (Suzuki, 2005) of the organ. The significant increase in green sturgeon whole body moisture content may be indicative of a compromised osmoregulation, given the extensive damages seen in the tubular epithelium. Other factors such as deprivation of energy and higher damages in the livers may also have contributed to the severe kidney lesions observed in green sturgeon, despite having a comparatively lower kidney Se burden compared to the white sturgeon.

4.5. Liver

The livers of both sturgeon species exposed to SeMet treatments exhibited adverse histological changes such as GD and VD, and are consistent with the histopathological lesions reported by Tashjian et al. (2006). Swollen hepatocytes and vacuolation were also reported in livers of green sunfish exposed to Se-elevated water (Sorensen et al., 1982, 1984). Reproductive failure was noted in the study and marked population decline followed suit. In the current study, the extent of the liver lesions may have also affected organ function, as seen in the decreased hepatocyte glycogen storage. Such will have an effect on glycogenesis and glycolysis, leading to an interruption of energy metabolism, as supported by the decrease in whole body energy content, growth, and the higher mortality in green sturgeon.

In addition, GD and single cell necrosis were also reported in Sacramento splittail (*Pogonichthys macrolepidotus*) fed SeMet-supplemented diets (Teh et al., 2004). Significant glycogen depletion was suggested as a result of increased liver glycogenolysis due to the excessive energy demand for repairing SeMet-induced damage and/or reduced food intake (Teh et al., 2004). Significant GD seen in the current study is thought to be an adaptation by the sturgeon to meet the high energy demand when exposed to high levels of dietary SeMet.

Laboratory studies reported hepatic oxidative stress in mallard ducks (*Anas platyrhynchos*) exposed to dietary SeMet (Hoffman, 2002). Increased dietary Se elevated plasma and hepatic GSH peroxidase activities, followed by an increased ratio of oxidized to reduced glutathione (GSSG:GSH) and hepatic lipid peroxidation. The oxidative effects were associated with teratogenesis, reduced growth, diminished immune function, and histopathological lesions. Similarly, oxidative stress is believed to have induced the histological changes observed in the current study. Deposition of dark pigments, which is thought as indicators of oxidative stress in northern pike (*Esox Lucius*; Drevnick et al., 2008), were also observed in the livers of sturgeon in the highest SeMet treatment groups and were found to be especially numerous in green sturgeon. Thus, liver damage, likely a result of Se-induced oxidative stress, may be a major factor contributing the higher susceptibility to Se toxicity by the green sturgeon in this study.

It is possible that the comparatively faster initial growth rates of juvenile green sturgeon have resulted in their energetically vulnerable states. As growth requires an increase in protein synthesis, green sturgeon may have experienced a higher frequency of Met substitution by SeMet in their functional proteins. Consequently, normal physiological functions may have been compromised by an increase in non-functional proteins, as well as the associated oxidative stress. The high energetic demands of their initial growth phase may have also compromised the species' ability to repair damages induced by Se Toxicity, leading to the stunted growth and higher mortality observed during the latter part of exposure trial.

5. Summary

The objective of this study was to compare the effects of high Se diets in the juvenile stage of two sturgeon species native to SFB. Effects on growth parameters and histopathological alterations clearly indicated that green sturgeon is more sensitive to Se-laden diets compared with white sturgeon. Furthermore, the low SeMet diet (19.7 ± 0.6 mg Se/kg dw), which caused severe adverse effects in green sturgeon, is similarly to that of the levels found in SFB benthic macro-invertebrates, which are a major dietary component of young sturgeon. As such, our results suggest that juvenile green sturgeon is more sensitive to Se toxicity and should be monitored and managed separately from white sturgeon when developing conservation measures to protect this threatened SFB population segment from Se exposure.

Acknowledgment

Funding for this study was provided by CalFed Project number SP2006–035 and partially by P.O.R. Sardegna F.S.E. 2007–2013—Axis IV—L.a. I.3.1. and Fondazione Banco di Sardegna, Italy. We are also grateful for the technical assistance provided by Paul Lutes and Eric Hallen of the Center of Aquatic Biology and Aquaculture at the University of California, Davis. The infrastructure support of the Department of Animal Science and the College of Agriculture and Environmental Sciences of the University of California, Davis was also acknowledged.

Abstract

Many factors have been implicated in the decline of Delta Smelt *Hypomesus transpacificus* in the upper San Francisco Estuary, and the importance of each factor is difficult to determine using field data alone. We describe a spatially explicit, individual-based population model of Delta Smelt configured for the upper estuary. The model followed the reproduction, growth, mortality, and movement of individuals over their entire life cycle on the same spatial grid of cells as the Delta Simulation Model (DSM2) hydrodynamics model. Daily values of water temperature, salinity, and densities of six zooplankton prey types were represented on the spatial grid. Reproduction was evaluated daily, and new individuals were introduced into the model as yolk sac larvae. Growth of feeding individuals was based on bioenergetics and zooplankton densities. Mortality sources included natural mortality, starvation, and entrainment in water diversion facilities. Movement of larvae was determined using a particle tracking model, while movement of juveniles and adults was based on salinity. Simulations were performed for 1995–2005. The baseline simulation was generally consistent with the available data. Predicted daily fractions of larvae entrained and annual fractions of adults entrained were similar in magnitude to data-based estimates but showed less interannual variation. Interannual differences in mean length at age 1 had large effects on maturity and subsequent egg production. Predicted and observed spatial distributions in the fall showed moderately good agreement for extremely low- and high-outflow years. As indicated by the population growth rate, 1998 was the best year and 2001 was the worst year. Water year 1998 (i.e., October 1997–September 1998) was characterized by fast growth in fall 1997, low entrainment, and high stage-specific survival rates, whereas water year 2001 had opposite conditions. Our analysis further shows how multiple factors can operate simultaneously to result in the decline in abundance of Delta Smelt.

Understanding the critical drivers and environmental changes that influence the population dynamics of fish is vital for effective resource management and restoration. Most fish species live multiple years and show ontogenetic shifts in the habitats they utilize, which exposes them to multiple environmental and biological factors spread over several points in their life cycle (Rose 2000). Identification of the relative importance of these factors and how they may interact with each other is an important step toward understanding and managing fish populations. A major debate is underway about the status of many harvested marine and coastal fish populations (Myers and Worm 2003; Hilborn 2007; Worm et al. 2009), as human development of coastal areas (McGranahan et al. 2007) and demand for high-quality freshwater (Vörösmarty et al. 2000) continue to accelerate. Identification of the major factors affecting population dynamics (especially declines in population) is critical because the high economic costs of protection and restoration demand efficient and effective responses.

The need to understand mechanisms of population decline for Delta Smelt *Hypomesus transpacificus* in the San Francisco Estuary is critical. This endemic species is listed as threatened under the U.S. Endangered Species Act and is listed as endangered under the California Endangered Species Act. Delta Smelt have generally been at low abundance since the 1980s and showed an even further sharp decrease starting in about 2002 (Bennett 2005; Sommer et al. 2007; Thomson et al. 2010). Delta Smelt have also become the focus of contentious debate because of perceived conflicts between the conservation of this species and the operation of facilities that divert water from the Delta Smelt's habitat for agricultural and urban uses (Brown et al. 2009; NRC 2010). These facilities alter seasonal patterns of flow, and they entrain and kill large numbers of Delta Smelt (Kimmerer 2008).

Many factors may be involved in the decline of Delta Smelt, and quantifying the importance of each factor has proven to be elusive despite the availability of extensive long-term field data (NRC 2012). Factors examined as possible contributors to the decline include entrainment of Delta Smelt by the two large water diversion facilities in the Sacramento–San Joaquin River Delta (hereafter, “the Delta”), shifts in the composition and densities of the zooplankton (prey) community, and changes in physical habitat related to salinity and turbidity (Baxter et al. 2010). A sharp decline in four fish species (juvenile Striped Bass *Morone saxatilis*; Longfin Smelt *Spirinchus thaleichthys*; Threadfin Shad *Dorosoma petenense*; and Delta Smelt) within the upper San Francisco Estuary beginning in approximately 2000 led to a substantial effort at synthesizing existing data to determine the cause (Sommer et al. 2007). The results to date have narrowed the possible factors to some extent (e.g., contaminant effects are likely small) and have facilitated the conclusion that the recent decline in Delta Smelt was due to multiple factors acting together (Baxter et al. 2010). Two statistical analyses (Mac Nally et al. 2010; Thomson et al. 2010) examined the dynamics of the four fish species by using mon-

itoring data collected from the 1970s to 2007. Both analyses, which used similar data but different statistical methods, showed several covariates that were related to abundance of the fish, but they could not resolve the cause of the recent declines.

An alternative approach to the analysis of the effects of multiple factors on fish populations is simulation modeling of the growth, mortality, reproduction, and movement processes underlying the population dynamics. Population modeling allows the investigator to control everything and thus to perform simulation experiments for isolating the effects of individual factors and for exploring the effects of previously unobserved combinations of conditions (Rose et al. 2009). However, model results must be interpreted with caution because models are always simplifications of reality, and their predictions can be biased by decisions about which processes to include and at what temporal and spatial scales to represent those processes.

In this paper, we describe a spatially explicit, individual-based population model of Delta Smelt configured for the upper San Francisco Estuary. We chose this approach because many of the factors that are thought to contribute to the Delta Smelt's decline vary in space (Baxter et al. 2010), and simulating fish movement is more straightforward with an individual-based approach than with other modeling approaches (Tyler and Rose 1994). We first briefly describe the San Francisco Estuary and the life cycle of Delta Smelt. We then describe the spatial grid, environmental conditions, and reproduction, growth, mortality, and movement processes that are represented in the individual-based model. Hydrodynamic model output for the spatial grid and field data for temperature, salinity, and zooplankton densities were used as inputs to the population model for simulation of the period 1995–2005. The results of the baseline simulation are compared with the observed data, and we contrast the conditions between a “good year” and a “bad year” for Delta Smelt growth and survival within the baseline simulation. We conclude with a discussion of our results relative to other analyses and the strengths and weaknesses of our current model formulation. In our companion paper (Rose et al. 2013, this issue), we show that the results presented here are robust to alternative baseline assumptions, and we further explore the factors causing good and bad years by using a simulation experiment approach.

UPPER SAN FRANCISCO ESTUARY AND DELTA SMELT

The San Francisco Estuary is the largest estuary on the U.S. Pacific coast, with a watershed covering approximately 40% of California (Figure 1). The estuary connects the Sacramento and San Joaquin rivers through San Francisco Bay to the Pacific Ocean. Freshwater enters via the Sacramento River from the north and the San Joaquin River from the south; the confluence is roughly the landward limit of ocean salt penetration (Kimmerer 2004). We focus on the upper portion of the estuary (including the Delta and Suisun Bay), which encompasses the entire range of the Delta Smelt.

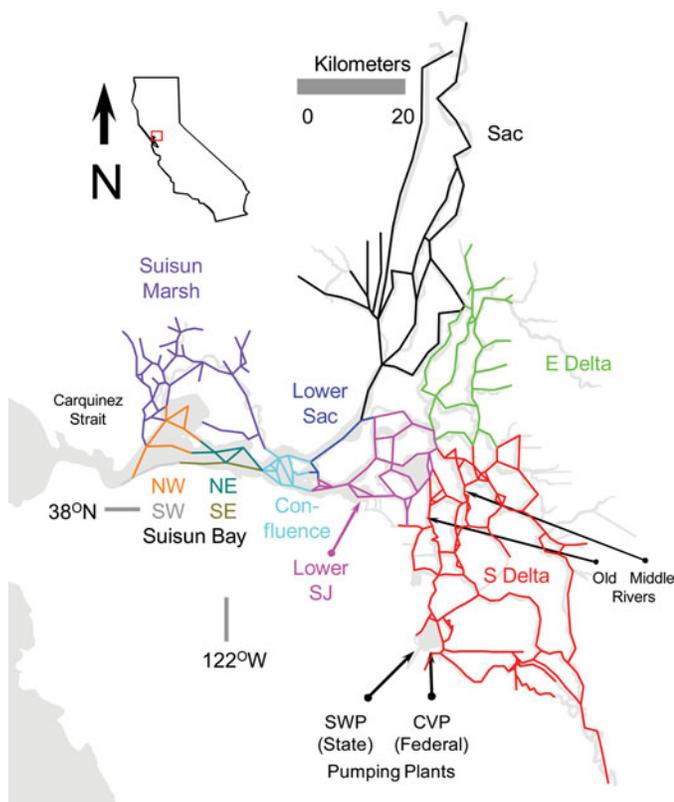

FIGURE 1. Location of the San Francisco Estuary, California, and the spatial grid and boxes used in the model. Gray represents the outline of the estuary. The 11 boxes are color coded and refer to (in numerical order): (1) Sacramento River region (Sac) of the Sacramento–San Joaquin Delta; (2) eastern Delta (E Delta); (3) southern Delta (S Delta); (4) lower Sacramento River region (Lower Sac); (5) lower San Joaquin River region (Lower SJ); (6) confluence (westernmost box in the Delta); (7) southeast Suisun Bay (SE); (8) northeast Suisun Bay (NE); (9) Suisun Marsh; (10) southwest Suisun Bay (SW); and (11) northwest Suisun Bay (NW). Additional labels show the Old River, Middle River, Carquinez Strait, and the State Water Project (SWP) and Central Valley Project (CVP) pumping plants.

The San Francisco Estuary has been described as one of the most highly altered estuarine ecosystems in the world (Nichols et al. 1986; Lund et al. 2010). Over the past 150 years, approximately 95% of the marshes surrounding the estuary have been isolated from tidal action, and numerous nonnative species have been introduced—some with substantial ecological effects (e.g., Nichols et al. 1990; Winder and Jassby 2011). The Delta, which formerly consisted of tidal marsh, is now a complex network of linked channels and sloughs surrounding islands that are protected by a constructed levee system. During the past 60 years, the upper estuary has increasingly been managed through large-scale manipulation of river flows in order to provide freshwater for agricultural, municipal, and industrial uses.

The two large water diversions in the south Delta have exported an average of 30% of the available flow into the Delta during 1960–2000, with the percentage generally increasing through time and exceeding 60% in some years and seasons

(Kimmerer 2004). The State Water Project (SWP) facility provides drinking water for over 23 million Californians, and together the two diversion facilities (the SWP and the Central Valley Project [CVP]) fuel an estimated $\$25 \times 10^9$ annual agricultural economy (Grimaldo et al. 2009). Elaborate fish recovery facilities attempt to screen fish from the diverted water but with mixed success (Kimmerer 2011). All of these changes have substantially altered both the physical and ecological aspects of the system (Nichols et al. 1986; Hollibaugh 1996; NRC 2012).

The life history of the Delta Smelt is summarized briefly here based on several sources (Moyle et al. 1992; Moyle 2002; Bennett 2005). The Delta Smelt has a relatively unusual life history strategy (Bennett 2005), as it exhibits the small size and short life span that are typical of an opportunistic life history strategy, but it has low reproductive rates that are more similar to those of an equilibrium strategist (Winemiller and Rose 1992). The Delta Smelt's life history also somewhat resembles those of salmonids (McCann and Shuter 1997) but without parental care. The geographic range of the Delta Smelt is confined to the upper San Francisco Estuary. It is primarily an annual species but with some small fraction of the population surviving a second year to spawn. Spawning takes place in freshwater during February–May at temperatures between 12°C and 20°C; spawning appears to be clustered in 2-week intervals, presumably related to the spring–neap tidal cycle. Eggs are demersal and attached; larval stages generally rear in freshwater before being transported to brackish waters, which are typically located between the confluence of the San Joaquin and Sacramento rivers and Carquinez Strait at the seaward margin of Suisun Bay (Figure 1). All life stages remain at a salinity of about 0.5–6.0 psu (the low-salinity zone) until the end of the year, when migration to freshwater begins. Delta Smelt eat primarily zooplankton throughout their lives, although adults also eat epibenthic crustaceans, such as amphipods. Delta Smelt are consumed by a variety of fish, principally visual predators.

MODEL DESCRIPTION

Overview

The model followed the reproduction, growth, mortality, and movement of individual Delta Smelt over their entire life cycle on a spatial grid of cells (Figure 1). The spatial grid was a one-dimensional network of 517 channels and 5 reservoirs used in the Delta Simulation Model (DSM2) hydrodynamic model (California Department of Water Resources [CDWR]). This one-dimensional model simulates non-steady-state hydrodynamics in a network of channels and has been widely used for analyses and water supply planning for the Delta (Kimmerer and Nobriga 2008). Simulations from DSM2 provided (1) hourly water velocities and water levels at the ends of channels and (2) hourly water flows into and out of the reservoirs. Daily water temperature, salinity, and densities of six zooplankton prey types as estimated from field data were also represented on the same spatial grid.

Each 365-d model year began on October 1, the start date for each water year. Individuals were aged on January 1 of each year. Whenever we refer to a year, it is the year that includes the summer period (e.g., model year 1996 extended from October 1, 1995, to September 30, 1996). Multiyear simulations were performed using reproduction to introduce the new individuals each year.

Reproduction was evaluated daily during the spring spawning season, and eggs developed as a daily cohort at a temperature-dependent rate. Upon hatching, new yolk sac larvae were pooled for each day and were introduced as model individuals. Individuals developed through life stages of yolk sac larva, larva, postlarva, juvenile, and adult. Growth was based on bioenergetics and zooplankton densities in the grid cells. Mortality included a stage-specific mortality rate, starvation, and mortality due to entrainment at the water diversion facilities. Movement of yolk sac larvae, larvae, and postlarvae was determined hourly by using a particle tracking model (PTM) that incorporates water velocities from the DSM2 hydrodynamic model. Movement of juveniles and adults was based entirely on a behavioral response to salinity, and the locations of individual fish on the grid were updated every 12 h.

All simulations used hydrodynamic conditions, temperature, salinity, and zooplankton densities for the period 1995–2005. This period was selected because (1) it encompasses the main period of Delta Smelt decline, (2) hydrodynamic simulations were available, and (3) field data on zooplankton and Delta Smelt were relatively complete.

Environment

A second grid of 11 coarser boxes was overlaid onto the channel grid (Figure 1) so that the more sparsely sampled field data could be used to specify daily water temperature, salinity, and zooplankton densities. The 11 boxes were determined based on previously identified regions of hydraulic similarity (e.g., Miller et al. 2012) and the availability of enough stations to ensure that at least several stations were present in each box.

Daily values of temperature, salinity, and zooplankton densities were estimated for each box and then were assigned to each channel within each box on each day (see details in Supplement A in the online version of this article). Final daily temperature and salinity values for each box are shown in Figure 2 for a year with high freshwater outflow (1998) and a year with low freshwater outflow (2001). All channels within a given box were assigned the box values. Temperature did not vary much among sampling stations within boxes, and the sampling density was too low to represent the within-box (channel-level) spatial gradients in salinity.

The food environment was represented by the biomasses of six zooplankton types: adults of *Limnoithona* spp. (calanoid copepods), calanoid copepodids, other calanoid adults, adult *Eurytemora* (calanoid copepods), adult *Acanthocyclops vernalis* (cyclopoid copepods), and adult *Pseudodiaptomus* (calanoid copepods). We included random variation when we used the

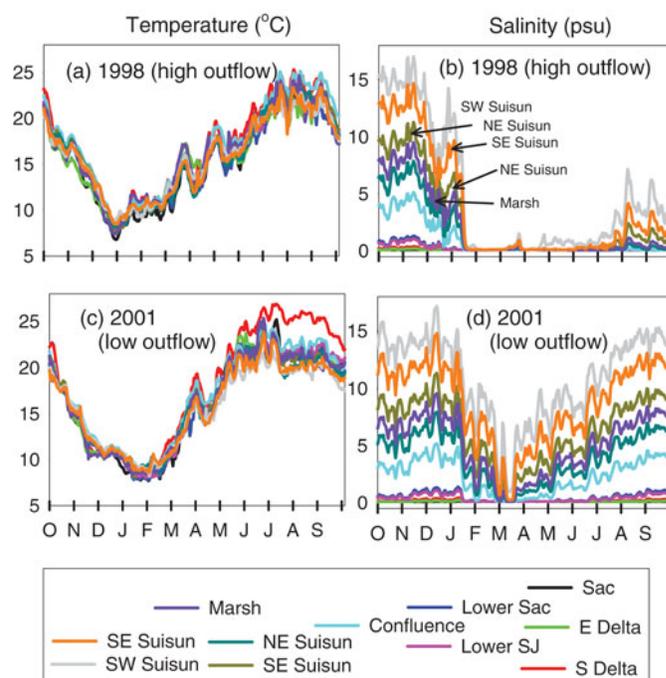

FIGURE 2. Daily temperature and salinity values in each box for (a), (b) 1998 (a year of high outflow) and (c), (d) 2001 (a year of low outflow). See Figure 1 for definition of box abbreviations. [Figure available online in color.]

boxwide mean to assign values to the channels within each box (see Supplement A). Daily zooplankton biomass densities in each box are presented for the same high-outflow (Figure 3) and low-outflow (Figure 4) years as were shown for temperature and salinity.

Spawning

Each female individual that was longer than 60 mm TL at the start of the spawning season was allowed to spawn up to two times within the spawning season. We used a simple threshold of 60 mm because it was well supported by data (Bennett 2005) and because the manner in which maturity varies around the 60-mm length was uncertain. We explore a smoother maturity function in our companion paper (Rose et al. 2013).

The earliest day of spawning was first determined each year on October 1 by looking ahead at temperatures and finding the first day on which temperature exceeded 12°C in any box. On the earliest possible day of spawning in each year, a temperature of first actual spawning was assigned to each mature individual from a uniform distribution between 12°C and 20°C. To mimic the clustering of spawning on spring–neap tidal cycles, an individual spawned at the end of the 14-d tidal cycle that followed the day when water temperature in that individual's channel exceeded its assigned spawning temperature. By the time of spawning, the migratory movement algorithm based on salinity had put adults near or into freshwater boxes.

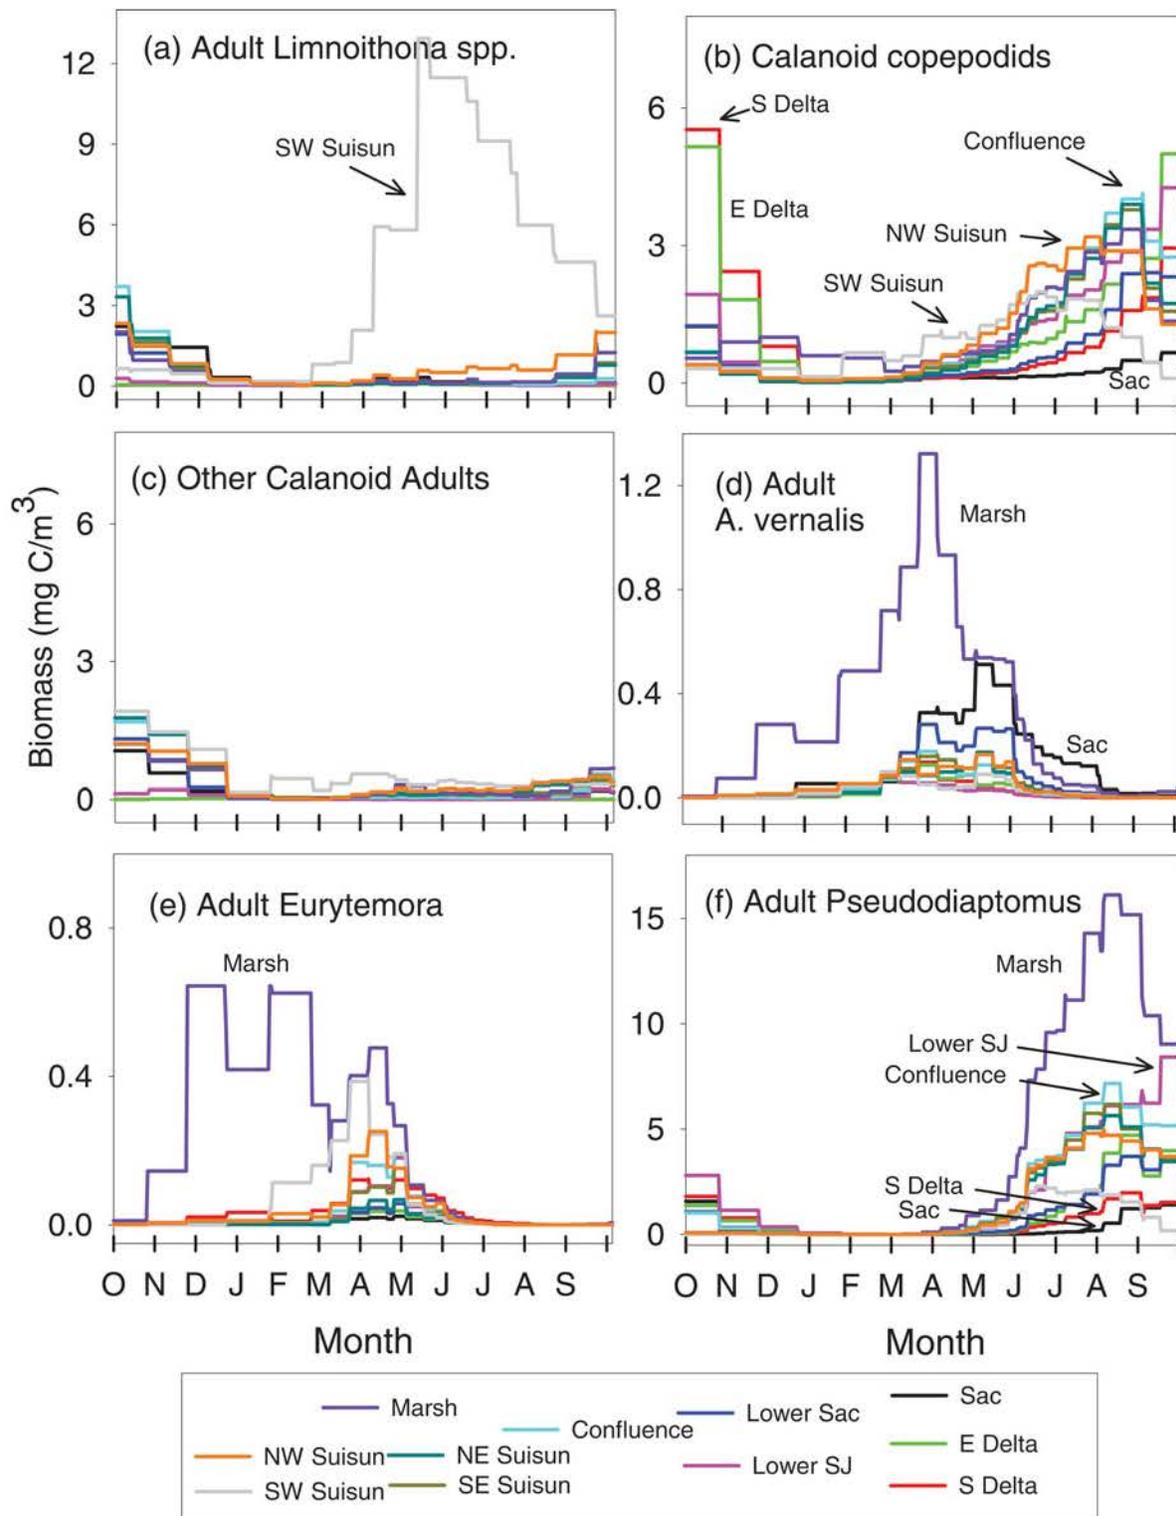

FIGURE 3. Daily biomass density values (mg C per m³ of water) for each of the six zooplankton groups in each spatial box during a year of high outflow (1998): (a) adults of *Limnoithona* spp., (b) calanoid copepodids, (c) other calanoid adults, (d) adult *Acanthocyclops vernalis*, (e) adult *Eurytemora*, and (f) adult *Pseudodiaptomus*. See Figure 1 for definition of box abbreviations. [Figure available online in color.]

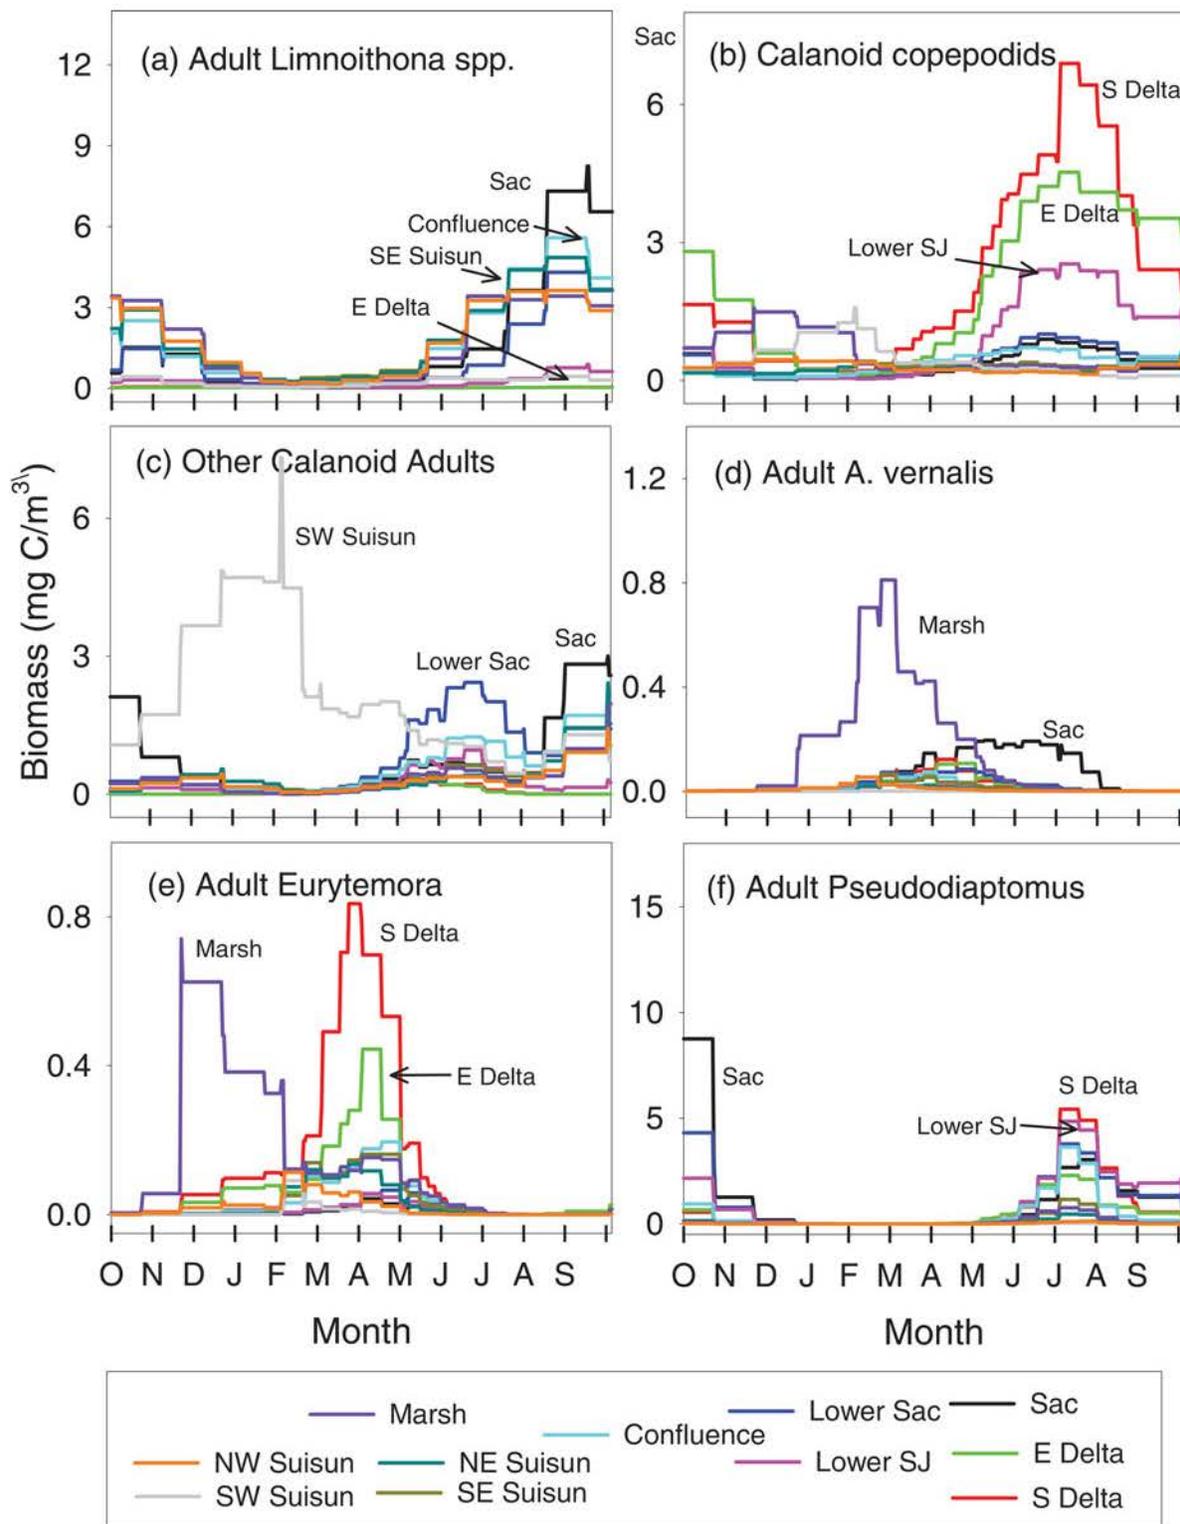

FIGURE 4. Daily biomass density values (mg C per m³ of water) for each of the six zooplankton groups in each spatial box during a year of low outflow (2001): (a) adults of *Limnoithona* spp., (b) calanoid copepodids, (c) other calanoid adults, (d) adult *Acanthocyclops vernalis*, (e) adult *Eurytemora*, and (f) adult *Pseudodiaptomus*. See Figure 1 for definition of box abbreviations. [Figure available online in color.]

Fecundity (D ; eggs/female) depended on the individual's weight on the day of spawning (Bennett 2005),

$$D = 175.4e^{\frac{L_{equiv}}{28.3}}, \quad (1)$$

where L_{equiv} (mm) is the length based on the actual weight of the fish. Upon spawning, the body weight of the individual Delta Smelt was reduced by 15%. We treated males the same as females (i.e., spawning temperatures and weight loss), but without any contribution of eggs, to produce similar weights at age.

After their first spawning event, females were evaluated daily to determine whether they would spawn a second time. Second spawning occurred if (1) the individual had regained enough weight (>95% of the weight expected from its length), (2) 14 or more days had passed since the first spawning, and (3) it was not too late (too warm) in the season for that individual to spawn in its box. The last possible day of spawning in each box was calculated as the first day after temperature exceeded 20°C plus 14 d to allow for the final tidal cycle to complete. The fecundity relationship used for the second spawning was the same as that for the first spawning, and weight was again reduced by 15%.

Eggs

Each female's first and second (if it occurred) spawns of eggs were followed separately as cohorts until hatching, when they became yolk sac larvae. Day of hatching was determined for each cohort by accumulating the daily fractional egg development (DV_e) until the degree of development exceeded 1.0. The daily fractional development towards hatching was based on temperature (Bennett 2005),

$$DV_e = \frac{1}{28.1 - 1.1 \cdot T}, \quad (2)$$

where T is the daily temperature (°C) in the box where spawning occurred. Spawning box temperature (which varied daily) was used because the eggs are attached. All eggs in each cohort that was spawned in a given box on a given day hatched on the same day. Daily egg mortality rates (M ; d^{-1}) were calculated by converting hatch rates observed at constant temperature in the hatchery to daily mortality (Bennett 2005),

$$M = \frac{-\log(s)}{DV_e} \quad (3)$$

and

$$s = -2.35 + 0.45 \cdot T - 0.016 \cdot T^2, \quad (4)$$

where s is the survival fraction through the egg stage.

Yolk Sac Larvae

Beginning with yolk sac larvae, new model individuals were created and followed for the rest of their lives. New individuals

were created from all those that hatched in each box on each day, and they were distinguished by whether they came from a first or second spawning event. Length (L ; mm) at hatch depended on the temperature on the day of hatching (Bennett 2005),

$$L = 5.92 - 0.05 \cdot T. \quad (5)$$

Weight (g wet weight) at hatch was determined from a field-based length–weight relationship (Kimmerer et al. 2005):

$$W = 0.005 \cdot L^3. \quad (6)$$

Similar to the method used for eggs, the duration of the yolk sac larval stage was determined by accumulating the daily fractional development (DV_y) of each model individual based on the temperature in its box (Bennett 2005) until the cumulative development exceeded 1.0:

$$DV_y = \frac{1}{7.53 - 0.08 \cdot T}. \quad (7)$$

Daily mortality rate of yolk sac larvae was assumed constant ($0.035 d^{-1}$) and was a key parameter adjusted as part of model calibration.

Feeding Life Stages: Development and Bioenergetics

Larvae became postlarvae at 15 mm, and postlarvae became juveniles at 25 mm; juveniles then became age-1 adults and age-1 adults from the previous year advanced to age 2 on January 1 (Bennett 2005). Age-2 adults were removed from the model just before attaining age 3. Larval to postlarval development coincided with the development of a swim bladder, and the juvenile stage marked the appearance of fin folds and an association with the low-salinity zone.

The daily growth of each feeding individual was represented by a difference form of the Wisconsin bioenergetics model (Ney 1993; Hanson et al. 1997),

$$W_t = W_{t-1} + (C - R - F - U - SDA) \cdot W_{t-1} \cdot \frac{e_p}{e_s} - Sp \cdot W_{t-1}, \quad (8)$$

where W is the weight of each individual, C is the realized consumption rate, R is the total metabolic rate, F is egestion, U is excretion, SDA is specific dynamic action, and Sp is loss due to spawning. All rates except Sp were in units of grams of prey per gram of Delta Smelt per day ($g \text{ prey} \cdot g \text{ smelt}^{-1} \cdot d^{-1}$ in wet weight); Sp was the fraction of weight lost (0.15) and occurred only on the day of spawning. The e_p and e_s terms (J/g) were used to convert grams of prey per gram of Delta Smelt to grams of smelt per gram of smelt, which was then multiplied by weight (W) to yield the weight change in grams of Delta Smelt per individual per day. The value of e_s was fixed at 4,814 J/g, while e_p was computed each day based on the fraction of *Limnoithona* in

the diet. All zooplankton groups had an energy density of 2,590 J/g; the exception was *Limnoithona*, for which energy density was assumed to be 30% lower (1,823 J/g) because Delta Smelt grow more slowly when fed *Limnoithona* (Lindsay Sullivan, San Francisco State University, personal communication).

Total length (L ; mm) was obtained from weight by using equation (6). Length was partially uncoupled from weight because length was allowed only to increase, whereas fish could lose weight. On days of weight gain, length was increased only after the individual's weight equaled that expected from its length. Thus, fish were allowed to become skinny but not fat.

Maximum consumption (C_{max}) depended on an individual's weight (W) and the water temperature (T):

$$C_{max} = a_c W^{b_c} f(T). \quad (9)$$

The temperature adjustment to maximum consumption ($f[T]$) increased from a value of CK_1 at temperature CQ to 0.98 at temperature T_O and then stayed at 0.98 until temperature reached T_M , after which the adjustment declined to CK_4 as temperature approached T_L (Table 1).

Realized consumption by the i th fish (C_i) was a functional response that depended on C_{max} and the densities of each zooplankton group j (prey density, PD_j) in the same channel as the fish:

$$C_{ij} = \frac{C_{max} W_i \left(\frac{PD_j \cdot V_{ij}}{K_{ij}} \right)}{1 + \sum_{k=1}^6 \left(\frac{PD_k \cdot V_k}{K_{ik}} \right)} \quad (10)$$

and

$$C_i = \sum_{j=1}^6 C_{ij}, \quad (11)$$

where C_{ij} is the daily rate of consumption of the j th prey type (six zooplankton groups) by individual fish i ; V_{ij} is the vulnerability of prey type j to fish i ; and K_{ik} is the half-saturation constant for fish i feeding on each prey type k . Equations (10) and (11) allowed an individual fish to consume multiple prey types without exceeding its maximum consumption. Vulnerabilities (V_{ij}) were set to 1.0 for all life stages eating all zooplankton types; the exception was Delta Smelt larvae, for which V_{ij} values of zero were used for all adult prey groups other than *Limnoithona* spp. The K -values were calibrated outside of the model to obtain diet and consumption rates that appeared realistic (Supplement B in the online version of this article).

The total metabolic rate (R) was an allometric function of weight and used an exponential relationship ($g[T]$) to adjust metabolism for temperature:

$$R = a_r W^{b_r} \cdot g(T), \quad (12)$$

where

$$g(T) = e^{(R_Q \cdot T)}. \quad (13)$$

Egestion (F) was a constant fraction of consumption, while SDA and excretion (U) were fractions of net assimilated energy

TABLE 1. Parameter values for each Delta Smelt life stage in the bioenergetics model.

Parameter	Description	Larvae	Postlarvae	Juveniles and adults
Maximum consumption (C_{max})				
a_c	Weight multiplier	0.18	0.18	0.1
b_c	Weight exponent	-0.275	-0.275	-0.54
CQ (°C)	Temperature at CK_1 of maximum	7	10	10
T_O (°C)	Temperature at 0.98 of maximum	17	20	20
T_M (°C)	Temperature at 0.98 of maximum	20	23	23
T_L (°C)	Temperature at CK_4 of maximum	28	27	27
CK_1	Effect at temperature CQ	0.4	0.4	0.4
CK_4	Effect at temperature T_L	0.01	0.01	0.01
Metabolism (R)				
a_r	Weight multiplier	0.0027	0.0027	0.0027
b_r	Weight exponent	-0.216	-0.216	-0.216
R_Q	Exponent for temperature effect	0.036	0.036	0.036
S_d	Fraction of assimilated food lost to SDA	0.175	0.175	0.175
Egestion (F) and excretion (U)				
F_a	Fraction of consumed food lost to egestion	0.16	0.16	0.16
U_a	Fraction of assimilated food lost to excretion	0.1	0.1	0.1

($C - F$; Table 1):

$$F = F_a \cdot C, \quad (14)$$

$$SDA = S_d \cdot (C - F), \quad (15)$$

and

$$U = U_a \cdot (C - F). \quad (16)$$

During calibration, we adjusted the bioenergetics parameter values developed for Rainbow Smelt *Osmerus mordax* (Lantry and Stewart 1993) until we obtained growth that was realistic for Delta Smelt. We adjusted the allometric and temperature-related parameter values of maximum consumption (a_c , b_c , CQ , T_O , T_M , and T_L in Table 1) and the temperature parameter that affected respiration (R_Q in Table 1). We determined parameter values that satisfied two conditions: (1) realistic daily growth rates and optimal temperatures for growth for mid-stage-sized larvae, juveniles, and adults; and (2) realistic weights and lengths for an individual that had grown from first feeding through age 2 under daily average temperatures and a consumption rate (C) that was equal to 0.8 of the maximum (i.e., proportion of maximum consumption [p -value] = 0.8; $C = p\text{-value} \times C_{max}$). The final bioenergetics rates for the mid-stage-sized larvae, postlarvae, juveniles, and adults are shown in Supplement B.

Mortality

Mortality occurred from stage-specific mortality rates (M), starvation, entrainment losses at the two water export pumping facilities, and old age. Stage-specific mortality rates represented predation and other causes of mortality not explicitly calculated from starvation or entrainment. Daily instantaneous mortality was temperature dependent for eggs (equations 3 and 4); M was set at 0.035 for yolk sac larvae (calibrated), 0.05 for larvae, 0.03 for postlarvae, 0.015 for juveniles, and 0.006 for adults. Starvation occurred if the weight of an individual fell below 50% of the weight expected from its length. Upon reaching age 3 (i.e., the individual's third January 1), the individual died from old age and was removed from the population.

Entrainment mortality for all life stages except eggs occurred when an individual entered Clifton Court Forebay (reservoir number 4; SWP) or arrived at node 181 (CVP; Figure 1). Yolk sac larvae, larvae, and postlarvae were transported there by the PTM, whereas juveniles and adults were unaffected by hydrodynamic conditions except through salinity. Use of only those individual juveniles and adults that arrived at the SWP and CVP by behavioral movements based on salinity resulted in underestimation of the numbers entrained by the pumping facilities. Delta Smelt are recovered at the south Delta fish facilities at higher rates when daily net flow in the southern Delta (Middle and Old rivers) is southwards toward the SWP and CVP (Grimaldo et al. 2009; Kimmerer 2011). Therefore, juveniles and adults that were located in the south Delta box (box 3) of the model were exposed to additional entrainment mortality

of 0.02 d^{-1} whenever the daily averaged flow in Middle River (downstream end of channel 90; Figure 1) was southward. The value of the added mortality (0.02 d^{-1}) was determined as part of model calibration.

Movement

Yolk sac larvae, larvae, and postlarvae were transported by water velocities on the spatial grid hourly by using a particle tracking approach, whereas juveniles and adults were moved every 12 h by using a kinesis approach to behavioral movement.

The PTM was a recoded version of the CDWR's PTM and used the same formulations (Wilbur 2000; Miller 2002). The CDWR's PTM has been used to examine entrainment impacts (e.g., Kimmerer and Nobriga 2008) and has been compared with other PTMs (Gross et al. 2010). Our recoded version used as input the hourly values of velocity at each end of each channel and the water level at each node that was generated by the DSM2 hydrodynamic model. The PTM kept track of the hourly positions of particles (the three larval stages) in three dimensions: along-channel (x = distance [m] from the upstream end of a channel), lateral (y = distance [m] from the center line of the channel), and vertical (z = distance [m] from the bottom of the channel). The y and z positions within a channel were altered by random perturbations and were used to adjust the x -direction velocity (Supplement C in the online version of this article).

Day-to-day movements and seasonal migrations of juveniles and adults were based on a kinesis approach (Humston et al. 2000, 2004), with salinity used as the cue. Salinity was used to simulate reasonable distributions of individuals within the system, but salinity did not directly affect growth or mortality. Rather, salinity was used to distribute individuals realistically, and individuals then experienced the local conditions (temperature and prey densities) in the channels.

Only the along-channel (x) position was tracked for juveniles and adults. At each 12-h time step, each individual's x position was updated, and its channel or reservoir location was determined. Kinesis represents the distance moved by each individual as the sum of an inertial component (IC) and a random component (RC), with the inertial component dominating when conditions (salinity) are good and the random component dominating when conditions are poor. The position in the x dimension (m from the upstream end of the channel) was updated every 12 h as

$$x_{t+1} = x_t + \Delta x_t \quad (17)$$

and

$$\Delta x_t = IC + RC, \quad (18)$$

where IC is the inertial component that depends on the movement velocity at the last time step (Δx_{t-1}), and RC is the random component based on fish swimming speed.

To compute IC and RC , we first computed the functions (f and g) that defined the degree to which salinity (S) in the box deviated from optimal salinity,

$$f(S) = H_1 \cdot e^{-0.5 \cdot \left(\frac{S-S_O}{\sigma_s}\right)^2} \quad (19)$$

and

$$g(S) = 1 - H_2 \cdot e^{-0.5 \cdot \left(\frac{S-S_O}{\sigma_s}\right)^2}, \quad (20)$$

where S_O is the optimal value of salinity (2.0 psu); σ_s ($= 3.0$) determines how quickly the function decreases as salinity deviates from its optimal value; and the H -values are constants (0.75 and 0.90) that define the maximum values of the functions. Inertial velocity (IC) was then computed using the distance moved in the last time step (Δx_{t-1}) and $f(S)$:

$$IC = \Delta x_{t-1} \cdot f(S), \quad (21)$$

Equation (21) results in the individual moving at the same total velocity (inertial and random combined) as in the last time step to the degree that conditions (salinity) are favorable; $f(S)$ is larger when salinity is near the optimal value (equation 19).

The random component of distance moved (RC) was computed based on $g(S)$ and a random component (r):

$$RC = r \cdot g(S). \quad (22)$$

The random component r was calculated as

$$r = N(0, 1) \cdot \frac{d}{2} + d \quad (23)$$

with

$$d = \sqrt{\frac{(0.001 \cdot L \cdot \Delta t \cdot 60 \cdot 60)^2}{2}}, \quad (24)$$

where r is a normal deviate with a mean of d and an SD of $d/2$. The numerator in equation (24) represents the distance (m) moved during one 12-h time step, assuming a swimming speed of 1.0 body length/s. The parameter d computed by equation (24) is typically about 70% of the distance to account for fish not swimming in a straight line. The probability of up-estuary movement (P_{up}) was specified as 0.50; for each individual and each time step, a random uniform number was compared with P_{up} to determine the x direction of movement (seaward or up-estuary) in a channel. The distance moved in that direction was determined by the computed velocity of the individual (Δx_i ; equation 18).

If individuals moved past the end of a channel, they then entered a node where they either continued into a new channel or entered a reservoir. The new channel or reservoir was randomly selected from all those connected to the node, regardless

of flow (Supplement C). Individuals were simply started at the beginning of a new channel. Supplement D (in the online version of this article) shows the results of testing the behavioral movement with simplified salinity patterns on the model grid.

Up-estuary migrations of adults and seaward migrations of juveniles were simulated using the above kinesis approach by changing S_O (equations 19 and 20) and P_{up} . On December 15 of each year, the spawning migration to freshwater began by changing S_O from 2 to 0 psu and by setting P_{up} to 0.85 (rather than 0.50) so that more moves were in the up-estuary direction. On May 1, the migration of adults and juveniles back to low-salinity water was simulated by setting S_O back to 2 psu and setting P_{up} to 0.15. Once individuals reached their new optimal salinity, P_{up} was switched back to 0.50.

Numerics

We used a super-individual approach (Scheffer et al. 1995) in order to accurately simulate the addition of new yolk sac larvae each year while ensuring that we did not exceed computer limitations (Supplement E in the online version of this article). Each super-individual represented some number of identical individuals in the population, which we term its "worth." Each year during spawning, the same number of super-individuals was added, but with their initial worth adjusted to reflect the yolk sac larvae produced. Mortality acted to decrement the worth of an individual, with the worth then being used to determine population-level numbers of eggs spawned and Delta Smelt densities and abundances. We used a complicated algorithm for determining how to allocate the fixed number of super-individuals each year among hatch dates and boxes (Supplement E). In all simulations, we used 150,000 super-individuals per age-class (450,000 super-individuals total) because this was sufficient for convergence (i.e., almost identical results were obtained when we followed more super-individuals). The model was coded in FORTRAN90.

Computation of Population Growth Rate

We used the individual-based model output to estimate a simple Leslie age-based matrix model for each year, which allowed us to summarize the multidimensional individual-based model results with a single variable of annual finite population growth rate (λ). The value of λ was based on the detailed dynamics of the individual-based model but allowed for easier comparison among years. A 2×2 matrix model was estimated for each year by computing the average maturity, fecundity, and age-specific survival rates (Supplement F in the online version of this article); eigenvalue analysis was then used to determine λ . The value of λ for a specific year is a measure of the conditions for Delta Smelt during that year. The λ value is also a reflection of conditions from the previous year by indicating how growth in the fall prior to spawning affected the elements related to maturity and fecundity in the matrix.

TABLE 2. Calculation of the major model output variables examined in Delta Smelt model simulations and the calculations for the data when model–data comparisons were performed. The corresponding figures for the results are noted; “text” means the results are described in the text.

Variable	Model calculations	Data calculations
(a) January adult abundance (Figure 5)	Summed worth of all individuals on January 1; includes young of the year that just became age 1 and age-1 fish that just became age 2 but does not include age-2 fish that were just removed as they became age 3.	Catch per trawl from the spring Kodiak trawl survey for 2002–2006 was averaged for January and February (first two trawls) and expanded to population size using volume sampled, 100% efficiency, and volume of Sacramento–San Joaquin Delta and Suisun Bay less than 4 m deep. November and December midwater trawl (MWT) abundance was computed the same way but by using volume of Delta and Suisun Bay less than 4 m deep. Log(Kodiak trawl abundance) was then regressed against log(MWT abundance), and the MWT values were used to estimate Kodiak trawl values for 1995–2001.
(b) Mean length of young-of-the-year, age-1, and age-2 fish (Figure 6)	Computed the weighted mean lengths on January 1 (just before their birthdays) using worth as the weighting factor in the averaging.	Mean length of fish in the December MWT samples, excluding fish greater than 100 mm, which were assumed to be age 1 or older.
(c) Annual number of adults entrained in diversion facilities (Figure 7)	Summed worth of individuals that were killed by arrival at reservoir 4 (State Water Project) or node 181 (Central Valley Project), plus the worth associated with the added mortality of all individuals in box 3 (South Delta) when Middle River flow is negative. The amount of worth (w) attributable to Middle River-related mortality (R) versus natural mortality (M) is $w(\frac{R}{M+R})(1 - e^{-M+R})$.	Methods are described by Kimmerer (2008), and results used here are shown in Figure 12a of that paper.
(d) Fraction of adults on January 1 subsequently entrained during that year	Ratio of numbers entrained (see variable c) divided by the January adult abundance (see variable a)	Methods are described by Kimmerer (2008), and results used here are shown in Figure 12c of that paper.
(e) Fraction of age-1 individuals that were mature and the number of eggs per entering age-1 individual (Figure 8)	Fraction mature was computed as the summed worth of age-1 individuals greater than 60 mm at the time of projected spawning divided by the summed worth of all age-1 individuals on the same day. The ratio of eggs to entering age-1 fish was computed as the cumulative number of eggs produced by age-1 individuals divided by the summed worth of age-1 fish on January 1 prior to spawning.	No data.
(f) Salinity weighted by densities of larvae, juveniles, and adults (Figure 9)	First, the worth of larvae (including postlarvae) was summed for each box on each day and then divided by the volume of the box to obtain number per m^3 by box on each day. Salinity in each box on each day was used to compute average salinity across boxes, weighted by the larval densities in each box. This process was repeated for juveniles and for adults. This was done for calendar years to better match following a year-class from the early spring spawning.	Number per trawl in each sample of the 20-mm, summer towntnet, fall MWT, and spring Kodiak trawl surveys was used to weight the salinity value measured with the trawls. Data values include a mix of larvae, juveniles, and adults that varied throughout the year depending on the survey.
(g) Proportion of individuals in and seaward of the confluence box for adults on December 14 and April 30, for postlarvae on June 24, and for juveniles and adults on September 1 (Figure 10)	For each stage and day, we summed the worth of individuals in each box and then divided the sum of worth in the confluence box and seaward boxes by the total summed worth over all boxes.	All of the fall MWT data from all stations during September–December were aggregated for each year, assigned to up-estuary of the confluence box (47 stations) or in or seaward of the confluence box (39 stations). The proportion in Figure 10f was computed from these two totals.

TABLE 2. Continued.

Variable	Model calculations	Data calculations
(h) Daily fraction of larvae plus postlarvae entrained in diversion facilities (Figure 11)	Summed worth of larval and postlarval individuals reaching reservoir 4 and node 181 divided by the summed worth of larvae and postlarvae at the end of the day plus the numbers lost to pumping plant entrainment during that day.	Methods are described by Kimmerer (2008), who used the 20-mm survey data, and the results are shown in Figure 14 of that paper. Note: Kimmerer's (2008) estimates included some juveniles as well as larvae and postlarvae. Also see recent papers about the estimation by Kimmerer (2011) and Miller (2011).
(i) Diets (text)	Computed averaged diets for each life stage using the biomass of zooplankton types eaten by every 500th individual on every 30th day. We first computed the proportions for each individual and then averaged the proportions over individuals. This resulted in individuals covering all life stages for the time periods during which the stages were present.	Diets reported by Lott (1998), Nobriga (2002), and Baxter et al. (2010), who summarized unpublished data from Steven Slater (California Department of Fish and Game); data were only sufficient for qualitative and general comparison.
(j) Annual finite population growth rate (λ ; Figure 12)	The λ value was computed from a 2×2 Leslie matrix model with parameter values determined from the individual-based model output each year (see Supplement F).	No data.
(k) Stage-specific survival rates (Figure 13)	Summed worth of individuals entering each life stage during the year divided by the summed worth of individuals entering the next life stage.	No data.
(l) Averaged temperature and proportion of maximum consumption (p -values; text)	Computed average temperature and average p -value for all individuals (weighted by their worth) each day and then computed seasonal averages weighting the daily values for total daily worth of age-1 individuals during February 27–June 7 (spawning) and total daily worth of juveniles during April 18–October 1 (growing season) and October 1–December 30 (fall).	

MODEL SIMULATIONS

Calibration

The model was calibrated in three steps. We first tested the movement of juveniles and adults on test grids with fixed salinity patterns to understand movement in contrived situations where we knew the correct movement patterns (Supplement D). Once the entire model had been calibrated, we again evaluated the movement patterns among years to confirm that simulated movement was realistic under dynamic salinity conditions. The results using the full model are presented below as part of the 1995–2005 historical simulation.

The second step was to determine the K -values (equation 10) for each Delta Smelt life stage and each zooplankton prey group (Supplement B). We averaged daily temperature and the biomass of each zooplankton group in each box over the periods when each life stage would be in the system. We assumed that larvae, juveniles, and adults remained in each of the 11 boxes, and we then iteratively adjusted the K -values so that the average consumption rate (i.e., with p -value = 0.8) and diets were reasonably close to the available observations.

The third and final step was to put the above two calibrated components (movement and growth) into the full model and then to simulate the period 1995–2005 by adjusting only the yolk sac larval mortality rate and the entrainment mortality multiplier based on Middle River flow. The mortality rate of yolk sac larvae was adjusted because this mortality was relatively simple (i.e., only temperature dependent and of short duration). The entrainment mortality multiplier was adjusted because the role of Middle River flow in affecting entrainment is well documented (Grimaldo et al. 2009), although the magnitude is uncertain, and we had data on adult entrainment mortality (Kimmerer 2011). We adjusted the yolk sac larval mortality rate until the predicted average January abundance for 1995–2005 was close to the data average of 2.7×10^6 ; we then adjusted the entrainment mortality multiplier until the average annual fraction of adults removed by diversions was close to the data average of 10%. We did not try to fit to individual years or to the pattern in the time series of annual abundances. Thus, any interannual differences in model output were generated by differences in temperature, salinity, entrainment, and zooplankton densities.

Historical Simulation

We report the results from the last step of the calibration: the 1995–2005 historical simulation. The calculations that were performed to obtain all reported model outputs and to summarize the field data used for model–data comparisons are shown in Table 2. The field data for Delta Smelt originate mostly from four surveys that are conducted annually by the California Department of Fish and Game (www.dfg.ca.gov/delta/): (1) the fall midwater trawl (MWT) survey began in 1967 and samples juveniles and adults monthly during September–December at 116 stations; (2) the spring Kodiak trawl survey began in 2002 and samples adults every 2–4 weeks during winter and spring at 39 stations; (3) the 20-mm survey (larval net) began in 1995 and samples larvae at 48 stations between March and July; and (4) the summer townet survey began in 1959 and samples mostly juveniles at up to 32 stations during June–August. These field data have been described and used extensively in previous analyses (e.g., Bennett 2005; Kimmerer et al. 2009; Sommer et al. 2011; Miller et al. 2012).

The model outputs and the model–data comparisons in Table 2 confirmed various aspects of the calibration or served to assess the realism of model behavior. None of the model–data comparisons can be considered as true model validation because no data were kept aside for independent comparison. Comparisons a–d in Table 2 were related to the three steps in model calibration as described above. Maturity of age-1 individuals and the number of eggs per entering age-1 individual (Table 2, comparison e) integrated the effects of growth differences (due to temperature and prey biomass) from the previous year on reproduction. Movement patterns were confirmed by using averaged salinities weighted by Delta Smelt density (comparison f) and the proportions of individuals in and seaward of the Sacramento River–San Joaquin River confluence box (comparison g). We used monthly Delta outflows (m^3/s) from DAYFLOW (www.water.ca.gov/dayflow/) to help interpret the spatial distributions in comparison g. Comparison h, the daily fraction of larvae lost to entrainment, confirmed the realism of the pumping-related mortality determined by the PTM. Overall average diets (comparison i) were examined to confirm reasonable shifts in diet from larvae to juveniles to adults. The λ values (comparison j) and stage survival rates (comparison k) provided condensed summaries of the differences among years. Finally, comparison l identified the between-year differences in temperature and food as actually experienced by the simulated fish.

MODEL RESULTS

Dynamics within the Historical Simulation

For the simulated period 1995–2005, calibration resulted in an average January adult abundance of 2.7×10^6 (compared to the data target of 2.3×10^6) and an average fraction of adults lost to the pumps of 11% (the target was 10%). The final calibrated mortality rates were 0.035 d^{-1} for yolk sac larvae and

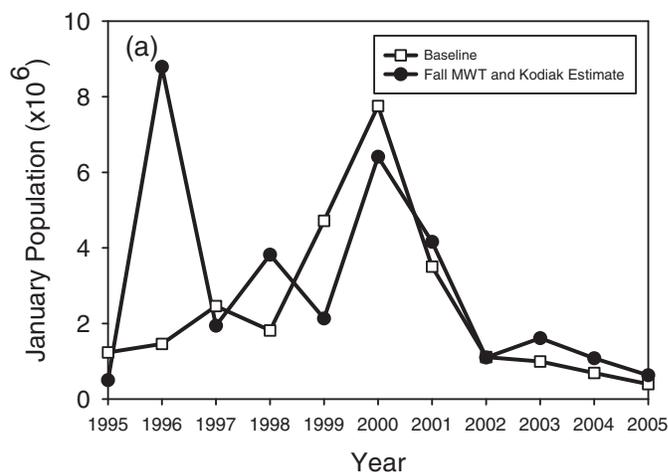

FIGURE 5. Annual abundance of adult Delta Smelt in January for 1995–2005 from the baseline simulation and as estimated from the fall midwater trawl (MWT) and spring Kodiak trawl sampling.

0.02 d^{-1} for Middle River-related pumping mortality. Annual January abundances varied from year to year in a pattern similar to that of data-based estimates, with a peak in 2000, a decline in 2001, and then low abundances in 2002–2005 (Figure 5). One exception was that the January adult abundance in 1996 had the highest data-based estimate but a relatively low simulated value.

Simulated lengths at age on January 1 were similar to data values for young of the year about to become age 1, with both model and data values varying between 55 and 65 mm (Figure 6). Faster growth was predicted for the summer and fall of 1995 (shown as the January 1996 value), 1997 (the January 1998 value), and 2001–2004. Simulated growth was slow in 1996, 1999, and 2000, resulting in shorter fish recorded during the

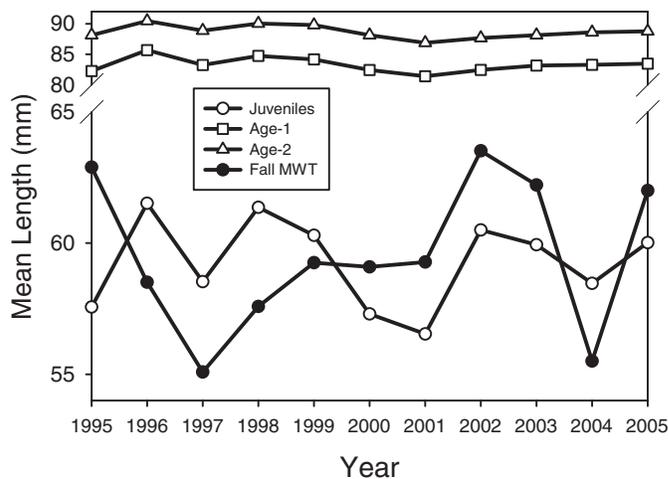

FIGURE 6. Mean total length of juvenile, age-1, and age-2 Delta Smelt on January 1 in each year (just prior to birthdays) of the 1995–2005 baseline simulation. Also included are the mean lengths of young-of-the-year fish from fall midwater trawl (MWT) sampling.

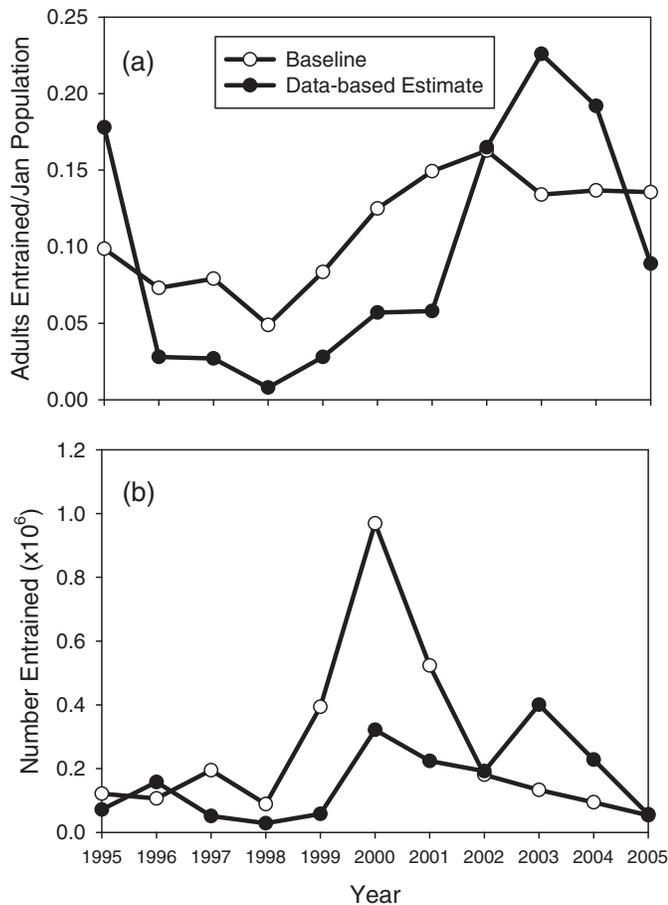

FIGURE 7. Predicted and observed annual values in 1995–2005 for (a) the fraction of adult Delta Smelt present in January that were entrained in pumping plants during the next few months (i.e., winter) and (b) the number of adults that were entrained during the same time period.

next January. Mean lengths of about 82 mm for age-1 fish (about to become age 2) and 90 mm for age-2 fish (about to become age 3) were consistent with the results of Bennett (2005).

The predicted annual fraction of adults entrained showed less interannual variation than the data-based values (Figure 7a), and the predicted numbers entrained were as much as two times the data values for 1999–2001 (Figure 7b). Predicted and estimated annual fractions entrained were low (<10%) for 1996–1999 and then increased to 15–20% for 2002–2004. Predicted fractions showed less variation and were higher than estimated values during the earlier, low-entrainment-loss years and were lower than estimated values during the latter, high-entrainment-loss years (i.e., in Figure 7a, the line connected by open circles is flatter than the line connected by black shaded circles). Substantially more model adults were entrained during 1999–2001 than were shown by the data (Figure 7b) because the fraction entrained was higher, and in two of those years the population estimate (Figure 5a) was higher than that in the data. Overestimation of the fraction entrained in early years and underestimation of the fraction entrained in later years suggested inaccuracies in the

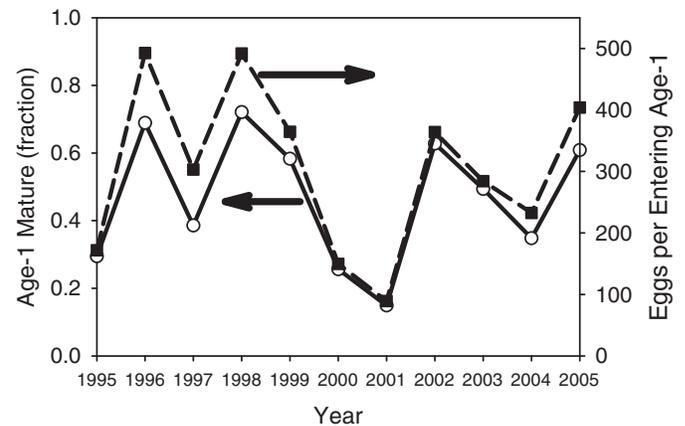

FIGURE 8. Annual fraction of age-1 individual Delta Smelt that were mature (solid line, open circles) and the number of eggs produced per entering age-1 individual (dashed line, black shaded squares) for the 1995–2005 baseline simulation.

simulated adult spatial distributions or in the use of a single value for the pumping mortality at any southward Middle River flow.

Even though the variation in mean length of age-1 adults was small (± 5 mm; Figure 6), interannual differences had large effects on maturity (Figure 8, solid line) and subsequent egg production (Figure 8, dashed line) by age-1 individuals. Age-1 individuals at the beginning of the spawning season (about 3 months into age 1) varied above and below 60 mm from year to year. This hovering around 60 mm caused the fraction of age-1 fish that were mature to range from 0.15 (in 2001) to 0.60–0.70 (in 1996, 1998, and 2002; Figure 8), tracking the slow and fast age-0 growth from the previous year (Figure 6). A greater fraction of individuals becoming mature and a higher weight of these individuals (equation 1) resulted in a fivefold difference among years in the number of eggs produced per entering age-1 individual (Figure 8). Egg production per entering age-1 fish was highest in 1998 (491.8) due to the fast growth of juveniles in 1997 and the high proportion (72%) of age-1 fish being mature at spawning; egg production per entering age-1 individual was lowest in 2001 (89.3; 15% maturity) due to slow juvenile growth in 2000. Such large variation in the fraction mature and eggs produced per entering age-1 fish seems extreme and may partially reflect the all-or-none maturity rule (100% mature if longer than 60 mm) we used. We further investigate the maturity rule in our companion paper (Rose et al. 2013).

Simulated Delta Smelt density-weighted salinities showed the up-estuary spawning migration of adults and the subsequent larval and juvenile movement seaward (Figure 9). Note that the years in Figure 9 are calendar years (i.e., they start on January 1) in order to follow a year-class. Salinity slowly rose for larvae and postlarvae during June–September as they were transported seaward (Figure 9a). Salinity also rose for juveniles during June–October (Figure 9b) after the S_0 for juveniles was changed from 0 to 2 psu on May 1. Salinity for adults went from near zero in January–May to approaching 2–6 psu beginning in June

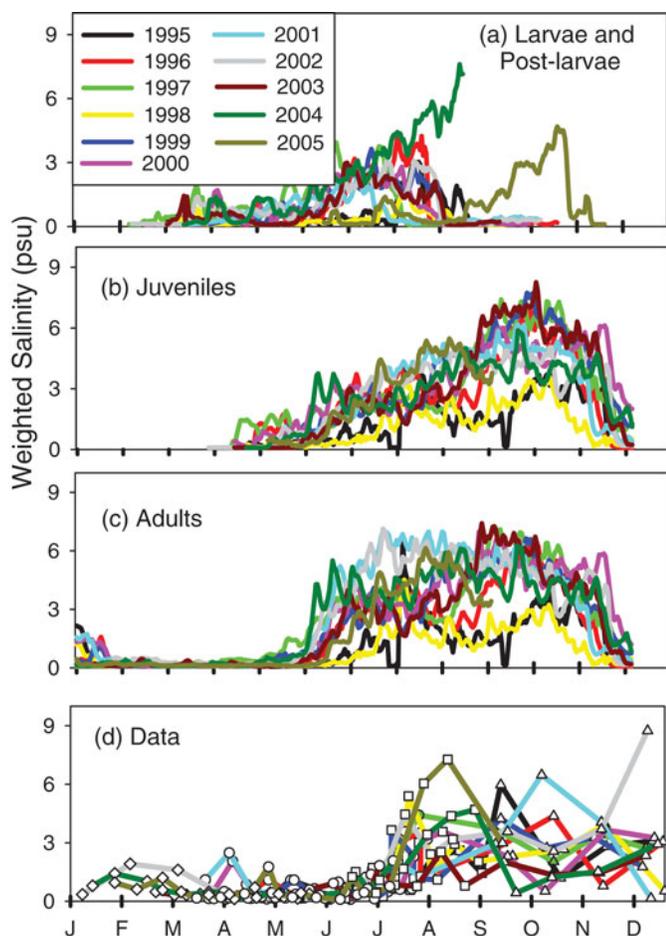

FIGURE 9. Average salinity (psu) weighted by Delta Smelt density computed daily during calendar years 1995–2005 for (a) larvae and postlarvae combined, (b) juveniles, and (c) adults in the baseline simulation. Panel (d) shows the weighted salinity values obtained by merging catch per unit effort data from the 20-mm, summer townet, fall midwater trawl (MWT), and spring Kodiak trawl surveys for 1995–2005. Years are calendar years rather than water years (e.g., 1997 refers to January–December). [Figure available online in color.]

(Figure 9c), triggered by a change in the adults' S_0 back to 2 psu on May 1. During most years, the density-weighted salinity values for juveniles and adults caused their seaward migration to occur earlier than was shown in the data (June in Figure 9c versus 9d), and they occupied water during the late summer and fall with salinities of 2–6 psu, whereas the data suggested somewhat lower-salinity waters of 1–4 psu during the late summer and fall (August–October in Figure 9c versus 9d).

The interannual influence of Delta outflow on the proportion of individuals in each spatial box is shown in Supplement G (in the online version of this article) and is summarized here by using a single metric: the proportion of fish that were within or seaward of the confluence box (Figure 10). In December, prior to their up-estuary spawning migration, adults were distributed based on salinity, which was roughly correlated with average October outflow (Figure 10a). During the high-outflow years of

1996 and 1999, more than 80% of adults were in or seaward of the confluence box, whereas during the remaining years fewer than 60% were in or seaward of the confluence box.

Spawning migration (including young-of-the-year fish that became age 1 on January 1) began in January and ended by April 30, with almost all individuals located up-estuary of the confluence box (Figure 10b). Once hatched, larvae were transported by the PTM; by June 24, when postlarvae were about to become juveniles, proportions again roughly reflected outflow conditions (Figure 10c). During 1995 and 1998, which were years of high May outflow, over 80% of postlarvae were in or seaward of the confluence box, whereas during relatively low-outflow years (2001, 2002, and 2004) only 20–30% of postlarvae were located in or seaward of the confluence box. Data for 1997 appear anomalous relative to May outflow because that year had a low May outflow but the highest June outflow over the simulation time period ($2,033 \text{ m}^3/\text{s}$ versus less than $1,327 \text{ m}^3/\text{s}$). Juvenile and adult distributions on September 1 (Figure 10d, e) resembled each other because both reflected behavioral movement towards 2-psu water. Juveniles and adults were farthest seaward during the high outflow of August 1998 and were situated up-estuary during the low-outflow years of 2001, 2002, and 2004.

Finally, the predicted and observed proportions of adults that were in or seaward of the confluence during the fall showed moderately good agreement for extremely low- and high-outflow years but not for years of intermediate flow (Figure 10f). Predicted and observed proportions showed relatively more fish in and seaward of the confluence during 1996 and 1999 and more fish being relatively up-estuary during 1995, 2004, and 2005. October outflow was highest in 1996 and 1999 and was low in 1995 and 2004 (Figure 10a); October outflow for 2005 was not low, but the summed October–December outflow in 2005 was relatively low. However, predicted proportions were flatter than observed proportions (proportions under low outflow were above the 1-to-1 line, and proportions under high outflow were below the 1-to-1 line in Figure 10f), indicating that simulated adults were generally too far seaward under low outflow and too far up-estuary under high outflow.

The simulated daily proportion of larvae and postlarvae entrained, which results from transport by the PTM, generally agreed with the data-based estimates (Figure 11). Model predictions showed less interannual variation than the data-based values. A few extreme model values of 0.2–0.3 were predicted, whereas data values never exceeded 0.1. In both the simulation and in the data, entrainment was relatively low during 1995, 1996, and 1998 and was high during 2002 and 2003. Model-predicted entrainment was also high during 2000, 2001, and 2005, which were intermediate entrainment years in the data.

Simulated diets were reasonable and consistent among years, even between the most extreme years (not shown). Larvae consumed *Limnoithona* spp. (20% of consumed biomass) and calanoid copepodids (80%) because other prey had vulnerabilities of zero. As Delta Smelt increased in size, they consumed

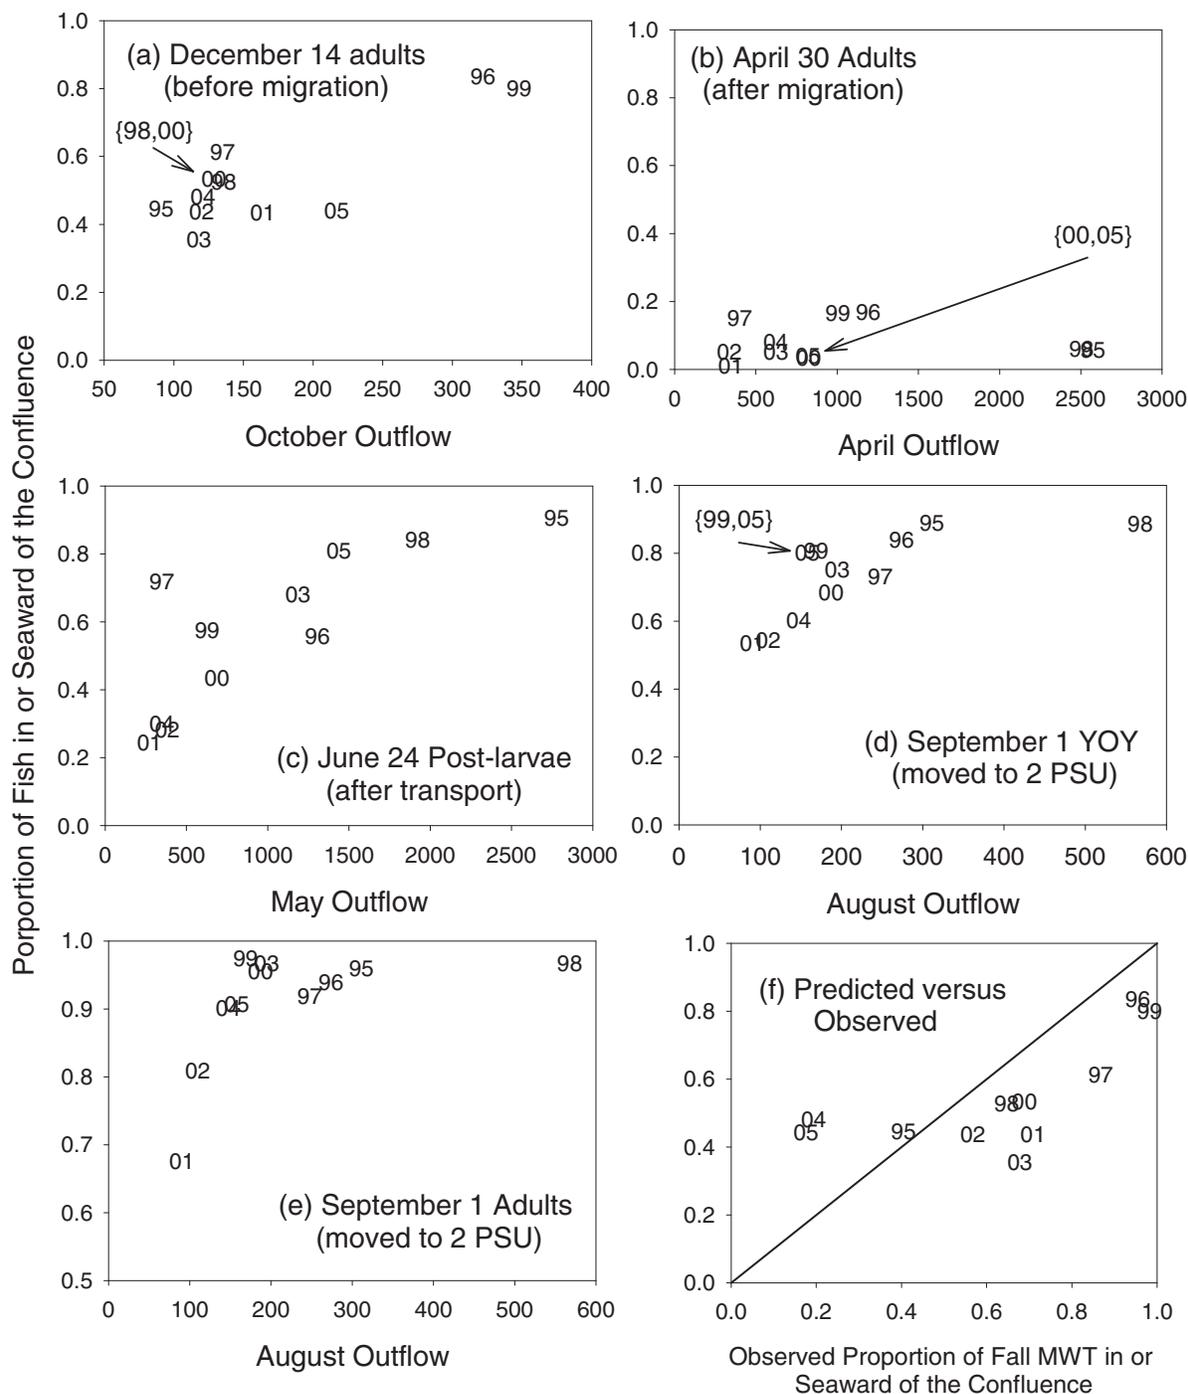

FIGURE 10. Predicted proportion of Delta Smelt individuals in the confluence and seaward boxes (see Figure 1) versus monthly Sacramento–San Joaquin Delta outflow (m³/s) in the immediately preceding months for 1995–2005 of the baseline simulation: (a) adults on December 14 (before the spawning migration), (b) adults on April 30 (after the spawning migration), (c) postlarvae on June 24 (after particle tracking model transport), (d) juveniles (young of the year) on September 1, and (e) adults on September 1. Two-digit numbers indicate water years (e.g., 96 = 1996; 02 = 2002). Panel (f) is a comparison of the predicted proportion of Delta Smelt in and seaward of the confluence box from December 14 versus the proportion estimated from the fall midwater trawl (MWT) survey. Panel (a) uses outflow from October of the previous year (e.g., October 2001 outflow for the year 2002).

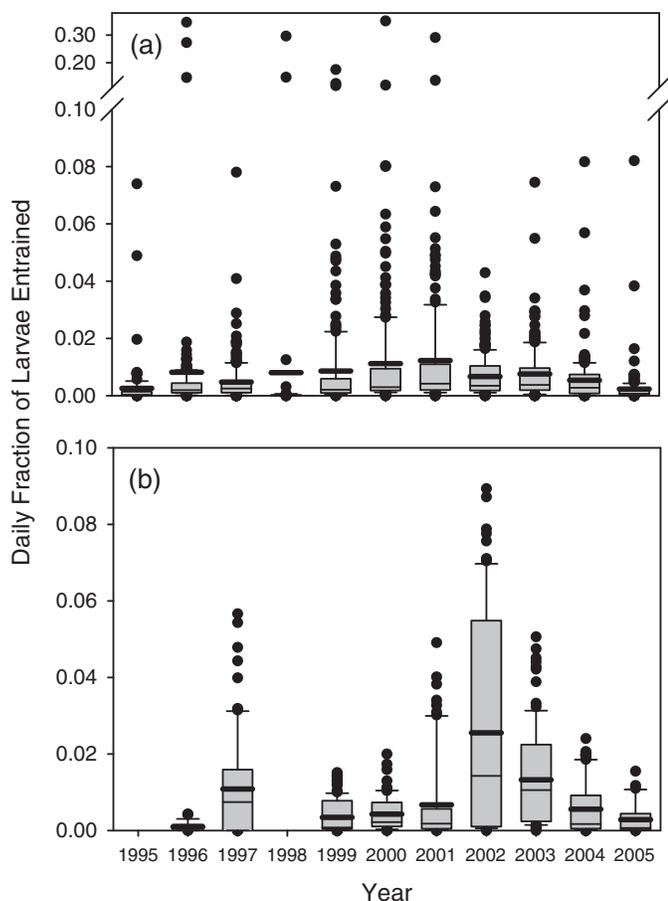

FIGURE 11. Daily entrained fraction of (a) Delta Smelt larvae and postlarvae combined as determined by the particle tracking model for 1995–2005 of the baseline simulation and (b) larvae (and some juveniles) as estimated by Kimmerer (2008). The thin line within each box is the median, the thick line is the mean, the ends of the box represent the 25th and 75th percentiles, the ends of the whiskers represent the 10th and 90th percentiles, and the black circles are points outside of the 10th and 90th percentiles.

less *Limnoithona* spp. and calanoid copepodids and more of the other four adult zooplankton types (50% [*Limnoithona* spp. and calanoid copepodids] and 50% [other types] for postlarvae; 79% and 21% for juveniles; 92% and 8% for adults). *Pseudodiaptomus* increased in the diet as fish transitioned from postlarvae to juveniles, but the *Pseudodiaptomus* contribution then decreased slightly between juvenile diets and adult diets as the biomass of this zooplankton type decreased in the fall. These results qualitatively agreed with several diet studies of Delta Smelt (Table 2), but more rigorous comparison was not attempted because of the difficulties in interpreting field diets involving rapidly digested zooplankton and without simultaneous measurement of zooplankton densities.

Best versus Worst Years in the Historical Simulation

Population growth rate (λ) from the Leslie matrix model showed that water year 1998 was the best year and water year 2001 was the worst year for the simulated Delta Smelt popula-

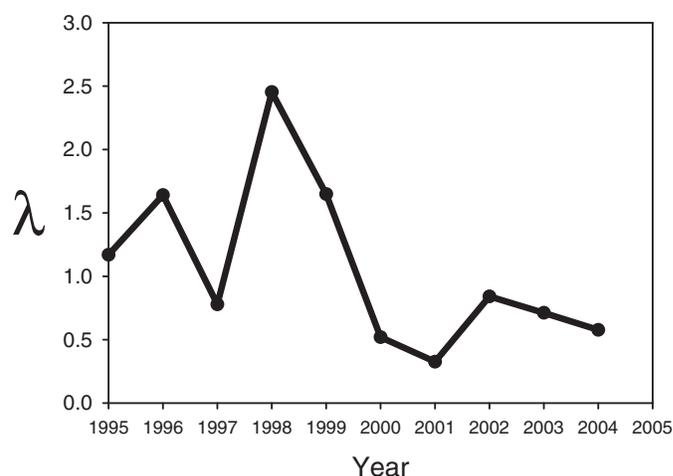

FIGURE 12. Population growth rate (λ ; fraction per year) of Delta Smelt as determined by the age-based Leslie matrix model applied to individual-based model output for each year of the 1995–2005 baseline simulation. No value for 2005 was possible because the simulations ended on September 30, 2005; information through December 31, 2005, would be needed to estimate the matrix model for 2005.

tion (Figure 12). The λ in each year resulted from a combination of (1) growth in the prior year affecting subsequent reproduction and (2) higher stage-specific survival rates in the current year for most of the life stages. Thus, water year 1998 extended from October 1997 to September 1998 and included the fall of 1997, which led up to spawning in spring 1998. Fast growth in fall 1997 resulted in large new adults at the beginning of 1998 (Figure 6) and therefore a high fraction of mature age-1 fish and a high number of eggs per entering age-1 individual (Figure 8). The year 1998 also had moderately high growth during summer (Figure 6), the lowest entrainment losses (Figure 7a, 11), and the highest stage-specific survival rates for all life stages (Figure 13). The bad year, 2001, had the second slowest growth in the prior year (2000; Figure 6) and consequently had the lowest number of eggs per entering age-1 fish (Figure 8). In addition, 2001 had moderately high entrainment losses (Figure 7) and low survival of eggs (Figure 13a), juveniles (Figure 13e), and adults (Figure 13g, h).

Compared with 2001, water year 1998 had a relatively cool and delayed warming in spring that benefited Delta Smelt larvae, but both years had similar growth conditions for juveniles during summer. Mean temperature experienced by age-1 individuals during February 27–June 7 (spawning) was 14.8°C in 1998 versus 16.4°C in 2001. Average day of spawning was April 28 in 1998 versus April 6 in 2001, and average duration of the larval stage (inversely related to growth rate) was 25.2 d (1998) versus 28.6 d (2001). Although juveniles also experienced cooler temperatures during the early summer (16.7°C versus 22.2°C for April 18–June 7), differences became smaller when viewed over the entire growing season. Average temperature experienced by juveniles during April 18–October 1 was slightly cooler during 1998 than during 2001 (20.9°C versus

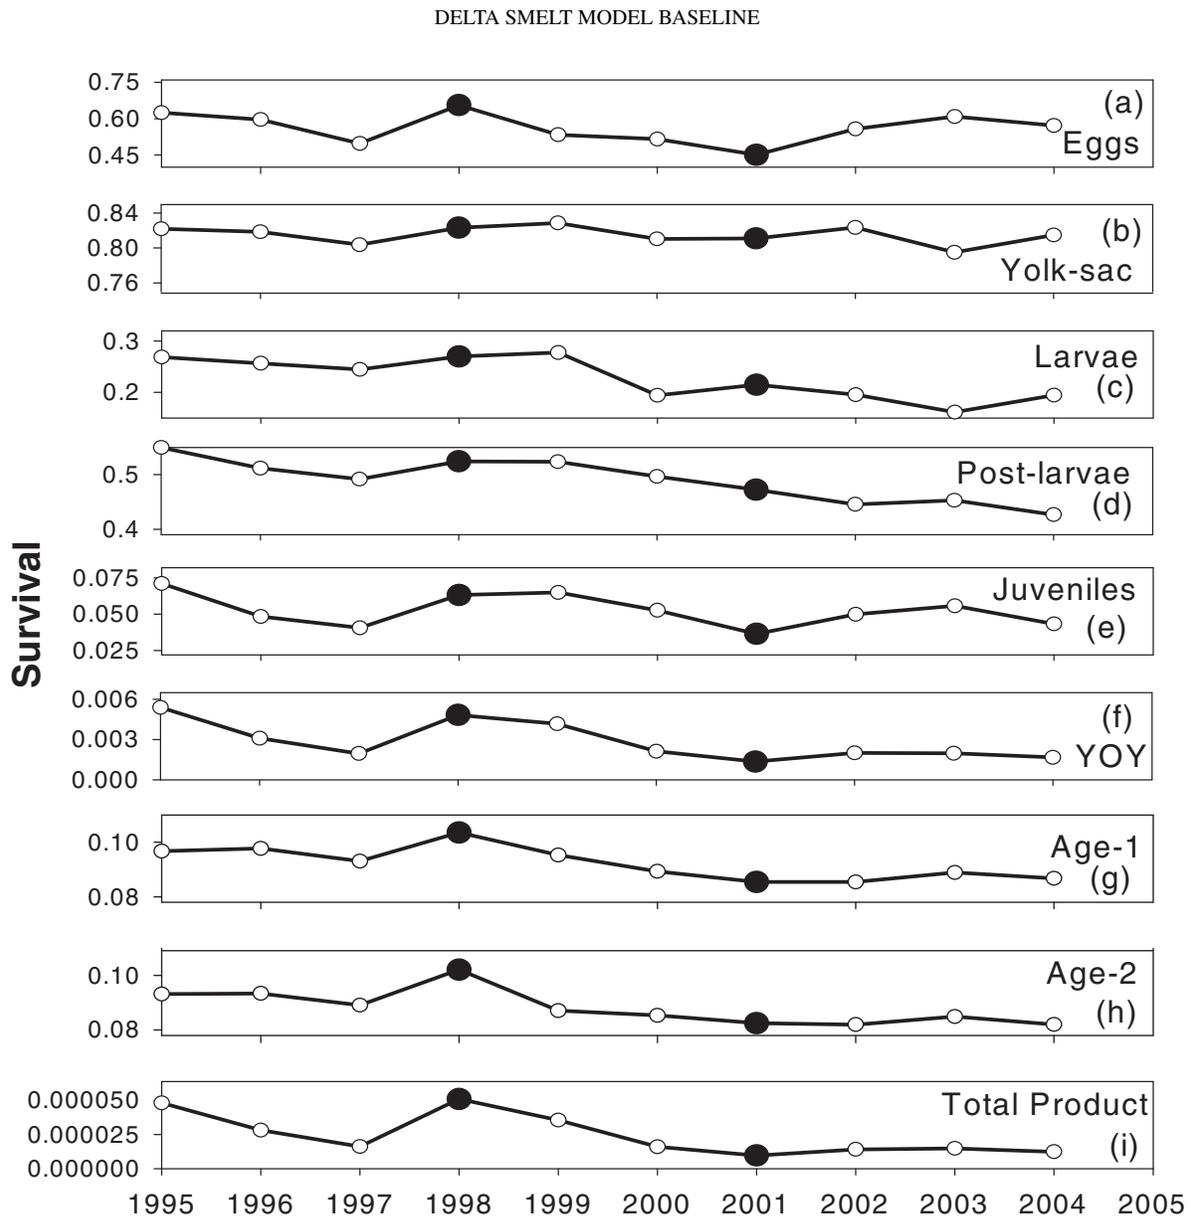

FIGURE 13. Delta Smelt stage-specific survival (fraction) from the 1995–2005 baseline simulation for (a) eggs, (b) yolk sac larvae, (c) larvae, (d) postlarvae, (e) juveniles, (f) total young of the year (product of a–e), (g) age 1, (h) age 2, and (i) total (product of f–h).

22.1°C), and the average p -value was higher in 1998 (0.89 versus 0.84). However, mean lengths of juveniles were similar between 1998 and 2001 (60.3 mm in 1999 versus 60.5 mm in 2002; Figure 6), so the difference in summer growth of juveniles between 1998 and 2001 was not a major factor.

The higher number of eggs per age-1 individual in 1998 compared with 2001 was due to faster growth during fall 1997 compared to fall 2000. Mean length of juveniles on January 1 (just before their birthday to age 1) was 61.4 mm for 1998 versus 56.5 mm for 2001. The mean p -value for October 1–December 30 was 0.76 in 1997 versus 0.68 in 2000; 1997 was also warmer than 2000 (15.9°C versus 15.0°C).

Delta outflow was generally higher in 1998 than in 2001 (Figure 10), so individuals were farther seaward, resulting in lower entrainment mortality during 1998. The PTM put 84% of post-larvae in or seaward of the confluence box on June 24 in 1998 compared with 24% on June 24 in 2001 (Figure 10c). Similarly, behavioral movement of juveniles resulted in about 88% of them occurring in or seaward of the confluence box on September 1, 1998, versus 53% on September 1, 2001 (Figure 10d). Almost no larvae were predicted to be entrained during 1998, whereas a daily average loss of 1.2% was predicted for 2001 (Figure 11a); the fraction of January adults entrained was 0.05 in 1998 versus 0.14 in 2001 (Figure 7a).

DISCUSSION

We used a detailed, individual-based approach to model the population dynamics of Delta Smelt during a time period that included a major population decline. The model was completely density independent; a density-dependent version is analyzed by Rose et al. (2013). The Delta Smelt has been declining since the 1980s and was one of four species to show a step decline around 2002 (Sommer et al. 2007). The choice of a detailed individual-based model may seem odd because of the extensive data demands of this general approach. Survey data-based modeling approaches are easier to justify in terms of calibration and in testing the degree of fit (e.g., Thomson et al. 2010; Miller et al. 2012); however, unlike our process-based approach, survey data-based approaches do not provide a means of assessing cause-and-effect relationships and so far have not helped to settle the controversy over the causes of the decline.

We opted for a spatially explicit, individual-based approach to explore the potential causes for the Delta Smelt's decline and the conditions that result in good versus bad years for Delta Smelt. The term "spatially explicit" refers to multiple, linked spatial boxes with different conditions among them. The individual-based approach allows for relatively easy simulation of movement and for local experiences to accumulate as each individual moves among the spatial boxes. A spatially explicit approach was required to enable a model that could (1) represent feeding, growth, reproduction, and movement in some detail; and (2) simulate how interannual variation in spatial distributions by life stage interacted with dynamic habitat. The chief disadvantage of such a complicated mechanistic model is that describing how it works can be difficult (Grimm et al. 2006), and many of the assumptions and parameter values must be based on judgment; thus, replication of the modeling by others is a challenge (Wilensky and Rand 2007). Indeed, the output of our model was sufficiently complicated that we chose to fit an age-structured matrix model to its output to provide a more straightforward summary of each year's condition. Our model is designed for exploring hypotheses about some of the factors affecting Delta Smelt population dynamics but is not designed for forecasting future Delta Smelt population abundances. Hypotheses about future conditions can be explored with our model but in a relative way, whereby simulated values are compared with some simulated baseline condition.

Maunder and Deriso (2011) also fitted a stage-based model of Delta Smelt by using the same extensive long-term monitoring data used here. By including covariates such as annual entrainment rate in their model, Maunder and Deriso (2011) were able to evaluate the relative importance of different factors. Their data-based modeling approach is relatively easy to describe (mathematically compact) and can be easily judged for its performance and skill (fit to data), but the approach also inherits problems with the monitoring data in terms of bias and process versus observation errors and is heavily correlation based. Clearly, the data-based approach of Maunder and Deriso (2011) and the detailed, process-based approach used here can

complement each other, and detailed comparison between the two approaches would likely allow for more insights than either approach alone can provide.

Calibration of complicated individual-based models is always a challenge. Our approach was first to adjust the movement and feeding algorithms externally under simplified conditions and then calibrate by adjusting two mortality-related parameters for the 1995–2005 historical simulation to get the averaged population abundance and averaged fraction entrained to match the data. None of the calibration steps involved adjustments to fit the model to specific years.

Model results were generally consistent with the available data and information (Table 2) about Delta Smelt. The model reasonably matched a variety of measures related to growth, mortality, and movement. Predicted growth resulted in realistic lengths at age (Figure 6). The PTM produced reasonable larval entrainment rates (Figure 11), and a simple function of Middle River flow yielded annual adult entrainment fractions that mimicked the observed values (Figure 7). Movement was confirmed both based on salinity experienced by individuals (Figure 9) and geographically (Figure 10). The fraction of individuals in the confluence box and seaward boxes during the fall agreed with estimates from fall MWT sampling. Thus, the calibrated model is a good descriptor of the 1995–2005 conditions and is useful for comparing Delta Smelt dynamics among those years. We caution that our bioenergetics model was sufficient for relating prey and temperature to growth, but it must be re-evaluated for other purposes.

There were several major discrepancies between model results and observed values. First, the model underestimated the January abundance in 1996 (Figure 5), and the reason for this is unclear. Second, the model overestimated the degree of adult entrainment in early years and underestimated the degree of adult entrainment in later years (Figure 7). This lack of sufficient interannual variation in simulated adult entrainment may be attributable to the simulated movement of adults being too similar among years (Figure 10f); the center of distribution for simulated adults was less variable across years than the center of distribution for fish caught by the fall MWT. Another possible explanation is that adult entrainment mortality was switched on or off depending on the sign of Middle River flow, whereas analyses showed that the actual entrainment rate probably increases with the magnitude of southward flow toward the diversion facilities (Kimmerer 2011).

A third discrepancy between the model and the data was that movement in the model tended to put juveniles and adults in water that was too saline during late summer to winter (Figure 9). This could reflect a conceptual difference between the data-based and modeled density-weighted salinities. Because the model tracks each individual, an individual-weighted salinity is unbiased by any sampling error. In contrast, the sampling programs catch relatively few fish and do not sample all salinities equally. However, even with the sampling issues, the results suggest that the model is contributing to this discrepancy. Two

possibilities are that (1) behavioral movement of juveniles in the model may be too slow to react to local salinity changes (Supplement D) and (2) the starting locations from the PTM were too far seaward. Some of the movement of late larval Delta Smelt in nature likely is a result of both transport (which we assumed) and behavior as the fish gain competence to direct their movements.

Finally, the model showed wide fluctuations in the fraction of age-1 individuals that were mature and the number of eggs per entering age-1 individual (Figure 8) from small changes in mean length (Figure 6). Although we lack data with which to compare these results, these differences among years seemed larger than what we would expect to see in the real population. We partially address this in Rose et al. (2013) by including length-dependent maturation as one of the alternative baselines.

We performed many comparisons of model results with the available data (Table 2), but we did not perform the classical model calibration and validation comparisons and we did not compare model predictions with commonly used abundance indices from the monitoring programs. We focused on using most of the data for calibration and often in a pattern-matching mode (Grimm et al. 2005) rather than a more traditional comparison of predicted values versus observed data (Stow et al. 2009); thus, some of the consistency between the model and the data was a result of calibration. While Delta Smelt abundance indices from the various monitoring programs have been used extensively as indicators of population abundance and survival (Bennett 2005; Maunder and Deriso 2011; Miller et al. 2012), we found the model–data comparisons using the indices to be uninformative due to the sensitivity of the indices to calculation details, such as the months included and the gear selectivity (e.g., Newman 2008).

Our analysis of model results and data for 1995–2005 clearly illustrated why it has been difficult to ascribe the Delta Smelt's decline to a single causative factor, either over the long term or as part of the recent 2002 decline. Interannual variation in λ (Figure 12) was due to a combination of the effects of temperature, salinity, larval growth, hydrodynamics, and growth of juveniles in the prior year affecting the movement, growth, mortality, and reproduction in various combinations of life stages. Small changes in mean length of young-of-the-year fish from the previous year (Figure 6) were amplified into large effects on egg production (Figure 8), and temperature affected the timing of spawning and the subsequent growth of larvae.

We did not include an explicit representation of turbidity in the final version of our model. Turbidity affects spatial distributions (Feyrer et al. 2007; Nobriga et al. 2008) and larval growth (Baskerville-Bridges et al. 2004) of Delta Smelt. We initially included turbidity (estimated from extensive Secchi depth measurements) in the same way that we included salinity and temperature (Supplement A). Turbidity showed the expected decrease during the modeled time period, which is part of a longer-term downward trend (Kimmerer 2004; Wright and Schoellhamer

2004; Nobriga et al. 2008). However, we had no basis upon which to determine relationships between turbidity and growth rate or mortality rate, and thus we could have simulated a decline in the Delta Smelt population based solely on the lower turbidity in the later years. Because we predicted the decrease in Delta Smelt without turbidity (i.e., based on hydrodynamics, temperature, salinity, and zooplankton), a turbidity effect was not included.

In the companion paper (Rose et al. 2013), we further explore Delta Smelt dynamics using the individual-based model. We configure alternative baseline simulations and perform a simulation experiment to further refine our understanding of bad versus good years for Delta Smelt. We vary salinity, temperature, zooplankton, hydrodynamics, and eggs per entering age-1 individual between the best year (1998) and the worst year (2001) to systematically quantify the effects of each factor and their combined effects on λ . We then show that these results are robust to alternative baseline configurations.

ACKNOWLEDGMENTS

This project was funded by a grant from the CALFED Science Program (SCI-05-C106). We acknowledge the many people who discussed various aspects of the model and their willingness to discuss and provide information. Stephen Monismith helped with the PTM. Rachael Miller Neilan derived the Leslie model formulation. Erik Loboschetsky provided the DSM2 output files. Lindsay Sullivan shared data on Delta Smelt feeding, and Steve Slater provided diet data. We also had discussions during model development with Rick Sitts, Joan Lindberg, and Kevin Fleming; in addition, we held a workshop in Santa Cruz, where many people provided information and advice on the modeling in its early stages. The comments of two reviewers and the Associate Editor greatly improved the clarity of the paper.

Abstract

We used a previously described individual-based population model to further explore the population dynamics of Delta Smelt *Hypomesus transpacificus* in the upper San Francisco Estuary. We formulated four alternative baseline configurations of the model and used a factorial design to systematically isolate the effects of factors that determined a good versus bad year. The alternative baseline conditions were obtained by substituting different assumptions about growth, maturity, and mortality into the original baseline configuration. In the simulation experiment, we varied five factors by setting each value to its 1998 (best year) or 2001 (worst year) value: salinity, temperature, zooplankton densities, hydrodynamics, and eggs per age-1 individual at spawning. Although some of the alternative baselines resulted in lower January abundances, estimated finite population growth rates were very similar for all versions. The simulation experiment showed that juvenile growth in the winter prior to spawning (i.e., eggs per age-1 individual) was the most important single factor in making 2001 a bad year, although no single factor alone was sufficient to fully account for the poor conditions in 2001 relative to 1998. Temperature played an important secondary role, and hydrodynamics played a more minor role. The results of the simulation experiment were robust, as similar results were obtained under the four alternative baselines. We compare our results with previous modeling and statistical analyses of the long-term monitoring data; we also discuss some implications of our results for Delta Smelt management and suggest future directions for analyses.

The Delta Smelt *Hypomesus transpacificus* resides only in the San Francisco Estuary and is listed as threatened under the U.S. Endangered Species Act and as endangered under the California Endangered Species Act. Abundance of Delta Smelt

started to decline in the 1980s, and a sharp decrease starting in 2001 led to a series of management actions that were intended to benefit the species but that also involved reducing the water available to be diverted for irrigation and water supply (NRC

*Corresponding author: karose@lsu.edu

Received November 9, 2012; accepted April 19, 2013

2012). The State Water Project and the Central Valley Project have exported an average of 30% of the freshwater flowing into the estuary during 1960–2000, with the percentage generally increasing through time and exceeding 60% in some years and seasons (Kimmerer 2004). The State Water Project facility provides drinking water for over 23 million Californians; combined, the two diversion facilities fuel an estimated $\$25 \times 10^9$ annual agricultural economy (Grimaldo et al. 2009).

A suite of factors has been identified as important in contributing to the decline of Delta Smelt. These factors include entrainment by water diversion facilities (Kimmerer 2008, 2011; Miller 2011), contaminant effects (Kuivila and Moon 2004; Connon et al. 2009; Brooks et al. 2012), shifts in the zooplankton (prey) community (Nobriga 2002; Feyrer et al. 2003; Winder and Jassby 2011), and changes in physical habitat (Feyrer et al. 2007; Nobriga et al. 2008; Kimmerer et al. 2009). The role of these factors in contributing to the Delta Smelt's decline has been examined by using statistical analysis of long-term field data (Mac Nally et al. 2010; Thomson et al. 2010; Miller et al. 2012) and population dynamics modeling (Maunder and Deriso 2011). These analyses have led to what many consider to be contradictory conclusions about the relative importance of various factors in affecting Delta Smelt population dynamics (NRC 2010; Kimmerer 2011; Miller 2011).

Determining the factors that affect Delta Smelt population dynamics is critical for formulating effective remediation actions. Remediation actions under the federal Endangered Species Act are termed "reasonable and prudent alternatives" (RPAs), and specific actions were proposed as part of the recent biological opinion for Delta Smelt (USFWS 2008) and were subsequently argued in court (NRC 2010). One RPA restricts water diversions during the winter to limit losses of Delta Smelt at the diversion facilities (Grimaldo et al. 2009; Kimmerer 2011). Another controversial RPA was designed to protect fall habitat by using reservoir releases to maintain the estuarine salinity field in certain spatial regions (NRC 2010). The high economic costs of these various management actions, coupled with uncertainty about how they may affect Delta Smelt population dynamics, have led to controversy (NRC 2012).

In a companion paper (Rose et al. 2013, this issue), we described an individual-based population model of Delta Smelt and used a historical baseline simulation for 1995–2005 to identify the factors leading to good and bad years for Delta Smelt. In the present paper, we extend the analysis of Rose et al. (2013) by formulating alternative baseline configurations of the model and by using a factorial design to systematically isolate the effects of factors that determined a good year versus a bad year. We formulated four alternative baseline conditions by substituting different assumptions about growth, maturity, and mortality into the baseline configuration. The four alternative baselines were (1) fixed larval growth instead of food-dependent larval growth, (2) size-dependent mortality instead of stage-dependent mortality, (3) density-dependent mortality instead of density-independent mortality, and (4) length-dependent maturity rather than a length

threshold for maturity. Each of these assumptions was important to baseline dynamics, and each was uncertain. Our earlier identification of good and bad years was from the historical simulation, and the effects of some factors can be confounded by the autocorrelation that is inherent in a historical simulation. Here, we follow up with a designed simulation experiment in which we systematically varied the factors that are potentially important in determining good and bad years, and we further show the robustness of the simulation experiment results by repeating the experiment for each of the four alternative baseline conditions. We demonstrate that the results obtained under the original baseline conditions were similar under the four alternative baseline conditions (i.e., robust), and we further refine the role of various factors in determining good and bad years.

MODEL DESCRIPTION

Overview

The individual-based model followed the reproduction, growth, mortality, and movement of super-individuals over their entire life cycle (from eggs to age 3) on the same spatial grid as the Delta Simulation Model (DSM2) hydrodynamics model that was developed by and is widely used by the California Department of Water Resources (baydeltaoffice.water.ca.gov/modeling/deltamodeling/models/dsm2/dsm2.cfm). A model year was defined as a water year: October 1 of the previous year to September 30 (e.g., model year 2001 extends from October 1, 2000, to September 30, 2001). The model is described in detail by Rose et al. (2013) and is briefly summarized here.

The spatial grid was one-dimensional, with 517 channels and 5 reservoirs (Figure 1 in Rose et al. 2013). The DSM2 hydrodynamics model provided hourly values of water velocities and flows into and out of channels and reservoirs, which were used as inputs to a particle tracking model (PTM) that was embedded in the Delta Smelt individual-based model. A second grid of 11 coarser boxes was overlaid onto the channel grid, and values of daily temperature, salinity, and biomass densities of six zooplankton groups in each box were used to assign values to each channel.

For each super-individual, we tracked a suite of traits, including life stage, growth rate, weight, length, age, diet, location on the grid, maturity status, fecundity, and worth. Worth was the number of identical population individuals represented by the super-individual. Rather than following every individual and removing them upon death, we followed a fixed number of super-individuals and decreased their worth in each time step to account for mortality (Scheffer et al. 1995). All computations were scaled from the super-individuals to the population by multiplying by the worth of the super-individuals. Individuals were assigned to five life stages: egg, yolk sac larva, postlarva, juvenile, and adult. Advancement to the next life stage (development) was based on (1) temperature for egg to yolk sac larva

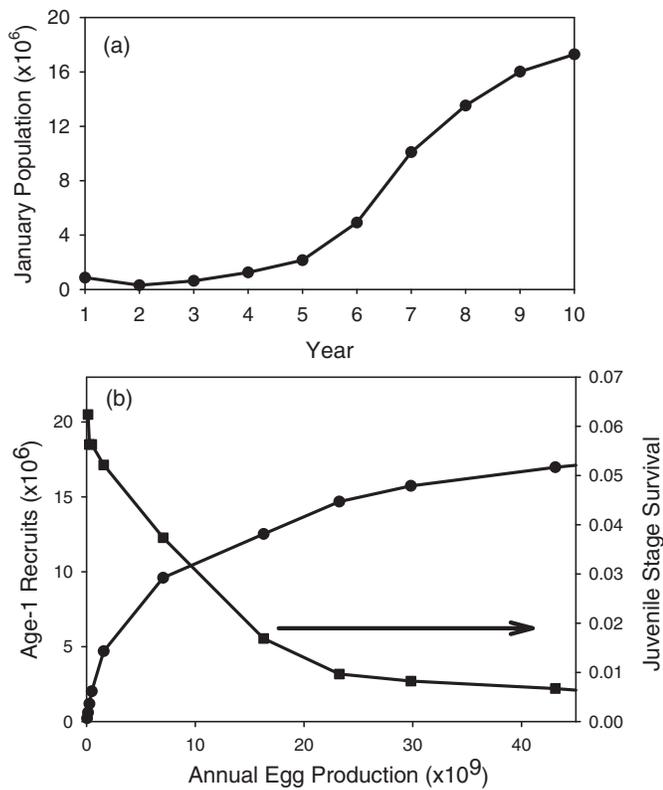

FIGURE 1. Simulated adult Delta Smelt abundance over time and juvenile survival from each year in a 15-year model run with artificially increasing egg production every year and density-dependent juvenile mortality: (a) adult abundance in January of each year and (b) age-1 recruits (circles, primary y-axis) and juvenile-stage survival (squares, secondary y-axis) versus annual egg production for each year.

to larva; (2) length for larva to postlarva to juvenile; and (3) date (January 1) for juvenile to age 1 and for age 1 to age 2.

Growth increments at each time step were determined from body weight, temperature, and the biomass densities of the six zooplankton groups (adult *Limnoithona* spp.; calanoid copepods; other calanoid adults; adult *Eurytemora*; adult *Acanthocyclops vernalis*; and adult *Pseudodiaptomus*). Length was then increased if fish weight had increased sufficiently. Mortality was a stage-specific, fixed rate plus starvation (if the weight of an individual fell below 50% of the weight expected for its length) and entrainment by the two water diversion facilities. Movement on the spatial grid was by physical transport using a PTM for yolk sac larvae, larvae, and postlarvae; movement was behavioral (in response to salinity) for juveniles and adults. Development, reproduction, growth, and mortality were updated daily, whereas movement of eggs and all larval stages was updated hourly and movement of juveniles and adults was updated every 12 h.

Model Outputs

In our companion paper (Rose et al. 2013), we presented a detailed comparison between individual-based model outputs

and data. We focus here on model predictions involving a small subset of those output variables. The major outputs presented for all simulations in this paper are the annual adult abundance in January and the annual finite population growth rate (λ). Annual adult abundance in January was computed as the summed worth of all individuals on January 1, including the young of the year that just became age 1 and the age-1 fish that just became age 2; it did not include age-2 fish that were just removed as they became age 3. We used the individual-based model output to estimate a Leslie age-based matrix model for each year to summarize the complicated individual-based model results with a single variable, λ . The value of λ was based on the detailed dynamics of the individual-based model but allowed for easier comparison among years. A 2×2 matrix model was estimated each year by computing the average maturity, fecundity, and age-specific survival rates and by using eigenvalue analysis to determine λ (see Supplement F in the online version of Rose et al. 2013).

Additional model outputs were used selectively to configure or confirm the alternative baselines and to provide some explanation for how the factors in the simulation experiment (described below) affected Delta Smelt. These outputs were defined and their calculations were described by Rose et al. (2013): stage-specific survival rates, recruitment (number of entering age-1 individuals on January 1), fraction of entering age-1 fish that were mature at the time of spawning, number of eggs per entering age-1 individual, percentage of individuals in and seaward of the Sacramento River–San Joaquin River confluence box at various times during the year (together with monthly average Sacramento–San Joaquin River Delta [hereafter, “Delta”] outflows), average daily fraction of larvae that were entrained in water diversions during a year, and annual fraction of adults that were entrained. Finally, we used a Lagrangian approach and reported the averaged values of p (proportion of maximum consumption) and temperature experienced by individuals for selected time periods in the simulations.

MODEL SIMULATIONS

Alternative Baselines

We configured four additional versions of the baseline model: fixed larval growth, size-dependent mortality, density-dependent mortality, and length-dependent maturity. We used the historical baseline simulation of 1995–2005 to help configure and calibrate the alternative baselines.

Fixed larval growth.—Model predictions of Delta Smelt abundance in the historical simulation were sensitive to larval growth rates, and we were uncertain about our formulation of larval feeding and bioenergetics. Use of a fixed duration for the larval stage eliminated variation in larval growth as a factor in year-to-year differences. Larval growth was fixed by specifying the larval duration in days rather than letting the transition from larva to juvenile be determined by length. We used the average

larval duration over years from the baseline simulation (26 d) for all simulations with the fixed larval growth rate.

Size-dependent mortality.—Mortality in the original baseline version was constant within each stage but decreased with successive stages, so penalties in survival for slow growth occurred only through the delay in transition from larvae to postlarvae and from postlarvae to juveniles. Making mortality length dependent reflected the idea that vulnerability to predation mortality decreases with increasing size (Sogard 1997; Bailey and Duffy-Anderson 2010; Gislason et al. 2010), so that faster growth would increase cumulative survival regardless of how stage transitions were triggered. We assumed that mortality rate was a function of length (M_L ; d^{-1}) for larvae through adults; we then fit the function to the constant stage-specific mortality rates from the baseline simulation, associating the rate with the midpoint length of each stage:

$$M_L = -0.034 + 0.165 \cdot L^{-0.322}. \quad (1)$$

We re-ran the 1995–2005 simulation and compared averaged annual stage-specific fractional survival rates between the baseline and the alternative with size-dependent mortality (Table 1) to confirm that this alternative produced mortality rates that were generally similar to those from the original baseline. Survival from yolk sac larva through age 2 was similar (4.4×10^{-5} in the baseline versus 3.5×10^{-5} under size-dependent mortality); juvenile survival increased (0.054 in the baseline; 0.073 under size-dependent mortality), and age-1 survival was approximately halved (0.092 in the baseline; 0.044 under size-dependent mortality).

Density-dependent mortality.—The original baseline version was set up as density independent because the recent Delta Smelt population is at such a low level that density-dependent effects seem unlikely. To allow for subsequent simulations at higher Delta Smelt densities, we included an alternative baseline with density-dependent mortality. The juvenile stage is the likely stage for density dependence based on general theory (Rothschild 1986; Cowan et al. 2000). Bennett (2005) and Maunder

and Deriso (2011) found evidence for a density-dependent relationship between summer and fall Delta Smelt indices, and this relationship occurs in our simulation for the juvenile life stage. We assumed a multiplier of the juvenile daily mortality rate based on the normalized density of juveniles in each box on each day,

$$M' = M \cdot e^{3.0 \left(\frac{D_t}{0.005} \right)}, \quad (2)$$

where D_t is the density of juveniles (number/ m^3) and 0.005 is an average juvenile density (number/ m^3).

We calibrated the value of 3.0 in equation (2) to obtain realistic maximum January adult abundances of about 20–25 million; the highest abundance estimate from the spring Kodiak trawl and fall midwater trawl (MWT) data during 1968–2006 was 24.3 million in 1981. We ran the model by repeating 1995 conditions from the historical simulation (high Delta Smelt survival) but with artificially increased egg production each year to generate a spawner–recruit curve under ever-increasing January adult abundances. We adjusted the multiplier in the exponent within equation (2) (final value = 3.0) until it generated a leveling off at high egg production that occurred roughly with about 20–25 million adults in January (Figure 1a). Juvenile-stage survival decreased with increasing population abundance from 0.06 to less than 0.01, resulting in a leveling off of age-1 recruits at about 20 million (Figure 1b). Abundance of age-1 recruits was similar to January adult abundance because most of the adults were age-1 individuals.

Length-dependent maturity.—The simple maturity rule (fish > 60 mm TL are mature) in the original baseline was substituted with a smoother, length-dependent maturity relationship (Figure 2). Model results were potentially sensitive to small

TABLE 1. Stage-specific durations (d) and survival (fraction) of Delta Smelt averaged over the 1995–2005 simulations for the original baseline and the alternative baseline that used size-dependent mortality.

Stage	Duration (d)		Survival (fraction)	
	Baseline	Size dependent	Baseline	Size dependent
Eggs	10.5	10.4	0.56	0.57
Yolk sac larvae	4.88	4.87	0.82	0.71
Larvae	26.3	26.0	0.23	0.25
Postlarvae	21.7	22.2	0.49	0.50
Juveniles	186	187	0.054	0.073
Age 1	365	365	0.092	0.044
Age 2	365	365	0.088	0.11

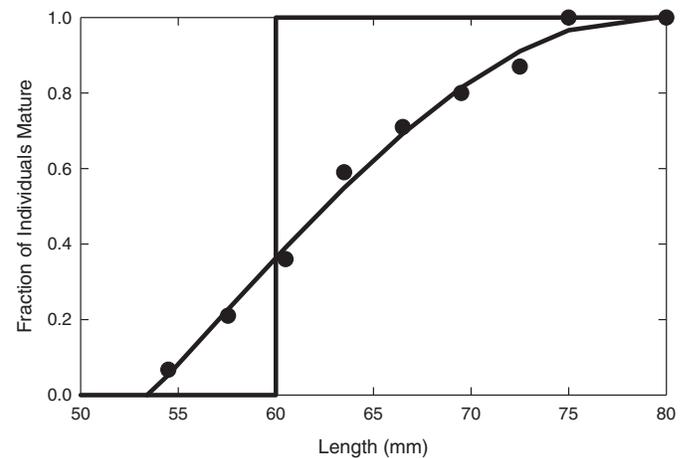

FIGURE 2. Fraction of Delta Smelt individuals that were mature as function of length for the baseline (60-mm cutoff) and the length-dependent maturity alternative. The points (circles) represent the fractions mature by length, estimated by assigning females (from the spring Kodiak trawl survey for 2002–2010) to 3-mm length bins and using ripe or spent individuals (condition codes 4–6) as mature.

changes in length of young of the year causing large changes in the mature fraction of individuals because typical lengths varied around 60 mm when maturity was determined. The relationship between fraction mature and fish length was fitted by allocating females that were sampled in the spring Kodiak trawl survey during 2002–2010 into 3-mm length bins and using ripe or spent individuals (codes 4–6) as mature. This resulted in an asymmetric relationship of fraction mature at around 60 mm (Figure 2). Use of other definitions for maturity resulted in relationships that were more symmetric at around 55–65 mm. We used the asymmetric relationship because it was justifiable based on the data and it provided a better test of model robustness.

Simulations under alternative baselines.—The 1995–2005 historical simulation with the original baseline (analyzed by Rose et al. 2013) was repeated with each of the four alternative baselines. We compared simulated January adult abundances and λ values among the original baseline and the four alternative versions. Results from a single simulation are presented. The individual-based model has stochastic aspects in assigning zooplankton biomass densities to channels and spawning temperatures to females, the y and z movements of the PTM, and the random component of behavioral movement. Because of the summing and averaging over many individuals and over time, population-level outputs (e.g., mean length at age, spatial distributions, and λ) varied by less than 5%—and often by less than 2%—among replicate simulations.

Good versus Bad Years

In this paper, we further explore the factors affecting the good year (1998) and bad year (2001) for Delta Smelt recruitment as identified in the analysis of the historical simulation (Rose et al. 2013). We performed a factorial simulation experiment to identify the conditions that caused the differences between water year 1998, which had the largest λ (2.45) within the baseline historical simulation, and water year 2001, which had the smallest λ (0.33) in the simulation. We varied five factors: salinity (S), temperature (T), zooplankton densities (Z), hydrodynamics (H), and eggs per entering age-1 individual (i.e., recruit) on January 1 (E). Each of these five factors was set to either its 1998 value or its 2001 value, resulting in a total of 32 (2^5) combinations.

Salinity.—Salinity affected the movement patterns of juveniles and adults and thus affected their spatial distribution and vulnerability to entrainment. The year 1998 was a high-outflow year, and salinities were very low for the modeled area from roughly March to August, after which salinity increased but remained below 5 psu (Figure 2b in Rose et al. 2013). Salinity in boxes down-estuary from the confluence was higher during the low-outflow year, 2001, than during 1998; this higher salinity occurred throughout 2001 except for a short period in March (Figure 2d in Rose et al. 2013). In the original baseline historical simulation, adults were located farther seaward with the salinity distribution in 1998. Average August outflow was 568 m^3/s in 1998 versus 90 m^3/s in 2001, and the percentage of adults that

were in or seaward of the confluence box on September 1 was 97% during 1998 versus 67% during 2001 of the original baseline simulation (Figure 10e in Rose et al. 2013). The fraction of January adults that were entrained was 0.05 in 1998 versus 0.14 in 2001.

Temperature.—Temperature affected the initial date and duration of the spawning period; the egg and yolk sac development and mortality rates; and the bioenergetics (growth) of larvae, postlarvae, juveniles, and adults. When viewed systemwide, differences in temperature between 1998 and 2001 were not obvious (Figure 2a, c in Rose et al. 2013). More detailed analysis of the historical simulation using the average temperature experienced by model individuals showed two major differences between 1998 and 2001: (1) warmer fall and winter at the beginning of the water year and (2) cooler and delayed warming in the spring. Fall 1997 and winter 1998 were warmer than fall 2000 and winter 2001. During October 1–December 30, juveniles experienced an average temperature of 15.9°C in 1997 versus 15.0°C in 2000. Mean temperature experienced by these individuals (which became adults after January 1) during February 27–June 7 (the spawning period) was 14.8°C in 1998 versus 16.4°C in 2001. The warming in the spring also occurred later in 1998, and the average day of spawning was April 28 in 1998 versus April 6 in 2001.

Zooplankton.—The effect of switching 1998 and 2001 zooplankton densities would seem to be the simplest to interpret because this factor only affected feeding rate and therefore growth rate; however, the use of multiple prey groups made interpretation difficult. Dominant prey groups in the annual diets of postlarval, juvenile, and adult Delta Smelt in the baseline simulation were other calanoid adults and adult *Pseudodiaptomus*. The differences between 1998 and 2001 in the biomass densities of these two key prey groups were complicated (see Figure 3c versus 4c and Figure 3f versus 4f in Rose et al. 2013). Although adult *Pseudodiaptomus* biomasses were generally higher during summer and fall in 1998 than in 2001, biomasses of other calanoid adults during summer and fall were higher in 2001 and biomass in the southwest Suisun Bay box during winter and spring was much higher in 2001. Biomass densities of the other zooplankton groups also showed complicated differences. For example, the biomass density of adult *A. vernalis* was higher (and occurred at high levels for a longer period) in the Suisun Marsh box during 1998, but adult *Eurytemora* biomass density was higher in the southern Delta and eastern Delta boxes during 2001 (see Figure 3d versus 4d and Figure 3e versus 4e in Rose et al. 2013).

We relied on the p -value from the bioenergetics model to infer prey availability. The p -value reflects prey availability scaled for maximum consumption rate, which also depends on temperature. The historical simulation using the original baseline version showed that average p -values experienced by juveniles during the faster fall–winter growth (October 1–December 30) was 0.76 in 1997–1998 versus 0.68 in 2000–2001. This difference, in combination with warmer temperatures, led to longer recruits

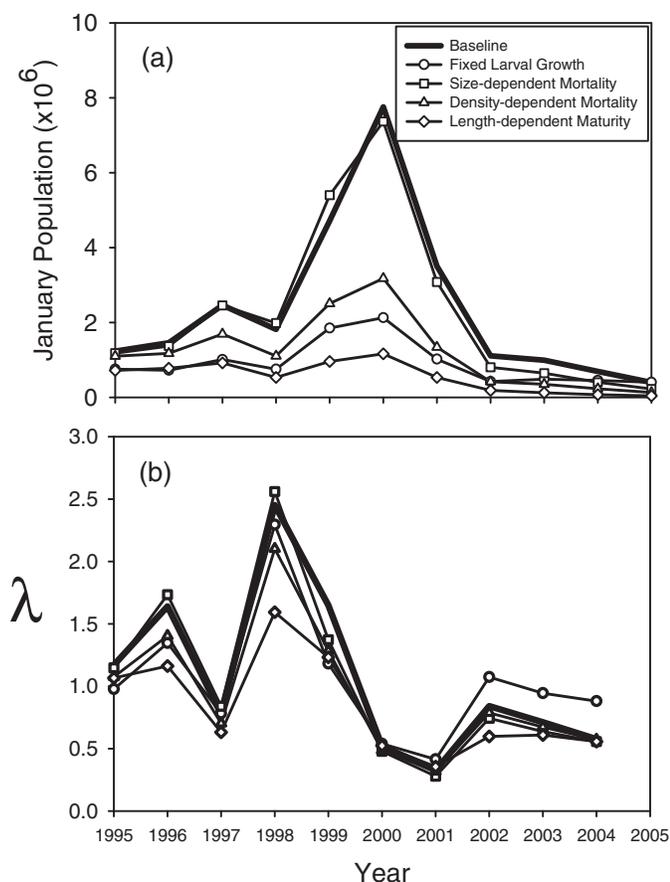

FIGURE 3. Simulated (a) annual adult Delta Smelt abundance in January and (b) finite population growth rate (λ ; fraction per year), 1995–2005, for the original baseline simulation and the four alternative baseline simulations. The values of λ were determined by using an age-based Leslie matrix model applied to individual-based model output for each year. No value for 2005 is possible because the simulations ended on September 30, 2005; information through December 31, 2005, would be needed to estimate the matrix model for 2005.

on January 1 in 1998 than in 2001 (mean TL = 61.4 mm versus 56.5 mm). Averaged p -values in 1998 were also somewhat higher during the summer growth period (April 18–October 1) for young of the year (0.89 in 1998 versus 0.84 in 2001), although by October the mean lengths of young of the year were only slightly greater in 1998 than in 2001 (54 mm versus 52 mm).

Hydrodynamics.—Hydrodynamics affected the entrainment of yolk sac larvae, larvae, and postlarvae via the PTM; the entrainment of juveniles and adults; and the starting locations of new juveniles by determining the transport of larval life stages. Average May outflow was 1,922 m³/s in 1998 versus 273 m³/s in 2001, and the percentage of postlarvae that were in or seaward of the confluence box after transport (June 24) was 84% in 1998 versus 24% in 2001. Almost no larvae were predicted to be entrained during 1998, whereas the daily average entrainment loss was 1.2% in 2001.

Eggs per age-1 individual.—Unlike the other factors, which had readily available values for 1998 and 2001, the number of eggs per age-1 individual required additional calculations in the model to achieve 1998 or 2001 values in the factorial simulation experiment. The number of eggs per age-1 fish reflected growth that occurred in the fall and winter leading up to spawning. In the original historical simulation, the mean length of young of the year on October 1 was somewhat greater in 1997 (starting value for 1998) than in 2000 (54.0 mm versus 52.0 mm) due to the more favorable summer conditions in 1997 than in 2000. This small difference was amplified by warmer temperature and higher prey densities in the fall and winter of 1997, resulting in a mean length of 61.4 mm on January 1, 1998, versus 56.5 mm on January 1, 2001. These lengths straddled the 60-mm maturity cutoff, and whereas 72% of entering age-1 individuals were mature in 1998, only 15% of entering age-1 fish were mature in 2001 of the historical baseline simulation. Thus, although there were fewer recruits on January 1, 1998, than on January 1, 2001 (0.159×10^7 versus 0.258×10^7), the number of mature age-1 female spawners was greater in 1998 (0.287×10^6 versus 0.1105×10^6) and egg production was about 1.5 times higher in 1998 (0.942×10^9 versus 0.641×10^9).

In the historical baseline simulation, the average number of eggs per age-1 individual was 491.8 for 1998 versus 89.3 for 2001. We did not explicitly simulate the previous year's conditions for the simulation experiment, in which either 1998 or 2001 conditions were repeated year after year. Rather, we adjusted the fecundity of entering age-1 individuals each year when we projected spawning so that the total projected number of eggs divided by the number of simulated entering age-1 individuals would be either 491.8 or 89.3.

Simulations in the good year versus bad year experiment.—Simulations were for 15 years, with 4 years of spin-up using 1999 conditions as in the baseline simulations, followed by 11 years of 1 of the 32 combinations of 1998 or 2001 conditions repeated every year. We used the two extreme years because they provided the best contrast for separating out the effects of multiple factors and thus for identifying which factors were most important in determining year-class strength. Eleven years of repeated conditions were simulated in order to ensure that we had the long-term (equilibrium) population responses to the specified conditions; shorter simulations could be affected by initial conditions and still reflect aspects of the transient solutions. We refer to the 32 combinations by using the letters of the factors that were set to 2001 values (i.e., S for salinity, T for temperature, Z for zooplankton, H for hydrodynamics, and E for eggs per entering age-1 individual). For example, in the simulation labeled “ EH ,” eggs per age-1 fish and hydrodynamics were set at 2001 values, while salinity, temperature, and zooplankton were set at 1998 values. We report λ averaged over years 10–14 of each 15-year simulation. As with the baseline simulations, results from a single simulation are presented because replicate simulations differed by less than 5% in their population-level outputs. Values of λ that were 25% and 50% higher than the

2001 value are shown for reference to aid in judging how close the other λ values were to the 2001 value.

Robustness

To confirm the robustness of results based on the original baseline, we also repeated all of the 32 simulation combinations under each of the four alternative baseline conditions. We only report the averaged λ for years 10–14 for four combinations (*ET*, *EH*, *ETH*, and *ETHS*) that resulted in low λ values to illustrate that the full set of combinations was robust to the alternative baselines. We focused on these four combinations because they resulted in low λ values near the 2001 value and because their robustness is particularly important, as they form the basis for identifying which factors determine how a good year differs from a bad year.

RESULTS

Alternative Baselines

The use of size-dependent mortality resulted in January adult abundances similar to those in the original baseline, while the alternative baselines with fixed larval growth, density-dependent mortality, and length-dependent maturity resulted in January abundances that were lower than those in the original baseline (Figure 3a). Lower peak abundances were expected for the density-dependent mortality version because juvenile survival was specified to decrease under high abundances. Larval growth (and therefore larval-stage survival) had an important influence on both good and bad years. Lower abundances under length-dependent maturity occurred because the maturity relationship was not symmetric around 60 mm (Figure 2) and thus would, on average, result in a lower fraction of young of the year becoming mature than was observed with the simple 60-mm rule in the original baseline.

Despite these differences in January abundances, λ values were very similar for all versions of the baseline, with the length-dependent maturity alternative differing the most from the original baseline (Figure 3b). Relatively high January adult abundance occurred in 2001 (Figure 3a), despite the lowest λ being observed in that year, because January abundance was related to conditions in the previous summer and fall and was not reflective of the spring and summer conditions in 2001. The high λ values during years prior to 2001 led to high January adult abundance in 2001. The temporal pattern in λ values for length-dependent maturity was the same as that for the original baseline, but values in all years were lower than baseline values, with the largest difference occurring in 1998 ($\lambda = 1.59$ for length-dependent maturity versus 2.45 for the original baseline). The original baseline and the four alternatives all identified 1998 as the best model year and 2001 as the worst model year for Delta Smelt.

Systematic Comparison of Best versus Worst Years

The intersimulation variability in λ values decreased and more combinations approached the 2001 value as the number of factors set to 2001 values increased (Figure 4). The percentage of combinations that resulted in λ values within 50% of the 2001 λ value increased from 0% when one factor was set to the 2001 value to 10% for two factors at 2001 values, 50% for three factors at 2001 values, and 60% for four factors at 2001 values. All but one of the combinations that generated a λ value within 50% of the 2001 value involved either eggs per age-1 individual or temperature being set at the 2001 value.

Juvenile growth in the fall prior to spawning (i.e., as reflected by the number of eggs per age-1 fish) was the most important single factor in making 2001 a bad year, although no single factor alone was sufficient to fully account for the poor conditions in 2001 relative to 1998 (Figure 4). Temperature (*T*) played an important secondary role (Figure 4, shaded circles), and hydrodynamics (*H*) played a more minor role; salinity (*S*) and zooplankton (*Z*) as single factors were unimportant. When one factor at a time was switched from 1998 to 2001 values (Figure 4, leftmost section), only eggs per age-1 fish (*E*) resulted in a λ value less than 1.0. The single factors *T* and *H* (each at the 2001 value) generated the second- and third-lowest λ values (1.1 and 1.5). As a single factor, *Z* (which determined

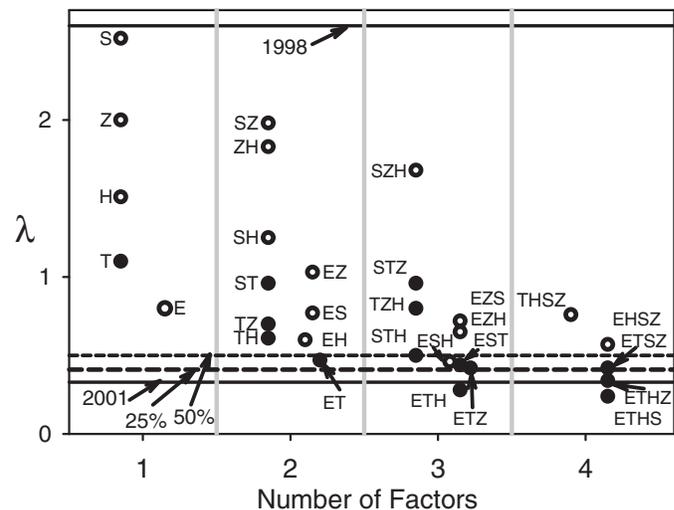

FIGURE 4. Contributions of five factors to differences between the best year (1998) and worst year (2001) for Delta Smelt. Each circle represents the mean finite population growth rate (λ) for years 10–14 of a 15-year simulation of repeated conditions for each factor (salinity [*S*], temperature [*T*], zooplankton [*Z*], hydrodynamics [*H*], and number of eggs per age-1 individual [*E*]) at either 1998 or 2001 values. Results are organized by the number of factors that were set to 2001 values (i.e., 1–4 factors; each combination code [e.g., “*STZ*”] lists the factors set at 2001 values); within each section, results with the number of eggs per age-1 individual at its 1998 value are shown on the left and results with that factor at its 2001 value are shown on the right. Shaded circles denote all combinations that included the 2001 temperature. The 1998 and 2001 values of λ are indicated by solid horizontal lines; the dotted horizontal lines represent λ values that are 25% and 50% higher than the 2001 value.

growth) generated a λ of 2.0, which was lower than the value for 1998 ($\lambda = 2.6$) but still much higher than the value for 2001 ($\lambda = 0.33$). When only S was set to the 2001 value, there was almost no effect on λ (2.52 versus 2.60).

All combinations of two factors set at 2001 values with eggs per age-1 individual at its higher 1998 value (left-side points in Figure 4, second section) generated λ values above 0.6; among these two-factor combinations, temperature and hydrodynamics at 2001 values together (*TH*) resulted in the lowest λ (0.61). The three lowest λ values all included 2001 temperature (Figure 4, shaded circles). The two-factor combinations that included the 2001 value for eggs per age-1 fish (right-side points in Figure 4, second section) resulted in λ values less than 1.0, and the *ET* and *EH* combinations produced λ values less than 0.6. Again, the lowest of these λ values was from the combination *ET* (Figure 4, shaded circle) and approached the λ value predicted for 2001 (0.47 versus 0.33).

Among the three-factor combinations set at 2001 values with eggs per age-1 individual set at the 1998 value (left-side points in Figure 4, third section), temperature and hydrodynamics were important. The highest λ (1.68) was predicted for the one combination that did not include 2001 temperature (*SZH*). The combinations with the three lowest λ values included the 2001 value for temperature (*STZ*, *TZH*, and *STH*; Figure 4, shaded circles); the two lowest of these λ values were from combinations that also included 2001 hydrodynamics ($\lambda = 0.8$ for *TZH* and 0.5 for *STH*).

When the number of eggs per age-1 fish was included as one of the three factors set at 2001 values (right-side points in Figure 4, third section), all λ values were less than 1.0. The combinations also including 2001 temperature (*ETH*, *ETZ*, and *EST*) generated the lowest λ values (0.28, 0.42, and 0.44, respectively), which were close to the λ value for 2001. The combinations that did not include 2001 temperature (Figure 4, open circles) generally had higher λ values (0.72 for *EZS* and 0.65 for *EZH*); the exception was *ESH*, which yielded a λ value (0.46) similar to those from the three combinations that included the 2001 temperature.

The number of eggs per age-1 individual and temperature continued to be very important in four-factor combinations. All four-factor combinations that included the 2001 value for eggs per age-1 fish (right-side points in Figure 4, fourth section) resulted in λ values less than 0.5, and those combinations that also included 2001 temperature (Figure 4, shaded circles) generated λ values that were close to the 2001 value. Of the four combinations that included the 2001 value for eggs per age-1 fish, the three combinations that also included 2001 temperature (*ETSZ*, *ETHZ*, and *ETHS*) all generated λ values less than 0.45, whereas the combination without temperature (*EHSZ*) generated the highest λ value (0.60). The remaining four-factor combination (*THSZ*; left-side point in Figure 4, fourth section), in which the number of eggs per age-1 individual was set at the 1998 value, generated the highest λ (0.85) observed for any four-factor combination.

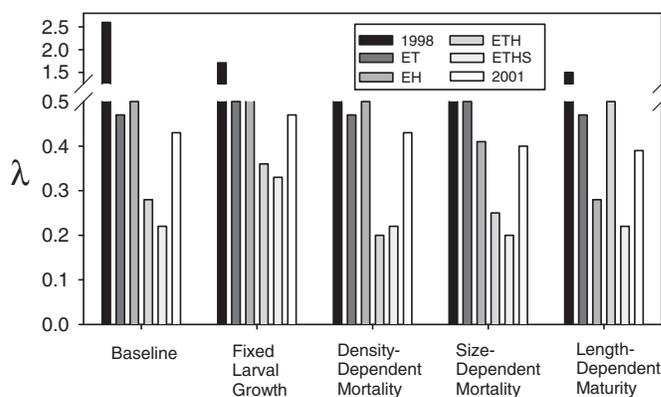

FIGURE 5. Averaged finite population growth rate (λ ; years 10–14) of Delta Smelt under the four alternative baselines and the four factor combinations that resulted in low λ values near the value for 2001. Factors are salinity (S), temperature (T), zooplankton (Z), hydrodynamics (H), and number of eggs per age-1 individual (E); each combination code (e.g., “*ETH*”) lists the factors that were set at 2001 values, and the remaining factors (i.e., with letters not shown) were set at 1998 values.

Robustness

The conditions leading to the good year (1998) were more sensitive to alternative baselines than the poor conditions leading to the bad year (2001; Figure 5). The four combinations (i.e., selected from Figure 4) that produced low λ values when set to their 2001 values under the original baseline generated similarly low λ values under the four alternative baselines. In contrast, the λ values varied more among the 1998 simulations. The alternative of density-dependent mortality produced the greatest reduction in λ for 1998 (λ decreased from 2.45 to 1.00). Larval growth and length-dependent maturity were also important in attaining the high λ predicted for 1998 in the original baseline. When larval growth was fixed at the overall average value (fixed duration), λ was reduced from 2.45 in the original baseline to 1.7; under length-based maturity, λ was reduced to 1.5. Size-dependent mortality was associated with the smallest reduction in the λ value for 1998 (λ decreased from 2.45 to 2.13).

DISCUSSION

Our analysis using a simulation experiment approach further clarified the relative influence of factors affecting Delta Smelt recruitment and population dynamics. In our companion paper (Rose et al. 2013), we compared conditions in 1998 with those in 2001 by using the 1995–2005 historical simulation. The five factors analyzed were inferred to be important in the historical simulation because their values differed, at least in some ways, between the best year and the worst year. In this paper, we systematically varied the five factors in a factorial simulation experiment to look for main and interaction effects. We moved away from the historical sequence of years and performed 15-year simulations with either 1998 or 2001 values repeated every year to allow the simulated population to reach a quasi-steady-state response. We also showed that our results, when viewed

in a comparative mode, were generally robust to alternative versions of the baseline model.

Our results demonstrated that among the factors we examined, no single factor completely accounted for the difference between the high λ in the best year (1998) and the low λ in the worst year (2001). Growth of juveniles in the fall–winter, temperature, and hydrodynamics clearly had the strongest effects, but λ could not be brought down from its 1998 value to near its 2001 value without some combination of factors. Thus, our results support the growing consensus that no single factor explains the Delta Smelt decline that occurred during 1995–2005 (Bennett and Moyle 1996; Bennett 2005; Baxter et al. 2010; Thomson et al. 2010).

Although we have shown that growth conditions in fall–winter were an important factor, there are many ways to achieve the faster growth that was predicted for 1998 relative to 2001. The growth conditions in winter affected the lengths of entering age-1 fish on January 1, with a 1998 value of 60.2 mm versus a 2001 value of 58.8 mm, and consequently affected the fraction mature (0.55 versus 0.41) and the egg production per entering age-1 fish (502.6 versus 107.6). These values for 1998 and 2001 differ from those reported in Rose et al. (2013) because the present values are averaged from the repeated years in the simulation experiment, whereas in our other paper (Rose et al. 2013) we reported values for 1998 and 2001 within the historical simulation. The difference in predicted mean lengths between 1998 and 2001 was well within the range of observed interannual values (see Figure 6 in Rose et al. 2013). Our analysis did not, however, distinguish how juveniles attained greater lengths prior to becoming age 1 and spawning. We used 1998 and 2001 conditions, but other years can also generate similar differences in growth based on combinations of zooplankton conditions and temperature; essentially, any mechanism that allows new age-1 recruits to have a greater length prior to spawning would result in a high number of eggs per age-1 fish and would set the stage for a good year. This can be achieved via warmer winter temperature (as in 1998) or by higher zooplankton densities causing faster growth at any time from the previous summer through early spring. If zooplankton conditions are better at higher salinity (seaward), then hydrodynamics (via its effect on transport) or salinity could also produce faster growth by putting individuals in boxes with higher prey biomass densities. We did not systematically examine how temperature, zooplankton, hydrodynamics, and salinity during the growing season of the year before or during the winter–spring period could potentially combine to promote faster growth and larger spawners in the spring. Rather, we used the suite of conditions for 1998 and 2001 to contrast a good year with a bad year.

A second way to increase egg production without faster growth of spawners would be to increase young-of-the-year survival prior to spawning. Total egg production was calculated as the number of eggs per entering age-1 fish times the number of age-1 fish. Our results were robust to the size-dependent mortality and length-based maturity versions of the baseline, so the

growth of adults affected the number of eggs per age-1 individual but not the abundance of age-1 fish. Higher Delta outflow at key times resulted in reduced entrainment, and hydrodynamics were consistently an important factor. Further analysis should explore spatial (box-scale) differences in mortality, which, if sufficient, could benefit the Delta Smelt via management manipulation of hydrodynamics and salinity, generating differences in starting age-1 abundances for spawning. We assumed that except for entrainment losses, mortality was stage dependent but not spatially variable.

Our results for the importance of food (zooplankton) are similar to those of Maunder and Deriso (2011), but we disagree about the roles of entrainment and density dependence. Maunder and Deriso (2011) used a stage-based life cycle model, and by introducing covariates into life stage survival (spawner–recruit) relationships, they determined that food abundance, temperature, predator abundance, and density dependence were the most important factors controlling the population dynamics of Delta Smelt. They further stated that there was some support for negative effects of water clarity and adult entrainment.

Our simulation experiment contrasting the best year versus the worst year agrees with the important role of temperature and zooplankton, but we did not examine the effects of predator abundance or water clarity. Maunder and Deriso (2011) used spring and summer zooplankton conditions: minimum *Eurytemora* and *Pseudodiaptomus* densities for April–June; average *Eurytemora* density for July; and average *Pseudodiaptomus* density for July–August. We found that fall, winter, and early spring growth was potentially important, at least for the comparison between 1998 and 2001. Maunder and Deriso (2011) examined a longer time period (1970–2006) that covered larger changes in the zooplankton community, and this could emphasize the importance of spring and summertime zooplankton relative to other factors, such as winter growth and its consequences for spring reproduction. We recommend that conditions in the winter and early spring and conditions from the year before be further evaluated for their potential to benefit Delta Smelt.

We disagree to some extent with Maunder and Deriso (2011) about the role of entrainment and density dependence. Examination of Figure 8 of Maunder and Deriso (2011) to assess the role of entrainment showed more agreement with our analysis than did their general statement of “some support for a negative relationship with . . . adult entrainment.” They showed an approximately twofold increase in adults during 2002–2006 by eliminating entrainment. This agrees with our analysis, showing higher entrainment mortality during the same years as in our simulation; however, we would term their Figure 8 results as providing more than “some” support for a negative effect of adult entrainment. The Maunder and Deriso (2011) analysis covered a longer time period (1970–2006) than our analysis (1995–2005); thus, the role of covariates can differ and density dependence likely played a larger role at the earlier, higher abundance levels (see Bennett 2005). In addition, direct comparisons between the models are somewhat confounded because our analysis and the

Maunder and Deriso (2011) analysis shared some information, such as the entrainment estimates from Kimmerer (2008) and the spawner–recruit information from long-term monitoring.

Several statistical analyses of similar monitoring and covariate data as used by Maunder and Deriso (2011) also implicated various indicators of spring and summer zooplankton food availability as being important. Thomson et al. (2010) used Bayesian change point analysis to examine variation in the fall MWT index; Mac Nally et al. (2010) used multivariate autoregressive modeling to analyze the fall MWT index in a multispecies approach; and Miller et al. (2012) used Ricker spawner–recruit relationships to analyze the ratio of indices as survival indicators. These analyses all inferred that various combinations of water temperature, water clarity, zooplankton indicators, and entrainment were correlated to various degrees with the historical pattern in the Delta Smelt abundance indices.

Other assumptions that are inherent in our modeling merit further analyses as possible alternative versions of baseline conditions. The representation of predation on Delta Smelt was partially explored by using size-dependent mortality, but there are also temporal trends and spatial patterns to the key predators of Delta Smelt that could be important. Striped Bass *Morone saxatilis* and Largemouth Bass *Micropterus salmoides* show distinct spatial distributions within the San Francisco Estuary and have also exhibited recent temporal trends, with young Striped Bass declining and Largemouth Bass increasing (Nobriga and Feyrer 2007). Furthermore, exotic Mississippi Silversides *Menidia audens* are known to readily consume larval Delta Smelt and have increased substantially in recent years (Baerwald et al. 2012).

Another assumption worthy of investigation is that the Delta Smelt population in the individual-based model consisted of individuals that all exhibit the same migratory behavior. Limited field data indicate that there is partial or divergent migration (Secor 1999; Chapman et al. 2012) within the Delta Smelt population, with some individuals possibly remaining year-round in the Cache Slough region, which is located in the southwestern portion of our Sacramento River model box (Merz et al. 2011; Sommer et al. 2011). An alternative version of the baseline individual-based model could include some proportion of individuals that remain resident in some areas. Resident individuals, or individuals with reduced or altered migrations, could exhibit different growth because of spatial variation in temperature, zooplankton, and susceptibility to entrainment.

Our detailed individual-based approach is not commonly used to simulate the population dynamics of endangered fish species, although it can be adapted for use in the more traditional population viability analysis (PVA) and risk framework. The individual-based approach is increasingly being used to simulate fish population and community dynamics for purposes of answering ecological and fisheries management questions (DeAngelis and Mooij 2005). However, although the individual-based approach is usually mentioned in reviews of PVA approaches (e.g., Akçakaya and Sjögren-Gulve 2000; Morris et al. 2002; Petersen et al. 2008), the number of examples

of its use specifically for PVA remains quite limited. Some commonly used general models apply an individual-based approach, but they employ a very simple representation of processes (e.g., Jarić et al. 2010). Examples in which a more mechanistic individual-based model approach was used include models of endangered birds (Letcher et al. 1998), turtles (Mazaris et al. 2005), and recruitment of Colorado Pikeminnow *Ptychocheilus lucius*. Using an individual-based approach very similar to our Delta Smelt modeling, Jager et al. (2001) analyzed the effects of habitat fragmentation by dams on the White Sturgeon *Acipenser transmontanus*, which is a species of concern and has been listed as endangered elsewhere. Population viability analysis usually involves many realizations of a modeled population trajectory to generate risk values. Our individual-based model cannot easily be used to perform thousands of simulations. A possible link to a PVA-type analysis of Delta Smelt would be to (1) use the individual-based model in a systematic way to create crude probability distributions for the elements of the Leslie matrix model (which can generate λ values with Monte Carlo simulation) or (2) use the coupled individual-based model and Leslie model to directly generate distributions of λ values. Once sets of λ values are obtained for a variety of environmental and biological conditions, they can be used in more traditional PVA projections of long-term persistence (see Morris et al. 2002).

Our analysis addresses several ongoing methodological issues in fish population dynamics: spatial dynamics in complex habitats, coupled biological–physical modeling, and recruitment and population dynamics at low abundances. The need for studies of long-term population dynamics to deal with spatial dynamics has recently been discussed (Giske et al. 1998; Struve et al. 2010), and approaches that deal with spatial variation explicitly are receiving greater attention (e.g., Kerr et al. 2010). Increasingly, fish-related management issues require an integrated approach that combines the physics of water with the biology of the fish and other biota (Shenton et al. 2012), and one method is the direct coupling of fine-scale hydrodynamics with long-term fish population dynamics (Buckley and Buckley 2010; Rose et al. 2010; Hinrichsen et al. 2011; Stock et al. 2011).

Our model expands on the classical particle tracking approach by simulating detailed biological processes, relatively complicated behavioral movement, and multiple generations. Our Delta Smelt model simulated growth, survival, reproduction, and movement of individual fish on the same spatial grid as the hydrodynamics, and the super-individual method allowed for 15-year simulations. Although PTMs are commonly embedded within hydrodynamics models (North et al. 2009; Hinrichsen et al. 2011), the PTMs typically do not include detailed descriptions of growth and reproduction. Rather, these studies usually invoke, at most, simple movement behavior as an addition to passive transport and are mostly used for short-term (<1 year) simulations (Miller 2007; Lett et al. 2009; Gallego 2011). However, a consequence of full life cycle modeling that includes juveniles and adults within a detailed

spatial grid is that now we must simulate behavioral movement on relatively fine scales. Modeling behavioral movement is critical to ensure that individuals experience the appropriate conditions over time, but this remains a challenge (Watkins and Rose 2013). Delta Smelt movement patterns in our simulations were generally realistic but require further refinement.

Finally, much fish population modeling has focused on the effects of harvesting from high-number populations, whereas there is an increasing need to examine dynamics of fish populations at low abundances due to overharvest and in support of recovery plans for listed species (Keith and Hutchings 2012). The focus on harvesting leads to an emphasis on density-dependent mortality, often via the spawner–recruit relationship (Rose et al. 2001). Our approach differs from this by focusing on Delta Smelt population dynamics under density-independent conditions. We emphasized how individuals were transported through or navigated through their spatially complex and temporally varying habitat. Our analysis can be viewed as part of the broader idea of multiple factors within the match–mismatch theory of controls on young-of-the-year survival and therefore recruitment (Peck et al. 2012), coupled with the idea that adult bioenergetics are important for determining maturity and annual egg production (Neil et al. 1994; Rose et al. 2001). Because our model was density independent, all of the predicted variation in stage-specific survival rates was due to variation in how spatial distributions interacted with dynamic environmental conditions. Our results showed how the spatial and temporal positioning of all life stages each year (based on physical transport and salinity), combined with the pattern in daily water temperature and the amount of Delta outflow, affected the magnitude and location of egg production and the subsequent dynamic matching of larval and juveniles with their prey types, thus affecting recruitment success. However, even our modeling results were not simple to interpret, and therefore they also illustrate how spatially and temporally dynamic habitat can create complicated match–mismatch situations.

Delta Smelt have been at the center of escalating controversy in the San Francisco Estuary region for several decades (NRC 2010; Kimmerer 2011; Miller 2011). What initially arose as a conflict between water demands for export versus for the environment (including Delta Smelt) has metastasized as the number of ostensible factors behind the decline of Delta Smelt has grown (e.g., Mac Nally et al. 2010; Maunder and Deriso 2011; Miller et al. 2012). The conflict has now evolved into a complicated situation in which multiple factors operate in interactive ways and are continually being argued over in court (Delta Smelt Consolidated Cases 2010). Our results contribute to the growing number of examples showing that multiple factors affect aquatic ecosystems (Breitburg and Riedel 2005; Ormerod et al. 2010; Cloern and Jassby 2012) and that the search for a single factor controlling fish population dynamics is unlikely to be successful (e.g., Rose 2000; Krebs 2002; Hecky et al. 2010; Lindgren et al. 2011).

Our results to date suggest that management actions to benefit Delta Smelt must deal with multiple stressors that occur at different points in the life cycle. An increase in prey would induce relatively large responses in reproduction but may not be feasible. We showed that growth leading up to spawning was important for subsequent population growth; it remains to be seen whether it is possible to promote growth of Delta Smelt or higher young-of-the-year survival prior to spawning (fall–spring) via management actions. We also showed that no single factor can alone account for the differences between good and bad years and that promoting growth should be done in combination with other actions (if feasible) to (1) ensure good temperatures for summer growth and delayed spawning and (2) ensure sufficient outflow and avoidance of high entrainment (see results in Rose et al. 2013). Our results also demonstrate that expectations should be clearly stated, as most management actions are unlikely to generate large, immediate responses because the influence of stressors varies from year to year and because the reduction in a single stressor during any one year may be moderated by the conditions in other, non-manipulated stressors occurring in that year.

We envision two other areas for future analyses using the individual-based model. First, extending the model simulations for the periods before 1995 and after 2005 would allow for more comparisons and contrasts of good versus bad years to determine other combinations of factors that may be important; climate change scenarios should be included in these simulations to allow for future-looking comparisons. This would require use of the DSM2 hydrodynamic model or another hydrodynamic model and the development of synthetic temperature, salinity, and zooplankton data. Second, a more rigorous side-by-side comparison of the Maunder and Deriso (2011) model and our individual-based model would facilitate an understanding of the relative effects of key stressors on Delta Smelt population dynamics. The population dynamics and reasons for the decline of Delta Smelt are complex. However, complexity is not a reason to avoid rigorous quantitative analyses—indeed, it is perhaps the best reason to develop and compare alternative modeling approaches.

Sudden Clearing of Estuarine Waters upon Crossing the Threshold from Transport to Supply Regulation of Sediment Transport as an Erodible Sediment Pool is Depleted: San Francisco Bay, 1999

David H. Schoellhamer

Received: 21 June 2010 / Revised: 23 December 2010 / Accepted: 28 January 2011 / Published online: 19 February 2011

Abstract The quantity of suspended sediment in an estuary is regulated either by transport, where energy or time needed to suspend sediment is limiting, or by supply, where the quantity of erodible sediment is limiting. This paper presents a hypothesis that suspended-sediment concentration (SSC) in estuaries can suddenly decrease when the threshold from transport to supply regulation is crossed as an erodible sediment pool is depleted. This study was motivated by a statistically significant 36% step decrease in SSC in San Francisco Bay from water years 1991–1998 to 1999–2007. A quantitative conceptual model of an estuary with an erodible sediment pool and transport or supply regulation of sediment transport is developed. Model results confirm that, if the regulation threshold was crossed in 1999, SSC would decrease rapidly after water year 1999 as observed. Estuaries with a similar history of a depositional sediment pulse followed by erosion may experience sudden clearing.

Introduction

Suspended-sediment concentration (SSC) in an estuary is commonly determined by a periodic cycle of erosion and deposition (for examples see Grabemann et al. 1997; Schoellhamer 2002; Tattersall et al. 2003; Wolanski et al. 1995). Slack tides, neap tides, and periodic stratification enable deposition on the bed, and tidal currents, spring tides, and wind waves apply shear force to the bed that resuspends sediment. At any moment, the amount of sediment that estuarine waters can suspend is regulated either by the available hydrodynamic energy (transport regulation) or by the mass of erodible sediment in the estuary (supply regulation). In addition, estuaries can be transport-regulated if the quantity of suspended sediment is limited by the duration of resuspension. For example, the duration of tidal resuspension may be limited by the time between slack tides, and the duration of wind-wave resuspension may be limited by the duration of storms, diurnal wind, or shallow depths that allow surface waves to apply sufficient shear to the bed. The concept of transport and supply regulation has been applied to riverine sediment transport (Rubin and Topping 2001).

A simple conceptual model of estuarine sedimentation is that an estuary contains an erodible sediment pool, some or all of which is suspended or resting on the bed at any given time (Fig. 1a). If all of the erodible sediment is suspended, then sediment transport is supply-regulated. If some of the erodible sediment is always on the bed, then sediment transport is transport-regulated. Outflow to the ocean and permanent deposition such as in a wetland reduce the erodible sediment pool. Supply from the watershed or ocean increases the erodible sediment pool. An estuary is in dynamic equilibrium when the erodible bed sediment

mass is constant. A time scale of perhaps decades must be considered for dynamic equilibrium because of seasonal and annual variations in watershed hydrology and oceanography.

The purpose of this paper is to demonstrate that SSC in an estuary can suddenly decrease when an erodible sediment pool becomes depleted, and this may explain a decrease in SSC in San Francisco Bay beginning in 1999. First, the motivation for this work, a decrease in SSC in San Francisco Bay beginning in 1999, is presented. Analysis of bathymetric change data supports the hypothesis that the bay contained an erodible pool of sediment that was depleted in the late 1990s. A simple quantitative conceptual model is then developed to test the plausibility of the hypothesis that depletion of an erodible sediment pool causes a step decrease in SSC. Homogeneity within the estuary is assumed as this paper focuses on the net functionality of the estuary as a component in the watershed/estuary/ocean system.

San Francisco Bay Sedimentation

San Francisco Bay is composed of four subembayments, Suisun, San Pablo, Central, and South Bays, connected to the Pacific Ocean through the Golden Gate (Fig. 2). The bottom sediments in South Bay and in the shallow water areas (less than 3–4 m) of Central, San Pablo, and Suisun Bays are composed mostly of silts and clays. Silts and sands are present in the deeper parts of Central, San Pablo, and Suisun Bays and in Carquinez Strait (Conomos and Peterson 1977). The average depth of the Bay is 2 m at mean lower low water. Tides are mixed with a range of 1 to 3 m. About 90% of freshwater inflow to the Bay comes

from the Central Valley of California and flows through the Sacramento-San Joaquin River Delta to Suisun Bay. South Bay receives much less freshwater flow than Suisun Bay. Tributaries from much smaller local watersheds provide the rest of the freshwater inflow. About 89% of SSC variability is associated with semidiurnal, fortnightly, monthly, and semiannual tidal cycles, seasonal wind, and river supply (Schoellhamer 2002). Winds and wind wave resuspension are greatest in spring and summer. There are two distinct hydrologic seasons: a wet season from late autumn to early spring with the remainder of the year being dry. Sediment from the watershed is delivered during the wet season (McKee et al. 2006). Thus, the water year (WY), which begins on October 1 and ends on September 30, is a convenient period to average water quality data such as SSC because it begins in the dry season, includes a single wet season, and ends in the dry season.

Watershed sediment supply to the bay from the Central Valley has been severely disturbed by humans since the late 1800s (Fig. 3). Hydraulic mining for gold in the late 1800s washed sediment into Central Valley rivers and the bay (Gilbert 1917). During the 1900s, many dams that trap sediment were constructed in the watershed (Wright and Schoellhamer 2004). The largest source of watershed sediment is the Sacramento River, for which 87–99% of the total load is suspended load (Porterfield 1980; Schoellhamer et al. 2005; Wright and Schoellhamer 2004). More than one half the banks of the lower Sacramento River were riprapped during the later half of the twentieth century, protecting them from erosion and decreasing sediment transport in the river (USFWS 2000). Flood control bypasses built in the Sacramento River floodplain during the early twentieth century trap sediment and reduce downstream sediment supply (Singer et al. 2008). Diminishment of the hydraulic mining sediment pulse, sediment trapping behind dams and in flood control bypasses, and bank protection all contribute to decreased sediment supply from the Central Valley to the bay. Suspended sediment supply from the Sacramento River gradually decreased by one half from 1957 to 2001 (Wright and Schoellhamer 2004). Total suspended-solid concentration in the Sacramento-San Joaquin River Delta decreased from 1975 to 1995 (Jassby et al. 2002). Canuel et al. (2009) found that sediment and carbon accumulation rates in the Sacramento-San Joaquin River Delta were 4–8 times greater before 1972 than after. At the end of the 1900s, sediment supply from the Central Valley was about equal to that from other more local bay tributaries (Schoellhamer et al. 2005).

The hydraulic mining sediment pulse deposited in Suisun, San Pablo, and Central Bay in the 1800s (Cappiella et al. 1999; Fregoso et al. 2008; Jaffe et al. 1998). In the 1900s, these subembayments became erosional.

San Francisco Bay Suspended-Sediment Concentration Step Decrease

The US Geological Survey has used automated optical sensors to measure SSC every 15 min at several stations in San Francisco Bay beginning in December 1991 (Fig. 2, Buchanan and Lionberger 2009; Schoellhamer et al. 2007). Sensors from several manufacturers have been deployed. An optical sensor transmits a pulse of light that scatters off of suspended particles and is measured by the sensor. Every

3–4 weeks, the sensors are cleaned, data are downloaded, and calibration samples are collected. About one half of the data are invalid due to biofouling of the optical sensor, but the quantity of valid data in more recent years is approaching three quarters because self-cleaning sensors have improved.

An example time series of SSC data from mid-depth at Point San Pablo shows a decrease in SSC in the late 1990s (Fig. 4). This time series is shown because it is relatively lengthy and complete. Much of the tidal variability of the

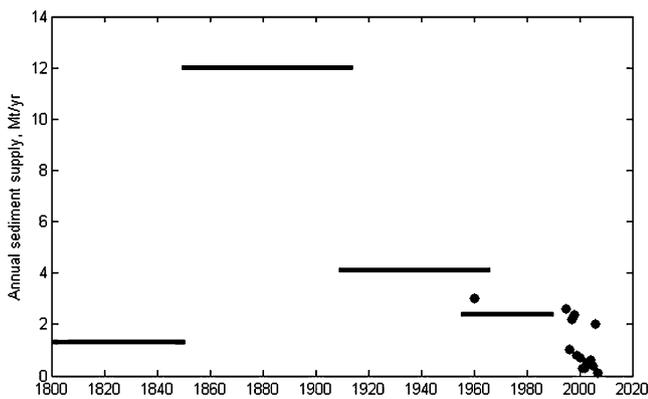

Fig. 3 Estimated annual sediment supply from the Central Valley to San Francisco Bay. Estimates from Gilbert (1917), Krone (1979), Porterfield (1980), Ogden Beeman and Associates (1992), McKee et al. (2006), and David et al. (2009). Bars indicate estimates over entire period, and points indicate yearly estimates. A bulk density of 850 kg/m³ was assumed (Porterfield 1980)

data is compressed into what appears as a solid band of data. The band is generally thickest in the spring and early summer when wind waves resuspend sediment deposited during the previous winter wet season. The band is thinnest in autumn when wind decreases and before the wet season delivers new sediment from the watershed. Maximum values of SSC were observed during floods in early 1997 and 1998.

SSC at most sites from the early 1990s to WY 1998 was almost double that from WYs 1999 to 2007 (Table 1). Mean SSC after September 30, 1997 was 36% less than before. The step change in the water year mean SSCs from WY 1998 to 1999 was significant (one-sided rank-sum test $p < 0.01$) at all sites except San Mateo Bridge. Water year mean SSC was analyzed rather than monthly mean SSC to avoid problems with variation of the timing of seasonal inflow, turbidity maxima, and seasonal wind from year to

year and by increased susceptibility of missing data biasing monthly means.

The SSC time series are derived by editing data from optical instruments and are subject to some interpretation, but the step change also appears in the water samples collected to calibrate the sensors. At Point San Pablo, 248 water samples were collected at mid-depth from WY 1993 to 2006, and SSC had a statistically significant step decrease (rank-sum test $p = 3.4 \times 10^{-10}$) from WYs 1993–1998 to WYs 1999–2006. The same laboratory method was used for all samples (Buchanan and Lionberger 2009).

Data from monthly water quality cruises by the US Geological Survey provide some confirmation of a step decrease despite a significantly smaller sampling frequency. At specified stations along the axis of the bay from South Bay to the Delta, vertical profiles of basic water quality properties are measured (<http://sfbay.wr.usgs.gov/access/wqdata/>). Suspended particulate matter (SPM) is measured, for which the laboratory analysis is identical to SSC measured by the continuous monitoring program (Gray et al. 2000). SPM in Suisun Bay and San Pablo Bays 1 m below the water surface had a significant step decrease

(one-sided rank-sum test $p=0.00$) from WYs 1975–1998 (median 34 mg/L) to WYs 1999–2008 (median 23 mg/L). SPM in South Bay south of the Dumbarton Bridge also had a significant step decrease (one-sided rank-sum test $p=6.2 \times 10^{-5}$) from a median of 36 to 27 mg/L. Central Bay and South Bay north of the Dumbarton Bridge did not have a significant decrease. Cloern et al. (2007) found that SPM from 1978 to 2005 in South Bay had an increasing trend that was not statistically significant. Their results differ from the analysis presented here because they tested for a trend rather than a step decrease, used a slightly smaller data set, and combined all South Bay data.

The step decrease in SSC does not appear to be due to a sudden decrease in sediment supply from rivers. In general, most measured years before the step decrease had large sediment loads, and all but 1 year after the decrease had small sediment loads (Fig. 5). The exceptions, however, indicate that SSC in a given year cannot be explained by river supply during that year. Before the step decrease, WY 1994 was a dry year (7,419 Mm³ of runoff from the Central Valley), but mean SSC was relatively large (95 mg/L, Table 1). Freshwater inflow is used here as a surrogate for sediment supply (Fig. 5) because no sediment supply data are available for WY 1994. After the step decrease, WY 2006 was a wet year (50,020 Mm³), yet mean SSC was only 39 mg/L (Table 1). If river sediment supply in a given water year is the only source of suspended sediment, then SSC would vary with river sediment supply. WYs 1994 and 2006 indicate that river supply does not directly determine SSC.

A hypothesis to explain these data is that the bay contained an erodible pool of sediment that was depleted in the late 1990s (Fig. 1b). Prior to the step decrease, bay SSC would remain high in water years with little watershed sediment supply because the erodible sediment pool supplied suspended sediment and SSC was transport-regulated. Bathymetric surveys (Cappiella et al. 1999;

Fregoso et al. 2008; Foxgrover et al. 2004; Jaffe et al. 1998) and sediment budgets prior to 1999 (Ogden Beeman and Associates 1992; Schoellhamer et al. 2005) show that the bay was eroding. WY 1998 was a wet year for which high flow persisted well into summer, probably flushing sediment from the bay to the Pacific Ocean. Despite a large sediment supply, sediment export from Suisun Bay was 8–9 times greater than sediment supply (Ganju and Schoellhamer 2006). After the step decrease in WY 1999, bay SSC is lower because the erodible pool decreased enough that sediment transport crossed the threshold from transport to supply regulation. Suspended and bed sediment exchange through erosion and deposition, but the erodible sediment pool is smaller. Not even wet years (e.g., 2006) supply enough sediment to restore the pool and transport regulation of suspended sediment, so SSC remains low. The transport capacity of bay waters exceeds the river supply and the depleted erodible pool, so sediment transport is now supply-regulated.

San Francisco Bay Erodible Sediment Pool

Analysis of historical changes in bed sediment volume supports the hypothesis that the bay contained an erodible pool of sediment that was depleted in the late 1990s. Bed sediment volume changes in the four subembayments of San Francisco Bay from the mid 1800s to late 1900s were calculated by comparing successive bathymetric surveys by Cappiella et al. (1999), Fregoso et al. (2008), Foxgrover et al. (2004), and Jaffe et al. (1998). The analyses used nearly identical methods and corrected for tidal epoch, sea level, dredging, borrow pits, and subsidence. Readers should refer to these reports for details. Systematic errors within a subembayment are less than 10 cm and typically range from one to several centimeters (Fregoso et al. 2008). In the best case, these errors would be random between subembayments, and they would cancel. In the worst case, these subembayment errors would be additive, and the maximum error for baywide sediment volume change would be 12–120 Mm³ (3–30% of the maximum bay volume change). Surveys were conducted at different times in different subembayments, and not all surveys covered an entire subembayment. From 1855 to 1990, the entire bay was surveyed five times, and for each survey, 11 to 14 years passed from surveying the first to last subembayment. Thus, the change in bed sediment volume from the first survey period (1855–1867) can be calculated for the four subsequent periods. Bed sediment volume change for incomplete surveys was estimated by multiplying the measured volume change by the ratio of total to measured surface area.

Supply of hydraulic mining sediment increased bed sediment volume by at least 260 Mm³ in the late 1800s

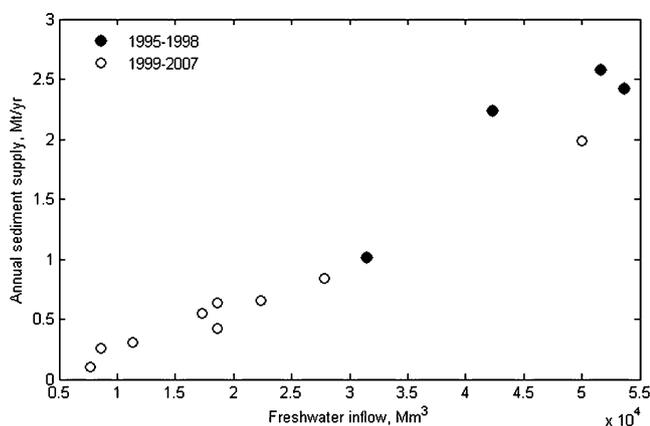

Fig. 5 Sediment supply from the Central Valley to San Francisco Bay, water years 1995–2007 (McKee et al. 2006; David et al. 2009)

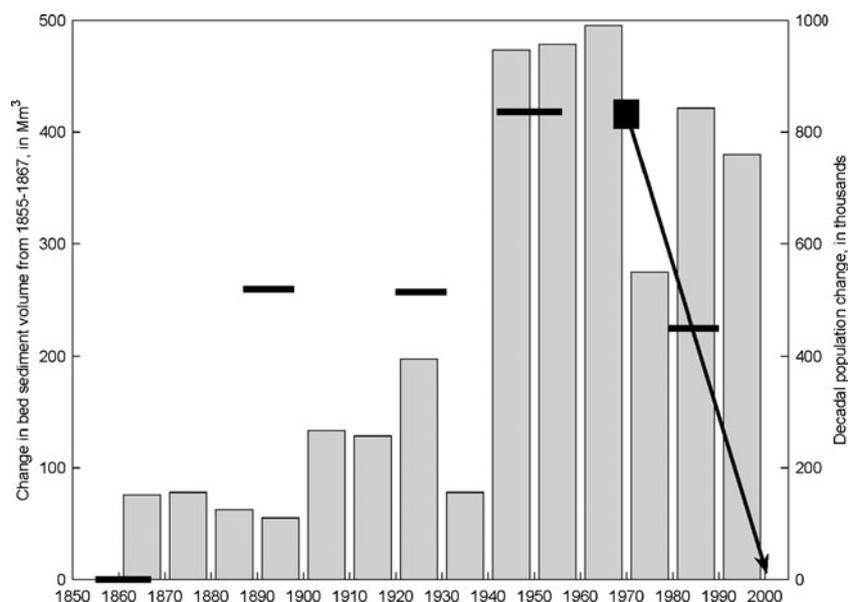

Fig. 6 San Francisco Bay sediment volume change from the 1855 to 1867 surveys (*lines*) and decadal population change (*bars*). Each subembayment was surveyed during the period shown by *each line*. Population is within the nine counties bordering San Francisco Bay (Bay Area Census 2009). Bathymetry data are from Cappiella et al. (1999), Fregoso et al. (2008), Foxgrover et al. (2004), and Jaffe et al.

(1998). Assuming that the bed sediment volume in 1970 was equal to the mid-1900s value (*square*, see text for explanation), a *line that passes through the midpoint of the late 1990s bed sediment volume measurement period* indicates that bed sediment volume would equal the 1855–1867 value in 2001

(Fig. 6), almost entirely in Suisun and San Pablo Bay. There was little change in total bed sediment volume in the early 1900s as hydraulic mining sediment continued to enter the bay at what was probably a smaller rate (Fig. 3) and the pulse of hydraulic mining sediment moved into the intertidal zone or Pacific Ocean.

From the early to mid-1900s, bay sediment volume increased by 160 Mm^3 . This second pulse of sediment was about 60% of the hydraulic mining sediment pulse and may have been caused by urbanization or increased agricultural land use. Unfortunately, there are no sediment load measurements in rivers supplying sediment to the bay during this time, so ascription of this sediment pulse is somewhat speculative. The probability that a given extremely large freshwater inflow, which are responsible for most sediment supply from the Central Valley to the bay (McKee et al. 2006), would be exceeded increased from the 1861 to 1984 (Fig. 7). Thus, freshwater inflow is an unlikely explanatory variable for the variation in bay sediment volume or the mid-1900s sediment pulse. Population of the nine county San Francisco Bay Area increased by almost one million people per decade from 1940 to 1970 (Fig. 6) as the population increased from 1.7 to 4.6 million people (Bay Area Census 2009). To accommodate this growth, land use shifted from agricultural to suburban. Population in the 18 counties of the Central Valley increased from 1.1 to 2.8 million people from 1940 to 1970 (California Department of Finance 2009). Erosion

controls for land being graded for construction increased during the 1970s (Tran et al. 1999); thus, urbanization may have produced a greater yield of sediment prior to the 1970s than after. In addition, the portion of the Central Valley used for irrigated agriculture was constant from 1922 to 1940 then approximately doubled from 1940 to 1970 to 15,000 km^2 (Nady and Larragueta 1983) and has been about 16,000 km^2 since 1980 (California Department

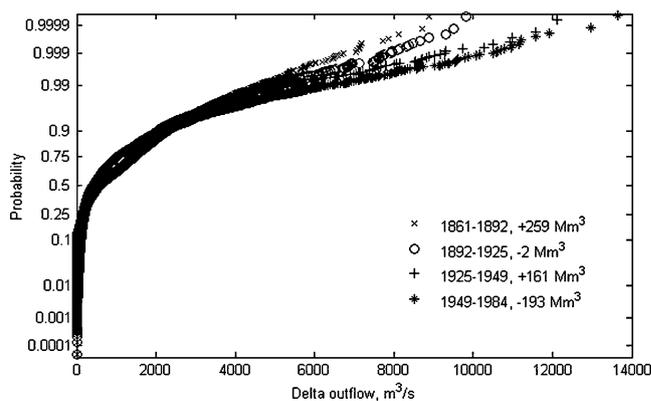

Fig. 7 Probability of flow exceedance for Delta outflow for the periods between the midpoints of San Francisco Bay bathymetric surveys. Daily flow data are from Ganju et al. (2008). Bay sediment volume change is given in the legend. The probability that a given extremely large freshwater inflow will be exceeded has increased with time. Changes in freshwater inflow cannot explain the variation in bay sediment volume

of Finance 2009). Conversion to agriculture and urban land use and overgrazing can increase sediment loads (Pasternack et al. 2001; Ruiz-Fernandez et al. 2009; Warrick and Farnsworth 2009; Wolman 1967) and thus may have supplied this second pulse of sediment. Sediment load measurements began in water year 1957, probably too late to detect the rising limb of such a pulse. Sediment yield from the Sacramento River decreased by about one half from WY 1957 to 2001 (Wright and Schoellhamer 2004). In addition, the Guadalupe River in South San Francisco Bay has a smaller (414 km²) and more urban watershed than the Sacramento River (60,900 km²), and provides evidence of an urbanization sediment pulse in the mid-1900s. Suspended sediment yield from the Guadalupe River watershed during WYs 1958–1962 was a factor of 4 to 8 greater than during WYs 2003–2005 (Schoellhamer et al. 2008).

San Francisco Bay was eroding in the late 1900s as bed sediment volume decreased (Fig. 6). As discussed previously, diminishment of the hydraulic mining and urbanization sediment pulses, sediment trapping behind dams and in flood bypasses, and bank protection all contribute to decreased sediment supply to the bay. Erosion by tides and wind waves exceed sediment supply, causing net erosion.

Prior to 1855, the San Francisco Bay and its watershed were relatively undisturbed and probably were in dynamic equilibrium with a small erodible sediment pool. In the late 1900s, however, anthropogenic sediment pulses from the late 1800s and mid-1900s were eroding and leaving the bay. Therefore, the bed sediment volume change from the 1855 to 1867 surveys can be assumed to approximate the erodible sediment pool (Fig. 6).

Changes in the erodible sediment pool caused by changes in hydrodynamic forcing, specifically decreased tidal prism due to construction fill and levees, are assumed to be negligible. Approximately 95% of tidal marsh in San Francisco Bay and the Delta was leveed or filled from 1850 to the late twentieth century, and the tidally affected surface area decreased by about two thirds (Atwater et al. 1979). Tidal marsh elevations are mostly near mean-higher-high water, however, so the fraction of lost tidal prism volume would be much smaller than the fraction of lost surface area and the decrease in tidal marsh would decrease tidal currents only during the highest of tides.

For a mean bay volume of 8,446 Mm³ (USGS 2009) and assuming the mean bay SSC equaled the mean SSC up to 1998 in Table 1 (75 mg/L) and a bed density of 850 kg/m³ (Porterfield 1980), the erodible sediment pool in the mid-1900s (420 Mm³) was about 560 times greater than the mean suspended sediment mass. Thus, the pool would have largely resided on the bed rather than in suspension, and sediment transport would have been transport-regulated.

The size of the erodible sediment pool in the mid-1900s was about 60 times greater than the mean annual sediment

supply from 1909 to 1966 (6.6 Mm³/year, Porterfield 1980). Thus, in a dry year with little watershed sediment supply, the erodible sediment pool was large enough to supply sediment to bay waters and maintain SSC without being depleted.

Linear extrapolation of the late 1900s erosion rate indicates that the bed sediment volume would return to 1855–1867 levels around 2001. If the sediment pulse observed in the mid-1900s was caused by urbanization, it likely would have continued until at least 1970 because of population growth and minimal, if any, erosion controls on suburban development. If the sediment pulse was caused by agriculturalization, it likely would have decreased around 1970 when expansion of irrigated agriculture markedly slowed. Assuming that the bed sediment volume in 1970 was equal to the mid-1900s value, a line that passes through the midpoint of the late 1990s bed sediment volume measurement period indicates that bed sediment volume would equal the 1855–1867 value in 2001 (Fig. 6). With the assumption that the bed sediment volume change equals the erodible sediment pool, the erodible sediment pool would become depleted around 2001. This rough estimate is essentially identical to when the step decrease in SSC was observed beginning in WY 1999 and thus supports the hypothesis that the SSC decrease was caused by depletion of the erodible sediment pool. A more refined model is developed in the next section.

Quantitative Conceptual Model of an Erodeable Sediment Pool

In this section, a simple numerical model of a depleting erodible sediment pool is derived and applied. The model quantifies the concepts of sediment supply, storage, and outflow in an estuary under transport and supply regulation. The model is intended to test the plausibility of the hypothesis that SSC would undergo a step decrease as an erodible sediment pool is depleted and transport-regulated sediment transport becomes supply-regulated. The model is also intended to simulate the general behavior of an erodible sediment pool. Details on bathymetry, tides, winds, and other factors that affect estuarine sediment transport are not included. This is an exploratory model designed to explain sudden clearing by simulating only the essential processes, rather than a simulation model designed to reproduce the estuary as completely as possible (Murray 2003).

Assume that the estuarine waters can be represented as a well-mixed volume with suspended sediment mass $S(t)$ that varies with time t . The maximum value of $S(t)$ due to transport regulation of suspended sediment is S_{\max} . An erodible sediment mass $M(t)$ resides in suspension and on the bed. When suspended sediment is supply-regulated, $S(t)$

is proportional to $M(t)$. Thus, $S(t)$ equals the minimum of S_{\max} and $c_s M(t)$ where c_s is a dimensionless suspension coefficient. River supply of sediment is $R(t)$ with units of mass per unit time. Outflow of sediment to the ocean $O(t)$ is proportional to $S(t)$ such that $O(t) = c_o S(t)$ where c_o is an outflow coefficient with units of time^{-1} . By conservation of mass (inflow – outflow = change in storage),

$$R(t) - O(t) = dM(t)/dt \tag{1}$$

Transport Regulation

For the case of transport regulation, suspended sediment mass $S(t) = S_{\max}$ is a constant. Then,

$$R(t) - c_o S_{\max} = dM(t)/dt \tag{2}$$

For exponentially decreasing river supply $R(t) = R(0)e^{-\alpha t}$, the solution to Eq. 2 is

$$M(t) = M_T(0) + \frac{1}{\alpha} (1 - e^{-\alpha t}) R(0) - c_o S_{\max} t \tag{3}$$

where $M_T(0)$ is the initial erodible sediment mass for transport regulation. For constant $R(t) = R_o$,

$$M(t) = (R_o - c_o S_{\max})t + M_T(0) \tag{4}$$

Supply Regulation

For the case of supply regulation, $S(t) = c_s M(t)$. Then,

$$R(t) - c_o c_s M(t) = dM(t)/dt \tag{5}$$

For declining $M(t)$, when transport regulation ends and supply regulation begins, time t is reset to zero for convenience. The initial condition for supply regulation is that the erodible sediment mass is $M_S(0)$. At the threshold where regulation changes from transport to supply, $c_s M_S(0) = S_{\max}$. For exponentially decreasing $R(t)$, the solution to Eq. 5 is

$$M(t) = \left(M_S(0) - \frac{R(0)}{c_o c_s - \alpha} \right) e^{-c_o c_s t} + \frac{R(0)}{c_o c_s - \alpha} e^{-\alpha t} \tag{6}$$

For constant R , the solution to Eq. 5 is

$$M(t) = \left(M_S(0) - \frac{R}{c_o c_s} \right) e^{-c_o c_s t} + \frac{R}{c_o c_s} \tag{7}$$

and the suspended mass is $S(t) = c_s M(t)$, so

$$S(t) = \left(c_s M_S(0) - \frac{R}{c_o} \right) e^{-c_o c_s t} + \frac{R}{c_o} \tag{8}$$

At infinite time constant inflow R equals outflow $c_o S_{\infty}$ or $S_{\infty} = R/c_o$ and $M_{\infty} = R/(c_o c_s)$.

The time scale over which suspended mass decreases in a supply-regulated estuary with a diminishing erodible sediment pool and constant sediment supply is quantified as follows. As suspended mass declines from the threshold between transport and supply regulation to a supply-regulated equilibrium, the midpoint of $S(t) = (S_{\max} + S_{\infty})/2$ occurs at $t_{1/2}$. Equation 8 then gives

$$\frac{1}{2} (S_{\max} + S_{\infty}) = (S_{\max} - S_{\infty}) e^{-c_o c_s t_{1/2}} + S_{\infty} \tag{9}$$

Solving for $t_{1/2}$ gives

$$t_{1/2} = \frac{\ln(2)}{c_o c_s} \tag{10}$$

$t_{1/2}$ is a parameter indicating the time scale over which suspended mass decreases in a supply-regulated estuary with a diminishing erodible sediment pool and constant sediment supply. The product $c_o c_s$ is the rate at which sediment mass leaves a supply-regulated estuary, so as the outflow increases, $t_{1/2}$ decreases (Fig. 8).

Application to San Francisco Bay

Application of the quantitative conceptual model to San Francisco Bay demonstrates that depletion of an erodible sediment pool in 1999 would cause a sudden decrease in SSC. The initial erodible mass is calculated from the bed volume from the 1942 to 1956 surveys when the bed volume was 418 Mm^3 greater than in 1855–1867. San Francisco Bay bed dry density varies from about 500 to 1,300 kg/m^3 (Caffrey 1995; Sternberg et al. 1986). Assuming a value of 850 kg/m^3 (Porterfield 1980) and that the change in bed sediment volume from the 1855 to 1867

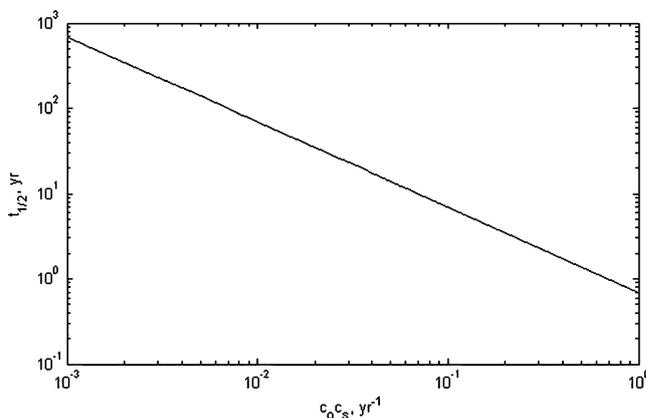

Fig. 8 $t_{1/2}$ as a function of $c_o c_s$. As suspended mass declines from the threshold between transport and supply regulation to a supply-regulated equilibrium, the midpoint of suspended mass between the two states occurs at $t_{1/2}$

Table 2 Initial year, initial river sediment supply $R(0)$, suspension coefficient c_s , outflow coefficient c_o , and resulting mean suspended mass 1999–2007 for simulations of an erodible sediment pool in San Francisco Bay

Initial year	$R(0)$, Mt/year	c_o , year ⁻¹	c_s	1999–2007 mean suspended mass (Mt)
1949	2.57	10.5	0.00529	0.53
1960	2.23	13.4	0.00668	0.48
1970	1.96	20.2	0.01875	0.26

The best estimate of mean suspended mass for WYs 1999–2007 is 0.40 Mt (Table 1)

surveys equals the erodible sediment pool, the erodible sediment pool was 355 Mt in 1949. Schoellhamer et al. (2005) estimated that the mean river sediment supply to San Francisco Bay was 1.91 Mt/year from 1955 to 1990. Hestir et al. (submitted) applied the Seasonal Kendall test to flow-adjusted SSC (Schertz et al. 1991) in the Sacramento River at Freeport and the San Joaquin River at Vernalis and found that each decreased 1.31%/year. These rivers drain the Central Valley of California and account for the majority of sediment entering San Francisco Bay (Schoellhamer et al. 2005). Suspended sediment discharge was not measured on any other tributaries to San Francisco Bay from 1974 to 1999. Suspended sediment discharge in the Guadalupe River decreased by a factor of 4–8 from 1957–1962 to 2003–2008 (Schoellhamer et al. 2008). The change in suspended sediment discharge in Alameda Creek from circa 1960 to the 2000s is ambiguous because water discharge increased but sediment yield decreased. Thus, river sediment supply is assumed to decrease at 1.31%/year ($\alpha = 0.0131 \text{ year}^{-1}$). At this decay rate, river supply would have been 2.57 Mt/year in 1949 ($R(0)$). Maximum suspended mass is assumed to equal the mean of SSC measured through WY 1998, 75 mg/L (Table 1), multiplied by the mean bay volume (8,446 Mm³, USGS 2009), which is 0.63 Mt. The outflow coefficient c_o is determined by forcing the erodible sediment mass M to equal the remaining mass for the 1979–1990 surveys, 289 Mt in 1985.

As the erodible sediment pool decreases, the time when the threshold between transport and supply regulation of suspended sediment is reached t_T is given by $S_{\max} = c_s M(t_T)$. Substitute this expression into Eq. 3, assuming t_T corresponds to the beginning of the observed SSC step decrease in WY 1999, and given α , c_o , $R(0)$, $M(t_T)$, and S_{\max} , Eq. 3 can be solved for

$$c_s = S_{\max} / (M(t_T) + \frac{1}{\alpha} (1 - e^{-\alpha t_T}) R(0) - c_o S_{\max} t_T) \quad (11)$$

These initial values and coefficients are used to solve Eq. 1 with a 1-year time step and the second order Runge–Kutta method. This approach calculates c_o such that the erodible sediment mass is correct in the 1980s and calculates c_s such that the threshold from transport to supply regulation is crossed in 1999. The initial time to start the simulation is

uncertain so initial times of 1949 (midpoint of mid-1900s surveys), 1960 (intermediate point), and 1970 (end of large urbanization period, Fig. 6) are used. For these three initial times, $R(0)$, c_s , and c_o are given in Table 2.

As the start time of the simulation gets later, the exponential decrease in suspended mass after the threshold from transport to supply regulation is passed becomes steeper and more step like (Fig. 9). Assuming the mean SSC from WY 1999 onward (48 mg/L, Table 1) applied to the entire bay volume, the mean suspended mass was 0.40 Mt. The simulation started in 1960 overpredicts this value, and the simulation started in 1970 underpredicts it (Table 2). The model is sensitive to the chosen start time because, for the same initial erodible sediment pool mass, outflow to the ocean must increase as the start time becomes later. After the threshold is crossed, a later start time causes greater outflow (c_o) and a more rapid decrease in suspended mass. Deposition rates upstream from San Francisco Bay in the Sacramento-San Joaquin River Delta were 4–8 times greater from 1944 to 1972 than from 1972

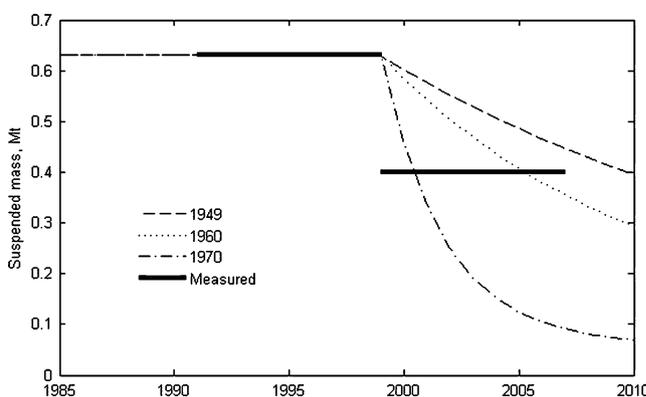

Fig. 9 Simulated and measured suspended sediment mass. Simulations specified (1) transport regulation before 1999 and supply regulation after 1999, (2) suspended mass before 1999 equals measured suspended mass (0.63 Mt), (3) initial erodible sediment mass equals the 1942–1956 estimate (355 Mt), and (4) erodible sediment mass in 1985 equals the 1979–1990 estimate (289 Mt). Dates refer to the starting time of the simulation when the initial sediment pool began to erode. The results support the hypothesis that crossing the threshold from transport to supply regulation of suspended sediment can cause the observed step decrease in suspended-sediment mass

to 2005 (Canuel et al. 2009), indicating that a downstream shift from deposition to erosion in the 1960–1970 period is reasonable.

The model is constructed to have a constant suspended mass until the threshold is reached at a specified time. These simulations demonstrate that given realistic rates of erosion, suspended mass, and river supply, if the threshold was crossed in 1999 as hypothesized, the result would be a rapid decrease in suspended mass.

If a constant river supply were used rather than an exponentially decreasing supply (not shown), then the time the threshold is crossed changes, but the suspended mass subsequently decreases rapidly in either case.

The assumption that the initial mass of the erodible sediment pool was equal to the change in sediment volume since the 1855–1867 surveys ignores the erodible sediment pool that would have existed before hydraulic mining. Prior to 1849, river supply to the bay was assumed to equal 2 million cubic yards per year (Gilbert 1917). A bulk density of 850 kg/m³ (Porterfield 1980) was used to estimate river supply $R = 1.3$ Mt/year. For the simulation started in 1960, the size of the pre-1855 equilibrium erodible sediment pool $M_{\infty} = R/(c_o c_s)$ is estimated to have been 14.5 Mt. This is only 4% of the increase in bay sediment volume from the mid-1800s to mid-1900s (355 Mt). Thus, the pre-1855 erodible sediment pool was probably much smaller than the subsequent sediment pulses and is unlikely to significantly alter these results.

To test the model, the hydraulic mining sediment pulse was hindcast with the coefficients derived for the 1949, 1960, and 1970 start times of the erosion simulations. This however is not a true validation because deposition calculated from bathymetry data was used to estimate river supply from 1849 to 1914 (Gilbert 1917), and these are the only data available to compare with the model. The three sets of coefficients in Table 2 and $R = 1.3$ Mt/year were used, and the model was run from 1700 to 1849 and established a steady state. Then, river supply from the Central Valley was increased to 18.4 million cubic yards per year for 1849–1914 (Gilbert 1917) or 12 Mt/year. This is the sum of depositional volume and outflow estimated by Gilbert (1917). The coefficients for the 1960 erosion simulation start date best match the 1880s and 1920s estimates of the erodible sediment pool from bathymetric change data (Fig. 10). Gilbert (1917) used the 1880s bathymetry data to estimate sediment supply to the bay, so that value does not offer a true validation. Deposition of the hydraulic mining pulse is too large for the 1949 coefficients and too small for the 1970 coefficients. The 1940s increase in the erodible sediment pool is not simulated because there is no corresponding quantified increase in sediment supply. Porterfield (1980) used suspended-sediment discharge measurements from the late 1950s and early 1960s to develop rating curves that were

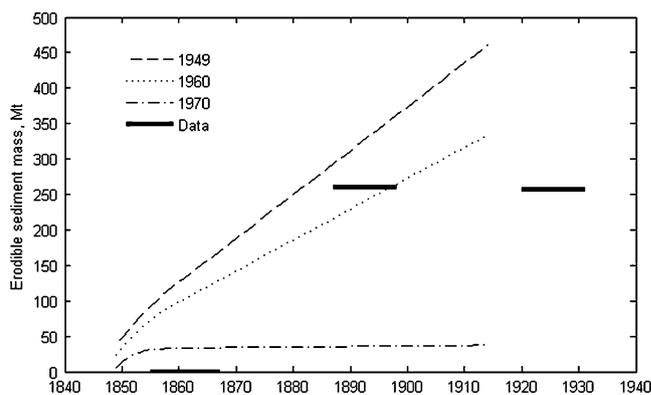

Fig. 10 Simulated and estimated mass in the erodible sediment pool during the hydraulic mining sediment pulse 1849–1914, San Francisco Bay. Simulations are for three different pairs of suspension and outflow coefficients determined by starting simulations of erosion at three different start times (1949, 1960, and 1970, Table 2). Sediment volume change from the 1855 to 1867 surveys is assumed to approximate the erodible sediment pool. A bulk density of 850 kg/m³ is also assumed (Porterfield 1980). Each subembayment was surveyed during the period shown by *each thick line*. Bathymetry data are from Capiella et al. (1999), Fregoso et al. (2008), Foxgrover et al. (2004), and Jaffe et al. (1998)

extrapolated back to 1909. Thus, there are no measurements of the second sediment pulse hypothesized to have occurred prior to the 1950s. In this simulation of the entire hydraulic mining sediment pulse, the threshold from transport to supply regulation of suspended sediment occurs in the early 1950s, and SSC decreases rapidly (not shown). Similar to the comparison with 1999–2007 suspended mass, simulation of the hydraulic mining pulse shows that the model produces reasonable results with the exception of the unquantified sediment pulse in the mid-1900s, that the coefficients for the 1960 erosion simulation start time are best, that coefficients for an erosion simulation that starts between 1960 and 1970 would be optimal, and that SSC declines rapidly once the threshold from transport to supply regulation of suspended sediment is crossed.

Discussion

The general progression of human land use has been characterized by disruptions (deforestation, mining, agricultural expansion, overgrazing, and urbanization) that create a sediment pulse to an estuary followed by dams that reduce sediment supply (Fig. 3, Hu et al. 2009; Pasternack et al. 2001; Ruiz-Fernandez et al. 2009; Syvitski et al. 2005; Warrick and Farnsworth 2009; Wolman 1967). In San Francisco Bay, hydraulic mining increased sediment discharge by a factor of 9 from the mid to late 1800s (Fig. 3, Gilbert 1917). Sedimentation rates increased 2–10-fold in other California estuaries in the nineteenth and twentieth

centuries (Warrick and Farnsworth 2009). These increases are typical of the 5–10-fold increase found in lake and marine sediment records downstream from disturbed watersheds (Dearing and Jones 2003). Sediment discharge from the primary sediment source to San Francisco Bay, the Sacramento River, decreased about 50% from 1957 to 2001 (Wright and Schoellhamer 2004). This magnitude of decrease is not uncommon; river sediment discharge to the coastal zone has decreased 45% in Southern California due to trapping behind dams (Warrick and Farnsworth 2009), 50–70% from the Mississippi River (Kesel 2003), 75% from the Trinity River in Texas (Ravens et al. 2009), and globally riverine sediment discharge to oceans has decreased $10\pm 2\%$ (Syvitski et al. 2005). Reforestation and dams have reduced the sediment discharge in the Changjiang (Yangtze River) 68% from the 1950s to 2000s, and the decrease is expected to reach 82% (Hu et al. 2009). Thus, the sequence of predevelopment equilibrium, a sediment pulse that creates an erodible sediment pool, and reduced sediment supply in San Francisco Bay is similar to that of other estuaries.

Conditions Required for Sudden Clearing

The quantitative conceptual model demonstrates that, when transport-regulated suspension becomes supply-regulated as an erodible sediment pool is depleted, suspended mass can rapidly decrease. An erodible sediment pool and crossing the regulation threshold are both necessary to have a rapid decrease in suspended mass.

Without an erodible sediment pool, annual suspended mass would be dependent on river supply and would not suddenly decrease, unless the river supply suddenly decreased. The river supply to San Francisco Bay varies annually and decreased 1.3%/year during the later half of the twentieth century (Hestir et al. submitted), which does not account for the sudden 36% decrease in suspended mass in 1999.

If sediment transport remained transport-regulated and the transport capacity does not suddenly change, then SSC would not change. Tides and seasonal winds are primarily responsible for sediment suspension in San Francisco Bay, and they are consistent from year to year, so transport capacity is likely to be constant (Schoellhamer 2002). If sediment transport were actually supply-regulated, SSC would have sharply declined from the 1950s to 1980s when the bay eroded. Data are not available for the earlier part of this period, but from 1969 to 1980, there was no significant trend ($p>0.15$) in discrete monthly SPM 2 m below the water surface at nine US Geological Survey sampling stations with enough data for analysis by the Seasonal Kendall trend test (Schertz et al. 1991). Thus, it is unlikely that there was a large decline in suspended sediment from the 1950s to 1980s and that sediment transport was supply-regulated.

For an estuary with an erodible sediment pool, decreasing river sediment supply hastens crossing the threshold from transport to supply regulation and the severity of the subsequent decrease in SSC, but decreasing river supply was not solely responsible for the SSC decrease. For San Francisco Bay, the simulation beginning in 1960 with constant sediment supply crossed the regulation threshold in 2002 (3 years later than observed) and increased the predicted 2010 suspended mass 34%. If an estuary is in equilibrium or is depositional, decreased river supply may make the estuary erosional, and if it is transport-regulated, set up the conditions required for eventual sudden clearing.

Erodible Sediment Pool

An erodible sediment pool in an estuary can be created or enlarged by a pulse of sediment from the watershed. A large flood can deliver a sediment pulse. For example, tropical storm Agnes produced 1 week of sediment discharge from the Susquehanna River to Chesapeake Bay equal to 30–50 normal years of sediment supply (Schubel 1974). Anthropogenic disturbance within the watershed can increase the quantity of erodible sediment, enabling normal runoff to deliver a pulse. Hydraulic mining increased the supply of sediment to San Francisco Bay by a factor of about 9 over several decades (Gilbert 1917). Deforestation and conversion to agricultural and urban land use are a more common anthropogenic mechanism for increasing sediment yield of a watershed (Pasternack et al. 2001; Ruiz-Fernandez et al. 2009; Wolman 1967). In general, sediment supplied from watersheds in the tropics and Indonesia in particular has increased due to deforestation (Syvitski et al. 2005).

This study applies the concept of an erodible sediment pool to an entire estuary. This is an extension of the erodible sediment pool concept used to explain tidal and fortnightly variability of SSC in some narrow estuaries and tidal rivers (Ganju et al. 2004; Grabemann and Krause 1994; Grabemann et al. 1997; Tattersall et al. 2003). At this smaller spatial scale, flood and ebb tidal currents alternately resuspend and transport the erodible sediment pool, which deposits during slack tide. The result is a tidally oscillating sediment mass that can create an estuarine turbidity maximum. The size of the oscillating sediment mass is greatest on spring tides and smallest on neap tides. The application of the erodible sediment pool concept to an entire estuary in this study differs from these previous applications in terms of spatial variability, temporal variability, and size of the erodible sediment pool.

Application of the concept to an entire estuary considers neither spatial variability in erosion, deposition, or SSC nor proximity to river inputs and the ocean. The objective of this study, however, is to understand the net functionality of the estuary as a component in the watershed/estuary/ocean system, for which the erodible sediment pool concept is applicable.

Annual to interannual time scales rather than tidal and fortnightly time scales are considered in this study. Temporal variability due to tides, wind, and river flow are not considered. At annual and interannual time scales, these forcings suspend sediment, some of which is transported from the estuary to the ocean. The quantitative conceptual model simulates this process.

At the tidal time scale, an erodible sediment pool is the quantity of sediment suspended by a particular tide. In both the Weser Estuary and Petaluma River, the size of the pool is less than the annual river supply, 4% and 82%, respectively (Ganju et al. 2004; Grabemann and Krause 1994). At the interannual time scale of this study, an erodible sediment pool is the difference between the existing sediment mass and the sediment mass of the estuary at equilibrium (no net deposition or erosion). To supply sediment during low-supply years, the pool must be larger than the average annual sediment supply. Thus, an erodible sediment pool at the interannual time scale is larger than at the tidal time scale.

Transport and Supply Regulation of Suspended Mass

As an estuarine sediment pool erodes, crossing the threshold from transport to supply regulation of suspended sediment mass can trigger a rapid decrease in SSC. In the quantitative conceptual model, the entire estuary is assumed to be either transport- or supply-regulated, and seasonal and tidal variations in regulation are neglected. In reality, some parts of an estuary may be transport-regulated while others are supply-regulated. Regulation may also vary seasonally and fortnightly. For example, in San Francisco Bay and other estuaries, there is a seasonal cycle of sediment inflow during the wet season and winnowing and redistribution of sediment by tides and waves during the dry season (Deloffre et al. 2005; Krone 1979; Lesourd et al. 2003; Ryu 2003). Thus, suspended mass may be transport-regulated after delivery of sediment from the watershed and supply-regulated at the end of the dry season. In addition, SSC in San Francisco Bay and other estuaries varies with the spring/neap tidal cycle (Brennan et al. 2002; Grabemann et al. 1997; Schoellhamer 2002; Wolanski et al. 1995), and the depth of bed sediment reworking decreases during neap tides (Brennan et al. 2002; Deloffre et al. 2005). Thus, suspended mass may be transport-regulated during neap tides and supply-regulated during spring tides. Identification and quantification of transport and supply regulation in estuaries need further research.

Ramifications of Decreased SSC

A less turbid estuary has ramifications for dredging, wetland restoration, water quality, and the ecosystem.

Smaller SSC reduces deposition, which in turn reduces maintenance dredging volumes and increases the life

expectancy of dredged-material disposal sites in an estuary. In San Francisco Bay, ocean disposal is now about equal to the average supply of sediment from the Central Valley (Schoellhamer et al. 2005). Bay disposal sites may be able to accommodate more material, reducing the need for costly ocean disposal.

Wetland restoration typically involves opening a diked area to tidal action, allowing sediment to deposit until the bed elevation is high enough for plant colonization. The rate of deposition is proportional to SSC (Krone and Hu 2001). The time required to create a wetland increases as SSC decreases. If the rate of deposition is less than the rate of sea level rise, a vegetated wetland will never form. Thus, decreased SSC affects restoration of subsided land to tidal marsh by (1) increasing the time needed to restore tidal marsh vegetation and (2) increasing the possibility that natural sedimentation cannot restore tidal marsh as sea level rises.

Many contaminants are associated with sediment (David et al. 2009; Luengen and Flegal 2009; Schoellhamer et al. 2007; Turner and Millward 2002). Smaller SSC decreases the water column concentration of sediment-associated contaminants. Water quality standards written in terms of total (dissolved and sediment-associated) concentration are more likely to be achieved because SSC is smaller. Suspended sediment moving into, within, and out of estuaries provides a pathway for the transport of sediment-associated contaminants (Bergamaschi et al. 2001; David et al. 2009; Le Roux et al. 2001; Turner and Millward 2000). Decreased SSC decreases the pelagic flux of contaminants within an estuary and from an estuary to the ocean.

In some estuaries including San Francisco Bay, suspended sediment limits light in the water column which limits phytoplankton growth (Cloern 1987). Thus, a decrease in SSC would increase phytoplankton. In San Francisco Bay beginning in 1999, chlorophyll concentrations increased, and autumn blooms occurred for the first time since at least 1978 (Cloern et al. 2007). Both SSC and chlorophyll indicate that the bay crossed a threshold and fundamentally changed in 1999. San Francisco Bay has been transformed from a low-productivity estuary to one having primary production typical of temperate-latitude estuaries. Cloern et al. (2007) also state that a shift in currents in the Pacific Ocean, improved wastewater treatment, reduced sediment inputs, and introductions of new species may be responsible for the chlorophyll increase. Larger phytoplankton blooms may also affect contaminant fate. Blooms dilute methyl mercury concentrations in phytoplankton cells, but decay of phytoplankton after a bloom increases dissolved methyl mercury (Luengen and Flegal 2009). Thus, the net effect of increased phytoplankton blooms on methyl mercury uptake into the food web is uncertain.

Reduced SSC may be one of several factors contributing to a collapse of several San Francisco Bay estuary fish

species that occurred around 2000 (Sommer et al. 2007). Abundance of some fish species increases in more turbid waters (Feyrer et al. 2007). The population collapse has had the most serious consequences for Delta smelt which require turbid water for successful feeding and predator avoidance. The relation between decreased SSC and fish decline, however, is not well established, and the concurrence of less SSC, more phytoplankton, and fewer fish merits additional study.

Conclusions

Anthropogenic disturbances in a watershed, such as mining, deforestation, and urbanization, can create a pulse of sediment that deposits in an estuary, creating an erodible sediment pool. As the erodible pool is depleted, regulation of suspended sediment can cross the threshold from transport regulation to supply regulation. A quantitative conceptual model demonstrates that upon crossing this threshold, suspended sediment mass in the estuary can decrease rapidly, suddenly clearing the estuarine waters. In San Francisco Bay, this sequence of events appears to explain a 36% step decrease in SSC beginning in WY 1999. Changes in the San Francisco Bay ecosystem in the 2000s have been symptomatic of this sudden clearing. A decreasing watershed sediment supply averaging 1.3%/year contributes to decreased SSC but cannot account for the step decrease in SSC. Human development of watersheds follows a similar pattern: disturbance creates a pulse of sediment followed by decreased sediment supply, often due to trapping behind dams. Thus, many estuaries may be susceptible to sudden clearing.

Acknowledgments I would like to thank those that have helped collect, process, and publish the continuous SSC data: Rick Adorador, Greg Brewster, Paul Buchanan, Laurie Campbell, Mike Farber, Amber Forest, Neil Ganju, Tom Hankins, Megan Lionberger, Allan Mlodnosky, Tara Morgan, Heather Ramil, Cathy Ruhl, Rob Shepline, Brad Sullivan, and Jessica Wood. Bruce Jaffe, Neil Ganju, John Oram, and two anonymous reviewers provided helpful comments on earlier versions of this article. This work was supported by the US Army Corps of Engineers, San Francisco District, as part of the Regional Monitoring Program for Water Quality in the San Francisco Estuary.

Scientific Foundation for the San Francisco Bay Nutrient Management Strategy

Draft FINAL – October 2014

David B Senn, Emily Novick, and additional co-authors to be determined

*Contact: dauids@sfei.org

Summary

Dissolved inorganic nitrogen (DIN) and phosphorus (DIP) are essential nutrients for primary production that supports estuarine food webs. However DIN and DIP concentrations in San Francisco Bay (SFB) greatly exceed those in other US estuaries where water quality has been impaired by nutrient pollution. SFB receives high nutrient loads from treated wastewater effluent, agricultural runoff, and stormwater. SFB has long been recognized as a nutrient-enriched estuary, but one that has exhibited resistance to some of the classic symptoms of nutrient overenrichment, such as high phytoplankton biomass and low dissolved oxygen. SFB receives high nutrient loads from treated wastewater effluent, agricultural runoff, and stormwater. Research and monitoring in SFB over the last 40 years have identified several factors that have historically imparted resistance to the adverse effects of high nutrient loads: high turbidity, strong tidal mixing, and abundant filter-feeding clam populations, all of which tend to limit the efficiency with which DIN and DIP are converted into phytoplankton biomass. While these factors have arguably had a protective effect in many areas of SFB with respect to nutrients, they have negatively impacted the northern estuary by severely limiting food web productivity there.

However, recent observations indicate that SFB's resistance to high nutrient loads may be weakening. These observations include: a 3-fold increase in summer-fall phytoplankton biomass in South Bay since 1999; frequent detections of algal species that have been shown in other nutrient-rich estuaries to form harmful blooms; frequent detection of the toxins microcystin and domoic acid that are produced by some types of algae; an unprecedented red tide bloom in Fall 2004; low dissolved oxygen in some margin habitats, including sloughs and salt ponds; and studies suggesting that the chemical forms of nitrogen can decrease phytoplankton productivity or alter their community composition. To address growing concerns that SFB's response to nutrients is changing, the San Francisco Bay Regional Water Quality Control Board worked collaboratively with stakeholders to develop the San Francisco Bay Nutrient Management Strategy (NMS), which lays out an overall approach for building the scientific understanding to support well-informed nutrient management decisions.

Among its early priorities, the NMS recognized the need for a conceptual model to lay the scientific foundation to guide the NMS' implementation. This report targets that need and aims to achieve four main goals:

- i. Develop conceptual models connecting nutrient loads and cycling with ecosystem response in SFB;
- ii. Apply those conceptual models to identify scenarios under which nutrient-related impairment may occur in SFB's subembayments; and
- iii. Identify knowledge and data gaps that need to be addressed in order for well-informed, science-based decisions to be made about how best to manage nutrient loads to mitigate or prevent adverse impacts.
- iv. Develop an approach to prioritizing among data and knowledge gaps, and apply that approach to generate an initial recommended set of highest priority activities to inform the development of a science plan to guide NMS implementation.

This report was developed in collaboration with a team of regional scientists whose areas of expertise cover a range of relevant disciplines (see Table 1.1). Its main observations and recommendations are:

1. Changes in SFB's response to nutrient loads over the past decade, combined with the Bay's high nutrient loads and concentrations, justify growing concerns about elevated nutrients.
2. The future trajectory of SFB's response to nutrients is uncertain. One plausible trajectory is that SFB maintains its current level of resistance to the classic effects of high nutrient loads and no further degradation occurs. A second, equally plausible scenario is that SFB's resistance to nutrients continues to decline until adverse impacts become evident. The highly elevated DIN and DIP concentrations Bay-wide provide the potential for future impairment. Any major reductions in loads to SFB will take years-to-decades to implement. Thus, if future problems are to be averted, potential impairment scenarios need to be anticipated, evaluated, and, if deemed necessary, managed in advance of their onset.
3. By considering current conditions in SFB, trends of changing ecosystem response, and a conceptual model for SFB's response to nutrients, we identified the following highest priority issues:
 - a) Determine whether increasing biomass signals future impairment. This issue is most pertinent for Lower South Bay and South Bay.
 - b) Characterize/quantify the extent to which excess nutrients contribute now, or may contribute in the future, to the occurrence of HABs/NABs and phycotoxins.
 - c) Determine if low DO in shallow habitats causes adverse impacts, and quantify the contribution of excess nutrients to that condition.
 - d) Further evaluate other hypotheses for nutrient-related adverse impacts to ecosystem health, including nutrient-induced changes in phytoplankton community composition and ammonium inhibition of primary production. That evaluation – to include data analysis, additional experimentation, or modeling – should assess their potential quantitative importance, and help to determine if they should be considered among the highest priority issues.
 - e) Test future scenarios that may lead to worsening conditions through the use of numerical models.
 - f) Quantify the contributions of nutrients by sources in different areas of the Bay, considering both their transport and in situ transformations and losses.
 - g) Evaluate the potential effectiveness of various nutrient management strategies at mitigating or preventing adverse impacts.
4. Although concern related to changing ecosystem response in SFB is warranted, widespread and severe nutrient-related impacts do not currently appear to be occurring, based on existing sampling locations and parameters commonly measured. This apparent lack of current severe impacts translates into time for conducting investigations to improve understanding of SFB's response to nutrients and allows for sound, science-based management plans to be developed and implemented. That said, the considerable amount of time required to implement any management strategy raises the level of urgency such that work should move forward expeditiously.
5. Given the stakes of no action - and the time required for data collection, analysis, and modeling tools to reach a useable state - work needs to move forward in parallel on implementing multiple aspects of the Nutrient Strategy. A well-coordinated program is needed to maximize the

effectiveness and efficiency of this effort. That program needs to integrate seamlessly across what might otherwise be (or become) semi-independent program areas. Specifically, we recommend the following set of highly-integrated program areas:

- a) **Monitoring:** Develop and implement a sustainably-funded and regionally administered monitoring program that continues routine monitoring, and fills newly-identified data gaps relevant to nutrients;
 - b) **Modeling:** Develop and apply linked hydrodynamic and water quality models to integrate observations, identify critical data gaps (to be addressed through monitoring or experimental studies), quantify processes at the ecosystem scale, and evaluate future scenarios (including management alternatives);
 - c) **Observational and Experimental Studies:** Undertake special studies (field investigations, controlled experiments) to address the highest priority knowledge and data gaps identified in #3; and
 - d) **Data Synthesis and Interpretation:** Analysis of existing and newly collected data (from monitoring and experimental studies), incorporating models, to improve understanding of linkages between nutrients and ecosystem response and to inform the development of an assessment framework.
6. The Delta/Suisun boundary, while an important regulatory boundary, is not meaningful from ecological and loading standpoints. Nutrient loads to and transformations within the Delta exert considerable influence over nutrient loads to and ambient concentrations within Suisun, San Pablo, and Central Bays. Furthermore, the ecology and habitat quality of the Delta and Suisun Bay are tightly coupled. A unified approach – one that spans the Bay-Delta continuum - for evaluating the impacts of nutrients on beneficial uses will best serve both ecosystem health in the Bay-Delta and the information needs of environmental managers.

The report is lengthy, but the majority of its length comes from sections devoted to the development of a detailed conceptual model (Sections 5-9). For a higher-level read that still covers the key issues, main findings, and recommendations, we suggest reading the following sections:

- Sections 1-2: brief description of report goals and approach, and background on the NMS.
- Section 3: Overview of current conditions and a description of how nutrient-related problems would be expected to manifest in San Francisco Bay
- Section 4: Brief description of the conceptual model structure/approach
- Section 11: Identifying highest the priority scenarios, science questions, and data/knowledge gaps
- Section 12: Summary of main observations and recommendations

Acknowledgements

This report was funded by the San Francisco Bay Regional Monitoring Program. The final version of the report benefited from valuable comments from stakeholders and collaborators on earlier. Most of the water quality data presented in this report was generated by the USGS San Francisco Bay Water Quality team based in Menlo Park (<http://sfbay.wr.usgs.gov/access/wqdata/index.html>) - thanks to Tara Schraga, Charlie Martin, and Erica Kress for on-going input on all things water quality. Valuable data was also obtained from the Interagency Ecological Program Environmental Monitoring Program (<http://www.water.ca.gov/iep/activities/emp.cfm>). Thanks also to Alan Jassby for advice on using the *wq* R package.

1 Introduction

San Francisco Bay (SFB) has long been recognized as a nutrient-enriched estuary, but one that has exhibited resistance to some of the classic symptoms of nutrient overenrichment, such as high phytoplankton biomass and low dissolved oxygen. However, recent observations suggest that SFB's resistance to high nutrient loads is weakening. The combination of high nutrient concentrations and changes in environmental factors that regulate SFB's response to nutrients has generated concern about whether SFB is trending toward, or may already be experiencing, adverse impacts due to elevated nutrient loads. In response to these concerns, the San Francisco Bay Regional Water Quality Control Board worked collaboratively with stakeholders to develop the San Francisco Bay Nutrient Management Strategy (NMS),¹ which lays out an overall approach for building the scientific understanding to support well-informed nutrient management decisions. Among its early priorities, the NMS recognized the need for a conceptual model to lay the scientific foundation to guide the NMS' implementation. This report targets that need and aims to achieve four main goals:

- i. Develop conceptual models connecting nutrient loads and cycling with ecosystem response in SFB;
- ii. Apply those conceptual models to identify scenarios under which nutrient-related impairment may occur in SFB's subembayments; and
- iii. Identify knowledge and data gaps that need to be addressed in order for well-informed, science-based decisions to be made about how to best manage nutrient loads to mitigate or prevent adverse impacts.
- iv. Develop an approach to prioritizing among data and knowledge gaps, and apply that approach to generate an initial recommended set of highest priority activities to inform the development of a science plan to guide NMS implementation.

Audience, anticipated use, and approach

The report's approach and structure are summarized in Figure 1.1. Its primary intended audience includes technically-oriented regulators, decision makers, and other stakeholders. With that audience in mind, the report assumes a certain baseline familiarity with SFB as well as a basic understanding of the biology, nutrient cycling, biogeochemistry, and physical processes in estuaries. The report is an outgrowth of workshops and discussions over the past 2 years with a team of regional scientists whose areas of expertise cover a range of relevant disciplines and much of whose work has focused on San Francisco Bay (Table 1.1).

The report's main anticipated uses are to inform and help prioritize the types of special studies, monitoring, and modeling that are needed to inform management decisions by identifying major priority science issues and related knowledge and data gaps; and inform the development of criteria that will be used to assess ecosystem health and determine whether subembayments or specific habitats within SFB are experiencing nutrient-related impairment. Figure 1.1 summarizes the report's structure and the overall approach. The report begins by identifying what a nutrient-related problem would look like in SFB, and then summarizes recent observations that suggest SFB's response to nutrients is changing (Section 3). Focused by this problem statement, we present a the conceptual model, layed out as a series of linked modules, extending from nutrient loads and cycling to

¹http://www.waterboards.ca.gov/sanfranciscobay/water_issues/programs/planningtmdls/amendments/estuarienNE/Nutrient_Strategy%20November%202012.pdf

ecosystem response (Sections 5-10). Each module ends with a table that summarizes data availability and state of knowledge about relevant processes. The conceptual models are then used to identify scenarios under which adverse impacts may occur, and scenarios under which those impacts may be mitigated or prevented (Section 11). The report closes with a summary of major observations and recommendations (Section 12). The report draws from several decades of research and monitoring in San Francisco Bay by USGS², multiple academic institutions, and the Interagency Ecological Program³, and also builds upon other recent reports (e.g., McKee et al., 2011).

2. Background

2.1 San Francisco Bay and the Bay Area

San Francisco Bay (SFB) encompasses several subembayments of the San Francisco Estuary, the largest estuary in California (Figure 2.1). SFB is surrounded by remnant tidal marshes, intertidal and subtidal habitats, tributary rivers, the freshwater “Delta” portion of the estuary, and the large mixed-land-use area known as the San Francisco Bay Area (Figure 2.2.A). San Francisco Bay hosts an array of habitat types (Figure 2.1), many of which have undergone substantial changes in their size or quality due to human activities. Urban residential and commercial land uses comprise a large portion of Bay Area watersheds, in particular those adjacent to Central Bay, South Bay and Lower South Bay (Figure 2.2.A). Open space and agricultural land uses occupy larger proportions of the watersheds draining to Suisun Bay and San Pablo Bay. The San Joaquin and Sacramento Rivers drain 40% of California, including agricultural-intensive land use areas in the Central Valley. Flows from several urban centers also enter these rivers, most notably Sacramento which is ~100 km upstream of Suisun Bay along the Sacramento River.

SFB receives high nutrient loads from 42 public owned wastewater treatment works (POTWs) servicing the Bay Area’s 7.2 million people (Figure 2.2.B). Several POTWs carry out nutrient removal before effluent discharge; however the majority perform only secondary treatment without additional N or P removal. Nutrients also enter SFB via stormwater runoff from the densely populated watersheds that surround SFB (Figure 2.2.A). Flows from the Sacramento and San Joaquin Rivers deliver large nutrient loads, and enter the northern estuary through the Sacramento/San Joaquin Delta (not shown, immediately east of the maps in Figure 2.1 and 2.2).

2.1 San Francisco Bay Nutrient Strategy

Dissolved inorganic nitrogen (DIN) and phosphorus (DIP) are essential nutrients for primary production that supports SFB food webs. However DIN and DIP concentrations in SFB greatly exceed those in other US estuaries where water quality has been impaired by nutrient pollution (Cloern and Jassby, 2012). SFB has long been considered relatively immune to its high nutrient loads. For example, the original San Francisco Bay Regional Basin Plan from 1975 stated that only limited treatment for nutrients was necessary because the system was considered to be light limited (SFBRWQCB, 1975). Research and monitoring over the last 40 years have identified several factors that impart SFB with its resistance to high nutrient loads (e.g., see Cloern and Jassby 2012; Cloern et al., 2007; Kimmerer and Thompson, 2014): high turbidity (low light), strong tidal mixing (breaks down stratification and fully mixes the water column, resulting in low light availability), and abundant filter-feeding clam populations (remove phytoplankton from the water column).

However, recent studies indicate that the response to nutrients in SFB is changing, indicate that the system is poised to potentially experience future impacts, or suggest that current nutrient levels are already causing adverse impacts. These observations include: a 3-fold increase in summer-fall phytoplankton biomass in South Bay since the late 1990s; frequent detections in SFB of algal species that have been shown in other nutrient-rich estuaries to form harmful blooms; detection of algal toxins Bay-wide; an unprecedented red tide bloom in Fall 2004; and studies suggesting that the chemical forms of nitrogen can influence phytoplankton productivity and composition. To address

growing concerns that SFB's response to nutrients is changing and that conditions may be trending toward adverse impacts due to elevated nutrient loads, the San Francisco Bay Regional Water Quality Control Board (SFBRWQCB) worked collaboratively with stakeholders to develop the San Francisco Bay Nutrient Management Strategy⁴, which lays out an approach for gathering and applying information to inform management decisions. Overall, the Nutrient Management Strategy aims to answer four fundamental questions:

1. Is SFB experiencing nutrient-related impairment, or is it likely to in the future?
2. What are the major nutrient sources?
3. What nutrient loads or concentrations are protective of ecosystem health?
4. What are efficacious and cost-efficient nutrient management options for ensuring that Bay beneficial uses are protected?

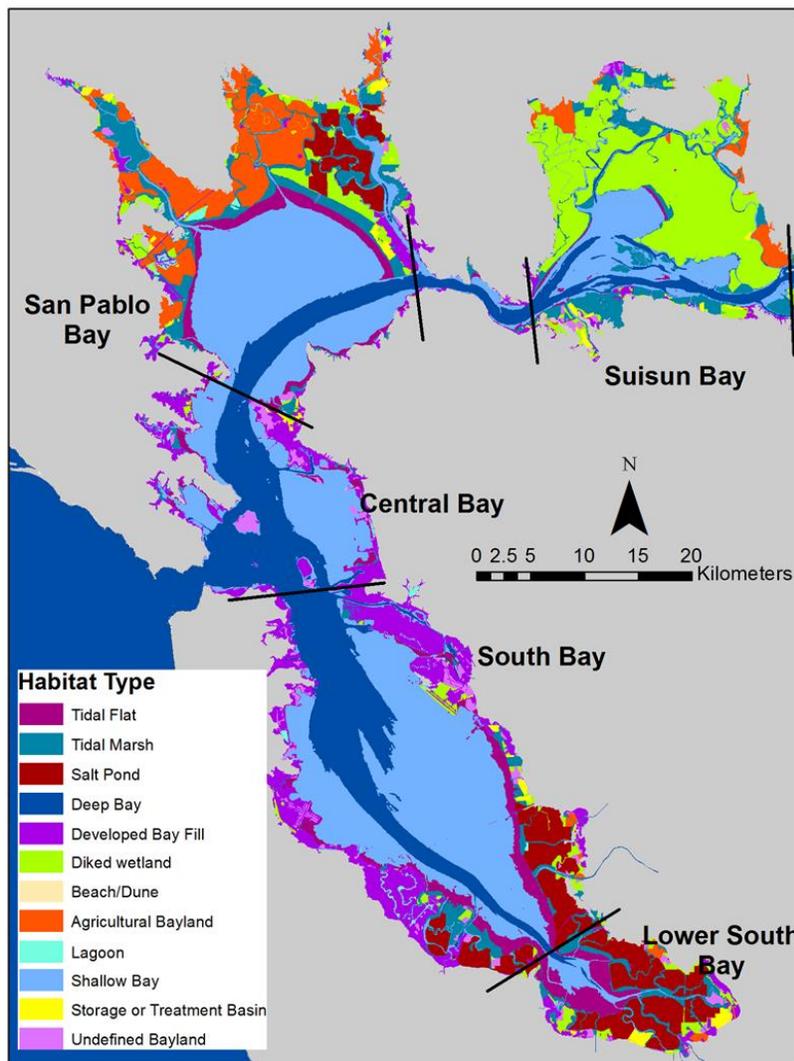

Figure 2.1 Habitat types of SFB and surrounding Baylands. Water Board subembayment boundaries are shown in black. Habitat data from CA State Lands Commission, USGS, UFWS, US NASA and local experts were compiled by SFEI.

The indications of changing SFB response to nutrients have come to the fore at a time when the availability of resources to continue assessing the Bay's condition is uncertain. Since 1969, a USGS research program has supported water-quality sampling in the San Francisco Bay. This USGS program collects monthly samples between the South Bay and the lower Sacramento River to measure salinity, temperature, turbidity, suspended sediments, nutrients, dissolved oxygen and chlorophyll a. The USGS data, along with sampling conducted by the Interagency Ecological Program (IEP), provide coverage for the entire Bay-Delta system (Figure 2.3). The San Francisco Bay

Regional Monitoring Program (RMP) has no independent nutrient-related monitoring program, but instead contributes approximately 20% of the USGS data collection cost. The Nutrient Strategy

⁴http://www.waterboards.ca.gov/sanfranciscobay/water_issues/programs/planningtmdls/amendments/estuarineNE/Nutrient_Strategy%20November%202012.pdf

highlights the need for a regionally-supported, long-term monitoring program that provides the information that is most needed to support management decisions in the Bay.

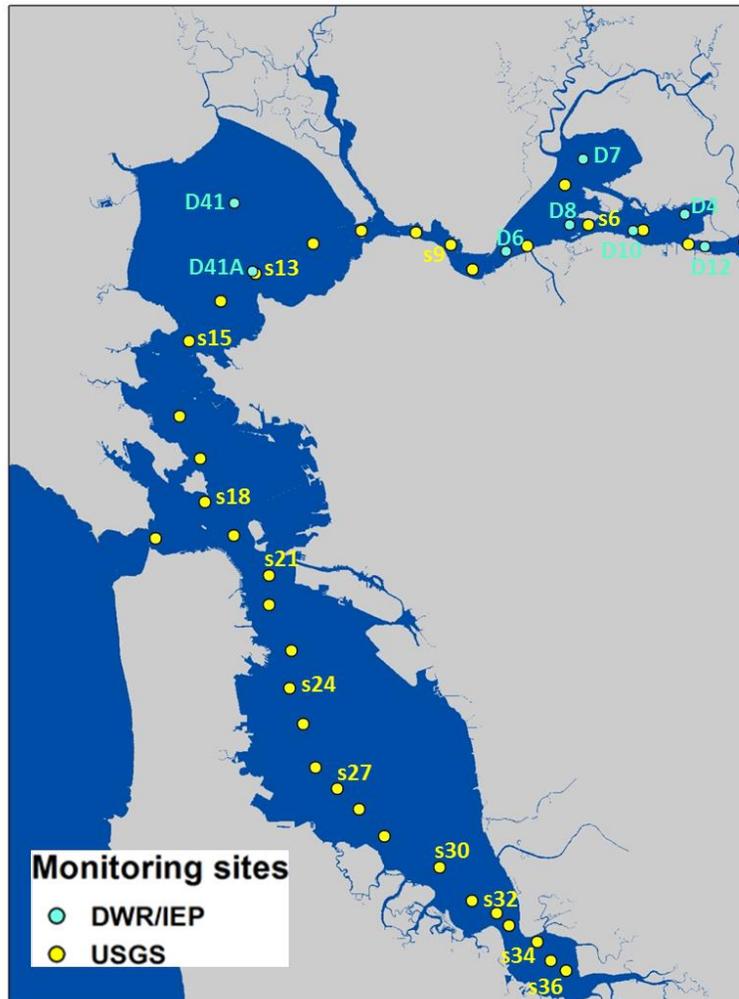

Figure 2.3 Location of DWR/IEP and USGS monthly sampling stations. Data from labeled USGS Stations (s6, s15, s18, s21, s27, s36) are used in Figures 5.7, 6.3-6.7 and 7.11.

NNE framework specific to SFB. That effort was initiated by a literature review and data gaps analysis that recommends indicators to assess eutrophication and other adverse effects of nutrient overenrichment in San Francisco Bay (McKee et al., 2011)⁵. McKee et al. (2011) evaluated a number of potential indicators of ecological condition for several habitat types based on the following criteria:

- Indicators should have well-documented links to estuarine beneficial uses
- Indicators should have a predictive relationship with nutrient and hydrodynamic drivers that can be easily observed with empirical data or a model

The timing also coincides with a major state-wide initiative, led by the California State Water Resources Control Board (State Water Board), for developing nutrient water quality objectives for the State's surface waters, using an approach known as the Nutrient Numeric Endpoint (NNE) framework. The NNE framework establishes a suite of numeric endpoints based on the ecological response of a waterbody to nutrient over-enrichment and eutrophication (e.g. excessive algal blooms, decreased dissolved oxygen). In addition to numeric endpoints for response indicators, the NNE approach includes models that link the response indicators to nutrient loads and other management controls. The NNE framework is intended to serve as numeric guidance to translate narrative water quality objectives.

Since San Francisco Bay is California's largest estuary, it is a primary focus of the state-wide effort to develop NNEs for estuaries. Through the Nutrient Strategy, the SFBRWQCB is working with regional stakeholders and with the State Water Board to develop an

⁵http://www.waterboards.ca.gov/sanfranciscobay/water_issues/programs/planningtmdls/amendments/estuarianNNE/644_SFBayNNE_LitReview%20Final.pdf

- Indicators should have a scientifically sound and practical measurement process that is reliable in a variety of habitats and at a variety of timescales
- Indicators must be able to show a trend towards increasing or/and decreasing beneficial use impairment due to nutrients

The report recommended focusing on subtidal habitats initially, and proposed the following primary indicators of beneficial use impairment by nutrients: i. phytoplankton biomass; ii. phytoplankton composition; iii. dissolved oxygen; and; iv. algal toxin concentrations. In addition, ‘supporting indicators’ and ‘co-factors’ were identified, and are summarized in Table 2.1. Supporting indicators provide additional lines of evidence to complement observations based on primary indicators, and co-factors are essential information to help interpret and analyze trends in primary or supporting indicators.

Regions of SFB behave quite differently with respect to nutrient cycling and ecosystem response due to a combination physical, chemical, and biological factors (discussed in Sections 5-9). To facilitate discussion of spatial trends in this report, SFB was divided into 5 subembayments, as depicted in Figure 2.1: Suisun Bay, San Pablo Bay, Central Bay, South Bay and Lower South Bay (LSB). These subembayment boundaries were chosen based on geographic features and not necessarily hydrodynamic features, represent one of several sets of boundaries that could be used. The boundaries illustrated in Figure 2.1 are similar to those defined by the SFBRWQCB in the San Francisco Bay Basin Plan, although we use different names for the subembayments south of the Bay Bridge.

Table 2.1 Recommended indicators within the context of the SFB NNE. Excerpted from McKee et al 2011

Habitat	Primary Indicators	Supporting Indicators	Co-Factors
All Subtidal Habitat	Phytoplankton biomass, productivity and assemblage Cyanobacteria cell counts and toxin concentration Dissolved oxygen	Water column nutrient concentrations and forms ¹ (C,N,P,Si) HAB species cell counts and toxin concentration	Water column turbidity, pH, conductivity, temperature, light attenuation Macrobenthos taxonomic composition, abundance and biomass Sediment oxygen demand Zooplankton

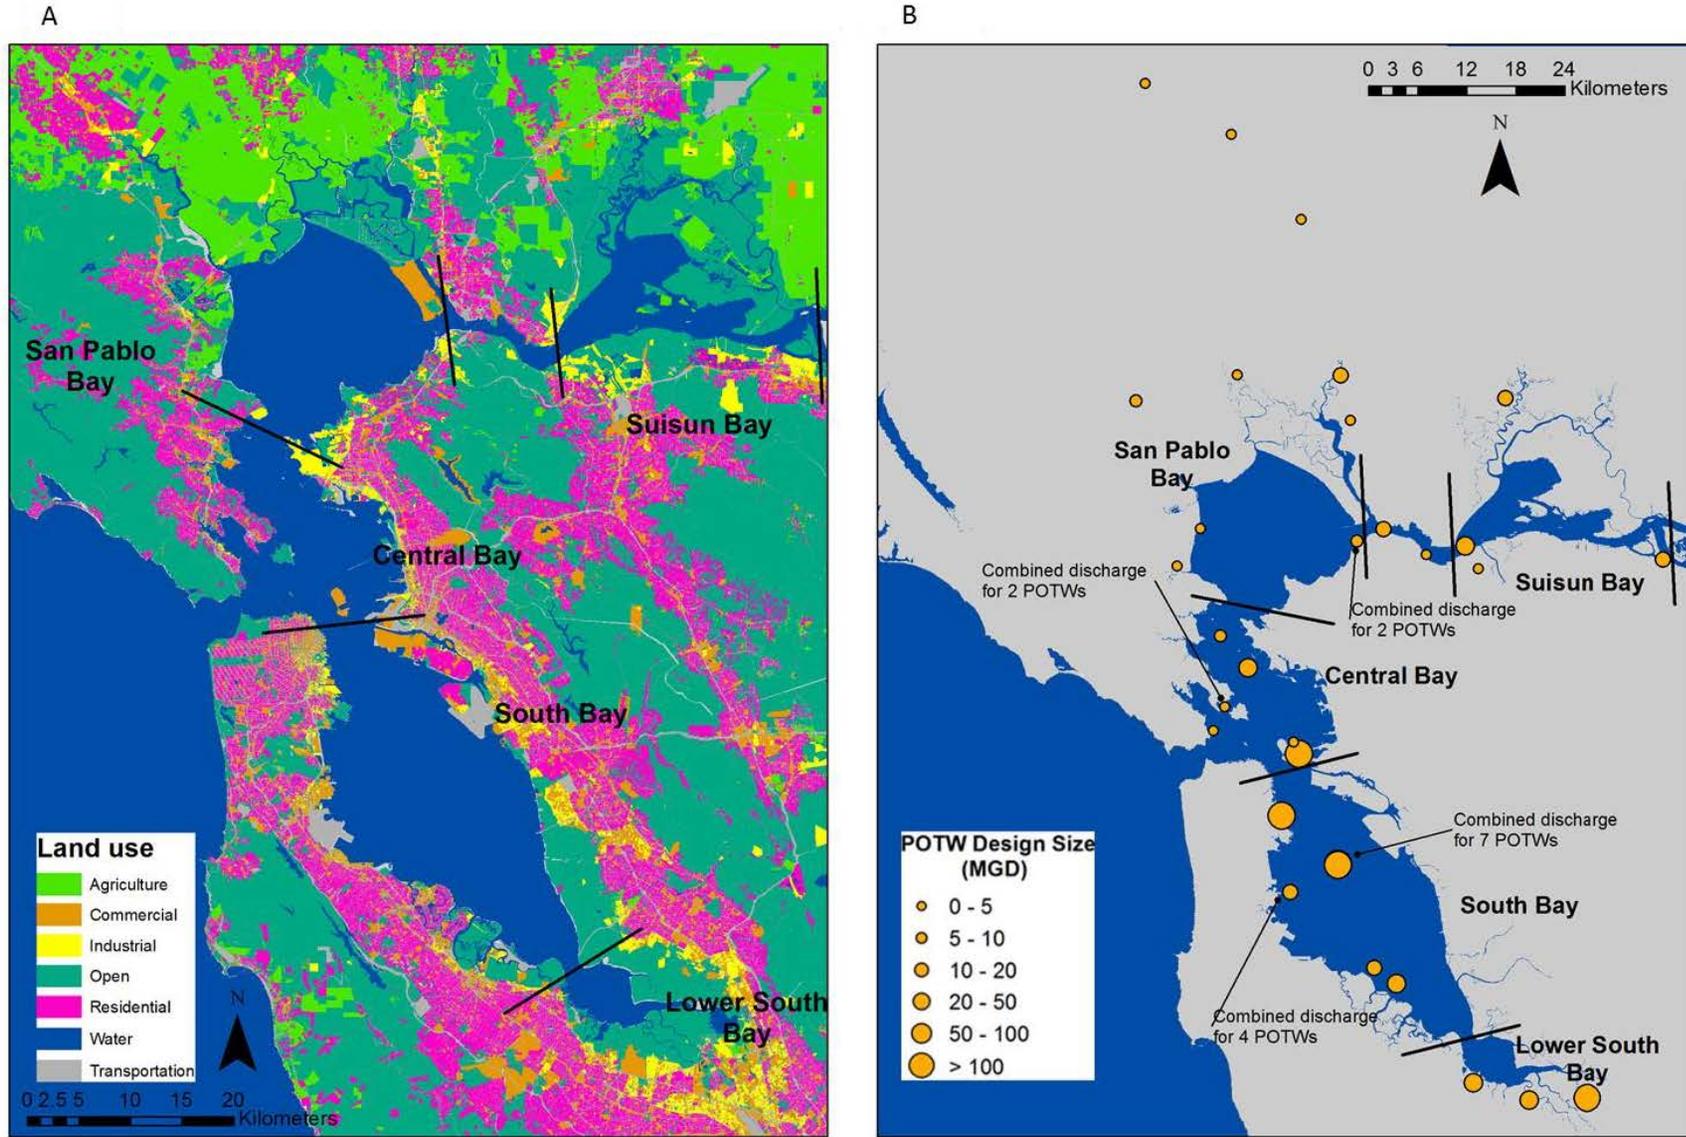

Figure 2.2 A. Land use in watersheds that drain to SFB (Data from Association of Bay Area Governments, 2000). B. Location and design size (in million gallons per day) for POTWs that discharge directly in SFB or in watersheds directly adjacent to subembayments. In both figures, Water Board subembayment boundaries are shown in black.

3 Problem Statement

3.1 Recent observations in SFB

In estuarine ecosystems in the US and worldwide, high nutrient loads and elevated nutrient concentrations are associated with multiple adverse impacts (Bricker et al. 2007). N and P are essential nutrients for the primary production that supports food webs in SFB and other estuaries. However, when nutrient loads reach excessive levels they can adversely impact ecosystem health. Individual estuaries vary in their response or sensitivity to nutrient loads, with physical and biological characteristics modulating estuarine response (e.g., Cloern 2001). As a result, some estuaries experience limited or no impairment at loads that have been shown to have substantial impacts elsewhere.

Figure 3.1 illustrates several potential pathways along which excessive nutrient loads could adversely impact ecosystem health in SFB. Each pathway is comprised of multiple linked physical, chemical, and biological processes. Some of those processes are well-understood and data are abundant data to interpret and assess condition; others are poorly understood or data are scarce. In Sections 5-9, we lay out a conceptual model describing the processes creating the pathways between loads and adverse response, and describe the current state of knowledge and data availability.

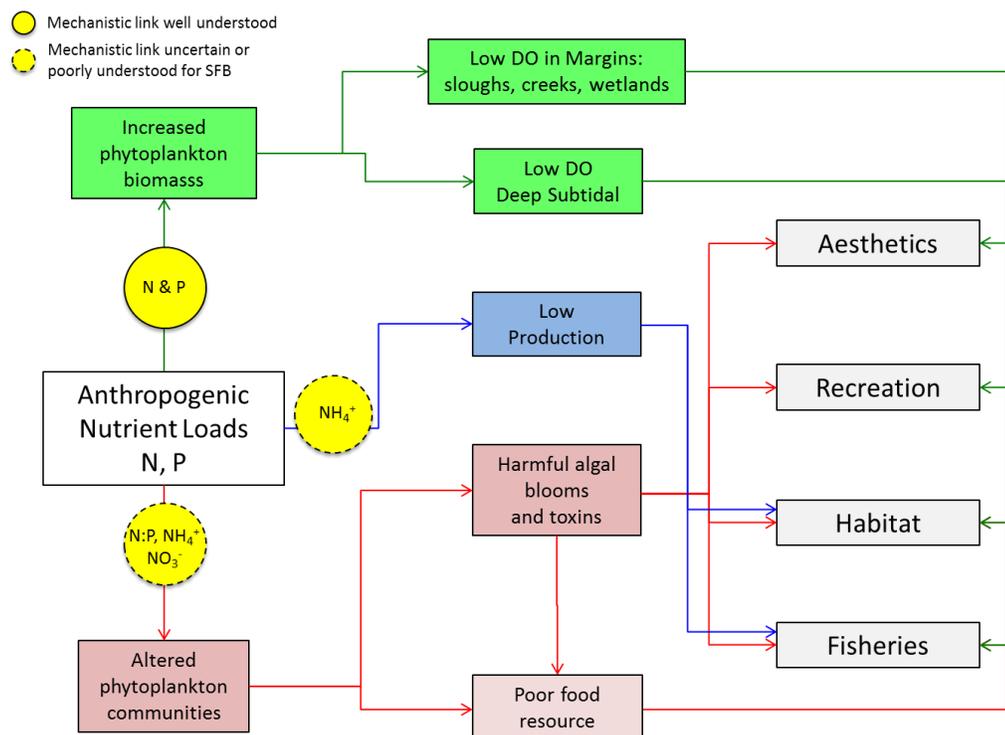

Figure 3.1 Potential adverse impact pathways: linkages between anthropogenic nutrient loads and adverse impacts on uses or attributes of SFB. The shaded rectangles represent indicators that could actual be measured along each pathway to assess condition. Grey rectangles to the right represent uses or attributes of SFB for which water quality is commonly managed. Yellow circles indicate the forms of nutrients that are relevant for each pathway

Current nutrient loads to some SFB subembayments are comparable to or much greater than those in a number of other major estuaries that experience impairment from nutrient overenrichment (Figure 3.2). Consistent with its high loads, SFB has elevated levels of dissolved inorganic nitrogen (DIN) and dissolved inorganic phosphorous (DIP) relative to other estuaries (Figure 3.3). Yet SFB does not commonly experience classic symptoms of nutrient overenrichment, such as massive and sustained phytoplankton blooms, or low dissolved oxygen over large areas in the subtidal zone. SFB has been spared the most obvious adverse impacts of high nutrient loads along these pathways due to a combination of factors that have imparted it with a degree of inherent resistance to these effects (Figure 3.4; discussed further in Sections 6 and 8). However, several recent sets of observations indicate that nutrient-related problems may already be occurring in some areas of SFB, or serve as early warnings of problems on the horizon.

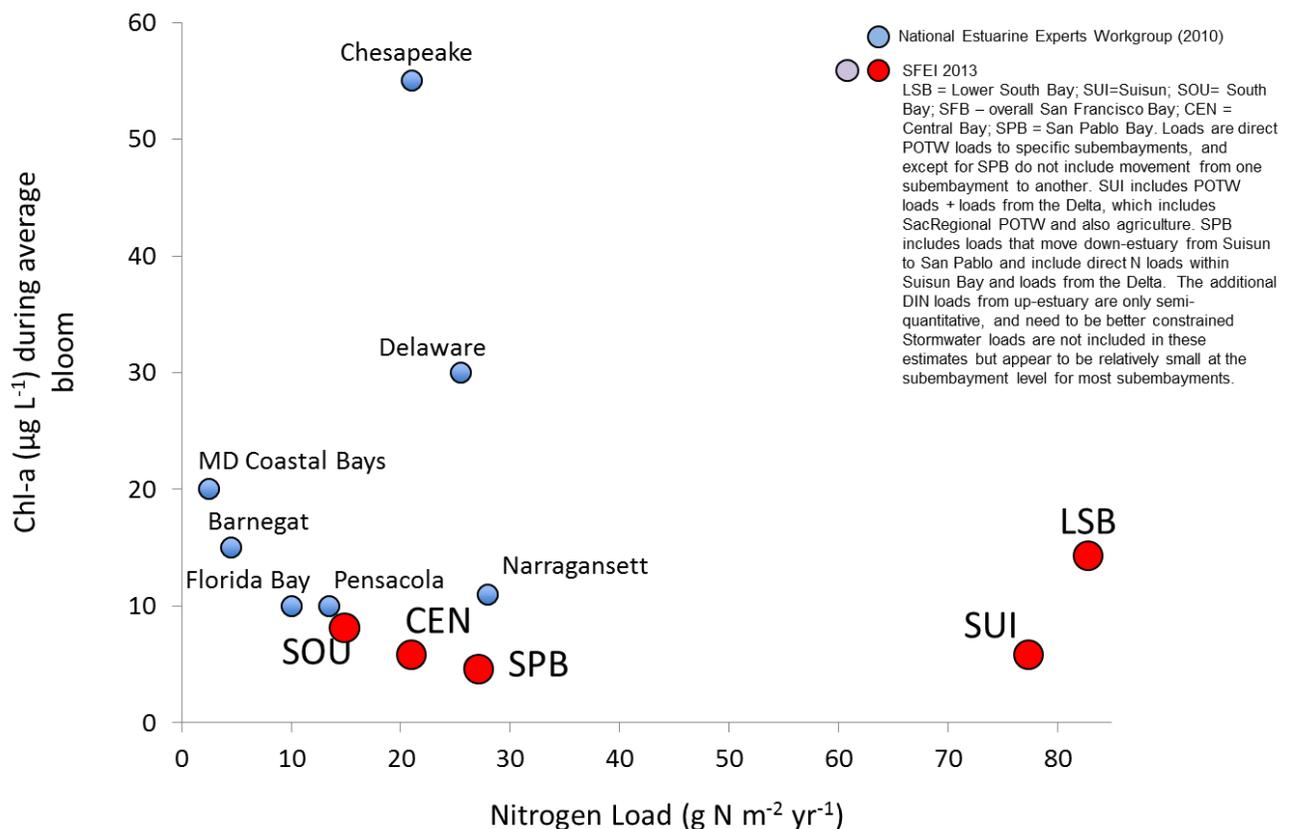

Figure 3.2 Chl-a concentration during an average bloom vs. nutrient loads to San Francisco Bay subembayments, compared to other estuaries that are considered to experience adverse impacts from nutrients. Loads considered include those from POTWs and loads entering from the Delta (which include N derived from upstream treated wastewater effluent and agriculture)

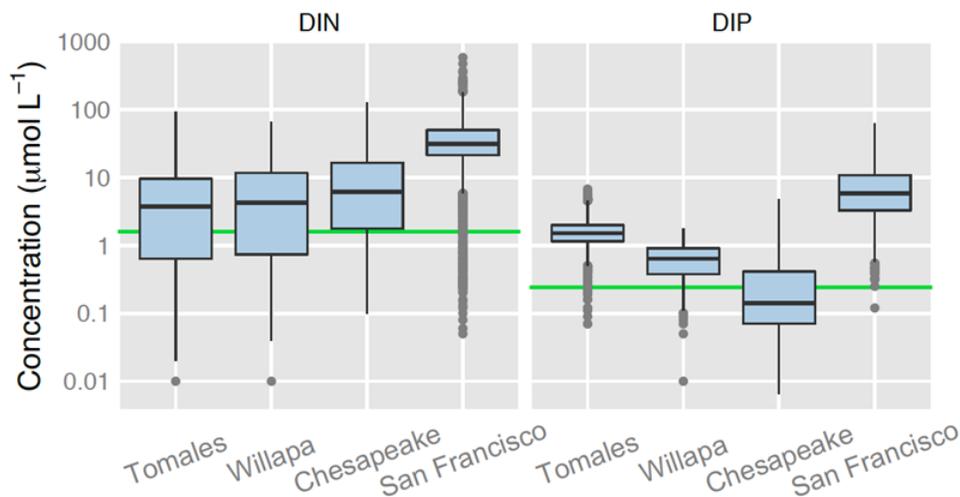

Figure 3.3 Nutrient concentrations in South Bay compared to other estuaries. Source: Cloern and Jassby (2012)

Over the past 15 years, statistically significant increases in phytoplankton biomass have been observed throughout SFB. Most notably summer/fall phytoplankton biomass tripled between the mid-1990s and the mid-2000s (Figure 3.5; Cloern et al., 2007) in South Bay and LSB, representing a shift in trophic status from oligo-mesotrophic (low to moderate productivity system) to meso-eutrophic (moderate to high productivity system) (Cloern and Jassby, 2012). More recent data from South Bay suggests that, at least presently, biomass concentrations have plateaued at a new level instead of continuing to rise (Figure 3.6; SFEI 2014a). Since the late 1990s, Fall blooms have begun occurring regularly in South Bay and LSB, areas where they seldom occurred previously (Figure 3.7 and Cloern and Jassby 2012). While the greatest magnitudes of biomass increase (i.e., in $\mu\text{g/L chl-a}$) have been observed in South Bay, other SFB subembayments have also experienced statistically significant increases in phytoplankton biomass (J Cloern, personal communication).

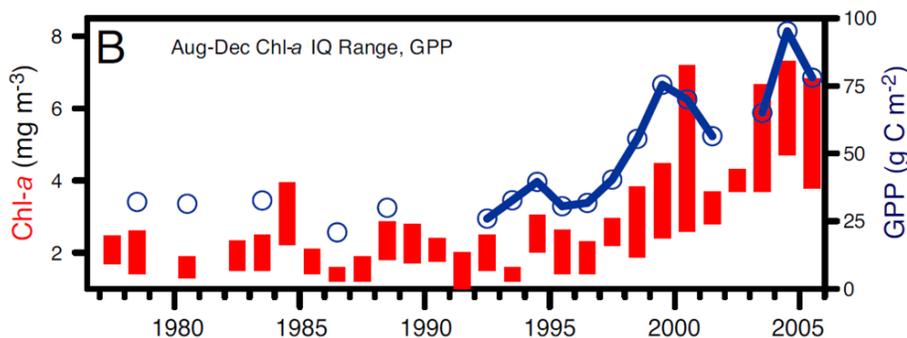

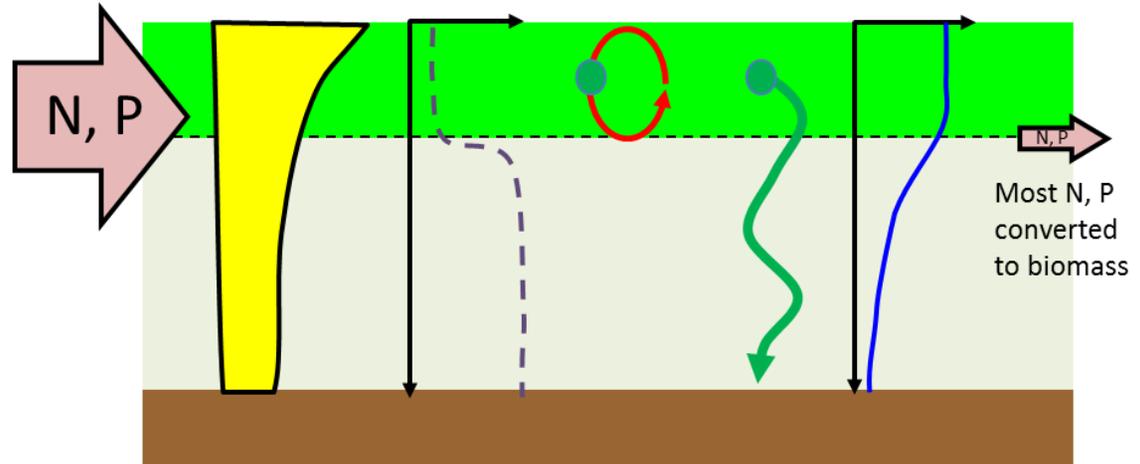

Figure 3.5 Interquartile range of Aug-Dec chl-a concentrations averaged across all USGS stations between Dumbarton Bridge and Bay Bridge, 1977-2005. Source: Cloern et al., 2007

Many other estuaries

1. Relatively high light levels over a substantial portion of the water column due limited light attenuation
2. Sustained periods of salinity- or temperature-stratification, during which phytoplankton residing in the surface layer grow rapidly on high light levels.

Nutrients are efficiently converted to phytoplankton biomass, and dissolved O_2 reaches low levels in the un-ventilated bottom waters where dead phytoplankton are respired by DO-consuming microorganisms. Discussed further in Sections 7 and 8.

San Francisco Bay

1. High turbidity, and most light attenuated within 1-2m of the surface low light
2. Strong tidal mixing, well-mixed water column
3. High abundance of filter-feeding clams that consume phytoplankton biomass

A lower proportion of nutrients is converted into biomass, benthic grazers reduces standing stock of phytoplankton which overall results in lower productivity, and less DO demand bottom waters due to lower biomass, mixing ventilates bottom waters limiting and so biomass that is respired by DO-consuming microorganisms seldom reaches low levels, prevents development of low DO.

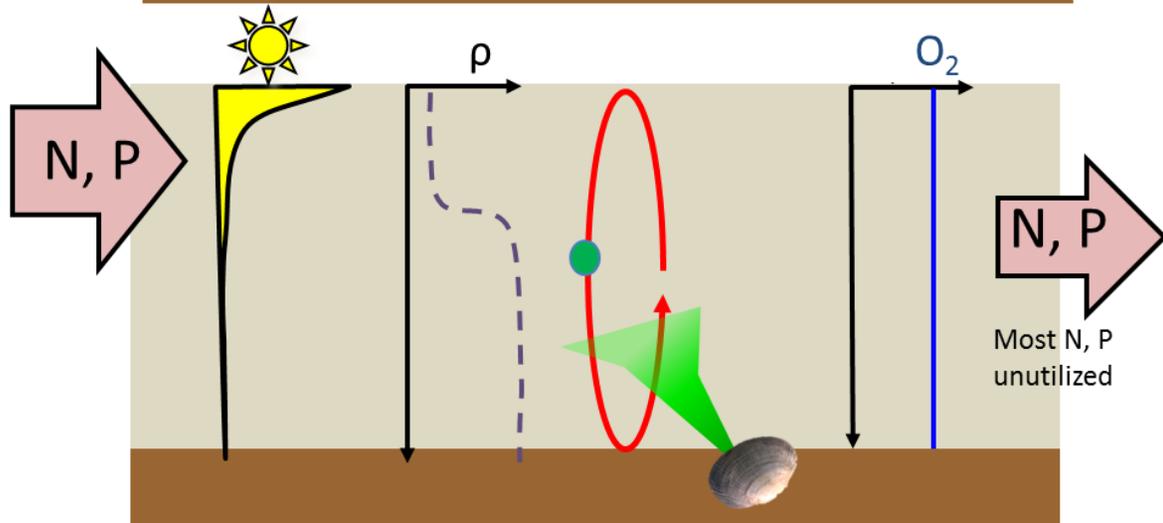

Figure 3.4 Simplified schematic illustrating key differences between SFB and many other estuaries that lead to SFB's attenuated response to nutrients in terms of phytoplankton biomass and dissolved oxygen.

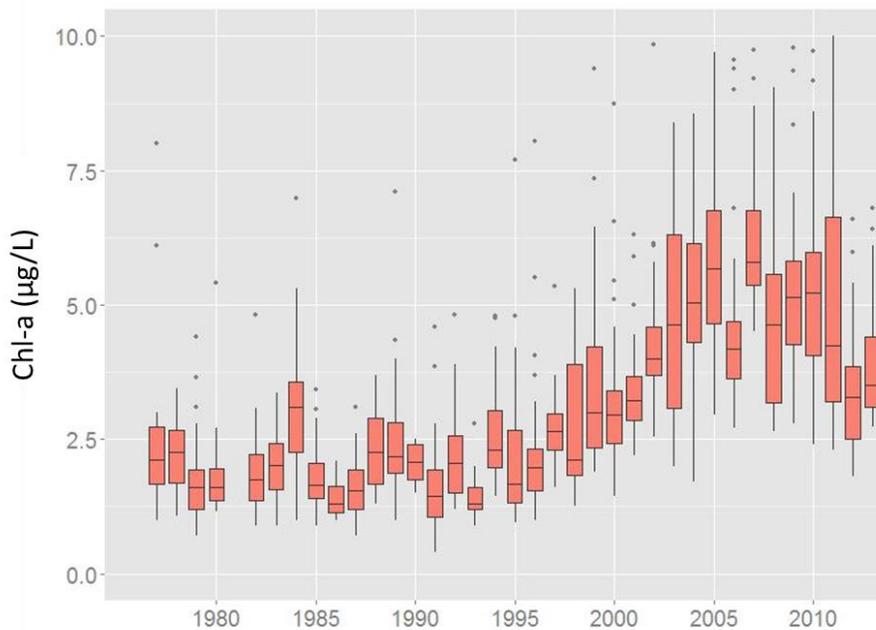

Figure 3.6 Same stations as and data as presented Figure 3.5, with data extended through 2013 (Interquartile range of Aug-Dec chl-a concentrations averaged across all USGS stations between Dumbarton Bridge and Bay Bridge, 1977-2013). Source: SFEI 2014c

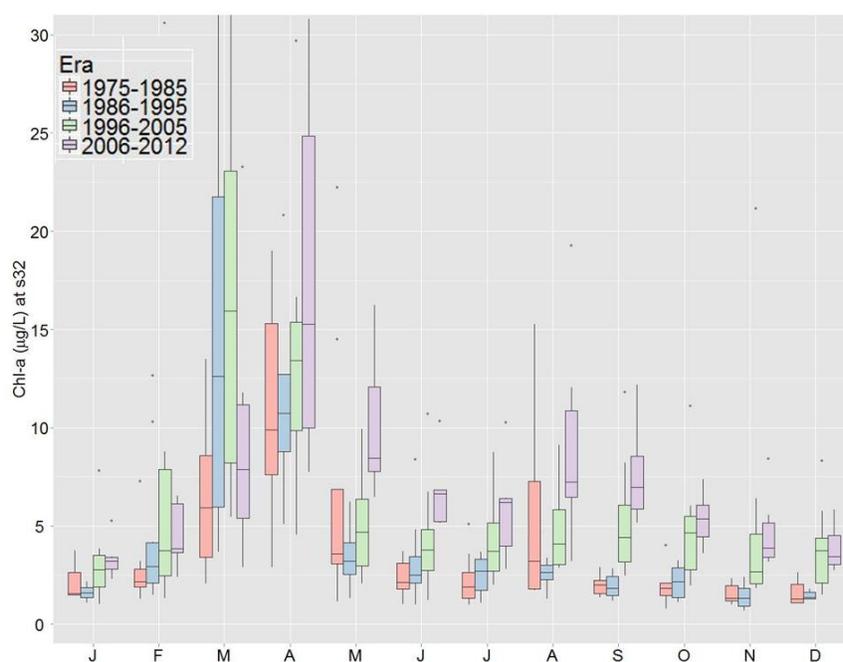

Figure 3.7 Seasonal box plot of chlorophyll-a concentrations near the Dumbarton Bridge (USGS s32), divided into ~10 year eras. Increases in summer baseline chl-a concentrations have been evident since 1996-2005. Fall blooms have also become a regular occurrence. The increases are statistically significant during all months except March and April.

In Suisun Bay, extremely low phytoplankton biomass has defined the system since 1987 (Figure 3.8), coincident in time with the invasive clam, *Potamocorbula amurensis*, becoming widely established. The extended period of low phytoplankton biomass and low rates of primary production are considered to be among the factors contributing to long-term declines in upper trophic level production in Suisun Bay and the Delta by limiting food supply (Baxter et al., 2010; NRC 2012). While the low phytoplankton biomass and productivity in Suisun Bay have generally been attributed to the impacts of *Potamocorbula* and low light levels due to high

suspended sediments (e.g., Kimmerer and Thompson, 2014), recent studies have argued that elevated ammonium (NH_4^+) concentrations in Suisun Bay also limit primary production rates and play an important role in both creating the low biomass conditions and exacerbating food limitation (Dugdale et al., 2007; Dugdale et al., 2012; Parker et al. 2012a,b). Other studies have proposed that high ambient concentrations of nitrate (NO_3^-) and NH_4^+ , and altered ratios of N:P cause shifts phytoplankton community composition toward species having poor food quality, adversely impacting Delta food webs (Glibert 2010; Glibert et al., 2011).

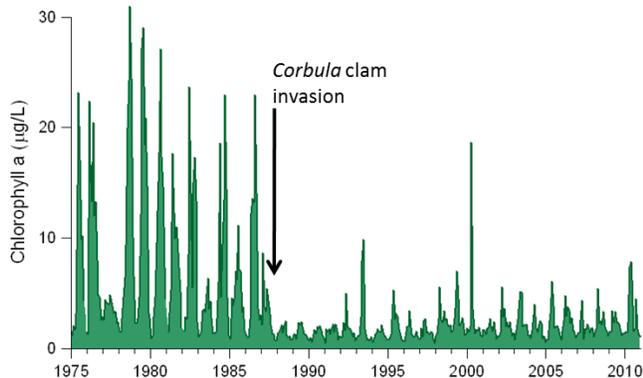

Figure 3.8 Phytoplankton biomass in Suisun Bay, 1975-2010. Source: J Cloern, USGS; Data: USGS, DWR-EMP

Harmful phytoplankton species also represent a growing concern. The harmful algae, *Microcystis spp.*, and the toxin they produce, microcystin, have been detected with increasing frequency in the Delta and Suisun Bay since ~2000 (Lehman et al., 2008). In addition, the HAB toxins microcystin and domoic acid have been detected Bay-wide (Figure 3.9). The ecological

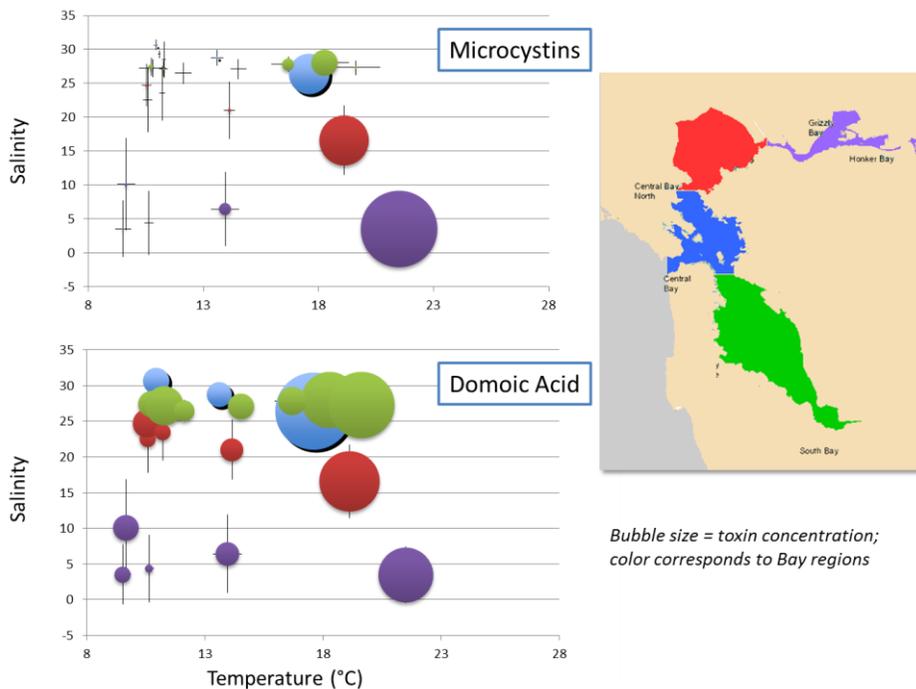

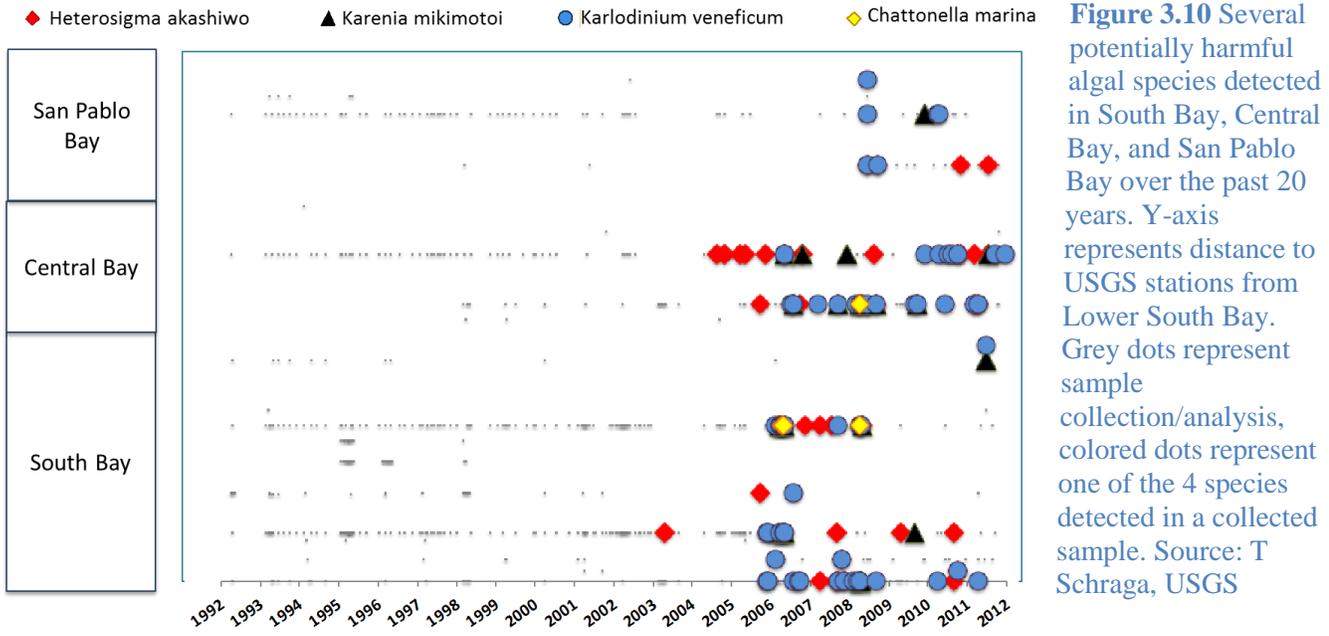

Figure 3.9 HAB toxins detected in SFB during 2011. Bars represent 1 SD for salinity and temperature Source: R. Kudela

significance of observed toxin levels in the Bay are not yet known. A number of phytoplankton species that have formed harmful algal blooms (HABs) in other systems have been detected throughout SFB (Table 3.1 and Figure 3.10). Although the abundances of HAB-forming

organisms in SFB have not reached levels that would constitute a major bloom, they do periodically exceed thresholds established for other systems (Kudela et al., in prep), and major *Microcystis spp* blooms and elevated microcystin levels have been observed with some regularity in the Delta (Lehman et al., 2008). Moreover, since HAB-forming species are present in SFB and nutrients are abundant, HABs could readily develop should appropriate physical conditions create opportunities that HABs can exploit. In fact, an unprecedented large red tide bloom

occurred in Fall 2004 following a rare series of clear calm days during which the water column was able to stratify, and chl-a levels reached nearly 100 times their typical values (Figure 3.11; Cloern et al. 2005). In addition, harmful-bloom forming species have been detected at elevated abundances in salt ponds in LSB undergoing restoration (Thebault et al., 2008), raising concerns that salt ponds could serve as incubators for harmful species that could then proliferate when introduced into the open bay.

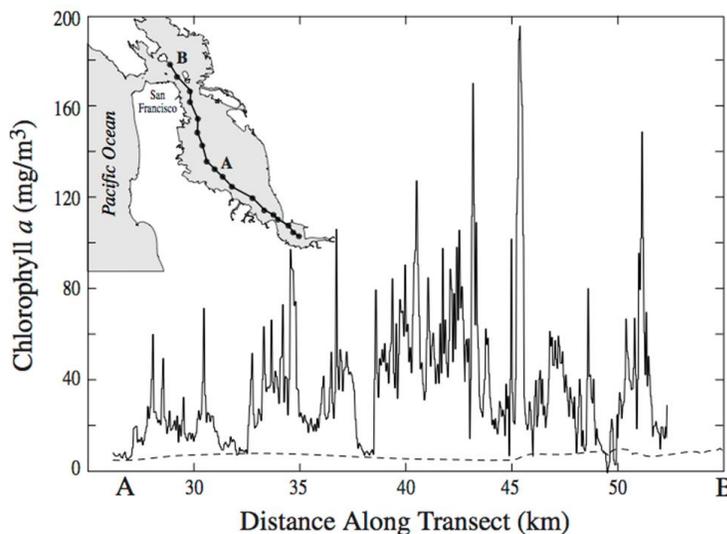

Figure 3.11 Phytoplankton biomass South and Central Bays. Measurements taken during a red tide on 8 September 2004 (solid curve). Phytoplankton biomass returned to typical seasonal levels on 14 September (dashed curve). Inset map shows location of the sampling transect A-B. Source: Cloern et al. 2005

Pseudo-nitzschia	Diatom	1992	2011	132	domoic acid		Large blooms occurred in central and south Bay (stn 27) in 1990s
Anabaena	Cyanobacteria	1993	2011	24	PSTs		Sacramento River and confluence.
Aphanizomenon flos-aquae	Cyanobacteria	1995	2011	13	PSTs		Sacramento River and confluence. Low #s in South Bay

Table 3.1 continued

Genus/Species	Division/Phyla	1st observed	Most recent observed	# of times observed	Toxin**	Impact	Location and timing of observations
Aphanocapsa	Cyanobacteria	1993	2011	22			South Bay 2005+6, 2011 Delta confluence (San Joaquin source most likely)
Aphanothece sp.	Cyanobacteria	1992	2011	32			South Bay 2005+6, 1990s and 2010-11 Suisun and Sac River
Cyanobium sp.	Cyanobacteria	1999	2008	79	microcystin		South and Central Bay
Lynghya aestuarii	Cyanobacteria	2011	2011	1	saxitoxin	human health impacts (skin, digestion, respiratory, tumors) and paralytic shellfish poisoning	September 2011 - large bloom in Suisun area (stn 3)
Planktothrix	Cyanobacteria	1992	2011	23	PSTs		South Bay 2005-2007, 1990s, 2010-11 Suisun and Sac River
Synechococcus sp.	Cyanobacteria	1992	2011	66			South Bay spring (March/April)
Synechocystis	Cyanobacteria	1997	2011	224	microcystin		South Bay and San Pablo Bay, mostly in fall

All of these species have had high biomass in SFBAY. Multiple species are grouped within a genera. If it's a single species, it is listed as such

*Known as exceptionally harmful in temperate estuaries such as in Japan and Atlantic coast estuaries. All were detected for the first time in SFB in the past 10 years and have persisted

** Not all toxins are known. Genera with PST have two or more Paralytic Shellfish Toxins = microcystin, cylindrospermopsin, anatoxin, saxitoxin. All cause Paralytic Shellfish Poisoning. PSTs microcystin and cylindrospermopsin cause liver damage in mammals, anatoxin and saxitoxin damage nerve tissues in mammals (humans, dogs, etc.)

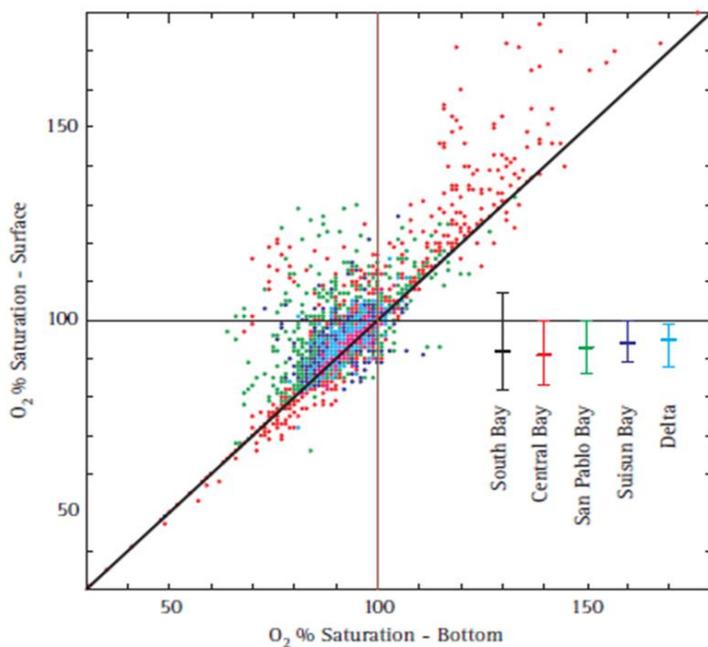

Figure 32. Oxygen concentration as percent saturation in near-surface and near-bottom samples. Color indicates region, and error bars give medians and 10th and 90th percentiles of the data. Data from USGS monitoring program, which focuses on channel stations and the portion of the Delta in the lower Sacramento River.

Figure 3.12 DO in deep subtidal areas of SFB. Source: Kimmerer 2004

DO concentrations in deep subtidal habitats throughout the Bay typically remain at levels above 5 mg L^{-1} , (Figure 3.12), the San Francisco Bay Basin Plan standard. However, in LSB, sampling has most frequently occurred at slack high tide. Recent continuous measurements at the Dumbarton Bridge indicate that DO levels at low tide are commonly $1\text{-}2 \text{ mg/L}$ lower than at high tide during summer months (e.g., Figure 3.13.A; SFEI, 2014c), and can occasionally dip below, 5 mg L^{-1} (SFEI, unpublished data). During Summer 2014, USGS sampling cruises detected $\text{DO} < 5 \text{ mg/L}$ at other deep subtidal stations south of the Dumbarton Bridge during two cruises⁶.

Low DO commonly occurs in some shallower margin habitats (Figure 3.14). For example, studies of salt ponds undergoing restoration in LSB show that they experience large diurnal DO fluctuations (Figure 3.15.A; Topping et al., 2009) and occasionally experience sustained periods of anoxia (Figure 3.15.B; Thebault et al., 2008). In some slough habitats of LSB, DO regularly dips below 5 mg L^{-1} , frequently approaches 2 mg L^{-1} (Shellenberger et al., 2008), and at a site in Alviso Slough, DO remained near or below 2 mg L^{-1} for sustained periods (up to 10-12 hours) during Summer 2012 (Figure 3.13.B) and Summer 2014 (SFEI, 2014c). Low DO has also been observed in Suisun Marsh, although whether that low DO is linked to nutrient issues in SFB is still being investigated (effluent from managed duck ponds is presumed to be a major cause; Tetra Tech 2013). Under natural conditions, shallow subtidal and tidal wetland habitats commonly experience low DO, and plants and animals native to these habitats are often well-adapted to these DO swings. However, there is a paucity of DO data in margin habitats, and the severity of low DO (frequency, duration, spatial extent, concentration), whether it is impacting biota, and the extent to which excess nutrients cause or contribute to the low DO conditions are all poorly known.

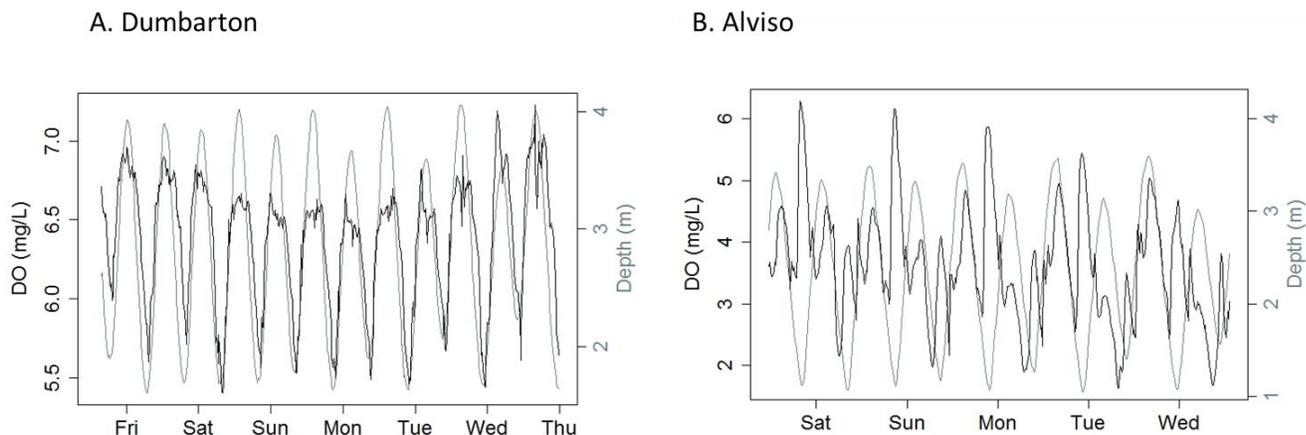

Figure 3.13 Time series of DO (mg/L) and depth at **A. Dumbarton Bridge** and **B. Alviso Slough**, Sep 5-12 2013.

In addition to characterizing and addressing any current nutrient-related problems in SFB, there is a need to anticipate potential future adverse impacts. The highly elevated DIN and DIP concentrations Bay-wide provide the potential for future impairment to develop. Any major reductions in loads to SFB will take years-to-decades to implement. Thus, if future problems are to be averted, potential impairment scenarios need to be anticipated, evaluated, and, if deemed necessary, managed in advance of their onset. A proactive approach to characterizing and managing potential problems – while they are on the somewhat-distant horizon, as opposed to imminent – will allow greater flexibility in the management options that can be pursued.

3.2 What would a problem look like in SFB?

At the outset of the SFB conceptual model development, we asked the question: *What would a nutrient-related problem look like in SFB subembayments, if a problem were currently occurring, or if one was to occur in the future?*

This report does not aim to answer the question of whether SFB subembayments are currently impaired or will be in the future. Instead, we used the answers to this question to help focus the conceptual model on issues most relevant for detecting impairment and anticipating potential future impairments, and to identify meaningful and measurable indicators of ecosystem response to nutrients and ecosystem health.

Table 3.2 summarizes nutrient-related adverse impacts (AI) that were identified as plausible in San Francisco Bay, divided into eight categories. The problem categories are specific examples that extend from the more general paths depicted in Figure 3.1.

High phytoplankton biomass can have direct adverse impacts (AI.1) in SFB, through acting as a nuisance (aesthetics, odor) or through direct impacts on biota (e.g., smothering or shading aquatic macrophytes, coatings on bird wings). However, among the most common and problematic impairments due to high phytoplankton biomass is low dissolved oxygen in deep subtidal areas that develops due to degradation of phytoplankton-derived organic matter by oxygen-consuming microorganisms (AI.2). In the case of both high phytoplankton biomass and low DO, the magnitude, duration, and spatial extent are important to consider. Extremely low DO (e.g., $<2 \text{ mg L}^{-1}$), and the high phytoplankton biomass that causes it, over large areas for extended periods of time could lead to considerable impairment, whereas moderate DO deficits, or spatially-limited or short-duration events may be less problematic. In addition, low DO occurs

naturally in shallow margin habitats (e.g., sloughs, salt marshes), and native organisms are adapted to these conditions. However, elevated anthropogenic nutrient loads could exacerbate these issues by increasing the intensity of these events (i.e., even lower DO), or increasing the spatial extent, temporal frequency, or duration (AI.3). Thus, both the severity of events and whether they are entirely natural or caused or exacerbated by anthropogenic nutrients need to be considered.

Elevated nutrient concentrations, or changes in relative abundance of nutrient forms, could increase the frequency with which HABs occur, the severity of a HAB event (abundance, duration, spatial extent), and the levels of HAB-related toxins (AI.4). Phycotoxins, i.e., toxins produced by phytoplankton, bioaccumulate and can exert toxicity to consumers at all levels of the food web, including humans. Some phycotoxins also exert direct toxicity (e.g., skin contact). High nutrient loads may also increase the frequency of so-called nuisance algal blooms (NABs), which are not toxic but may degrade aesthetics due to surface scums or odors.

Several recent studies, focused in the northern Bay-Delta, have hypothesized that high NH_4^+ levels contribute to the low biomass and infrequent phytoplankton blooms in Suisun Bay by inhibiting primary production (AI.5), in particular the growth of diatoms (Dugdale et al., 2007; Parker et al., 2012a,b; Dugdale et al., 2012). Low phytoplankton biomass stands among the factors thought to contribute to ecosystem decline in Suisun Bay and the Delta. To the extent that elevated NH_4^+ contributes to lower productivity, elevated nutrient loads – and in particular NH_4^+ loads – would adversely impact ecosystem health along this pathway (Figure 3.1).

Other recent studies have hypothesized that high nutrient concentrations, elevated NH_4^+ , or altered N:P in SFB adversely impacts food webs by shifting phytoplankton community composition away from healthy assemblages and toward suboptimal compositions that do not adequately sustain organisms at higher trophic levels (AI.6; Glibert et al., 2012). Another recent study observed that high NH_4^+ concentrations can exert chronic toxicity on an important Delta/Suisun copepod at concentrations (25 μM) that approach ambient concentrations in some areas along the Sacramento River and in the Delta (Teh et al, 2011). Other studies have argued that high nutrient concentrations or altered N:P can alter individual cell composition in ways that adversely impact primary consumers (Glibert et al., 2013). The latter two examples are included under “Other nutrient-related impacts” (AI.7), along with other potential adverse impact pathways not explicitly noted.

Table 3.2 What would a problem look like in SFB? Plausible adverse impacts (AI).

	Impacted State	Rationale or Link to Beneficial Uses
AI.1	High Phytoplankton Biomass High phytoplankton biomass of sufficient magnitude (concentration), duration, and spatial extent that it impairs beneficial uses due to direct or indirect effects (IS.2). This could occur in deep subtidal or in shallow subtidal areas.	Direct impairment due to aesthetics (odors, surface scum) and potentially directly impairing biota (at very high levels, e.g., coating birds wings). Other main concern is through causing low dissolved oxygen (IS.2, IS.3)
AI.2	Dissolved Oxygen – Deep subtidal Low DO in deep subtidal areas of the Bay, over a large enough area and below some threshold for a long enough period of time that beneficial uses are impaired.	Fish kills, die-off of beneficial benthos, loss of critical habitat that result in lowered survival or spawning/reproductive success or recruitment success of fish and beneficial benthos.
AI.3	Low DO – Shallow/margin habitats: DO in shallow/margin habitats below some threshold, and beyond what would be considered “natural” for that habitat, for a period of time that it impairs beneficial uses	Fish kills, die-off of beneficial benthos, loss of critical habitat that result in lowered survival or spawning/reproductive success or recruitment success of fish and beneficial benthos
AI.4	HABs/NABs and phycotoxins Occurrence of HABs/NABs and/or related toxins at sufficient frequency or magnitude of events that habitats reach an impaired state, either in the source areas or in areas to which toxins are transported.	<i>HABs and phycotoxins:</i> Passive or active uptake of toxins, or ingestion of HAB-forming species and accumulation of toxins. Ingestion of bioaccumulated toxins by is harmful to both wildlife and humans through consumption of tainted shellfish or fish. Skin contact and inhalation can also be problematic. <i>NABs:</i> Some species are considered nuisance for reasons other than toxins (e.g., rapid biomass production leading to low DO). Impaired aesthetics, surface scums, discoloration, odors
AI.5	Low Phytoplankton Biomass Low phytoplankton biomass in Suisun Bay or other habitats due to elevated NH_4^+ , which would exacerbate food supply issues.	Suisun Bay is considered a food limited system, and low levels of phytoplankton may contribute to impairment in this highly altered system.
AI.6	Suboptimal phytoplankton assemblages Nutrient-related shifts in phytoplankton community composition, or changes in the composition of individual cells (N:P), that result in decreased food quality, and have cascading effects up the food web.	Phytoplankton primary production is the primary food resource supporting food webs in SFB. Changes in the dominant assemblages would impact food quality.
AI.7	Other nutrient-related impacts. Other direct or indirect nutrient-related effects that alter habitat or food web structure at higher trophic levels by other pathways.	Several additional nutrient-related impacts on food webs in the northern estuary have been proposed that are not captured by IS.1-IS.6, and that are not explored in detail in this report.

4. Conceptual Model Overview

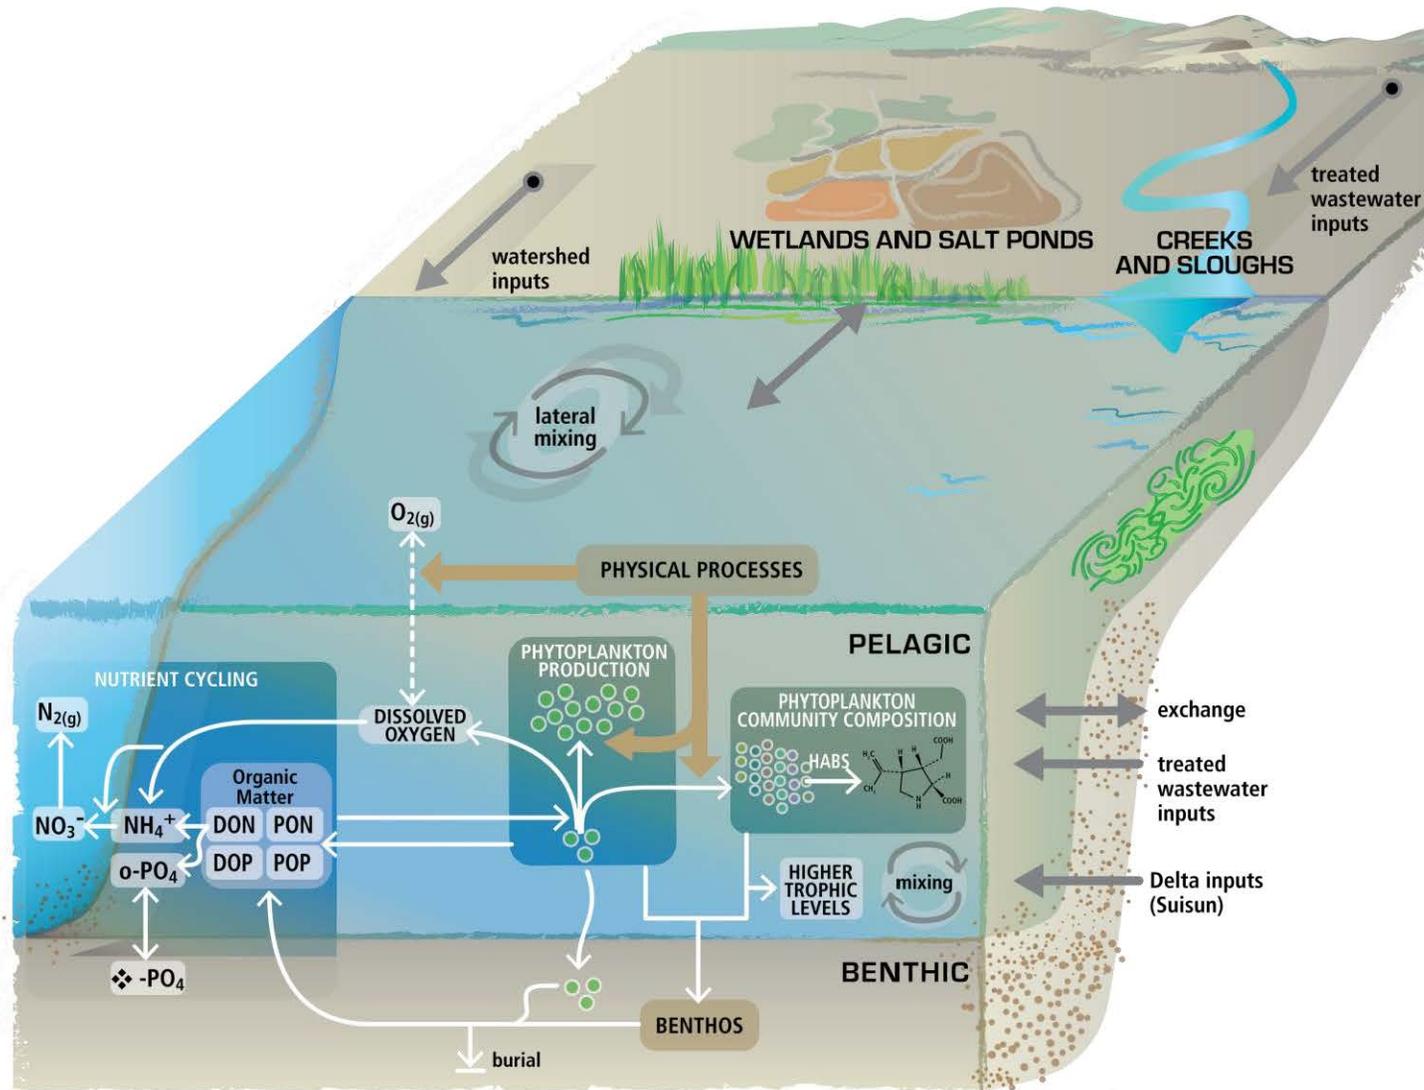

The conceptual model is described as a set of modules (Sections 5-9) that establish the mechanistic framework connecting nutrient loads with ecosystem response. Major components of the conceptual model are illustrated generally in Figure 4.1.A. The goal in developing this conceptual model was to make explicitly the multiple steps and mechanisms that fall along the path between nutrient loads and ecosystem response, and therefore views biogeochemistry, ecology, and beneficial uses in SFB through a nutrient-centric lens. In particular the conceptual model explores the pathways and mechanisms along the adverse impact pathways illustrated in Figure 3.1 and summarized in Table 3.2, and ties back to the proposed NNE indicators for assessing condition in SFB (Table 2.1).

The conceptual model is organized into five main modules:

- Section 5: Physical processes (hydrodynamics and sediments)
- Section 6: Nutrients
- Section 7: Primary production, with a major focus on phytoplankton biomass
- Section 8: Dissolved Oxygen; and
- Section 9: Phytoplankton Community Composition, HABs, and HAB toxins

The modules considered in this report extend only as far along the food web as phytoplankton biomass and community composition. Zooplankton, benthos, and fish played a central role in shaping the other modules: their habitat and food requirements were used to focus the modules for phytoplankton biomass, phytoplankton community composition, and dissolved oxygen on the most relevant processes and information needs; and the roles of primary consumers (benthic and pelagic grazers) were explicitly considered in as much as they influence phytoplankton biomass, phytoplankton community composition, and carbon flow in the system and are themselves influenced by food quality. Figure 4.1.B depicts the detailed conceptual model, with all components combined. The subsequent sections of this report focus on specific parts of this overall conceptual model. Physical processes play an important role in dictating ecosystem response to nutrients in SFB. Section 5 provides an introduction to hydrodynamic considerations, and hydrodynamic controls are woven throughout the discussions in Sections 6-9. Section 10 briefly summarizes pathways or indicators not included in the conceptual model at this time.

Although SFB's 5 subembayments have very different physical, biogeochemical, and biological characteristics that shape their individual responses to nutrients, a single set of modules was developed for all of SFB. This is appropriate since the same fundamental processes operate in each subembayment. Inter-subembayment differences in nutrient concentrations or forms and ecosystem response arise from differences in the relative importance of major drivers among subembayments, and these differences are discussed within each module.

5 Physical Processes: Hydrodynamics and Sediment dynamics

5.1 Introduction

Characteristics of the 5 SFB subembayments considered in this report are presented in Table 5.1. San Francisco Bay has an open water surface area of approximately 1100 km² and an average depth of approximately 7 m, resulting in a total volume of approximately 7400 km³ (Smith and Hollibaugh, 2006). Shallow shoals comprise large areas of LSB, South Bay, San Pablo Bay, and Suisun Bay (Figure 5.1; see also Figure A.1 in Appendix for higher resolution bathymetry).

The physical dynamics of San Francisco Bay are driven by the interplay of tidal, freshwater, and wind forcing with the complex topography of the Bay. In general terms, the Bay is made up of a series of subembayments: Central Bay is the deepest basin and is most strongly coupled to the Pacific. Landward from Central Bay, South Bay, Lower South Bay, and San Pablo Bay are each characterized by a single deep channel that bisects broad subtidal shoals. Upestruary from San Pablo Bay, on the landward side of Carquinez Strait, lies Suisun Bay, which is distinguished from the other embayments by its braided channels and the presence of two distinct shallow subtidal embayments: Grizzly Bay and Honker Bay. Finally, the Sacramento-San Joaquin Delta is not so much an embayment but a network of channels connecting the landward estuaries with the Bay. This complex topography sets the environment for tidal forcing, wind forcing and freshwater flows, which define the variability of tidal stage (inundation regime), salt and nutrient transport, stratification, turbulent mixing and sediment dynamics.

Freshwater inputs vary greatly among the subembayments. Suisun Bay and San Pablo Bay are river-dominated estuaries. The Sacramento and San Joaquin Rivers, enter SFB through Sacramento/San Joaquin Delta east of Suisun Bay, and 90% of the annual freshwater to SFB enters through the Delta. Additional freshwater inputs to SFB come from smaller perennial tributaries that drain the immediate surrounding watersheds, and stormwater runoff. Suisun Bay hydraulic residence times range from less than 1 day during high-flow periods to ~1 month during dry periods. Low salinity conditions generally define Suisun Bay, while San Pablo Bay is considerably more saline due to exchange with Central Bay. Compared to the northern estuary, freshwater inputs to Lower South Bay and South Bay are quite limited and consist mainly of wastewater treatment plant effluent and stormwater during the rainy season. LSB and South Bay behave more like tidal lagoons, and residence times can range from weeks to months.

Hydrodynamics and sediment dynamics play a critical role in determining San Francisco Bay's direct and indirect responses to nutrients. The intensity of vertical mixing and the length of time that a stratified water column (i.e., a surface layer and bottom layer) can be maintained strongly regulate the timing, magnitude, and duration of phytoplankton blooms in deeper sections of this turbid (light-limited) yet nutrient-rich estuary. Suspended sediment loads, tidal mixing, and wind-driven mixing maintain high levels of particles in the water column resulting in light-limiting conditions for phytoplankton growth. Exchange between the Bay's channels and broad shallow shoals – where higher average light availability allows for faster phytoplankton growth – can influence the degree to which blooms develop in the shoals and propagate to the channels. Vertical mixing rates, duration of stratification, and rates of exchange or flushing between subembayments and habitats determine the extent to which low oxygen levels can develop. A

comprehensive review of the hydrodynamics of San Francisco Bay is beyond the scope of this document. Instead, this section first describes four major physical forcings (tides, wind, freshwater flow, and coastal ocean exchange). We then focus on three issues that are particularly relevant to consideration of ecological change in response to shifting nutrient regimes: flushing times, density stratification and suspended sediment.

5.3 Major drivers

5.3.1 Tidal forcings

The spring-neap (~14 day) cycle in San Francisco Bay produces large diurnal asymmetries in the tides during the springs, which are characterized by one large tide and one small tide in each 24 hour cycle. The neaps, on the other hand, have more symmetric tides, which are intermediate in magnitude to the two tides seen each day during the springs. Tidal mixing energy also varies over the course of the year, with sustained highest-energy periods around the solstices (June, December), and sustained minimum energy periods around the equinoxes (March, September) (Figure 5.2)

Table 5.1 Subembayment area and volume, and watershed area and land-use

	Boundary	Bay area¹ (10 ⁶ m ²)	Bay volume¹ (10 ⁶ m ³)	Watershed area (10 ⁶ m ²)	% surface water²	% open²	% agriculture²	% commercial²	% industrial²	% residential²	% transportation²
Lower South Bay	South of Dumbarton Bridge	30	90	1320	1%	37%	2%	11%	5%	30%	14%
South Bay	Dumbarton to Bay Bridge	460	2530	1685	1%	55%	2%	8%	3%	21%	10%
Central Bay	Bay Bridge to Richmond Bridge	200	2620	255	1%	33%	0%	10%	4%	36%	16%
San Pablo Bay + Carquinez	Richmond Bridge to Benicia Bridge	310	1690	2180	3%	42%	33%	3%	2%	13%	4%
Suisun Bay	Benicia Bridge to Mallard Island	100	500	1465	4%	51%	18%	4%	2%	14%	7%

Spatially, there is an important distinction to be made between North Bay and South Bay in their response to tidal forcing. North Bay features a progressive tide, with the amplitude gradually dissipating as the tide propagates through each of the subembayments, eventually being completely dissipated upstream of the Delta. South Bay, by contrast, amplifies the tides by about 50% from the Golden Gate. This amplification is due to the specific geometry of South Bay and the nature of and position of the South Bay shorelines through a combination of reflection and funneling of the incoming tide. As a result, shoreline changes, whether development or wetland restoration, will have very different effects between North and South Bay. For example, wetland restoration in North Bay will reduce tidal energy primarily through increases in tidal dissipation due to friction. In South Bay, wetland restoration could alter the fundamental tidal dynamics in the basin, potentially reducing the tidal amplification significantly (with potential benefits for inundation, but negative effects on marsh habitat). The large areas of salt ponds slated for restoration in Lower South Bay and southern South Bay make changes in tidal dissipation a major consideration there (Figure 2.1).

5.3.2 Wind

Wind forcing is strongly diurnal during the summer months due to the afternoon sea breezes, which are from the west but modified by local topography. During the winter months, the dominant wind events are tied to storms, and they frequently are characterized by wind out of the south (on the leading edge of low pressure systems moving off of the Pacific). Winds during the fall and spring are more variable, but tend to be smaller in magnitude (Figure 5.2). The effects of the winds on transport include both direct effects on mixing and sediment resuspension and indirect effects on circulation, through the development of a surface tilt in response to sustained wind forcing.

5.3.3 Freshwater flow

Freshwater flow enters the Bay primarily through the Sacramento-San Joaquin Delta (Delta). Daily net outflow estimates from the Delta to Suisun Bay are provided in the CA Department of Water Resources “DAYFLOW”⁷ database. Daily net Delta outflow in DAYFLOW is calculated based on a combination of daily averaged inflows into the Delta, in-Delta consumptive water use, and water exports from the Delta. Other sources of freshwater flow around the perimeter of the Bay include several moderate rivers (Napa, Petaluma, Guadalupe, Alameda and Coyote Creek), small inflows from local watersheds and water treatment returns. Each of these categories of sources has its own distinct seasonal variability. The flows in the small and moderate rivers and streams entering directly into the Bay are tied to local precipitation events and peak during the winter (rainy) months. The larger inflows from the Delta are tied to Sierra snowmelt and the management of reservoirs, leading to a peak in the spring and moderate flows during the summer, decreasing into the fall (Figure 5.2). Finally, wastewater returns are much more uniform throughout the year. Spatially, the North Bay is dominated by the Delta flows, while the South Bay is influenced by a mix of local freshwater flows, wastewater returns and even Delta flows in the late Spring and early Summer months.

⁷ <http://www.water.ca.gov/dayflow/>

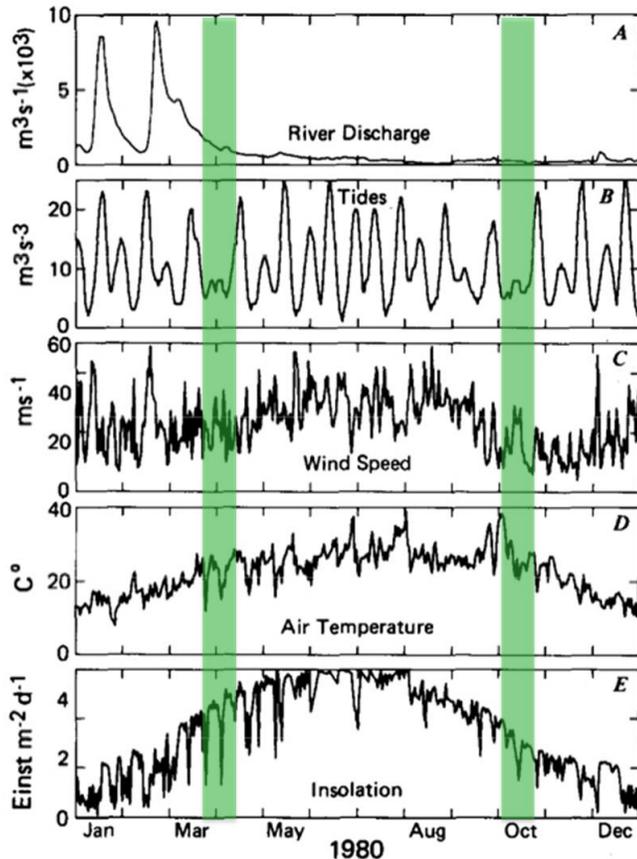

Figure 5.2 Physical drivers in San Francisco Bay. The green vertical bars illustrate the periods of minimum tidal mixing energy. In March/April, freshwater inputs and relatively low mixing energy allow the water column to stratify for ~10-14 days. In September/October, lower freshwater inputs limit the potential for salinity stratification. However, since winds are typically calm during this period, if sufficient insolation occurs (requires clear skies), surface layers will warm and the water column can be thermally stratified. Source: Cloern and Nichols, 1985

5.3.4 Coastal ocean exchange

In addition to providing tidal forcing, the oceanic boundary is also the source of salt water for the Bay. The interplay of freshwater flows and the tides leads to the intrusion of salt into the Bay, with the extent of salt intrusion, which is frequently characterized by $X2^8$ in the North Bay, being highly seasonally variable. Briefly, during high flow periods, the salt field is compressed down-estuary (Figure

5.3); when the flows relax, the salt field disperses back up-estuary. There is an asymmetry in the process for down-estuary and up-estuary movement of the salt field that is important to characterize. The down-estuary movement is advective and relatively rapid, whereas the up-estuary movement is primarily dispersive and more gradual. In South Bay, the seasonal variation of salinity is more complex: during winter, runoff events reduce the salinity locally, but it is not until late spring or early summer that the effects of Delta flows are felt south of the Bay Bridge. During winter and spring, it is possible for South Bay to have low salinities at both ends: reduced salinity in both Central Bay due to Delta flows and Lower South Bay and southern South Bay due to local flows. Finally, in the late summer and fall, evaporation in Lower South Bay can lead to hypersaline conditions and a reversed estuarine density gradient.

5.4 Estuarine circulation, flushing and residence times

The flushing (or, inversely, the residence time; see Monsen et al. 2002 for detailed discussion) of an estuary, or an embayment within an estuary, is driven by a combination of factors, including tidal forcing, density-driven circulation and, potentially, wind forcing. The combination of these influences define the “estuarine circulation”. Typical estuarine circulation has up-estuary flow in the subsurface waters due to denser saltier waters moving underneath freshwater. Less-dense

⁸ $X2$ is the distance in kilometers measured from the Golden Gate to the position along the North Bay’s axis where near-bottom salinity equals 2 psu. The position of $X2$ is strongly related to flow from the Delta, with a time lag.

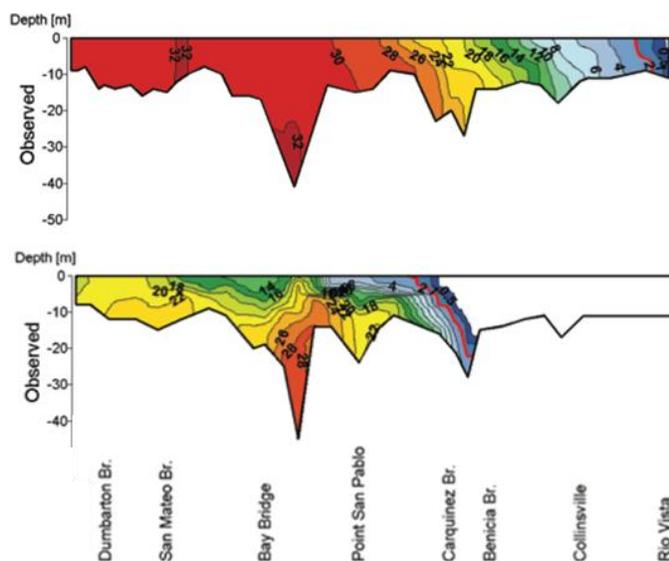

Figure 5.3 Observed salinity along main channel surveys of SFB. Top panel: Low flow period, October 26 1994. Bottom Panel: High flow period, January 18 1995. Source: Gross et al., 2009

freshier waters move down-estuary along the surface. These up-estuary salty and down-estuary exchanges occur along the axis of an estuary as well as laterally between deeper and shallower water regions. This circulation is defined both by direct forcing by the density gradient (gravitational circulation; Hansen and Rattray, 1965; Officer and Kester, 1991) and asymmetries in the tidal flows (Stacey et al., 2001; Stacey et al., 2008). The influence of wind is less established, and is likely to depend on the specific details of an estuary's geometry and a particular wind event. Supplementing the estuarine circulation, tidal dispersion processes, including tidal pumping (Fischer et al., 1979), tidal trapping (Okubo, 1973; MacVean et al., 2011) and shear dispersion (Fischer et al., 1979) will create exchanges between regions of an estuary. In many cases, these tidal processes will overwhelm the estuarine circulation and dominate flushing (Fram et al., 2007; Stacey et al., 2001; Monismith et al., 2002).

At the transition between embayments, or between the ocean and the estuary, the interplay of the tides, density-driven exchange and the topography determines the exchange. In one limiting case, pure density-driven (or gravitational) exchange determines transport between basins. In this hydraulic limit, there is no mixing in the strait and the waters of the two adjoining basins exchange under the influence of their density difference. The maximum exchange has been analyzed by Farmer and Armi (1986), and is set by the geometry of the strait and the density difference. The other limiting case is pure diffusive exchange, which results from tidal forcing interacting with the topography (see Hogg et al., 2001 for detailed discussion). The distinction between these two cases is important to the net transport: In hydraulic exchange, waters from each embayment are transported into the other in distinct layers; in diffusive exchange, net transport is directed down gradient.

At the mouth of San Francisco Bay, evidence suggests that tidal (diffusive) processes dominate the exchange, with density-driven circulation providing only about 10-15% of the total exchange (Fram et al. 2007). The implication is that the magnitude of flushing will primarily vary with the strength of the tides, which vary on the spring-neap and seasonal cycle. The Fram et al. estimate that approximately 80% of the exchange at the Bay's mouth is tidal is based on data spanning a spring-neap cycle, so spring-neap variability is aggregated in this estimate. Seasonal variability

of this result, however, is expected, with minima occurring during the spring and fall (just after the equinoxes) and maxima in the summer and winter (around the solstices). This variability was evident in the Fram et al. (2007) results, with fall dispersion coefficients reduced by about 45% relative to summer conditions. The dispersive nature of this exchange means that flushing is driven by the interaction of the tidal motions with the ocean-estuary gradient of the quantity being analyzed. In fact, the bi-directional nature of dispersive exchange means that net fluxes of individual species may be completely different from aggregate fluxes or exchanges, if their gradients are reversed (Martin et al., 2007). Similar results are to be expected at other narrow straits connecting embayments throughout San Francisco Bay.

Within individual subembayments, the residence time of subhabitats will be determined by the flushing and exchange flows along the perimeter of the subhabitat. An important distinction in much of San Francisco Bay is separating the deep channels from the broad shoals that characterize much of the Bay. In the channel, tidal and freshwater flows dominate along-channel transport, but the shoals are more strongly influenced by the interplay of tides and winds. The residence time of the shoals will be determined by the net exchange between the shoal and the adjoining channel, which has been recently examined in South Bay in a series of papers (Collignon and Stacey, 2012; Collignon and Stacey, 2013). In this work, the authors found that shoal waters were exchanged into the channel late in each ebb tide, but the nature of the exchange was a strong function of the local density gradients. Frequently, at the end of ebb the shoals are more saline than the channel (due to differential advection of the salinity gradient during the ebb), so the shoal waters that are pulled towards the channel by the tides late in the ebb tend to plunge down the slope and intrude into the channel at an intermediate depth. Although the net exchange from this transport process is not yet determined, the fact that shoal waters enter the channel at variable depths is likely to have important implications for the ecosystem through the effects on productivity. Although reversed salinity gradients were not analyzed at this site, they could develop in the early summer (due to the influence of Delta flows in northern South bay) or in the fall (due to evaporation in the Far South Bay). If the salinity gradient were reversed, then the late ebb flow of shoal waters towards the channel would lead to a surface flow in the channel, due to the shoal waters, in this case, being less saline than the channel.

At a much smaller scale, and considering local effects, recent analyses have looked at flushing of small perimeter habitats around the edge of the estuary (Hsu and Stacey, 2013). Using a combination of numerical and observational analyses, the authors found that tidal exchanges dominate the flushing of small slough-marsh complexes, but the net exchange is likely to be strongly affected by wind forcing, which is currently being analyzed. In the absence of wind, the Hsu and Stacey (2013) found that approximately half of the waters in a small slough-marsh complex in South San Francisco Bay was exchanged each tidal cycle.

Finally, small-scale features can result from local retention or convergence. The presence and maintenance of convergent fronts can lead to locally high residence times in relatively small regions. Simplified analyses of convergences and mixing (which must be in balance for the front to be maintained) can define representative timescales for retention and exchange (O'Donnell 1993; Stacey et al., 2007). Examples of these convergences are frequently associated with the

channel-shoal transition (Collignon and Stacey, 2012) or other lateral density-driven flows (Lacy et al. 2003).

5.5 Stratification

As outlined in the introduction, the Bay is characterized by large-scale salinity gradients along the Bay axes (Figure 5.3). At a large scale, the North Bay gradient is the most prominent in the estuary, defined by a transition from fresh to oceanic conditions over the length of the Bay; the gradient in South Bay is more variable and tends to be weaker than its North Bay counterpart. Moving away from the primary axis of the estuary, in other parts of the Bay salinity gradients may be comparable to or stronger than those along the North Bay axis. Specifically, the gradient along North Bay is approximately 0.5 psu/km, but salinity gradients in perimeter habitats may be 10 times that (Ralson and Stacey, 2005a,b). The presence of a horizontal salinity gradient makes the estuary susceptible to vertical stratification due to the tendency of the horizontal gradient to relax, or “lay down”, into a vertical gradient. The interaction of horizontal salinity gradients and tidal forcing, which can both create and destroy vertical stratification, leads to dynamic density stratification with important implications for vertical mixing.

In the estuarine water column, velocity shear (or vertical mixing energy) and density stratification are in competition in defining the state of the turbulence. Sheared velocity profiles act to increase the turbulent energy (and mixing), while stable density stratification acts to reduce the same (Fischer et al. 1979; Turner, 1980). The competition between shear and stratification plays a critical role in determining whether phytoplankton blooms develop (see Section 7).

The potential for stratification to develop depends on both longitudinal and lateral salinity gradients, related to the concepts of the Richardson number and Strain Induced Periodic Stratification (SIPS), whose discussion is beyond the scope of this overview. The magnitudes of these salinity gradients vary seasonally (Figure 5.3).

More recent studies of San Francisco Bay stratification dynamics (as well as other estuaries) have demonstrated the importance of lateral dynamics. If there is a lateral density gradient, as develops at the channel-shoal transition, and a lateral velocity, then lateral straining can contribute to the vertical stratification in the same way as the longitudinal does in the SIPS equation above. Examples of lateral straining’s influence on stratification come from South Bay (Collignon and Stacey, 2012); Suisun Bay (Lacy et al. 2003) as well as other estuaries.

Taken together, we expect an estuarine water column to stratify and destratify on a wide range of timescales that represent the variation of the density and tidal forcing as captured in the Simpson number. At seasonal timescales, the strength of the longitudinal density gradient varies; but just as importantly, its position changes so that the strongest density gradients may move between deep and shallow portions of the Bay (e.g., between Suisun Bay and Carquinez Strait, e.g.). As the density gradient strengthens, or moves into deeper regions, its effectiveness at creating stratification is increased and a stratified water column becomes more likely. Variations in tidal energy at the seasonal and spring-neap timescales can cause density stratification to adjust, and the strongest salinity stratification should occur during neap tides when the salinity gradient is compressed (following large freshwater flow events, e.g.). The ability of stratification to persist varies on multiple time scales due to changes in the vertical mixing energy of the tides with the spring-neap cycle: during neap tides, stratification is more persistent, but becomes periodic

during the springs (Stacey et al., 2001). The straining effects of the tidal flows lead to stratification that strengthens and weakens within the tidal cycle.

Beyond the spring-neap cycle, SFB experiences two annual minima periods in tidal energy (March/April, September/October). The green vertical bars in Figure 5.2 illustrate the periods of minimum tidal mixing energy. In March/April, freshwater inputs and relatively low mixing energy allow the water column to stratify for ~10-14 days. In September/October, lower freshwater inputs limit the potential for salinity stratification. However, it is also possible to have density stratification induced by temperature variations, although temperature induced stratification is not as commonly analyzed in estuaries (because of the dominance of salinity stratification) as in lakes or the deep ocean where it is an important factor. There are times, however, when temperature stratification may be an important factor for estuarine mixing: they result from a confluence of events involving warm, sunny days, neap (low energy) tides and low wind energy. Throughout much of the year in San Francisco Bay, this combination is unlikely, except perhaps during the fall, when the diurnal sea breeze is reduced, fog is less present, and tidal energy is at its annual minimum (Figure 5.2).

5.6 Suspended Sediment

The common paradigm for San Francisco Bay is that it is quite turbid due to high suspended sediment concentrations, or suspended particulate matter (SPM). Recent analyses (Schoellhamer 2011) have indicated that the Bay may be clearing, with Bay-wide SPM decreases of ~35% since 1998 (Figure 5.4.A), and up to 50% since 1975 in Suisun Bay (Figure 5.5). Within the Bay itself, the dynamics of the inorganic fraction of turbidity, suspended sediment concentration, is governed by its upstream supply, resuspension and deposition in the Bay, and transport throughout the Bay. The explanation for the decreased concentrations is that both external loads of suspended sediment and resuspension of material from the bed have decreased (because of a depleted erodible sediment pool; see Figure 5.4.B).

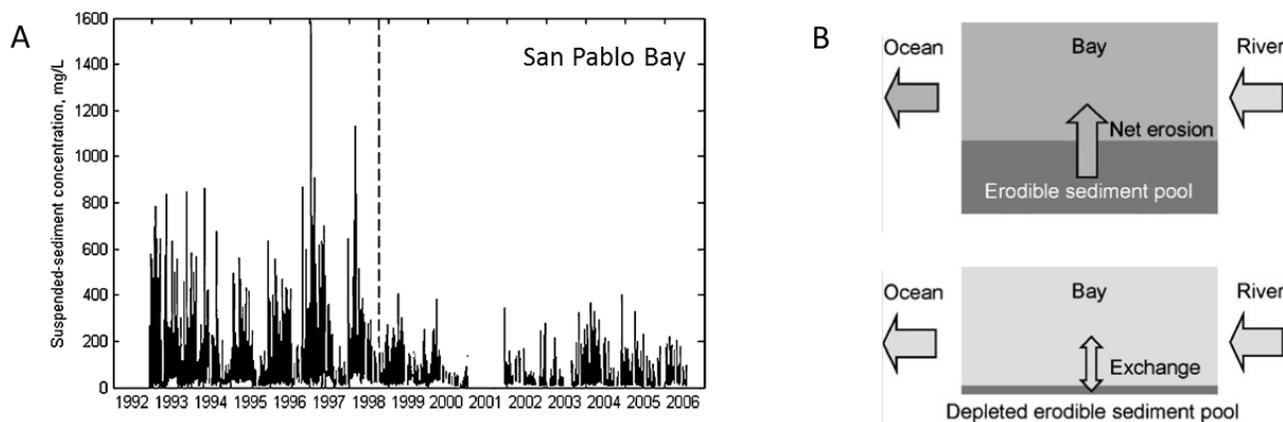

Figure 5.4 A. Time series of suspended particulate matter concentrations in San Pablo Bay measured by a continuous monitoring. **B.** Conceptualization of cause of declining sediment concentrations. Sediment inputs to SFB have declined substantially in recent years. Due to the lack of replenishment, the erodible sediment pool in the bed has been gradually depleted. As a result, less material is resuspended, resulting in lower concentrations.

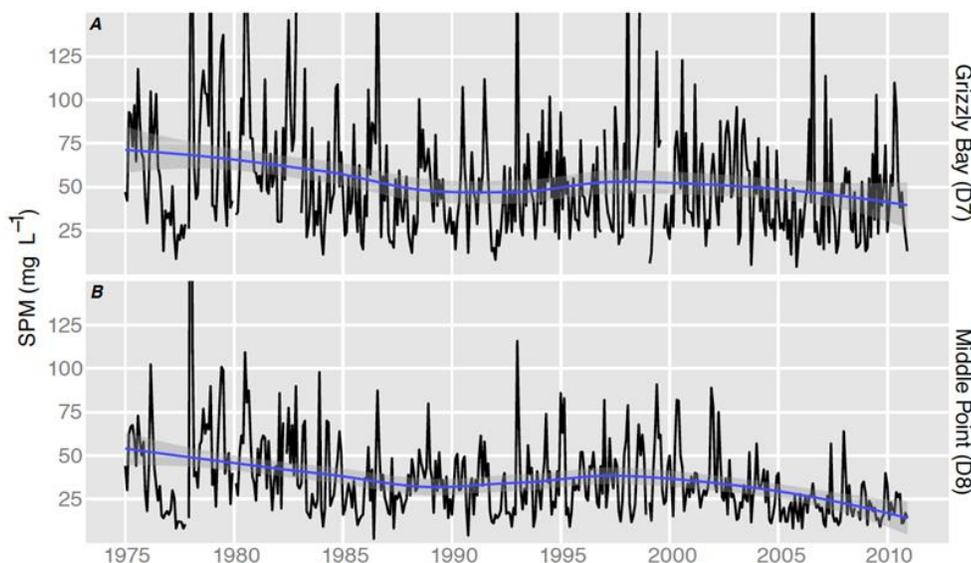

Figure 5.5 Suspended sediment concentrations in Suisun Bay: shallow Grizzly Bay (top) and in the channel (bottom). Source: Cloern and Jassby 2012

The circulation that governs sediment transport is largely the same as what governs salinity, flushing times and even stratification. The effects of supply have been considered elsewhere (Schoellhamer 2011), and we will focus here on resuspension and deposition and vertical transport. For sediment to be resuspended from the bed, the flow-induced bed stress, i.e., the frictional force at the sediment:water interface, must exceed a critical threshold (Sanford 2008; Wiberg et al. 1994). The magnitude of the critical stress will vary with the type of sediment and the degree of consolidation of the bed (Sanford 2008; Wiberg et al. 1994). Newly deposited sediments are more readily resuspended; after some time (approximately 3 days, Wiberg et al. 1994), the bed consolidates considerably and becomes more resistant to resuspension.

Both wind waves and tidal flows create stresses at the estuary bed that can act to resuspend sediments. In the deep channels, the effects of wind waves do not extend to the bed (Kundu et al. 2011), so only tidal forcing needs to be considered when analyzing resuspension. Although the tides are nearly symmetric, because of the threshold nature of sediment resuspension, even subtle asymmetries could have large impacts on the timing of sediment resuspension and net transport. The superposition of density forcing (flow in at the bed, out at the surface) with tidal flows adds to the bed stress on flood tides and reduces it on ebbs. If this asymmetry crosses the resuspension threshold, then sediment concentrations may be higher on floods than ebbs, leading to a net upstream transport of sediment. This effect is counteracted by large freshwater flow events, which add to the bed stress on ebbs and reduce it on floods. The net effect is expected to be a downstream push of sediments due to large freshwater flows events followed by tidally-driven up-estuary sediment transport once the flows reduce (Ralston and Geyer, 2009).

In the shallows, windwaves are able to reach the bed and create large oscillatory bed stresses that can resuspend sediments. The resuspended sediment from windwaves is largely contained in the wave boundary layer, which may only be a few centimeters thick, but if tidal flows coincide with this resuspension, then they can mix sediments further up into the water column. This combination of factors was found to be important to the sediment dynamics on South Bay shoals by Brand et al. (2010), who found that the highest sediment fluxes into the water column occurred on flood tides that followed wavy low water periods. The explanation was that wind

waves were able to resuspend sediments into the wave boundary layer, and then the following flood tide mixed the sediments into the water column. The importance of windwaves to resuspension mean that summer months, characterized by strong diurnal sea breezes, are likely to have the highest sediment concentrations in the shallows, even though the watershed supply is at its lowest during that period.

In the water column, settling and turbulent mixing define the evolution of the suspended sediment concentration profile. The settling velocity for the sediment depends on the particle size and density, which may be poorly defined for fine particles that form flocs. For large, dense particles, or during low energy periods, the suspended sediment is largely constrained to the near-bed region; for smaller particles, or less dense flocs, or during high energy periods, the suspended sediment is more widely distributed throughout the water column.

Figure 5.6 presents monthly-average SPM concentrations in SFB's five main subembayments. The suspended sediment concentrations in the waters of San Francisco Bay will vary tidally and diurnally (or in response to wind events), will vary between subembayments due to supply (Figure 5.6), and will vary within embayments due to spatially variable resuspension in response to the local depth. Seasonally, supply has a strong variation, with more turbid waters being brought into the Bay with winter rains, but the shoals may actually be more turbid during summer months due to resuspension of sediments from the bed.

5.7 Summary

This review is not meant as a comprehensive description of the hydrodynamics of San Francisco Bay, but is instead focused on the basics of flushing, stratification and suspended sediment. The key factors driving all three of these processes are tidal, wind and freshwater forcing. The variability of those factors, and their interactions, define the dynamics of the processes. Looking ahead several decades, the prospects for change in the Bay are extensive. Climate change and variability will bring with it warmer air temperatures and more frequent heat waves, creating the risk of more anomalous temperature stratification events. Precipitation may shift towards rain from snow, altering the timing of freshwater flows entering the Bay and the associated response in the salt field. Sea level rise will alter the tidal dynamics of the Bay, perhaps increasing the dissipation of energy due to extra inundation, or decreasing it if the Bay is made deeper (i.e. sediment accumulation does not keep pace with sea level rise). The changes the Bay faces are not limited to climate forcing, however, and anthropogenic changes may be just as pronounced. Along the Bay's shorelines, marsh restoration will alter the tidal dynamics by increasing tidal dissipation locally and, for large restoration projections, could potentially alter the tidal dynamics more broadly. The management of California's water resources through reservoir operations alters the timing and amount of freshwater flows that enter the Bay, perhaps in a more profound way than a shift in the type of precipitation would. Finally, land use practices, as well as the operation of reservoirs, alter the sediment supply that watersheds provide to the Bay. While these scenarios are all plausible, the potential magnitudes of their effects on nutrient cycling and ecosystem response remain highly uncertain.

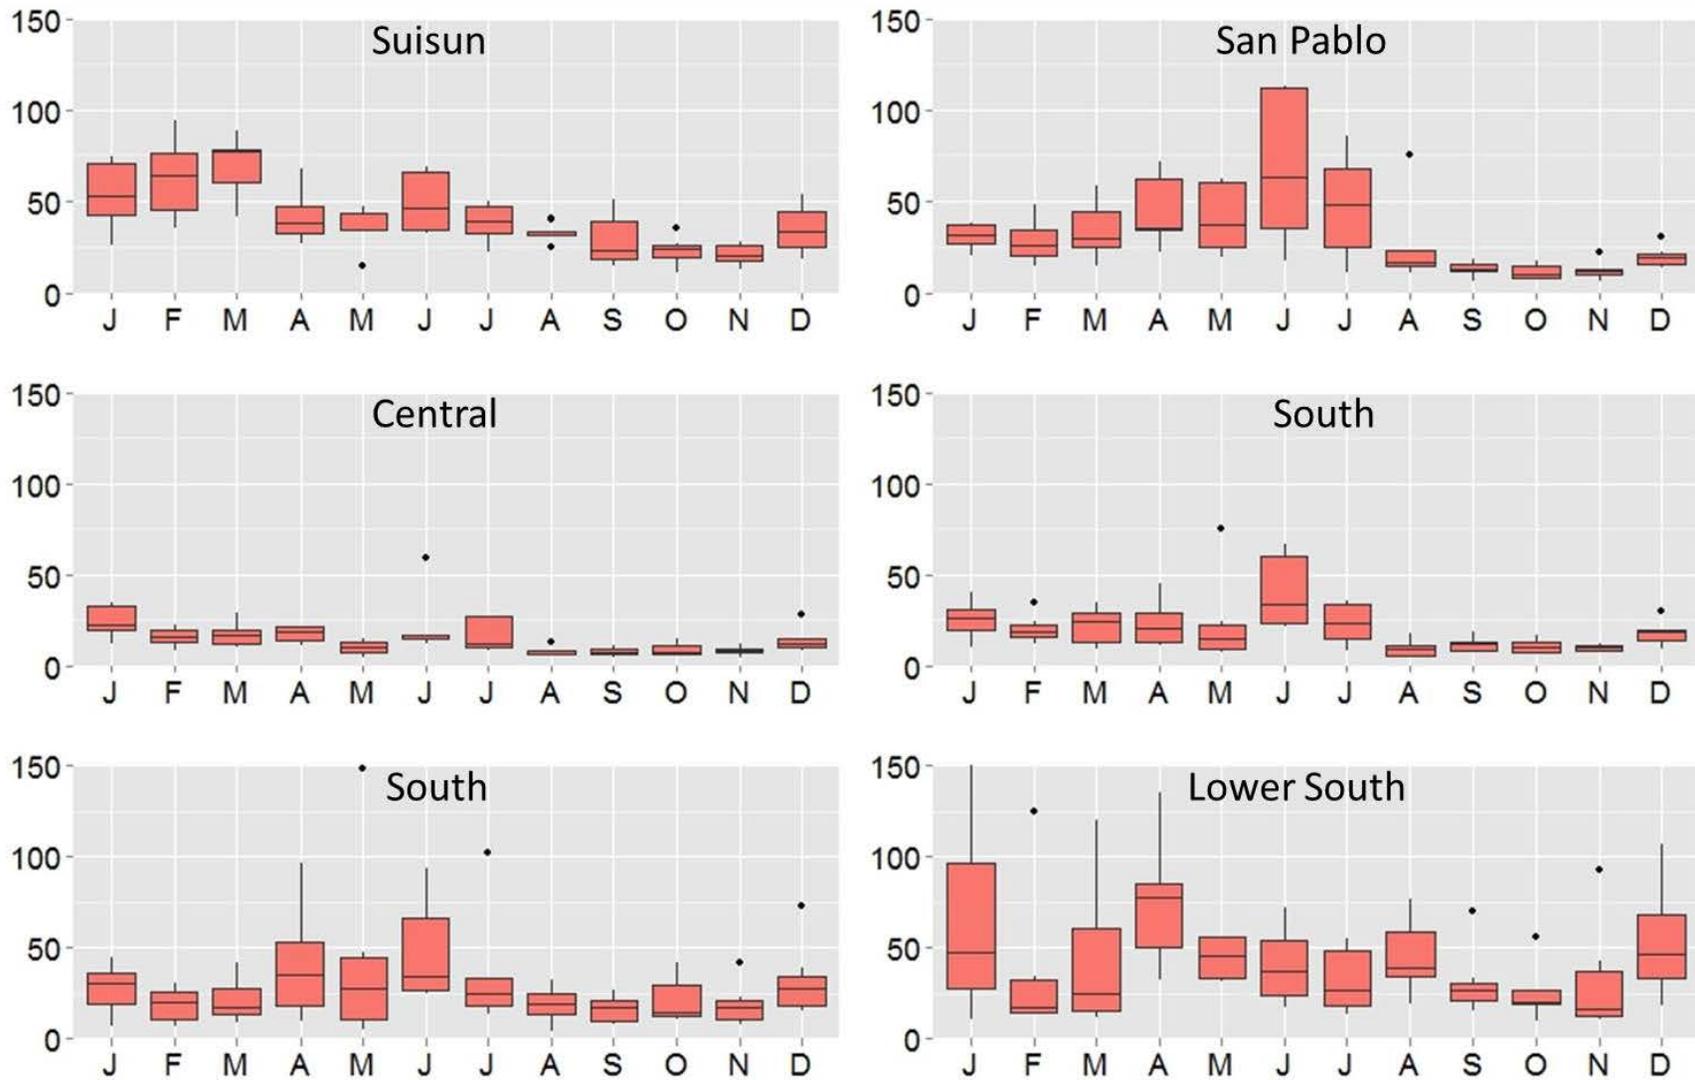

Figure 5.6 Monthly average SPM (mg/L) – 2006-2011. Data from USGS stations s6 (Suisun), s15 (San Pablo), s18 (Central), s21 (northern South Bay), s27 (southern South Bay) and s36 (Lower South) were used. Data source: <http://sfbay.wr.usgs.gov/access/wqdata/>

6 Nutrients

6.1 Introduction

The nutrient module focuses on the macro-nutrients N, P, and Si, with a greater emphasis on N and P because their loads and concentrations have been the most altered by anthropogenic activities. N, P, and Si are essential for primary production in all aquatic environments, including SFB. Cellular requirements for N, P, and Si differ among phytoplankton species, as do uptake rates. In addition, some species show a relative preference for certain forms of N. These requirements and preferences, along with the relative nutrient abundances, can influence the growth rate of phytoplankton and the magnitude (concentration) of phytoplankton blooms (Section 7). They may also influence the types of phytoplankton species that prosper under different conditions and influence the seasonal succession of the overall phytoplankton assemblage (Section 9).

The observed nutrient concentration at any given point in space and time in SFB represents a balance of multiple processes, including: input, export, mixing (vertical, lateral, longitudinal), uptake by phytoplankton, transformations, and losses. The discussion below covers the major processes that regulate nutrient cycling, with a focus on those that are important enough in SFB to be considered within a management-driven discussion, and only minimally treats some topics.

6.2 N, P, and Si cycling

6.2.1 N cycling

Nitrogen exists in several forms in aquatic systems and undergoes numerous biologically-mediated transformations between these forms (Figure 6.1). The major dissolved inorganic forms of N are the ions nitrate (NO_3^-), ammonium (NH_4^+), and nitrite (NO_2^-). Dissolved and particulate organic nitrogen (DON and PON) can comprise important fractions of N in some aquatic systems, and tend to represent lower portions of total N in systems that receive large nutrient anthropogenic inputs. Dissolved gaseous forms of N include di-nitrogen (N_2) and nitrous oxide (N_2O). N_2 is both an end-product of denitrification (discussed below) and a potential N source for a limited set of phytoplankton that perform nitrogen fixation, an energy-intensive process through which they convert N_2 into an usable organic form. Both NO_2^- and N_2O are important intermediaries in some N reactions, but typically present only at relatively low concentrations in estuarine water columns. The “bio-accessible” forms of N include NO_3^- , NH_4^+ , NO_2^- , DON, PON, and N_2O . The remainder of the N cycling description focuses primarily on NO_3^- and NH_4^+ , since they are the dominant bioaccessible N forms.

Figure 6.1 illustrates the major processes that will influence the forms and concentrations of N in SFB. Nitrogen inputs include: point-sources, primarily POTWs; large river inputs via the Sacramento-San Joaquin Delta; other freshwater inputs at the Bay margins (smaller perennial streams, along with stormwater inputs and ephemeral wet season streams); and other sources that are less readily quantified but expected to be relatively small (e.g., direct atmospheric deposition, groundwater). N is supplied to subembayments primarily in the form of NO_3^- , NH_4^+ , DON, and PON, and the relative proportions will vary by source. Atmospheric N deposition to the

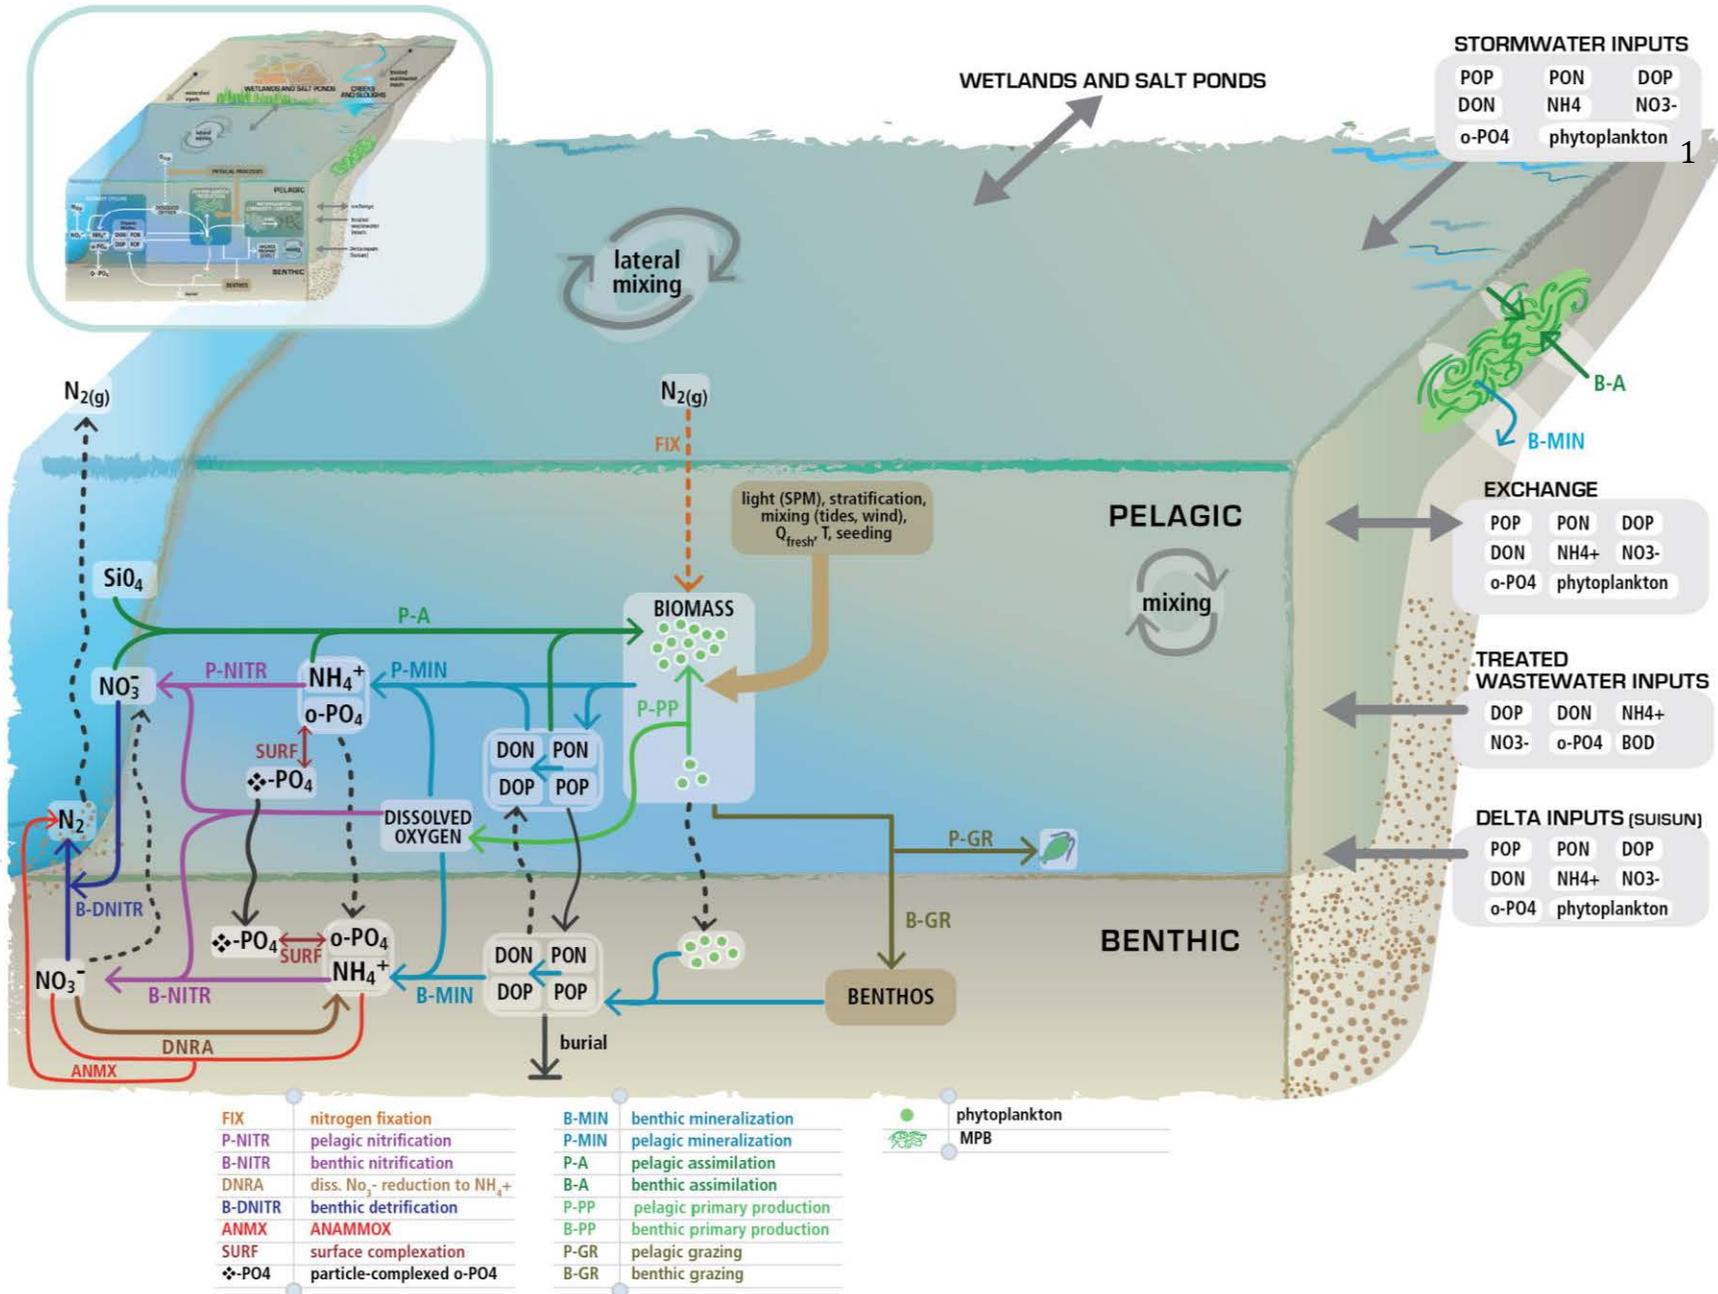

Figure 6.1 Nutrient cycling conceptual model

watersheds that drain to SFB could be an important N source; in this description, we include that source within inputs from the Delta and in freshwater inputs draining catchments that ring the Bay (N that deposited on land and was washed into rivers or streams). While N fixation can be an important source of N to some aquatic systems, it is unlikely to be an important internal source to SFB under current conditions because anthropogenic sources are so large. However, increased nitrogen fixation is a possible ecosystem-level response to nitrogen limitation should fixed N inputs from other sources decrease substantially without concomitant P decreases. Exchange with the Pacific Ocean at the Golden Gate can be either a net source or sink of N depending on coastal processes (i.e., upwelling or non-upwelling time period). Limited analysis to date suggests that SFB should be a net exporter of N throughout most of the year, except during some major upwelling events (Largier and Stacey, 2014). Hydrodynamic processes (tidal, gravitational, advective) transport N between subembayments.

Nitrogen transformations take place within the oxic water column, within the (typically) anoxic sediments, and within the narrow - but geochemically important - transition zone at the sediment:water interface. NH_4^+ and NO_3^- (and some forms of DON) can be readily taken up and assimilated into biomass by primary producers. When dead phytoplankton undergo degradation or mineralization by microbes, a portion of organic N is regenerated as NH_4^+ . Some of the regenerated NH_4^+ ammonium released is oxidized to nitrate either in the water column or at the sediment:water interface via the process of nitrification. Nitrification requires oxygen, but can proceed in environments where oxygen concentrations are low, including at the sediment-water interface. Denitrification is a form of respiration used by some heterotrophic microbes. In denitrification, NO_3^- is used instead of oxygen to oxidize organic matter, producing N_2 and carbon dioxide. Denitrification requires organic matter to proceed, and its rate can be limited by the amount and quality of organic matter, but only proceeds in anoxic environments, primarily within sediments, or biofilms, after NO_3^- diffuses from the water column into anoxic zones. Because denitrification converts NO_3^- to N_2 , it results in a true loss of N from the system. NO_3^- can also be transformed directly to NH_4^+ through a respiratory pathway used by some microbes called dissimilatory nitrate reduction to ammonium (DNRA). N can also be converted to N_2 through a microbially-mediated process called anaerobic ammonium oxidation (ANAMMOX) by which NH_4^+ and NO_2^- are converted to N_2 (Brunner et al., 2013).⁹ The coupled process of ammonium oxidation-denitrification at the sediment:water interface can be responsible for a substantial portion of the denitrification in some estuarine systems (ref). While denitrification is generally thought to be a more important pathway for NO_3^- reduction than DNRA, ANAMMOX could rival denitrification under some conditions (Kuypers et al. 2005), and does not require a labile organic matter source. A portion of the organic nitrogen produced in the Bay accumulates in the sediments where it undergoes gradual decomposition and release of NH_4^+ . N burial can take place anywhere in SFB, but burial is more likely in locations where there is net accumulation of sediments. Newly restored tidal salt marshes could be particularly important zones for denitrification because of the anoxic conditions and abundant organic matter in marsh sediments. Some of the buried PON continues to decompose, releasing ammonium into the sediment pore water, which either eventually diffuses back to the water column, or undergoes nitrification-denitrification as described above. PON is also subject to resuspension, especially

⁹ The actual expression is: $1\text{NH}_4^+ + 1.3\text{NO}_2^- \rightarrow 1\text{N}_2 + 0.3\text{NO}_3^- + 2\text{H}_2\text{O}$

in shoal environments. The fraction of sediment PON that is neither regenerated as NH_4^+ nor resuspended of the PON is buried permanently.

Nitrification, denitrification, and possibly ANAMMOX are likely to be quantitatively important processes that influence N form and fate at subembayment scales and at the full Bay scale. However, there are currently few direct measurements of these rates. Quantifying these processes and their influence on N fate will be one key component for determining the N loads that SFB subembayments can assimilate without adverse impacts. The importance of nitrification in SFB is evident, given that in some subembayments (e.g., South Bay) N is loaded as primarily NH_4^+ but is measured in the water column as primarily NO_3^- . Denitrification likely represents a substantial loss route for bioavailable N within SFB. However the magnitudes and importance of nitrification and denitrification relative to other processes (uptake by phytoplankton or microphytobenthos, transport out of the system) are currently poorly known. As a first step, the importance of denitrification and nitrification could be estimated through relatively straightforward biogeochemical modeling. At some point field studies will likely be needed to provide better rate estimates and factors that influence rates over space and time (e.g., Cornwell et al. 2013).

6.2.2 P cycling

The P cycle is also depicted in Figure 6.1. P cycling is relatively straightforward compared to N, since P only commonly occurs in two dissolved forms and does not undergo numerous transformations. P occurs as dissolved orthophosphate (o-PO_4), particle-complexed o-PO_4 , other solid mineral phases of P, and dissolved and particulate organic P (DOP and POP). o-PO_4 would generally be expected to comprise most of dissolved P in the water column. However, particle- or colloiddally-complexed P, either organic or inorganic, can also be important in the water column. o-PO_4 binds to the surfaces of iron(III)-oxide particles in both the sediments and water column. When complexed by iron(III)-oxides, o-PO_4 is essentially unavailable for uptake by primary producers; however, iron(III)-oxide particles are readily dissolved in anoxic sediments (discussed below), making this form of particle-bound o-PO_4 a temporary state. Other particulate mineral phases of P also occur, but they tend to be relatively refractory.

External P sources to SFB subembayments include: inputs from point sources, primarily POTWs; riverine inputs via the Sacramento-San Joaquin Delta of naturally-derived P (from dissolution of P-rich mineral phases) or anthropogenically-sourced P (fertilizer, livestock excrement, treated wastewater); other freshwater inputs at the Bay margins - perennial streams or rivers, stormwater inputs, and ephemeral wet-season streams; and other sources that are less readily quantified but believed to be relatively unimportant (ground water, atmospheric deposition, etc.). P has no analogous process to N-fixation. Similar to N, exchange with the Pacific Ocean at the Golden Gate can be either a net source or sink of P depending on coastal processes (i.e., upwelling or non-upwelling time period) and conditions within SFB. In addition, hydrodynamic exchange processes (tidal, gravitational, advective) transport P between subembayments.

P form and abundance are influenced by uptake and assimilation, surface reactions with particles, settling, and microbial mineralization and recycling. Within the water column, o-PO_4 can be readily taken up and assimilated by phytoplankton. During pelagic grazing on phytoplankton (by zooplankton) or mineralization of dead phytoplankton in the water column or

sediments, DOP and POP are released, a portion of which is converted to o-PO₄. Particle-complexed o-PO₄ and POP settle in the water column and eventually reach the bed sediments. Respiration using iron(III) is an important anaerobic reaction in sediments, which dissolves iron(III)-oxides and releases dissolved o-PO₄ to porewater, where it can then be transported to the water column, or undergo transformations (re-binding to particles, uptake by benthic algae or microbes). Transport back to the water column can occur slowly by diffusion, or, much more rapidly, due to burrowing by benthic organisms ('bioirrigation') or during sediment resuspension that also mixes porewater into the water column. Similar to N, burial of particulate P can take place anywhere in the bay, but is more likely in locations where there is net accumulation of sediments, like wetlands. Some of the o-PO₄ produced in sediments returns to the water column and re-enters the cycle of organic matter production and degradation.

6.2.3 Si cycling

Si cycling is also relatively straightforward compared to N cycling, since Si does not occur in multiple dissolved inorganic forms or undergo numerous transformations. However, unlike both N and P, the vast majority of Si comes from natural sources through the weathering of silicate-rich rock, and does not have major anthropogenic sources. Major sources include riverine inputs of naturally-derived Si via the Sacramento-San Joaquin Delta, and other freshwater inputs at the Bay margins. Exchange with the Pacific Ocean at the Golden Gate is a net sink for Si. Hydrodynamic exchange processes can result in net Si exchange between subembayments, although on average down-estuary exchange will be a net Si sink, since its primary source is freshwater inputs.

Si is supplied to subembayments primarily as dissolved silicate (SiO₄), solid mineral phase silicates, and reactive or refractory biogenic silicates. In the absence of biological uptake and assimilation, Si should behave conservatively in SFB, with no quantitatively important geochemical transformations other than those related to uptake/assimilation by organisms reliant on Si for growth. Although N and P requirements (C:N:P) can vary substantially among phytoplankton classes, all phytoplankton require N and P for growth. Si is distinct from N and P in this respect: among the major classes of phytoplankton, only diatoms require SiO₄ in substantial amounts. Only the growth of diatoms will influence silicate concentrations via assimilation.

The recycling of Si is slow relative to P and N. Si taken up and assimilated by diatoms is less readily regenerated during grazing or microbial degradation of cells. Instead, the silicate-rich frustules settle and accumulate as biogenic Si in the sediments, which tends to be more slowly mineralized than organic N and P. As such, compared to N and P, a larger proportion of biogenic Si that reaches the sediments is ultimately buried.

6.3 Estimated N and P Loads to SFB

Figure 6.2 presents an overview of DIN and DIP loads to SFB, broken into its five main subembayments. A separate report on N and P nutrient loads discusses loads, data gaps, and uncertainties in more detail (SFEI, 2014a). Groundwater and direct atmospheric deposition (i.e., directly to the Bay's surface) loads are expected to be small and are not discussed here. Discharge of treated wastewater effluent by publicly owned treatment works (POTWs) to SFB's subembayments is a major source of N and P. The San Francisco Bay Area has 42 POTWs (Figure 2.2.B) that service the regions 7.2 million people and discharge either directly to the Bay

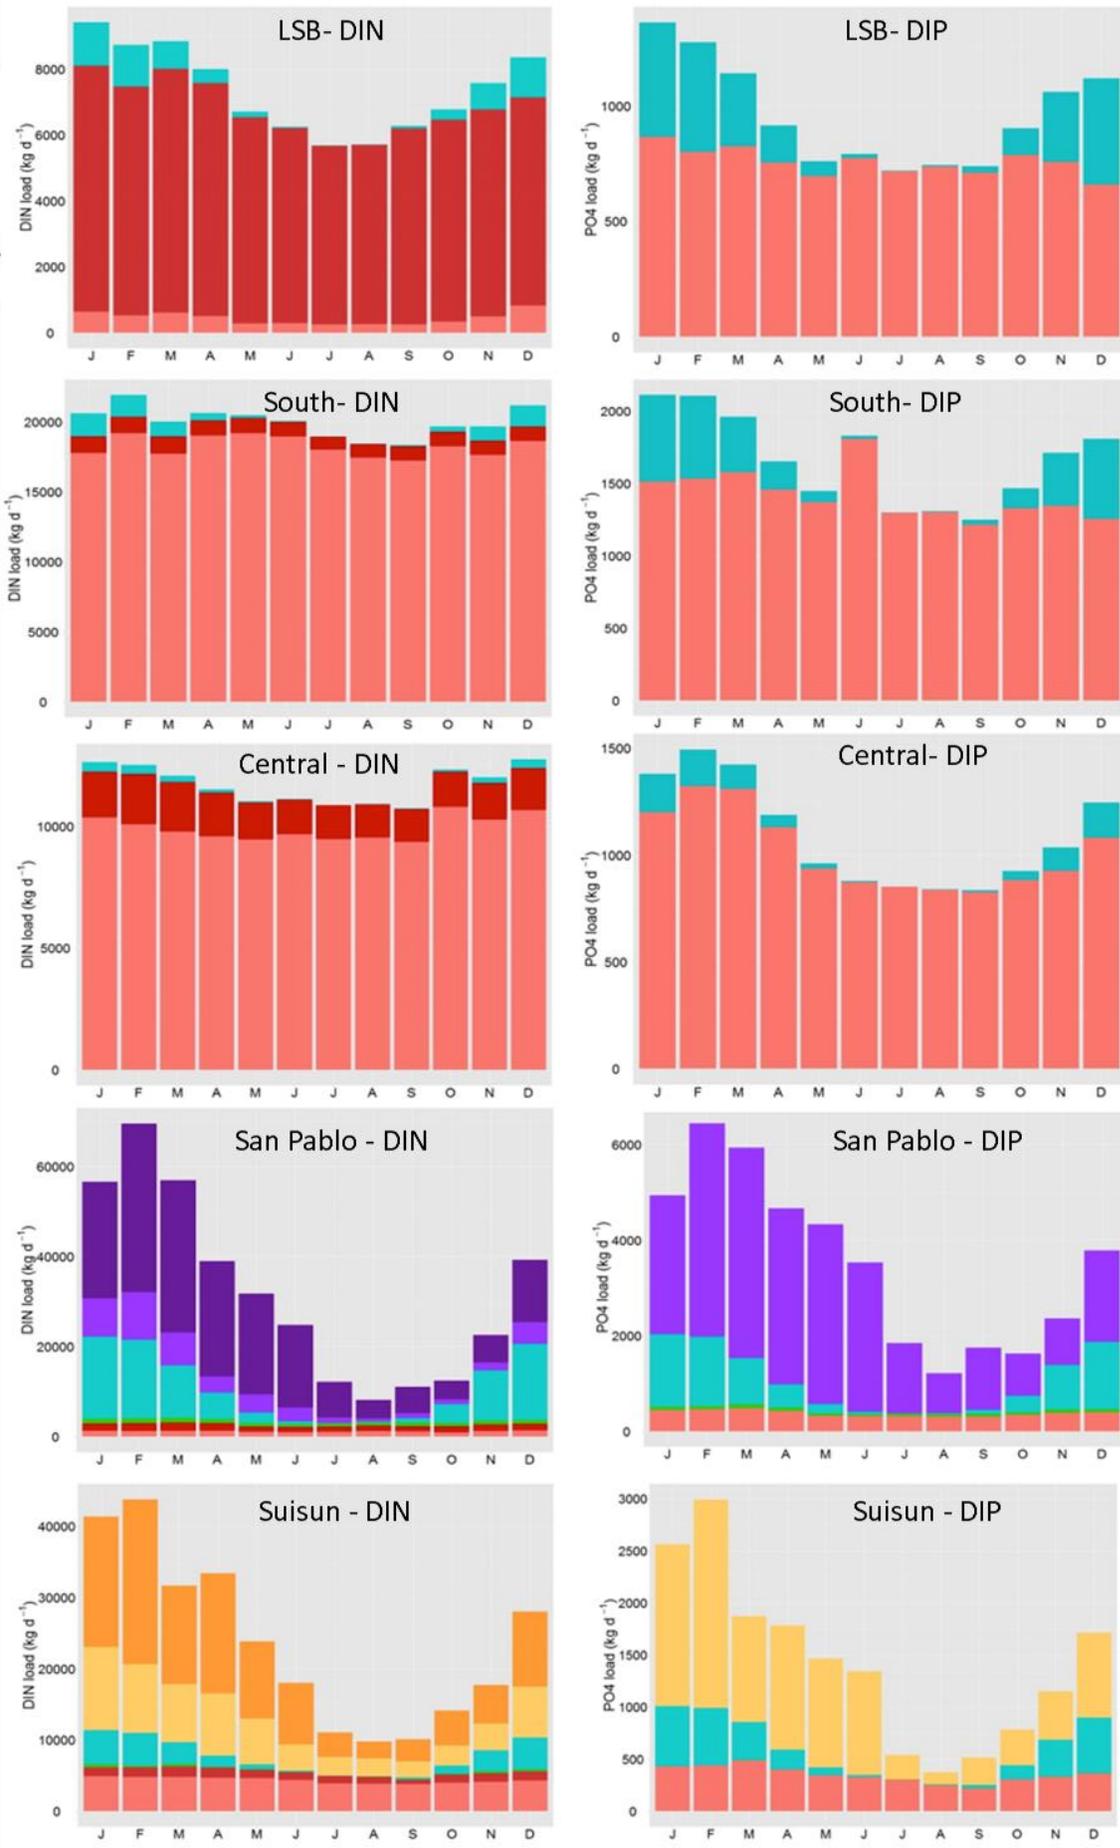

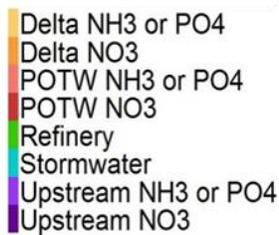

Figure 6.2 N and P loads to SFB subbays. In the cases of LSB, South Bay, and Central Bay, only direct loads to the subbays were considered and not exchange between subbays. Loads to San Pablo Bay include estimates of up-estuary loads from Suisun Bay. See SFEI 2014a for more

or to receiving waters in adjacent watersheds that drain to the Bay (note: these numbers do not include discharges east of Suisun Bay that enter through the Delta). While several of these POTWs conduct nitrification or denitrification plus some forms of advanced treatment that remove a portion of nutrients prior to discharge, most POTWs discharging to SFB carry out only secondary treatment, which transforms nutrients from organic to inorganic forms, but generally does not remove much N or P. Table 6.1 summarizes typical N and P concentrations and forms in effluent subjected to varying degrees of nutrient removal. Bay-wide, POTWs discharged (annual average) 34000 kg d⁻¹ NH₄⁺, 12000 kg d⁻¹ NO₃⁻, and 4000 kg d⁻¹ total P. Results from detailed effluent monitoring that began in July 2012 suggests ~90% of total N discharged was in the form of DIN and ~80% of total P discharged was in the form of o-PO₄ (SFEI, 2014a). Refineries also contribute N and P loads to Suisun Bay and San Pablo Bay, but their contributions appear to be relatively minor.

Table 6.1 Typical concentrations and forms of N and P in treated wastewater effluent at different treatment levels

Treatment type	NH ₄ (mg N L ⁻¹)	NO ₃ (mg N L ⁻¹)	TN (mg N L ⁻¹)	TP (mg P L ⁻¹)
Level 1: Secondary treatment	20-30	<1	25-35	4-6
Nitrification	<1	20-25	20-30	4-6
Level 2: Nitrification + biological nutrient removal	<1	8-12	10-15	0.5-1
Level 3: Nitrification + Advanced TN/TP removal	<1	3-6	4-8	0.1-0.3
Level 4: “Limit of Technology” not including Reverse Osmosis	<1	<1	<3	<0.1
Reverse Osmosis	<1	<1	<2	<0.02

¹Based on Falk, M.W., Neethling, J.B., Reardon, D.J. (2011). Striking the Balance Between Nutrient Removal in Wastewater Treatment and Sustainability, WERF research project NUTR1R06n and BACWA 2011 report

The dominant sources of N and P loads, and the form of N, vary substantially among subembayments (Figure 6.2). In LSB, South Bay, and Central Bay, POTWs are the dominant source of N and P. In LSB, NO₃⁻ is the dominant N form discharged because LSB POTWs carry out nitrification. In South Bay and Central Bay, NH₄⁺ is the dominant N form released by POTWs. In San Pablo Bay, direct POTW loads are relatively minor and primary release NH₄⁺. In Suisun Bay, NH₄⁺ is the primary form of N discharged, and the importance of those direct loads relative to other inputs varies seasonally (discussed more below).

Stormwater flows deliver seasonally-varying N and P loads to SFB. Only rough estimates of those loads have been made thus far due to data and modeling limitations. In most subembayments during most of the year, these estimates suggest that stormwater DIN and o-PO₄ loads are substantially less than POTW loads (Figure 6.2), with potential exceptions being loads

to San Pablo Bay and Suisun Bay. In this region, rain generally occurs only in the months of October-April; N and P loads from runoff are highest during this period and generally minor during the dry season, at least when considered at the subembayment scale. The relative uncertainty in the magnitude of stormwater-derived N and P loads is high. Furthermore, it is likely that the stormwater load estimates made thus far poorly represent those from perennial rivers and streams (other than the Delta). While more work is needed if more accurate stormwater N and P loads are a priority, it seems unlikely that these loads will rival POTW loads at the subcatchment scale in LSB, South Bay, and Central Bay. However, while stormwater loads may not play a dominant role at the subembayment scale in these subembayments, a more important role for stormwater-derived N and P loads in certain habitats (e.g., along the Bay's margins, including wetlands) cannot be ruled out.

N and P loads entering SFB from the Sacramento/San Joaquin Delta have the potential to be large and seasonally-dominant nutrient sources to Suisun and San Pablo Bays (Figure 6.3). Delta DIN loads far exceed those from Suisun direct POTWs for approximately half the year, and NO_3^- loads from the Delta exceed those from Suisun direct POTWs year-round. For NH_4^+ , however, direct POTW loads are comparable to or exceed Delta loads during late spring through fall. Most of the NH_4^+ entering Suisun Bay from the Delta likely comes from the Sacramento Regional County Sanitation District (Regional San) wastewater treatment plant, which currently does not nitrify and discharges ~70 km upstream of Suisun Bay. New permit requirements for Regional San require treatment upgrades over the next decade including nitrification and nitrogen removal, which will lead to both a shift in the N forms (predominantly NO_3^- instead of NH_4^+) and total N load (2-3 fold lower). Although the Delta load estimates to Suisun Bay are believed to be reasonable first approximations, they need to be further evaluated and refined using hydrodynamic and biogeochemical models for the Delta.

The load discussion thus far focused mostly on direct external loads to subembayments and not exchange between subembayments. Hydrodynamic exchange between subembayments may comprise a large proportion of loads to some subembayments. This is particularly true for San Pablo Bay, which has relatively low POTW direct loads but is down-estuary from Suisun Bay. The loads entering San Pablo Bay from Suisun Bay (which includes those that entered from the Delta) have thus far only been roughly estimated and need refinement through hydrodynamic/reactive-transport models. Nonetheless, the estimates illustrated in Figure 6.2 suggest that loads entering from Suisun could be the dominant source to San Pablo Bay for most of the year. Similarly, the southern reaches of South Bay are likely highly influenced by loads entering from LSB.

In general, SFB is a net source of nutrients to the coastal ocean throughout most of the year (Largier and Stacey, 2014). Exchange of water through the Golden Gate could conceivably act as a substantial net source of nutrients to the Bay during a limited time of the year and only under specific conditions. Freshly-upwelled coastal water contains up to $30 \mu\text{mol L}^{-1} \text{NO}_3^-$. However, the extent to which that NO_3^- -rich coastal water enters SFB depends on a complex set of hydrodynamic and climatological factors. Under maximal conditions, daily NO_3^- loads into the Bay through the GG could be substantial relative to POTW loads (Largier and Stacey, 2014), although the frequency with which the necessary hydrodynamic and climatological drivers align is unknown, and requires further investigation. The fate of the nutrient plume that leaves SFB,

and its potential impacts on biological response in coastal waters, has not received much attention to date and also warrants further investigation if coastal effects are among the issues being considered through the Nutrient Strategy.

6.4 Seasonal and spatial variation in N and P

There are large spatial and seasonal differences in nutrient forms and abundance in SFB (Figure 6.3-6.6). Yet the processes that determine the ambient forms and concentrations of N and P are the same throughout SFB. The observed seasonal and spatial differences because the importance or magnitude of those processes differ considerably within and between subembayments, as well as over a range of time scales (tidal, diurnal, seasonal), due to multiple physical factors, including morphology, freshwater inputs, proximity and magnitude of loads, and mixing (including due to tides).

The seasonal and spatial variations in NH_4^+ concentrations clearly illustrate how the time- and space-varying intensities of physical and biogeochemical processes influence nutrient form and abundance. The maximum NH_4^+ levels seen in Suisun Bay tend to be the highest concentrations observed throughout all of SFB; however Suisun NH_4^+ levels exhibit strong seasonal variability, with spring and summer concentrations being 20-30% of those observed in winter (Figure 6.3). Mass balance estimates suggest that, during spring and summer, ~75% of NH_4^+ that enters Suisun Bay is “lost”, presumably through either nitrification to NO_3^- or uptake by phytoplankton (SFEI, 2014b). This seasonality of Suisun NH_4^+ concentrations is likely due to warmer water temperatures and longer residence times in Suisun Bay and upstream of Suisun Bay in spring/summer, with the warmer temperatures favoring higher rates of nitrification, or NH_4^+ uptake by phytoplankton. Longer residence times during this time of year allow those reactions to proceed further, and longer days in May-Oct could also contribute to greater primary production and related uptake of NH_4^+ . NH_4^+ concentrations in LSB offer an interesting counter-example to Suisun Bay (Figure 6.3). A strong seasonality in NH_4^+ concentrations is also evident in LSB. Although LSB has one of the highest areal N loads of all SFB subembayments (Figure 3.1), the vast majority of N loaded directly to LSB is in the form of NO_3^- (Figure 6.3). Therefore, a sizable portion of the NH_4^+ observed in LSB is likely due to NH_4^+ regenerated from the sediments. Sediment sources of NH_4^+ may be more evident in LSB not necessarily because they are larger, but because of LSB’s morphology. LSB is quite shallow, and has a low ratio of water volume to sediment area compared to other subembayments; thus, any flux from LSB sediments would be mixed over a relatively small volume of water, causing a larger increase in concentration per unit mass of NH_4^+ . The local NH_4^+ concentration maximum in June-July is likely due in part to higher rates of mineralization of organic matter in the sediments due to higher water temperatures, and longer residence times during these months allowing the NH_4^+ to accumulate to higher levels. The NH_4^+ concentration minima in April and September coincide with periods of highest phytoplankton biomass (discussed in Section 7), and may be evidence of NH_4^+ uptake by phytoplankton.

NO_3^- concentrations also exhibit strong seasonal and spatial variability (Figure 6.4). LSB has the highest NO_3^- concentrations (40-80 $\mu\text{mol L}^{-1}$), due to several factors: all POTWs in LSB nitrify before discharging effluent; LSB’s volume is small relative to other subembayments and relative to the loads it receives; and there is limited net exchange of LSB water with the rest of the Bay, allowing NO_3^- to accumulate to higher concentrations. After LSB, NO_3^- concentrations are highest in Suisun Bay and South Bay. In Suisun Bay, the substantial NO_3^- loads entering from

the Delta likely contribute to these elevated NO_3^- concentrations. The lowest NO_3^- concentrations ($\sim 20 \mu\text{mol L}^{-1}$) are observed Central, San Pablo, and northern South Bay, all of which have greater exchange with coastal waters entering through the Golden Gate.

Nitrification and denitrification likely play quantitatively important roles in determining the observed forms of N and the seasonality in concentrations in SFB subembayments. For example, although the vast majority of N loaded to Central Bay and South Bay occurred in the form of NH_4^+ (Figure 6.2), ambient N was present primarily as NO_3^- (Figure 6.4), evidence of *in situ* nitrification's importance. Figure 6.5 presents DIN concentrations. Summer DIN concentrations in LSB were 30-40% lower than winter concentrations, with the lower concentrations likely due to a combination of denitrification at the sediment:water interface when water temperatures warm and higher uptake rates by phytoplankton during this time of year. DIN concentrations in southern South Bay (s27) exhibited similar seasonality. DIN concentrations in Suisun Bay are also lower in summer than winter. Initial box-model-derived estimates for Suisun Bay suggest that approximately $\sim 30\%$ of DIN input loads are lost via uptake or denitrification in Suisun Bay during summer months (Novick et al., 2014). These initial observations illustrate why developing accurate estimates *in situ* nitrification and denitrification rates will be important for identifying acceptable loads and apportioning observed concentrations to specific sources. LSB had the highest o-PO_4 concentrations, which were ~ 4 -fold higher than most other subembayments (Figure 6.6). In Suisun Bay, o-PO_4 does not show the same strong seasonality as NH_4^+ or NO_3^- exhibited. In the other subembayments, o-PO_4 concentrations showed more defined seasonality. Minimum o-PO_4 concentrations occur in April and May in San Pablo Bay, Central Bay, South Bay, and LSB, consistent with modest o-PO_4 drawdown occurring due to spring phytoplankton blooms. o-PO_4 concentrations then increase to relatively constant concentrations over summer and fall, before dropping to lower levels in wet season winter months (Nov-Feb).

Concentrations of organic N and organic P in SFB are uncertain, since they have not been consistently measured (except in Suisun Bay). However, because of the large anthropogenic DIN and DIP loads SFB receives, it is reasonable to hypothesize that DIN and DIP often dominate total N (TN) and total P (TP).

Dissolved SiO_4 concentrations vary both seasonally and spatially in SFB (Figure 6.7). The lowest SiO_4 concentrations are observed in Central Bay, with increasingly higher concentrations in more terrestrially-influenced areas of SFB. Suisun Bay has the highest SiO_4 concentrations, due to its large freshwater inputs, with lower concentrations observed in summer and fall, as Delta flows decrease and salinity increases. Seasonal drawdowns in SiO_4 concentrations in LSB and southern South Bay appear evident during spring, coincident with periods of high primary production rates and the dominance of diatoms (Sections 7 and 9).

6.5 Current state of knowledge

Table 6.2 summarizes the current state of knowledge and data/knowledge gaps related to N and P in SFB. The prioritizations in the rightmost two columns are related to the discussion in Section 11. Nitrification (water column or sediment:water interface) and denitrification (sediment:water interface) likely play important roles in regulating ambient concentrations of NH_4^+ and NO_3^- in the Bay. Developing models, initially basic and gradually more sophisticated, that would allow quantification of these processes is an essential early step for informing decisions about allowable N loads to subembayments and source attribution, and about needs for additional data collection. Assuming that mass balance estimates from modeling suggest that nitrification and denitrification play important roles in N cycling in SFB, field studies will likely need to be conducted to quantify transformations rates. Some work has been conducted to characterize organic matter mineralization and NH_4^+ production in sediments at multiple locations throughout the Bay (Caffrey 1995), and more recent studies have investigated nutrient flux or transformations across the sediment:water interface in Suisun Bay and the Delta (Cornwell et al., 2013). However more work would likely be needed to assess variability in rates as function of space and season.

Limited data exists on nutrient concentrations at time scales shorter than ~1 month. Finer temporal resolution data will be needed to improve understanding about nutrient transformation rates. There is also limited information on nutrient concentrations along the shoals and in shallow margin habitats. Finally, organic N and P (PON, POP, DON, DOP) have not been routinely measured in most locations in the Bay (except at IEP sites in Suisun Bay and San Pablo Bay), and their importance and bioavailability are poorly known.

Table 6.2 N and P loads and cycling: current state of knowledge for key processes and parameters

Process or Parameters	Importance for quantitative understanding	Current Level of Knowledge about magnitude, composition, or controls	Need for <u>additional or continued</u> data collection, process studies, modeling	Priority for study in next 1-5 years
Loads				
POTWs	High	Moderate: Comprehensive effluent monitoring is currently underway. Prior to 2012, data availability varies by POTW and in general is fairly sparse for several nutrient forms (NO ₃ , o-PO ₄ , TN, TP)	Very High	Very High
Stormwater runoff	Uncertain	Low: Limited stormwater data and limited modeling effort	High	High
Delta	High	Low: Initial estimates suggest Delta loads may be a large source but they need to be validated, and time-series of loads are needed.	Very High	Very High
Groundwater	Low	Low: Poorly quantified but not expected to be major source because of relatively high loads from other sources	Low	Low
Direct atmospheric deposition	Low	Low: Poorly quantified but not expected to be major source because of relatively high loads from other sources, including from the large Central Valley watershed	Low	Low
Exchange through GG	Uncertain	Low: Has the potential to be large, but highly uncertain	High	High
Processes				
Benthic denitrification	High	Low: see OM mineralization and NH ₄ and PO ₄ release below	Very High	Very High
Pelagic denitrification	Low	Low: not expected to be important because of oxic water column	Low	Low
Benthic nitrification	High	Low: see OM mineralization and NH ₄ and PO ₄ release below. Potentially large, but limited field measurements, and need for both field and model-based estimates.	Very High	Very High
Pelagic nitrification	High	Low: Potentially large, but limited field measurements, and need for both field and model-based estimates.	Very High	Very High
N fixation	Low/Uncertain	Low	Moderate	Low

Process or Parameters	Importance for quantitative understanding	Current Level of Knowledge about magnitude, composition, or controls	Need for additional or continued data collection, process studies, modeling	Priority for study in next 1-5 years
OM mineralization and release of NH ₄ and o-PO ₄ from sediments, and in the water column	High	Low: Potentially a substantial source from the sediments to the water column. Limited data from two studies in SFB, but well-studied in other systems and at least initially may be able to use that information. Field studies aimed at exploring this issue will also inform sediment oxygen demand, benthic primary production, benthic denitrification, and benthic nitrification.	Very High	Very High
Settling/burial of N and P	High	Low/Moderate: limited field estimates to date, although could be estimated based on other sedimentation data.	Moderate	Low
Rates of NH ₄ , NO ₃ , and o-PO ₄ uptake by phytoplankton	High	Moderate: field measurements exist for NH ₄ and NO ₃ in northern estuary, limited data in South Bay and LSB. Uptake rates for P are not well-studied. Both N and P uptake rates can be partially constrained by knowing phytoplankton C:N:P and productivity	Moderate	Moderate
Other processes: DNRA, ANAMOX	Low	Low: but expected to be relatively small	Low	Low
N and P budgets for subembayments: loads, transformations, sources/sinks, export	High	Low: The ability to quantify these will provide important information on the subembayments' ability to process/assimilate N and P. Basic modeling work needed.	Very High	Very High
Ambient concentration data				
Phytoplankton C:N:P	High	Low: Currently not routinely measured during monitoring	Very High	Very High
Concentration of NO ₃ , NH ₄ , and PO ₄	High	Moderate: monthly data available at ~15 stations Bay-wide but finer spatial and temporal resolution needed to inform process level understanding and modeling	Very High	Very High
Concentrations of NO ₂ ⁻ and N ₂ O	Low/Moderate	Moderate: not needed for nutrient budgets, but informative as diagnostic of processes	Moderate	Moderate
Concentration of DON, PON, DOP, POP within and loaded to the system	Moderate/uncertain	Low: Little current data, and information is needed. Given the high DIN and DIP concentrations, abundance organic forms may be relatively low.	High	High

1 **7 Primary Production and biomass accumulation**

2 **7.1 Introduction**

3 Primary production in SFB is carried out by phytoplankton, benthic algae (microphytobenthos,
4 MPB), macrophytes, and macroalgae. In its current form, the primary production module of the
5 conceptual model focuses mostly on phytoplankton, and to a lesser degree on MPB.
6 Macrophytes and macroalgae are not considered in this report. For more on the latter topics, the
7 reader is referred to the SFB NNE Literature Review and Data Gaps Analysis (McKee et al.,
8 2011).

9
10 Phytoplankton biomass is an important indicator of ecosystem health with respect to nutrient
11 loads, and is among the potential indicator of ecosystem health and nutrient-related adverse
12 impacts for SFB (Figure 3.1; Table 2.1). Phytoplankton reside at the base of the food web, and
13 are the predominant food resource for most pelagic and benthic primary consumers in SFB
14 (Jassby et al., 1993). Phytoplankton require nutrients for growth, and in many aquatic systems
15 there is a direct link between phytoplankton biomass and nutrient loads, with nutrient abundance
16 being one of several factors that can regulate both the rate of primary production and the ultimate
17 biomass that can be generated. As noted in Section 3, excessive phytoplankton biomass is one
18 plausible impaired state in SFB. Excessive phytoplankton biomass can have direct adverse
19 impacts, such as coatings on bird wings, odor, and degraded aesthetics. High rates of primary
20 production and accumulation of high levels of phytoplankton biomass are also problematic
21 because they lead to low dissolved oxygen levels in the water column and sediments when
22 phytoplankton die, settle, and are metabolized by microbes (Section 8). By absorbing light, high
23 phytoplankton biomass can also adversely impact the production of submerged aquatic
24 vegetation (SAV), which serves as valuable habitat in some estuaries. However, impacts of high
25 phytoplankton biomass on SAV is not considered to be among the most important adverse
26 impact pathways in SFB because of already low-light conditions due to high turbidity from
27 inorganic particles.

28
29 Phytoplankton biomass is actually comprised of multiple species, with complex community
30 responses caused by natural and anthropogenic drivers. Both the biomass and the types of
31 phytoplankton present (community composition) are important for adequately supporting food
32 webs. This section focuses on phytoplankton biomass; Section 9 addresses community
33 composition. Microphytobenthos are discussed in Section 7.3.

34 **7.2 Phytoplankton**

35 Phytoplankton biomass is the concentration of living phytoplankton material in the water
36 column. Phytoplankton biomass is commonly presented in units of mg chl-a m^{-3} or $\mu\text{g chl-a L}^{-1}$,
37 although it would be more accurate to describe it in units of $\mu\text{g C L}^{-1}$. The biomass measured at
38 any given point in space and time is the net result of multiple processes (Figure 7.1): growth;
39 settling; pelagic and benthic grazing; sinking and degradation or burial; and exchange or mixing
40 between areas through the movement of water masses (lateral, longitudinal, vertical) (Cloern,
41 1996). The magnitudes of these processes vary in space and time, and this variation leads to
42 spatial and temporal differences in biomass concentrations.

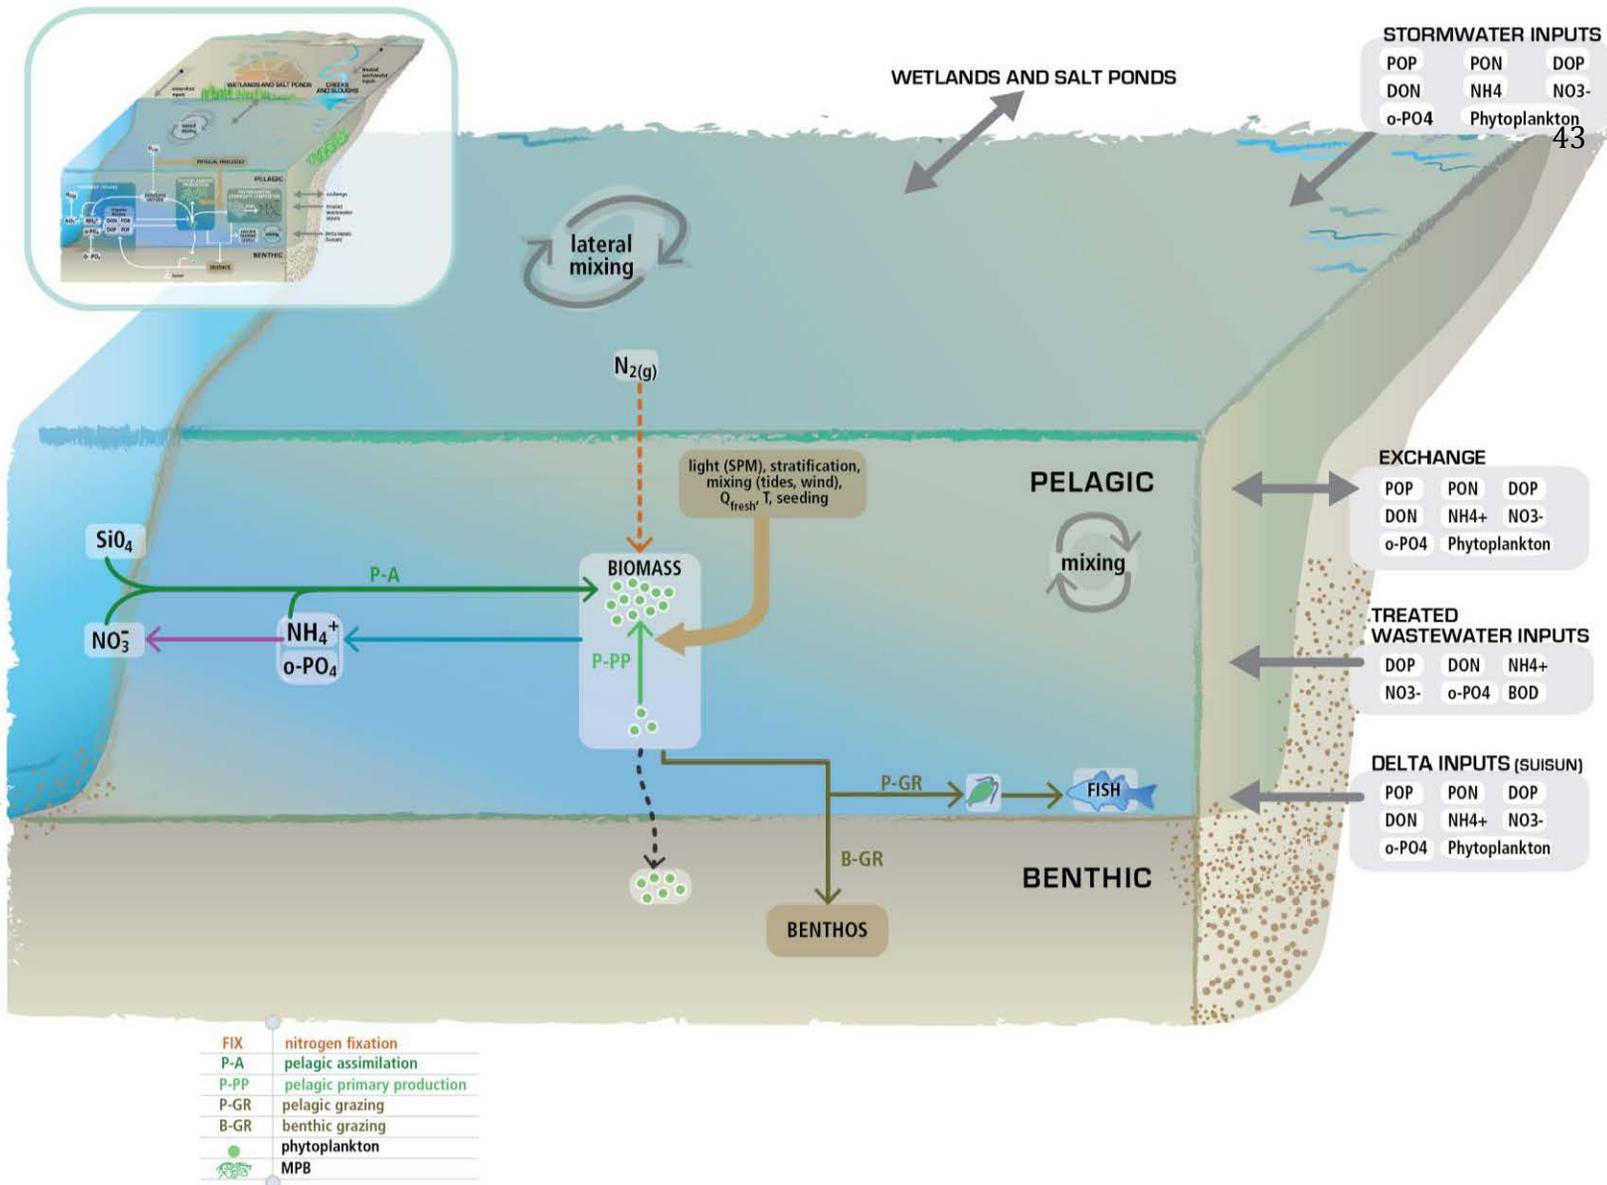

Figure 7.1 Phytoplankton primary production conceptual model. Physical processes play an important role in determining when and where phytoplankton blooms occur, their size, duration, and the concentration of biomass that accumulates. The relationship between physical processes and production are described in more detail in Figure 7.2.

7.2.1 Transport and Loads

Sources of externally-produced phytoplankton biomass to a subembayment include: flow from rivers, perennial streams, and stormwater carrying phytoplankton produced in adjacent systems; hydrodynamic exchange between adjacent subembayments or habitats (e.g., water movement between shoals and channel); and exchange with the coastal ocean. In general, the majority of phytoplankton biomass observed in SFB is produced within the Bay (Jassby et al., 1993). Suisun Bay may serve as a notable exception: Jassby et al. (1993) estimated that the load of phytoplankton-derived particulate organic carbon (POC) exported from the Delta to Suisun Bay could account for 20-80% (median ~ 50%) of Suisun's POC budget, including Suisun *in situ* production. Those estimates were based on data from 1975-1989. Considering the substantial ecosystem changes observed since the late 1980s both in the Delta and Suisun, these estimates likely need to be updated. In addition, the coastal ocean can be a non-trivial source of phytoplankton biomass to Central Bay, especially during the upwelling season (Martin et al., 2007).

7.2.2 Production and accumulation

The processes that control biomass can be divided into those that influence the rate of growth and those that influence the rate of accumulation. Typical modes of phytoplankton productivity and biomass accumulation in SFB are represented in Figure 7.2. The most common condition is low phytoplankton productivity and low biomass (Figure 7.2.A). Blooms develop when the water column becomes periodically stratified (Figure 7.2.B) or when appropriate conditions prevail in shallow areas (Figure 7.2.C and 7.2.D). Major processes and drivers are described below.

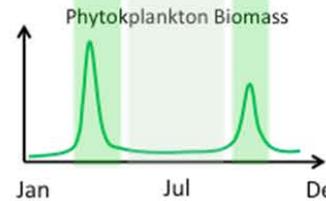

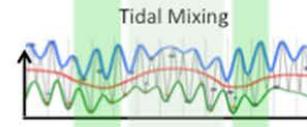

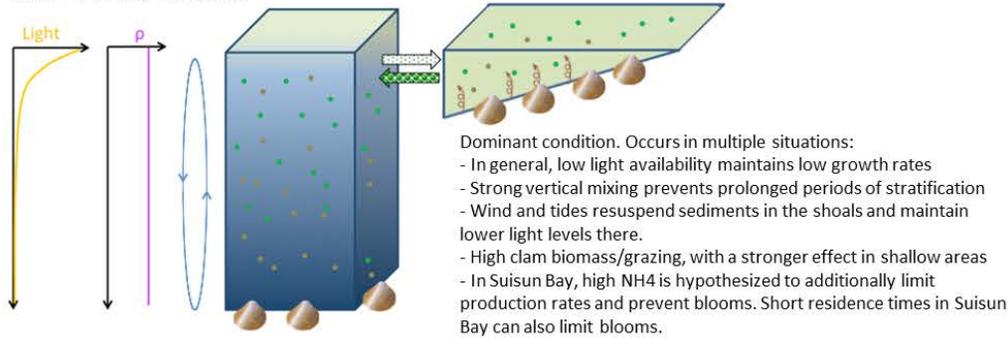

7.2.3 Factors that influence production rates

Several factors influence phytoplankton production rates, including temperature; light availability; nutrient concentrations; and potential anthropogenic factors, such as contaminants, that could inhibit or slow production rates, including pesticides or toxic metals (e.g., copper), or the hypothesized inhibition of growth by elevated NH_4^+ (e.g., Dugdale et al., 2007).

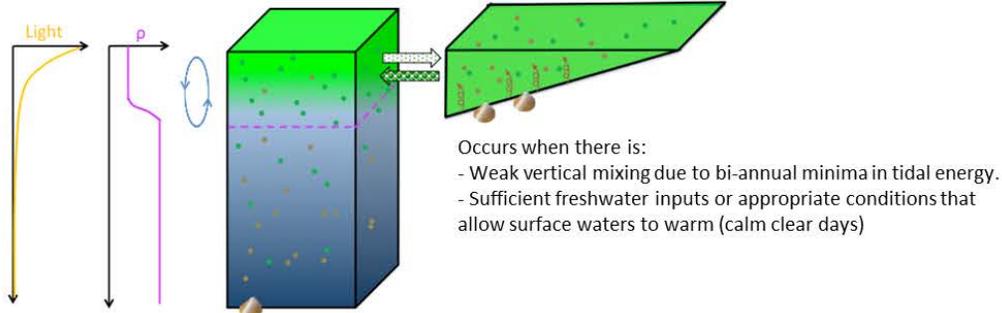

Temperature: Phytoplankton maximum growth rates vary strongly with temperature (e.g., Eppley 1972; Behrenfield and Falkowski, 1997). Bay-wide average temperatures vary seasonally from 10 °C to >20 °C, with as much as a 7 °C difference in maximum temperatures between subembayments. These temperature ranges translate into substantial differences in maximum growth rates: annual maximum growth rates could differ by up to a factor 1.4 between subembayments (LSB vs. Central), and by up to a factor of 2 seasonally (LSB summer vs. winter) (assuming $Q_{10} = 1.88$; Bissinger et al., 2008)

Light levels: Throughout much of SFB and during most of the year, light availability acts as the main limitation on phytoplankton growth rates. A number of field investigations and model-based estimates document the importance of light limitation in SFB (Cloern 1982; Cloern et al. 1985; Cole et al. 1986; Cole and Cloern 1987; Alpine and Cloern 1988; Caffrey et al. 1994; Jassby et al., 2002; Cloern et al., 2007). Phytoplankton growth rates depend primarily on the amount of time cells spend in light-rich zones (Figure 7.3) (e.g., Alpine and Cloern, 1988; Cloern et al., 1985). The amount of light reaching the water column surface (incident light or insolation) varies seasonally due to length of day, and over shorter time scales (hours-days) due to cloud cover (Figure 5.2). From the surface, light levels decrease exponentially with depth, primarily due to light scattering and absorption by suspended particulate matter (SPM).

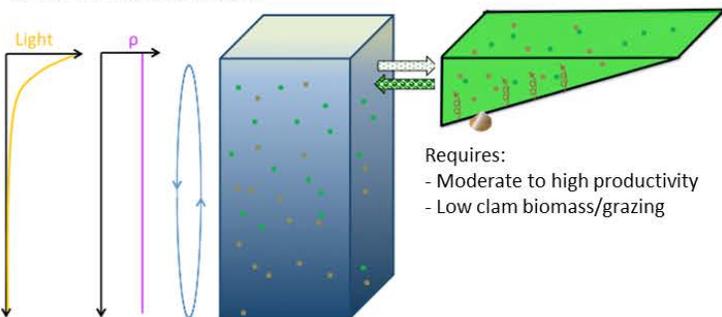

A. No bloom, baseline

B. Stratification-induced bloom

C. Shoal-induced bloom

D. Shoal-induced bloom that propagates to channel

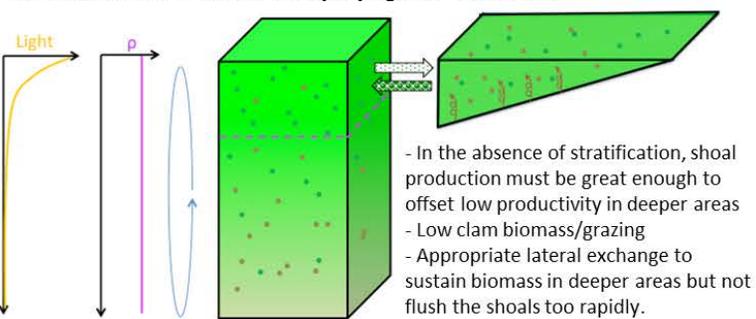

Figure 7.2 Modes of productivity in SFB, and factors influencing timing and magnitude of blooms

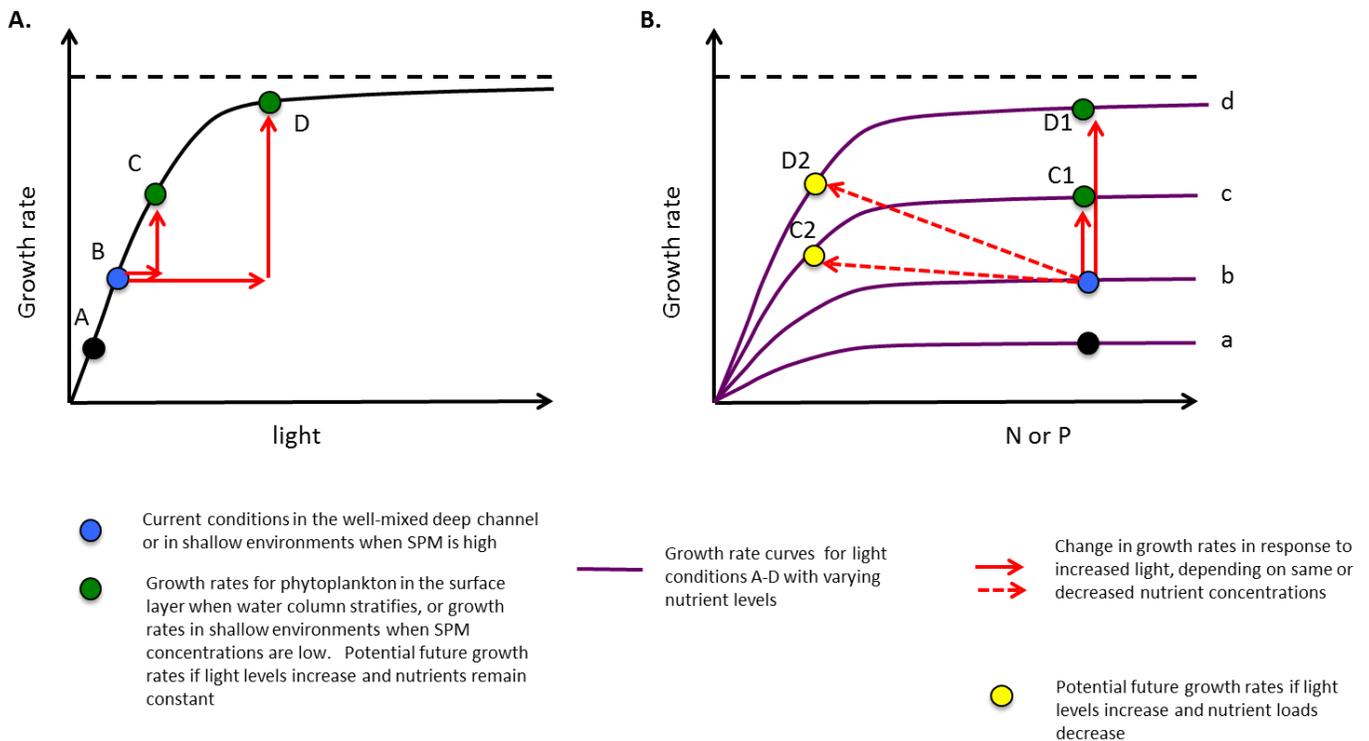

Figure 7.3 Phytoplankton Growth Rates: Light limitation vs. nutrient limitation. In general, throughout most of SFB, light limits phytoplankton growth most of the time. **A.** When nutrients are available at non-limiting levels, phytoplankton growth rate increases as a function of light to some maximum level (this maximum growth rate varies by temperature and species). Growth rates increase as light levels increase. **B.** The four curves (a-d) illustrate growth under four different light levels. At each constant light, growth rate varies as a function of nutrient concentration (x-axis). In SFB, N and P concentrations are typically high enough that growth rates are not nutrient limited. Instead, phytoplankton are thought to grow at their maximum growth rate for that specific light level (i.e., the flat part of the curves). Under current nutrient loads/concentrations, if light levels increase (shift from blue to green dots, due either to decreasing SPM, or in response to periodic stratification), growth rates and biomass accumulation will increase. However, if nutrient loads and concentrations were lower (blue to yellow dots) growth rates and biomass accumulation would not increase as much.

SFB is considered a turbid system, and the photic zone - the depth at which light levels are 1% of incident light - is typically only 1-2 m thick (Cloern et al., 1985). Unlike some other nutrient-rich systems in which phytoplankton cells can themselves contribute substantially to light attenuation, light attenuation in SFB is primarily due to non-phytoplankton SPM (Cloern, 1987).

SPM concentrations and photic zone depth vary substantially between subembayments, within subembayments, and as a function of season (Figure 5.6). SPM concentrations also increase when high winds resuspend more sediments, and show periodic increases and decreases in response to the spring-neap tide cycle (Schoellhamer, 2002). SPM and light attenuation coefficients are often higher along shallow shoals than in deeper areas, due to turbulent energy from wind and tides more readily resuspending particles from the bottom. Despite the higher SPM concentrations along shoals, though, average light levels that phytoplankton experience may still be higher there because they are mixed over a shallower depth. SPM concentrations have decreased significantly in some areas of SFB over the past several decades. For example, SPM concentrations have dropped by on-average 50% in Suisun Bay since 1975 (Figure 5.5;

Cloern and Jassby, 2012), due to decreasing loads, gradual loss of erodible bed sediments already in the Bay, and step declines in turbidity due to “washout events” (Schoellhamer, 2011). This 50% decrease in SPM translates to roughly a doubling of the photic zone depth. The Bay-wide average decrease in SPM is ~35% (Schoellhamer, 2011).

Hydrodynamic controls over phytoplankton’s access to light and production rates

The vertical and lateral movements of water masses - and the phytoplankton they contain - within SFB play an important role in regulating overall system productivity by controlling the average amount of time phytoplankton remain within the light-rich photic zone. Variability in the magnitude of vertical and lateral mixing also plays a role in determining if, when, and where phytoplankton blooms develop and terminate (Cloern 1991; Lucas et al., 1998). Thus, understanding and modeling hydrodynamics in the Bay are essential for understanding and predicting productivity and the accumulation of phytoplankton biomass.

The presence or absence of vertical stratification in the water column strongly influences productivity (Figure 7.2.A and 7.2.B). When the water column is vertically well-mixed (Figure 7.2.A), the amount of time phytoplankton spend in the photic zone decreases in proportion to water column depth. Vertical layering of the water column – stratification – develops when less dense layers of water overlay more-dense layers. These density differences arise due to differences in salinity (density increases with increasing salinity) and temperature (density decreases with temperature). The density difference limits vertical mixing and allows phytoplankton to reside in the relatively thin (e.g., 1-3 m), light-rich surface layer, as opposed to being moved over the entire water column. When confined to the surface layer, phytoplankton harvest more light, resulting in higher growth rates (Figure 7.2.B and 7.3.A). (Note: Stratification also positively influences biomass accumulation in the sense that filter-feeding benthos cannot access phytoplankton in the surface layer).

Factors that influence whether stratification occurs, and how long it persists, therefore have an important influence on productivity and biomass accumulation. SFB experiences strong tidal mixing which acts to break down stratification by vertically-mixing the water column (Cloern, 1991). Tidal mixing intensity varies periodically: two tidal cycles per day with different mixing energies; the spring/neap cycle by which tides vary in magnitude on ~14 day cycle; and twice-annual periods of lowest sustained tidal mixing energy (March, September) and maximum sustained mixing energy (December, June; Figure 5.2). Assuming there is sufficient freshwater input (or lateral or longitudinal gradients in salinity) for salinity gradients to be develop, stratification/destratification can occur with the same periodicity as tidal mixing intensity. Thus, the duration of stratification events can vary from hours (semi-diurnal to diurnal stratification) to days and weeks (during the weakest tides twice per year) depending on the strength of stratification relative to the tidal mixing energy. Cloern (1996) observed that blooms along the deep channel of South Bay generally developed in March, when periods of weak tidal mixing co-occurred with sufficient freshwater input to allow stratification to develop and persist for 10-14 days. The termination of these blooms corresponded with increased tidal energy that vertically-mixed the water column (Cloern 1996). This cycle is likely also important in other subembayments. In Suisun Bay, in the 1970s and early 1980s, IEP monitoring data indicates that phytoplankton biomass remained elevated over longer periods, i.e., throughout Spring, Summer, and Fall. Suisun receives larger freshwater inputs than other subembayments

Recently (past 10-20 years), fall blooms have been occurring with increased frequency in southern South Bay and LSB (e.g., Figure 3.7; Cloern and Jassby, 2012). The reason for these fall blooms in LSB and South Bay is unknown, but could be in part due to lower SPM (higher light levels) and lower grazing pressure (Section 7.2.3). If stratification plays a role in the increased biomass in fall, density differences during this time may have been due to surface water heating than freshwater inputs. Clear skies (greater solar insolation) and calm winds would thus be required for stratification to develop and persist. One particularly striking example of a fall bloom occurred in September 2004, when calm winds and weak tides occurred coincident with record temperatures and clear days, allowing a warm surface layer to establish (Figure 3.11). A bloom of the red tide organism *Akashiwo sanguinea* developed, with biomass levels reaching nearly 200 mg chl-a m⁻³ (Cloern et al., 2005), the highest levels observed in this region of SFB over the 40-year period of record. The bloom terminated after only 1 week, once mixing energy levels increased.

SFB's expansive shallow shoals are important zones for phytoplankton production. Large proportions of Suisun Bay, San Pablo Bay, South Bay, and Lower South Bay have water depths of <2 m. Field and modeling studies in South Bay indicate that phytoplankton blooms often originate along the shoals (Figure 7.2.C and 7.2.D), exploiting the relatively light-rich conditions of the shallow water column (Cloern et al., 1989; Huzzey et al., 1990; Lucas et al., 1999; Lucas et al., 2009 ; Thompson et al., 2008). This is well illustrated in South Bay and LSB in Figures 7.4 and 7.5. Under appropriate lateral mixing conditions, production along the shoals can lead to high biomass there, and appreciable biomass transport to the relatively unproductive channel (Figure 7.4; Thompson et al., 2009; Lucas et al., 2009). Figure 7.5 illustrates a sustained bloom (>1 month) with 60 to >100 ug/L over the entire water. Since average light levels in the deep channel, when well-mixed, are too low to support substantial growth, most of this biomass was likely produced along the shoals and subsequently mixed over the water column (i.e., Figure 7.2.D). Because sediments are more readily resuspended in shallow environments, higher turbidity, resulting from tidally- or wind-driven local resuspension of sediments, can decrease productivity on the shoals (Lucas et al., 2009). Furthermore, filter feeding by clams can more efficiently clear the shoal water column than the deep channel water column, and reign in shoal blooms (see Section 7.2.3; and Lucas and Thompson 2013). Despite the apparent importance of productivity along the shoals, there is relatively limited data available from these areas. Increased monitoring (including continuous monitoring with moored sensors, e.g, turbidity, chlorophyll, etc.) is needed to understand when shoal induced blooms (Figure 7.2.C and 7.2.D) drive overall production in subembayments.

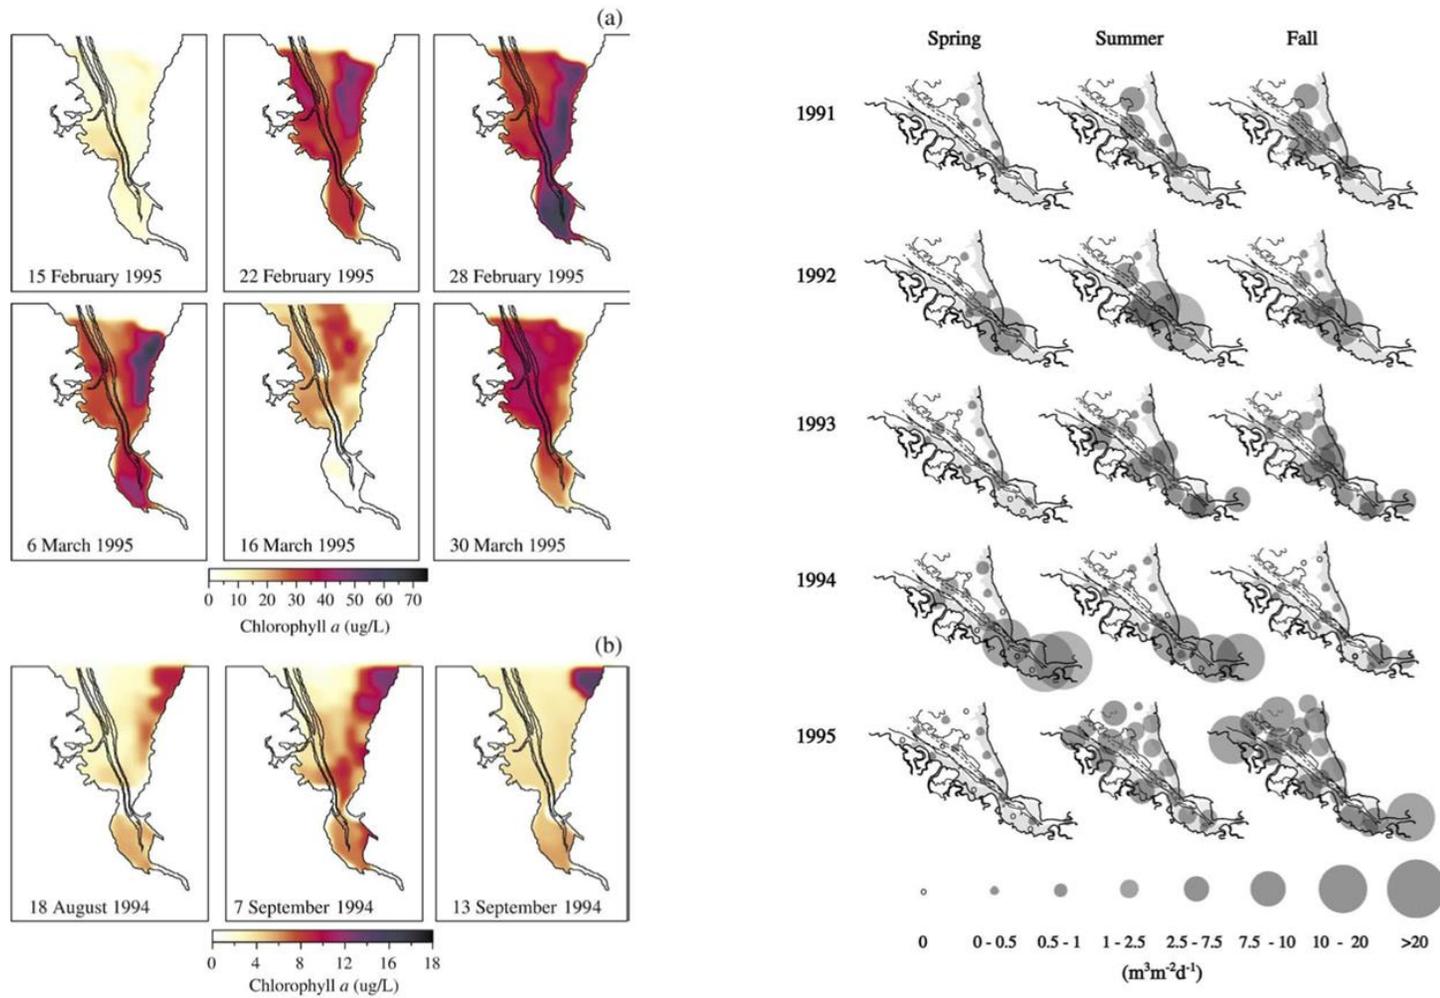

Figure 7.4 A. Phytoplankton biomass South Bay illustrating bloom initiation on shoals and propagating to the channel. **B.** Spatial, seasonal, and interannual variation in bivalve grazing rates in South Bay and LSB. Source: Thompson et al. 2008

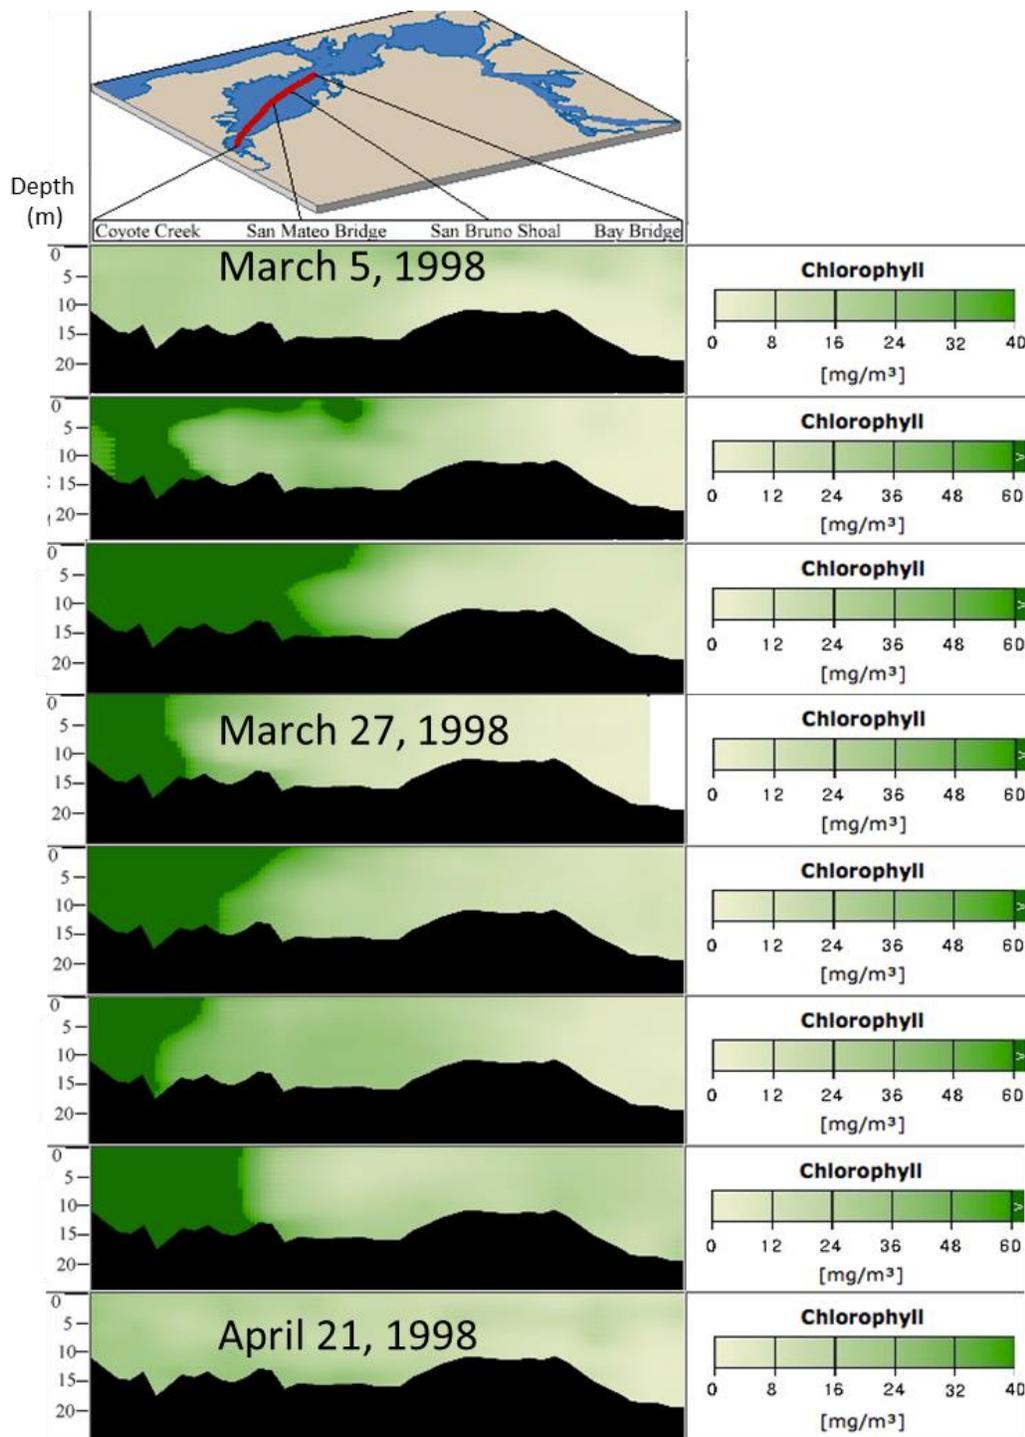

Figure 7.5 Phytoplankton biomass in LSB and South Bay during Spring 1998. Note that chl-a concentrations are constant over the full water column, illustrating the production scenario in Figure 7.2 D. Source: <http://sfbay.wr.usgs.gov/access/wqdata/archive/longterm.html>.

Cole and Cloern (1984) demonstrated that primary production rates in SFB could be reliably quantified by knowing incident light intensity, depth of the photic zone, and the concentration of phytoplankton biomass (as $\mu\text{g chl-a L}^{-1}$). This relationship is calibrated using an “efficiency factor”, ψ , for new biomass production per unit light energy (expressed in units $\text{mg chl-a [Einstein m}^{-2} \text{J}^{-1}]$), which is specific to the phytoplankton community of the system (Cole and Cloern, 1987; Jassby et al., 2002). Using this ψ -based relationship to estimate productivity is valid as long as ψ remains constant over space and time (Jassby et al., 2002 ; Kimmerer et al. 2012 ; Parker et al., 2012), and C:chl-a is reasonably well-known and constant. Recent studies focused in northern SFB have suggested that both ψ and C:chl-a may have changed considerably over the past 20 years, potentially due to large changes in phytoplankton community composition (Kimmerer et al., 2012; Parker et al., 2012). However, the analytical techniques for measuring production rate differed between Cole and Cloern (1984) and Parker et al. (2012), and some or all of the apparent difference in the calibration coefficients could be the result of these analytical differences. In either case, the overall ψ -based approach remains valid, although it may need to be periodically re-calibrated and validated, and different relationships (i.e., different values of ψ) may need to be developed to account for a range of conditions (light-inhibition, different phytoplankton communities, T).

Nutrients and phytoplankton production rates

In many estuaries nutrient concentrations both influence primary production rates and determine when a bloom terminates (due to nutrient depletion). However, in SFB, nutrients tend to be replete year-round, and thus they seldom control production rates (Figure 7.6, 7.7 and 7.3.B). Nutrient concentrations do exhibit periodic drawdowns in SFB, owing in part to phytoplankton growth (Thompson et al., 2008; Figure 3.14 in SFEI 2014b). However, at least in deep channel environments where most data is available, concentrations infrequently dip to levels that would be expected to substantially slow overall production rates (Figure 7.6 and 7.3.B). Instead, field and modeling studies in SFB suggest that phytoplankton bloom termination at the subembayment scale more commonly occurs due to other factors, especially break-down in stratification (Cloern 1991), and sometimes increase in grazing pressure (Thompson et al., 2008). The tops of the grey shaded areas in Figure 7.6 correspond to 2 times K (half-saturation constant) for N, P, or Si. A value of $10 \times K$ would be a more conservative estimate of when a concentration may begin to slow growth rates. If a value of $10 \times K$ is used, the interpretation of infrequent nutrient limitation remains generally the same, except for DIN in South Bay. Even in the case of South Bay using $10 \times K_N \sim 10 \mu\text{M}$, though, [DIN] rarely falls below that value ($\sim 15\%$ of the time). The case of South Bay and LSB are better illustrated in Figure 7.7, which presents DIN and DIP concentrations at individual stations in terms of their interquartile ranges, 95% confidence intervals and outliers. At all stations the interquartile ranges lie well above the $10 \mu\text{M}$; at stations 19-27 and 36, the 95% confidence intervals also lie above $10 \mu\text{M}$. DIP concentrations almost always exceed $\sim 2 \mu\text{M}$ ($10 \times K_P$). So, while there are windows in space/time when DIN falls below a potentially growth rate limiting concentration, DIN substantially exceeds rate-limiting concentrations the vast majority of time. Nonetheless, a closer examination chl-a, DIN, and other nutrient time series would be worthwhile for providing insights into when, where, and under what conditions DIN does reach these lower levels.

Low production rates due to elevated ammonium in Suisun Bay

Recent studies in SFB and the Delta have argued that the influence of nutrients on biomass production rate may be more complex than the generally accepted idea of nutrient limitation on growth. Dugdale and colleagues argue that elevated NH_4^+ levels in Suisun Bay and the Delta slow primary production rates and can prevent blooms from developing (Dugdale et al. 2007, 2012; Parker et al., 2012a,b). These studies refer to the phenomenon as the “ NH_4^+ paradox”: the

crux of the hypothesis is that when NH_4^+ concentrations exceed 2-4 μM , phytoplankton can not access the relatively large NO_3^- pool on which these studies suggest they can grow more rapidly than NH_4^+ . The NH_4^+ paradox studies acknowledges that other factors such as light limitation, clam grazing, and residence time also exert influence over phytoplankton production or biomass accumulation. However Dugdale and colleagues hypothesize that NH_4^+ -inhibition of productivity could be a quantitatively important mechanism during critical periods, such as during spring, when clam grazing may in fact be low due to seasonal variations in clam abundance (Dugdale et al., 2007).

There remains considerable disagreement within the scientific community – including among this report’s authors – about the mechanistic interpretations of the NH_4^+ -paradox studies, and about the potential ecosystem-scale importance of the mechanism relative to other factors that regulate phytoplankton growth rates and biomass accumulation. A detailed review of these studies was recently completed, and the reader is referred to that report for more information (SFEI 2014b). Experiments to explore the NH_4^+ -paradox are continuing. More integrative studies (e.g., modeling) and controlled experiments are needed to evaluate the importance of hypothesized NH_4^+ -inhibition mechanism relative to other processes.

7.2.3 Top-down biological processes that influence biomass accumulation

Benthic grazing

Benthic grazing plays an important and sometimes dominant role in regulating the amount of biomass that accumulates in the water column of some SFB subembayments, or habitats within those embayments. (e.g., Thompson et al. 2008; Kimmerer and Thompson, 2014; Cloern et al., 2007; Lucas and Thompson, 2013). The effect of benthic grazing rates on phytoplankton biomass is dependent on the filtration rates ($\text{m}^3 \text{g}^{-1} \text{d}^{-1}$) of the species present and the abundance of grazers (g m^{-2}). Grazer abundance varies seasonally and spatially based on individual species’ life histories, predation, and habitat preference (salinity, sediment type, etc.). Grazer abundance is also tightly coupled to their food supply: i.e., the biomass of grazers at any point in is related to the amount of food available prior to that time. The influence of the filtration rate on phytoplankton concentrations in the overlying water column also depends on water column depth: at a given filtration rate (which is proportional to clam biomass), a shallow water column will be cleared of its phytoplankton faster than a deep water column. The effect of benthos on phytoplankton biomass also depends on other factors such as benthic boundary layer thickness and stratification, which are themselves influenced by turbulent mixing energy.

Potamocorbula amurensis filtration efficiency is high on relatively large phytoplankton ($>5 \mu\text{m}$ = 100%; Kimmerer and Thompson 2014) and lower for smaller phytoplankton ($<5 \mu\text{m}$ = 75%; Kimmerer and Thompson, 2014; Werner and Hollibaugh, 1993). This size-dependent filtration efficiency may allow *Potamocorbula* to disproportionately graze larger cells from the water column and potentially influence size distribution of phytoplankton biomass. However, higher settling rates of large phytoplankton classes like diatoms would tend to increase their downward transport (relative to other size classes) to zones where they can be entrained by clams, and this could be an even more important factor on the relative impacts of grazing on different phytoplankton classes.

Three sets of observations offer insights into the strong influence that benthic suspension feeders can have on phytoplankton biomass. The first example is the observation that, based on mass

balances of phytoplankton biomass in South Bay, production paradoxically exceeded losses from zooplankton grazing and transport (Cloern 1982). This implied a missing sink of phytoplankton biomass in South Bay, which Cloern (1982) hypothesized was clam grazing

The second example is the *Potamocorbula amurensis* invasion in Suisun Bay. *Potamocorbula* was which first detected in Suisun Bay in 1987, and its effect on phytoplankton biomass was almost immediate (Figure 3.8). Baseline biomass values dropped considerably, and peak biomass levels decreased by a factor of 5-10. Overall, mean annual biomass and dropped five-fold after the *Potamocorbula* invasion, and the state of chronic low annual primary production has persisted since 1987. While substantial phytoplankton biomass was observed over multiple months (May-September) during most years prior to 1987, blooms have occurred only rarely post-1987. *Potamocorbula* biomass exhibits pronounced seasonality and large interannual variability (Figure 7.8), as well as considerable spatial variability (Figure 7.9). One reason for clam loss during late summer and fall is predation by migratory waterfowl. The seasonality in *Potamocorbula* abundance may allow windows for blooms to develop before clam grazing rates are high enough to draw down phytoplankton biomass. Occasional spring blooms have been observed over the last several years (Dugdale et al, 2012; R Dugdale, pers. comm.). A large fall bloom was also observed in September 2011. *Potamocorbula* tolerate salinities that are commonly encountered in Suisun Bay (Low Salinity Zone, LSZ), and are well-established at all depths throughout Suisun and at locations in San Pablo Bay (Figure 7.9). *Potamocorbula* do, however, have a fairly clear up-estuary boundary, apparently dictated by salinity (Figure 7.9). *Potamocorbula* are voracious filter feeders, and, at their current densities in the LSZ, grazing rates typically exceed phytoplankton growth rates in the LSZ (Figure 7.10; Kimmer and Thompson, 2013).

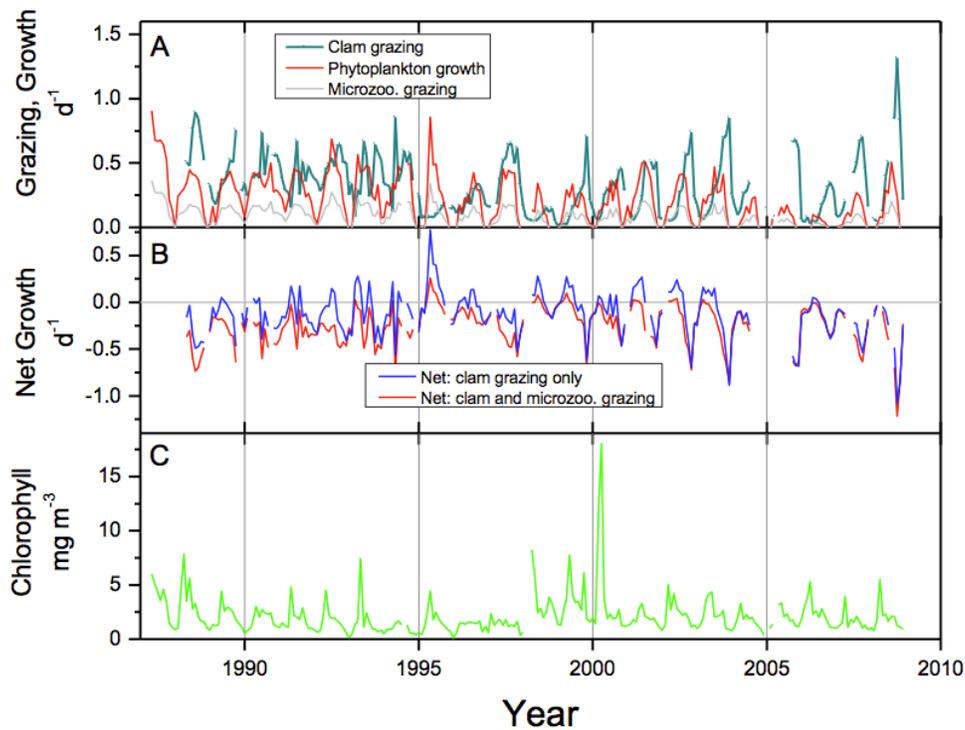

Figure 7.10 Calculated growth and grazing rates in the Low Salinity Zone (essentially Suisun Bay). Source: Kimmerer and Thompson (2014)

The third example of benthic grazer impacts on biomass is from South Bay. Through the mid-1990s, benthic filter feeding was considered to be one of the dominant controls on phytoplankton biomass accumulation and productivity in South Bay (Thompson et al., 2008 ; Lucas et al., 2009). Clams were heavily preyed upon by migrating birds in the fall. Thompson et al. (2008) observed that interannual variations in abundance and timing of spring reestablishment of benthic suspension feeders along the shoals dictated whether or not blooms could form on the shoals, and propagate from the shoals to the channel (Figure 7.4.B). In addition, Cloern et al (2007) observed sharp increases in chl-a and in gross primary production in the South Bay beginning in the late 1990s (Figure 7.11). After ruling out several potential drivers (e.g., changes in nutrient loads), they hypothesized that the increase in phytoplankton biomass was due, at least in part, to a pronounced loss of benthic suspension feeders. They argued that the decline in benthos abundance was due to an observed increase in benthivorous predators (sole, Bay shrimp, Dungeness crab; Figure 7.12), which they argued was attributable to large-scale climate forcings that resulted in increased oceanic production of juvenile predators that migrated into SFB to feed and grow (a change in the North Pacific Gyre Oscillation; Cloern et al., 2010).

The amount of historic data on benthos abundance and on-going benthos monitoring varies spatially in SFB. The IEP has several long-term monthly benthos monitoring stations in Suisun and San Pablo Bays (Peterson and Vayssières 2010). In recent years there has also been ample additional benthos monitoring by a semi-annual IEP pilot randomized monitoring program in San Pablo Bay, Suisun Bay, and the Delta; it is not yet known if this program will continue in future years. There are no sustained benthos programs in the other subembayments; however, there are multiple years during which intensive benthic sampling has taken place (e.g., Thompson et al. 2008; see Figure 7.4), and other opportunistic sampling efforts after which samples have been archived but not yet analyzed for biomass (J Thompson, personal communication). A consistent benthos monitoring program is needed in these other subembayments, most importantly Lower South Bay and South Bay, to better understand the drivers of recent change, and continue exploring cause and effect.

Pelagic grazing

Pelagic grazing rates by zooplankton are dependent on the types of zooplankton present, their abundance, and their biomass-normalized grazing rates. Copepods, mesozooplankton that are an important food resource in SFB and the Delta, derive most of their energy from phytoplankton as opposed to detrital organic matter (Mueller-Solger et al 2002; Sobczak et al 2002, 2004), and at least in Suisun Bay and the Delta are often food limited (Mueller-Solger et al 2002; Kimmerer et al 2005). Despite mesozooplankton's reliance on phytoplankton, modeling estimates by Kimmerer and Thompson (2014) suggest that they have only a limited effect on phytoplankton biomass in Suisun Bay. Cloern (1982) reached the same conclusion for South Bay. However, microzooplankton have the potential to substantially influence phytoplankton biomass in Suisun Bay (Figure 7.10; Kimmerer and Thompson, 2014). Outside of Suisun Bay there are limited data on mesozooplankton and microzooplankton biomass and feeding rates. While it may be reasonable to expect that the effect of mesozooplankton grazing on phytoplankton biomass is small Bay-wide, microzooplankton could play a substantial role, based on observations in Suisun Bay. Additional zooplankton monitoring in other subembayments is needed to better constrain pelagic grazing rates.

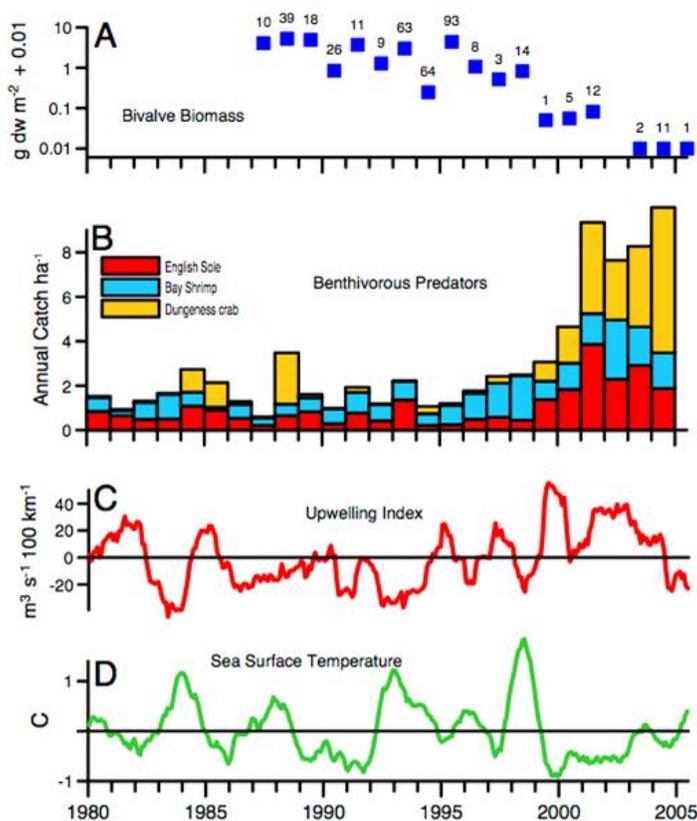

Fig. 3. Indices of biological community change within SFB and physical changes in the adjacent California Current. (A) Annual median biomass of filter-feeding bivalves across shallow habitats in South SFB; numbers above squares indicate sample number per year. (B) Mean annual catch ha^{-1} , normalized to 1980–2005 averages, of English sole, Bay shrimp, and Dungeness crab, from monthly sampling across the marine domains of SFB. (C) Anomalies in upwelling intensity computed by the National Oceanic and Atmospheric Administration from atmospheric pressure fields. (D) Sea surface temperature measured at the Farallon Islands. The bottom series (C and D) are 12-mo running averages of deviations from 1977–2005 monthly means.

Figure 7.12 Bivalve biomass, benthivorous predators, upwelling index, and sea surface temperature time series. Source: Cloern et al. 2007.

7.2.4 Spatial and temporal variations in phytoplankton biomass

Figure 7.13 presents monthly averages of phytoplankton biomass (2006-2011) broken down by subembayment; Figure 7.14 shows time series from 1975-2012. The highest phytoplankton biomass concentrations are generally observed in LSB. Bay-wide, the largest blooms typically occur in spring. Over the last ten years, however, pronounced fall blooms have also been occurring in LSB and South Bay (Figures 7.13 and 3.6). The rate of increase in chl-a concentration ($\mu\text{g L}^{-1} \text{yr}^{-1}$) is greatest in LSB and South Bay. More modest rates of increase are visually-evident in all subembayments based on rising baselines (Figure 7.14), and these increases are also statistically-significant (J Cloern, pers. comm.). Therefore, it is possible that there may be some Bay-wide common explanation that explains at least part of the increase (e.g, decreasing suspended sediment concentrations), and additional subembayment-specific explanations (e.g., decreased clam abundance).

7.3 Microphytobenthos

Microphytobenthos (MPB; i.e., benthic algae) primary production has received little attention in SFB relative phytoplankton production. However, given the large intertidal area in several of SFB's subembayments, primary production by benthic microalgae could represent a quantitatively important component of overall production. Although only roughly quantified due to limited data, Jassby et al. (1993) suggested that MPB production could account for as much as 30% of overall primary production in SFB. Thus, MPB production could have a substantial influence on food web structure (supporting organisms that utilize benthic microalgae), dissolved oxygen budgets, and nutrient cycling.

Many of the factors that influence phytoplankton growth rates will similarly influence MPB growth. These include: light availability, temperature, and nutrients (Figure 7.1). While MPB primarily occur attached to bed sediments, they are also commonly found in the water column due to physical resuspension. Benthic diatoms (mainly pennate, but some centric) have been the major MPB taxa identified in the limited studies carried out to date in SFB (Guarini et al. 2002). The standing stock of MPB biomass (often reported as mg chl-a m^{-2}) is a function of productivity rates ($\text{mg chl-a m}^{-2} \text{d}^{-1}$), grazing rates, and exchange with the water column. Light availability strongly influences MPB productivity and is a function of water column depth and light attenuation (i.e., SPM concentration), and of variations in depth due to tides. The amount of MPB resuspension depends on sediment type and consolidation, biofilm production in the sediment, and the magnitude of shear stresses (Macintyre, 1996; Underwood and Kromkamp 1999). Sediment resuspension reduces light penetration for MPB that remain at the sediment:water interface; however, MPB that are resuspended could experience increased light availability. MPB residing on intertidal mudflats experience unattenuated incident light levels during low tide, and productivity would be greatest then. Because of SFB's high turbidity, little MPB growth would occur in subtidal areas. Nutrient limitation is unlikely to be an important constraint on MPB growth, because MPB can readily access NH_4^+ and o-PO_4 diffusing out of the sediments and nutrients in the overlying water column. In sandy sediments with low organic matter content, MPB can be nutrient limited (Underwood and Kromkamp, 1999). MPB concentrations have been shown to be lower in sandy silts and sands than in finer, cohesive sediment (Cammen, 1982; Montagna et al, 1983; Cammen 1991; de Jong and de Jonge, 1995; Underwood and Smith, 1998a). Temperature will influence growth rates in way similar to

phytoplankton. CO₂ availability may also limit MPB productivity, but is likely a minor factor compared to light availability. Zoobenthos, some bottom-feeding fish, and birds would be the prime grazers on MPB. MPB biomass, however, would be generally unaffected by filter-feeding clams. Thus, MPB production may comprise a larger proportion of overall production in shallow areas with high abundance of filter-feeding clams.

While MPB production is potentially important in terms of its overall contribution to primary production in SFB, and some estimates of its magnitude have been made, little is known about how much it influences the food web, the net effect it has on dissolved oxygen budgets, or how it might respond to system perturbations (e.g, decreases in SPM). As noted above, Jassby (1993) estimated that MPB production could account for approximately 30% of overall primary production in both southern and northern SFB subembayments. Studies in other estuaries have found that MPB could account for up to 50% of total primary production (Underwood and Kromkamp, 1999). Guarini et al (2002) estimated that MPB productivity ($\text{mg C (mg chl-}a\text{)}^{-1} \text{d}^{-1}$) could be nearly 4x as large in South Bay as in Suisun Bay, due to spatial differences in MPB assemblage or bathymetry-induced differences in light exposure to intertidal areas. In a more recent study, direct measurements of sediment chl-*a* ($\text{mg chl-}a \text{ m}^{-2}$) were made in the Delta and Suisun Bay (Cornwell and Glibert 2014). Benthic chl-*a* abundance was roughly 30% greater in September 2011 than in March 2012 at both locations, which is consistent with higher expected biomass at the end of the warm season. In addition, Cornwell and Glibert (2014) found that benthic chl-*a* was approximately 4-fold higher in the Delta than in Suisun Bay, likely due in part differences in depth and light availability.

7.4 Current state of knowledge

Tables 7.1 summarizes the current state of knowledge and knowledge/data gaps related to primary production from phytoplankton biomass and MPB in SFB. The prioritizations in the rightmost two columns are related to the discussion in Section 11.

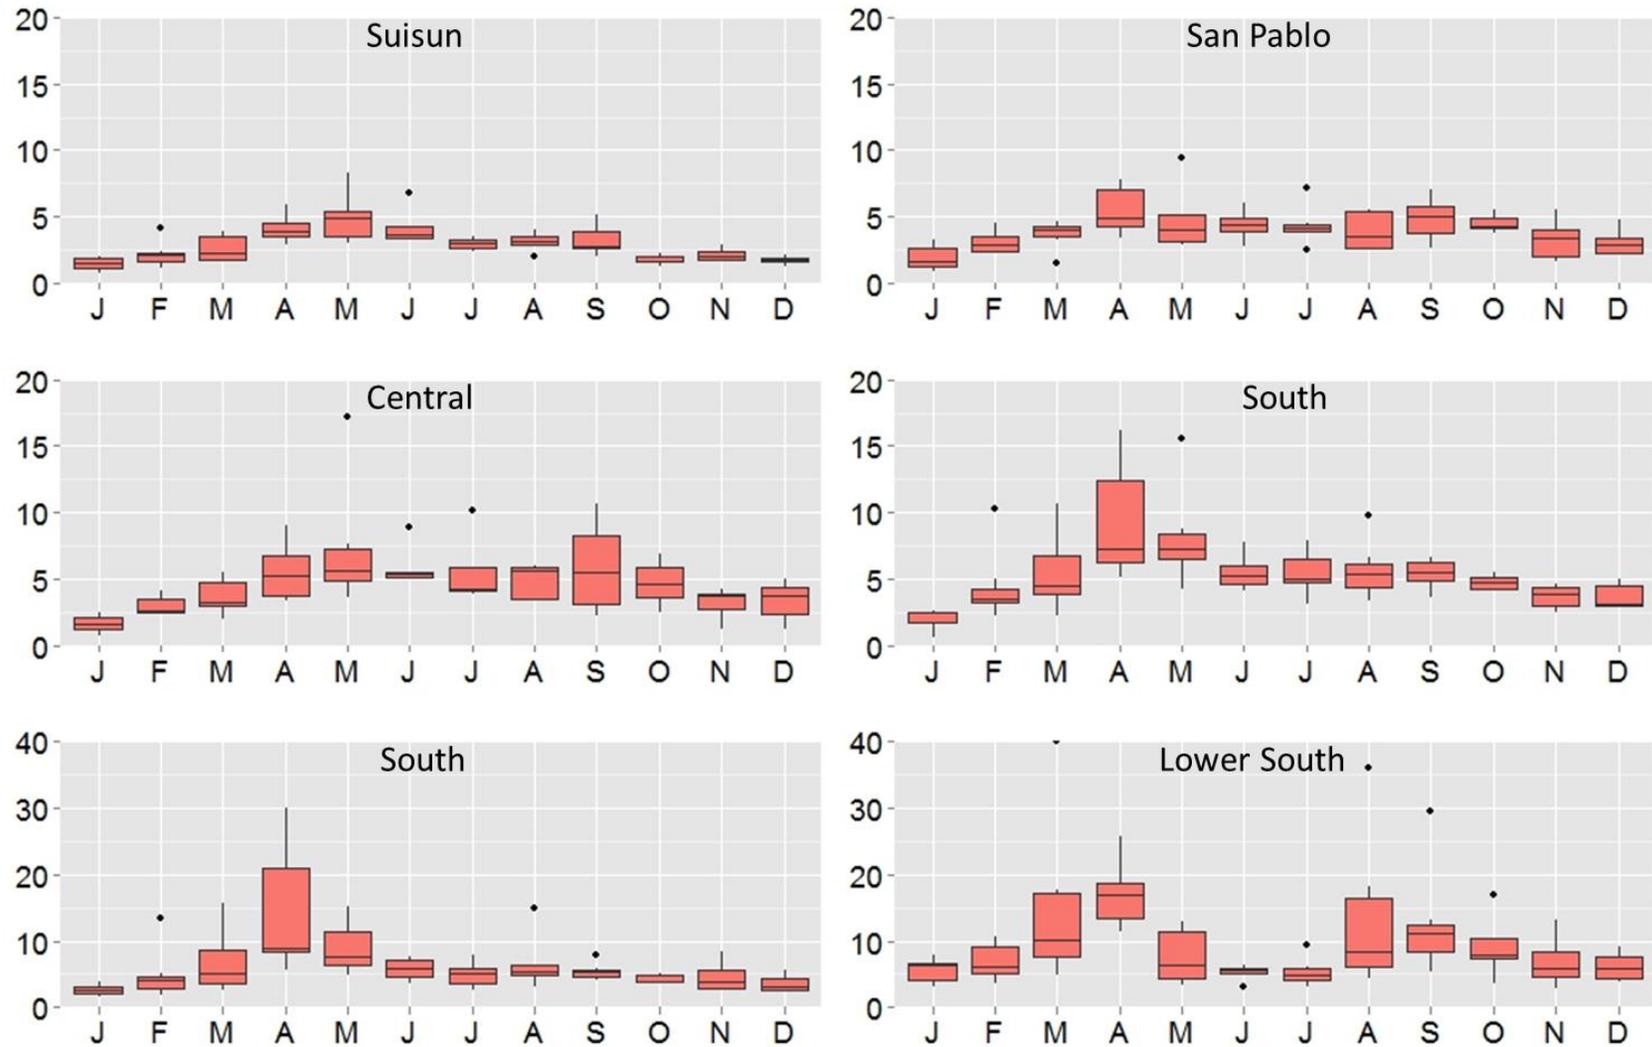

Figure 7.13 Monthly variations in chl-a ($\mu\text{g L}^{-1}$) 2006-2011. 2 Table 7.1 Phytoplankton and MPB productivity and biomass accumulation: current state of knowledge for key processes and parameters

Process or Parameters	Importance for quantitative understanding	Current Level of confidence about magnitude or mechanistic controls	Need for <u>additional or continued</u> data collection, process studies, modeling	Priority for study in next 1-5 years
PHYTOPLANKTON - Processes				
Primary production rates	High	Low/Moderate: Basic understanding about light limited production is well modeled. Recent studies suggest that the relationship may have shifted, and revisiting this may be important for estimating system productivity.	Very High	High
Pelagic grazing	High	Low: Long-term program in Suisun Bay/Delta for macrozooplankton, but limited micro-zooplankton data, which may be more quantitatively important in terms of overall grazing rate. No systematic zooplankton sampling in LSB, South Bay, Central Bay.	Very High	High
Benthic grazing	High	Low: good data to support estimates in Suisun Bay. Limited data in LSB South Bay. Monitoring of benthos abundance would inform this.	Very High	Very High
Sinking, respiration, burial	High	Moderate: Discussed within context of Dissolved Oxygen	Low	Low
Inhibition of primary production rates by elevated NH ₄ ⁺	High/ Uncertain	Low: Several studies have been completed and others are underway. Uncertainty remains about mechanism and relative importance of the process. Field/lab studies and modeling work can be done in parallel, with the former designed to further elucidate the mechanism and thresholds and the latter to quantify its role relative to other factors.	Very High	Very High
Production in the shoals vs. channels (during stratification), and physical or biological controls on bloom growth/propagation	High	Low: Considered to be an important process but limited data available. Data needed to better predict bloom magnitudes.	Very High	Very High
Germination of resting stages	Low	Low: Not considered among the highest priority processes to study	Low	Low
PHYTOPLANKTON - Ambient concentration data				
High frequency data in channel	High	Low: Very limited high temporal resolution (continuous) phytoplankton biomass data beyond of Suisun Bay. Needed to better predict blooms.	Very High	Very High
High temporal resolution data in shoals	High	Low: Very limited high temporal resolution (continuous) phytoplankton biomass data beyond of Suisun Bay. Needed to better predict blooms.	Very High	Very High
Biomass data along the Bay's deep channel	High	Moderate/High: USGS program has been collecting monthly data at along the channel for the past 35 years, and needs to be continued.	Very High	Very High
Phytoplankton C:N ,C:chl-a, and size-fractionated chl-a	High	Low: Valuable information to inform understanding of processes and for modeling	Very High	Very High

Process or Parameters	Importance for quantitative understanding	Current Level of confidence about magnitude or mechanistic controls	Need for <u>additional or continued</u> data collection, process studies, modeling	Priority for study in next 1-5 years
<i>Microphytobenthos - Processes</i>				
Primary production rates	Moderate	Low: may be able to predict productivity based on light levels and chl-a, although needs to be confirmed	Moderate	Moderate
Grazing	Moderate/Unknown	Low: Potentially important as a sink, but difficult to study.	Low	Low
<i>Microphytobenthos - Ambient abundance data</i>				
Basic biomass information, seasonal, spatial	High	Low: Very limited data on MPB abundance and productivity, despite the fact that MPB productivity may be comparable in magnitude to phytoplankton productivity.	High	High

8 Dissolved Oxygen

8.1 Introduction

Dissolved oxygen concentrations are a highly relevant indicator of nutrient-related impairment, both because maintaining sufficient dissolved oxygen levels is critical for sustaining aquatic life, and because low dissolved oxygen is a common ecosystem response to high nutrient loads. Oxygen is both produced and consumed within the estuary, and also transported into the water column across the air:water interface by gas exchange and by water inputs. If the oxygen loss rate exceeds the oxygen production or input rate, dissolved oxygen levels decrease and hypoxia or anoxia can develop. Persistent hypoxia or anoxia leads to aquatic organism stress or death, or, for organisms that can escape low DO areas, causes the loss of habitat. Anoxia leads to sulfide gas production, which can be toxic to aquatic organisms and causes both odor problems and infrastructure damage (corrosion, discoloration of painted exteriors). In addition, under low DO conditions NH_3 can accumulate to levels that exert direct toxicity on benthos.

Prior to the 1970s, areas of SFB, specifically LSB, did experience low DO (Cloern and Jassby, 2012). Implementation of secondary wastewater treatment addressed the issue of large-scale and persistent anoxia in deep subtidal areas. However, limited information is available about DO levels in margin habitats, including sloughs, tidal wetlands, and managed ponds, and the occurrence and potential impacts of low DO there are unknown.

8.1 General DO conceptual model

Dissolved oxygen concentration, measured at a given point in space and time in the water column, represents the concentration that results from multiple competing production and loss processes, as well as inputs, outputs, and mixing (Figure 8.1).

8.1.1 DO transport

O_2 is readily exchanged across the air:water interface, and is highly soluble in water, with the DO saturation concentration (DO_{sat} ; mg/L) varying in direct proportion to the O_2 partial pressure in the overlying air. DO_{sat} decreases with increasing water temperature and salinity. If DO concentrations in the water column are undersaturated relative to O_2 in the overlying air, atmospheric exchange will occur, with O_2 flux from the atmosphere into the water column. If DO concentration exceeds saturation (e.g., after periods of intense photosynthesis), DO flux will occur from water to the atmosphere. In both cases, exchange at a rate proportional to the magnitude of DO under- or over-saturation and the amount of mixing-energy at the air:water interface (determined largely by wind speed in open-water areas).

DO also enters (or leaves) a habitat through fluvial transport (from the Delta, perennial ephemeral streams, stormwater inputs, and treated wastewater effluent), water exchange between subembayments (advective, tidal, gravitational), and mixing or exchange between habitats within a subembayment. Exchange between adjacent subembayments or habitats can result in net increases or decreases in DO depending on whether the prevailing conditions differ substantially between the two systems. During coastal upwelling events, gravitational circulation (i.e., intrusions of denser (colder, more saline) water) has the potential to transport substantial volumes of relatively low DO water far up-estuary, displace an equal volume of relatively DO-

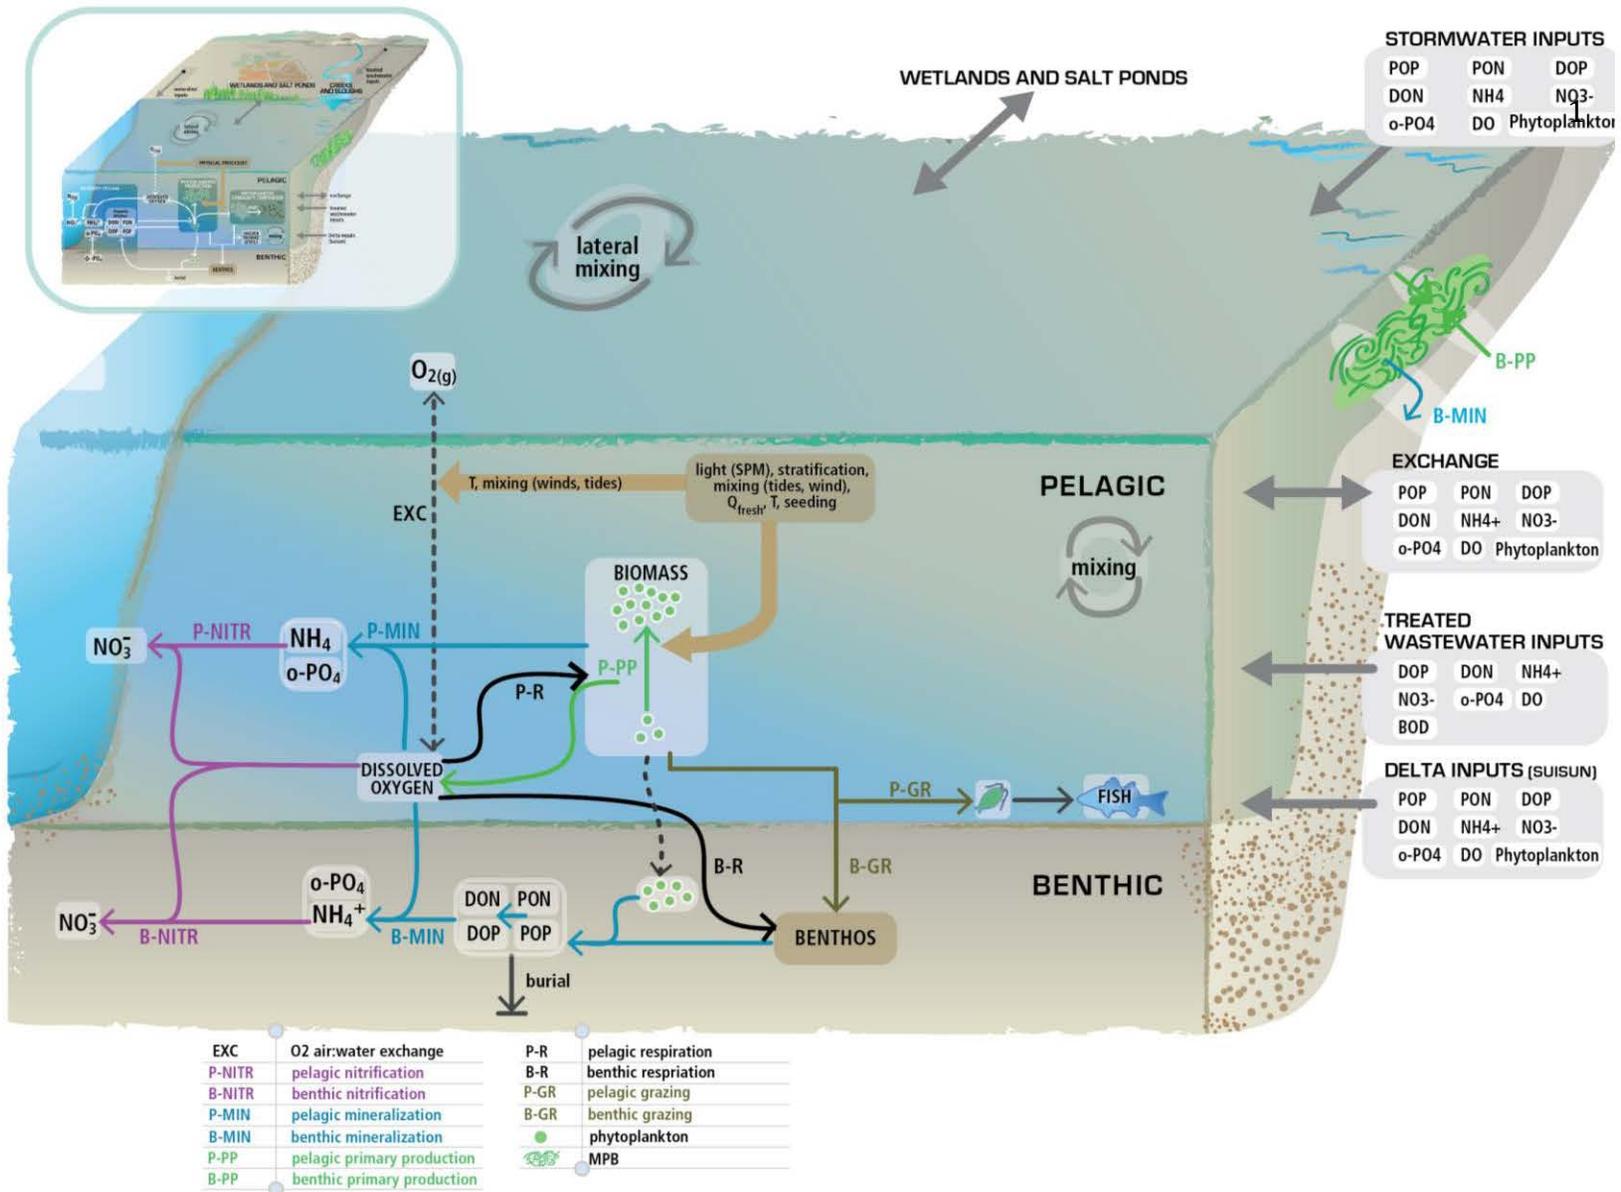

Figure 8.1 Dissolved oxygen conceptual model

rich water down-estuary, and measurably influence DO concentrations when the water column mixes. Tidal exchange between a subembayment and wetlands, salt ponds, and sloughs along its margins could be a net source or sink of DO, depending on the balance of O₂ production and consumption in those systems. This is discussed further below.

8.1.2 O₂ production and consumption

The major processes that result in DO production or consumption are illustrated in Figure 8.1 Primary production - by phytoplankton, MPB, and macrophytes – produces O₂ during daylight hours. The O₂ production rate varies in proportion to the primary production rate, which, for phytoplankton and MPB, is light-limited in most SFB habitats. Thus, analogous to primary production rates (Section 7), O₂ production rates exhibit large variability on hourly and seasonal time scales, respond to weather conditions that influence incident light (cloud cover or fog), and may vary substantially between shallow and deep habitats or in response to stratification.

Respiration by aquatic and benthic organisms consumes DO. Viable phytoplankton respire throughout the entire day, and consume oxygen in the process. During daylight hours, their O₂ production exceeds respiration, resulting in net O₂ production; however, during dark periods only respiration occurs, with net DO consumption. As a result DO levels can exhibit a diurnal sinusoidal-like cycle, with maxima and minima near mid-afternoon and sunrise, respectively. In some habitats, transport of water masses with differing DO concentrations by semi-diurnal tides whose magnitude varies on a spring-neap cycle can mask the diurnal signal generated by respiration and production (SFEI, 2014c).

The balance between O₂ production and consumption is also influenced by microbial respiration of dead organic matter (OM). Microbes consume oxygen while mineralizing or degrading OM derived from two broad source categories: biomass from during primary production by phytoplankton, MPB, and other plants within SFB (autochthonous OM); and terrestrial organic matter (allochthonous OM) carried to the Bay by freshwater inputs and treated wastewater effluent (i.e., the latter of which is commonly referred to as biochemical oxygen demand, BOD)., While BOD loads to SFB from POTWs used to be high, those loads decreased substantially once secondary treatment was implemented in the 1970s. Some OM mineralization occurs in the water column (pelagic respiration), but much of it happens in the sediments and at the sediment:water interface (benthic mineralization) where particulate OM accumulates after settling. Aerobic microbial respiration occurs continuously, although respiration rates are strongly influenced by temperature, the abundance of fresh or readily-degradable OM, and DO concentrations. In the sediments, when the DO supply is exhausted (which often occurs within a few millimeters or centimeters into the sediments), anaerobic respiration occurs using alternate electron acceptors (nitrate, manganese(IV), iron(III), sulfate). Although anaerobic respiration does not directly consume O₂, the reduced compounds produced during anaerobic respiration (Fe(II), Mn(II), sulfide) diffuse upward through the sediments into oxygenated sediment layers or into the water column, and react with and consume O₂ there.

Nitrification of NH₄⁺ to NO₃⁻ by nitrifying microbes also consumes O₂. Major NH₄⁺ sources to the Bay include the NH₄⁺ discharged in treated wastewater effluent from POTWs and NH₄⁺ produced *in situ* during OM respiration. Nitrification of NH₄⁺, and associated O₂ consumption, occur in both the water column (pelagic nitrification) and at the sediment:water interface (benthic nitrification).

Sediment oxygen demand (SOD) can play a dominant role influencing the O₂ budget of a habitat. SOD is an overarching term that includes benthic mineralization, benthic nitrification, and benthic oxidation of reduced compounds. SOD tends to exert greater influence over DO concentrations in shallow habitats, where the ratio of overlying water volume to sediment area is relatively small compared to deeper areas. While SOD includes several types of reactions, its magnitude is ultimately driven by the amount of OM loading to the sediments. That OM can be imported to the system (fluvial inputs; allochthonous OM) or produced *in situ* (autochthonous OM). As respiration proceeds, OM in the sediments is consumed. The rate and total amount of SOD depends on the rate and total amount of new OM delivery to the sediments. In SFB, a large portion of SOD likely traces back to autochthonous OM production by phytoplankton and MPB, and therefore to nutrient loads, although allochthonous inputs may contribute more substantially to SOD in margin habitats and in Suisun Bay (due to allochthonous inputs from the Delta).

8.1.3 Spatial differences in O₂ budgets and DO concentrations in SFB

An aquatic ecosystem's O₂ budget can be characterized in terms of whether it acts as a net producer or consumer of O₂, referred to as net ecosystem metabolism (NEM). If a system produces more (NEM > 0) or less (NEM < 0) oxygen than it consumes it is considered net autotrophic or net heterotrophic, respectively. NEM will vary considerably based on the time scale and location considered, because of temporal (e.g., diurnal variability in O₂ production rate) and spatial variability in the magnitudes of O₂ sources and sinks. Past studies have shown that SFB shallow shoals and intertidal areas are likely to have NEM > 0 (Caffrey et al. 2003). Atmospheric exchange, along with high rates of phytoplankton and MPB primary production (due to the shallow water column and higher average light levels), maintain high DO concentrations. While benthic mineralization, benthic nitrification, pelagic mineralization and pelagic respiration also occur in these areas, the DO inputs more than offset these O₂ sinks.

SFB's deep subtidal habitats more frequently have negative NEM (Caffrey et al. 1998), and, as a result, DO is often undersaturated in these areas. Due to light limitation, deep areas generally experience lower rates of pelagic primary production than shallow habitats, and little or no MPB primary production occurs due to insufficient light. As a result, O₂ production rates are lower. At the same time, deep channel areas receive both viable and dead/decaying phytoplankton inputs through lateral exchange with shallow subtidal areas, which exert O₂ demand. Although atmospheric flux of O₂ may occur at similar rates in shallow and deep habitats, the same O₂ flux entering the deep water column is diluted over a larger volume; thus this exchange may not keep pace with respiration losses. Primary production rates in deep channel areas can be higher when the water column stratifies (Figure 7.2.B). However, eventually this OM settles to the bottom where it is respired. During stratified periods, DO concentrations can decrease in bottom waters due to respiration, since DO cannot be replenished through vertical mixing or atmospheric exchange at the surface. Due to the relatively short duration of stratification events in SFB, DO in deep subtidal habitats seldom dip below 80% saturation (Figure 3.12). Low DO can also be observed in SFB bottom waters when plumes or "intrusions" of recently-upwelled and relatively dense (colder, more saline) coastal water containing low-DO enter through the Golden Gate and occupy the bottom layer of some subembayments. Monitoring data from USGS R/V Polaris cruises indicate that these events tend to be fairly short-lived, with the water column mixing fully over the period of days to weeks.

While ship-based measurements indicate that DO levels in deep subtidal areas generally fall above the 5 mg/L Basin Plan standard (Figure 3.12, Kimmerer, 2004), continuous monitoring data at Dumbarton bridge illustrate that DO concentrations do vary substantially. During summer and fall, DO concentrations at Dumbarton Bridge commonly vary by 1-2 mg L⁻¹, with lowest concentrations observed at low tide (Figure 3.13 A), and values occasionally dipping below 5 mg L⁻¹. The variability in DO is strongly associated with tidal stage (SFEI 2014, 2014c). One plausible hypothesis for the correspondence between low DO and low tide is that, at low tide, the water moving past sensors at Dumbarton Bridge has a higher percentage of water from margin habitats where DO may be lower. The large variability suggests that oxygen demand within LSB can be quite substantial at the subembayment scale. In LSB, USGS *Polaris* sampling has most frequently occurred at slack high tide. It is therefore possible that DO concentrations from USGS *Polaris* cruises are biased high. During Summer 2014, USGS sampling cruises detected DO < 5 mg/L at other deep subtidal stations south of the Dumbarton Bridge during two cruises (<http://sfbay.wr.usgs.gov/access/wqdata/archive/longterm.html>).

SFB's shallow margin habitats – e.g., sloughs, tidal wetlands, and restored salt ponds ringing LSB - experience large DO swings that are influenced by both temporal variability in DO production rates and tidal exchange (Thebault et al., 2008; Schellenbarger et al., 2008). Compared to the abundance of monitoring data available for deep subtidal habitats (Figure 3.12), DO data for shallow margin habitats is quite limited. However, the observations that are available suggest that DO concentrations commonly dip below 5 mg L⁻¹ in those habitats, and frequently reach much lower values (Figures 3.14 and 8.2; SFEI 2014c). Continuous DO measurements (moored sensors at a single location) in sloughs provide evidence of large DO swings occurring at a periodicity that points to a strong tidal influence (Figure 8.2). Sloughs are shallow habitats and may have higher average light levels and greater DO production during daylight hours than the open Bay during some low turbidity periods; but sloughs also frequently have elevated turbidity due to sediment resuspension, which decreases light levels. Connection of some sloughs to salt ponds or wetlands could deliver higher loads of dead organic matter to slough sediments, increasing benthic mineralization rates. At night, net O₂ production is negative, which in a non-tidal system would lead to early morning DO minima. However, the diurnal cycle in O₂ production is superposed upon semi-diurnal tidal exchange. During flood tide, relatively DO-rich water from the open areas of LSB moves into the margins and above the sensors (depending on distance upslough from the open water and tidal phase, i.e., spring or neap) and supplements the O₂ budget (Figure 8.2). In the cases illustrated in Figure 8.2, DO minima and maxima occur twice daily, with maxima sometimes occurring at night and minima during the day, suggesting that the tidal influence on DO can be as strong or stronger than the diurnal variations in DO production.

Some highly-altered habitats in SFB, such as restored salt ponds and the surrounding sloughs in LSB, have delicately balanced O₂ budgets. The ponds have extremely high primary production rates and O₂ production rates, made possible by relatively high average light levels because of the shallow environment, and high nutrient concentrations (Thebault et al., 2008). Benthic mineralization rates are also high due to the reservoir of labile OM in the sediments. As a result, large diurnal fluctuations in DO levels occur (Figure 3.15.A and 8.2). While Figure 3.15A shows a diurnal cycle of maxima and minima, DO also drops to low levels for longer periods of time. Thebault et al. (2008) observed that when primary production rates are periodically low

(e.g., during a prolonged period of summer clouds or fog), sustained periods of anoxia can occur (Figure 3.15.B). On the one hand, the high productivity in restored salt ponds supports wetland food webs, including those of migratory birds (Thebault et al. 2008). On the other hand, the extent to which the large diurnal fluctuations in DO, or the more prolonged periods of anoxia that occur on cloudy days (Thebault et al., 2008), may be having adverse impacts is not currently known.

The slough and salt pond examples discussed here were specifically for LSB. However, South Bay, San Pablo Bay, and Suisun Bay also have substantial shallow subtidal margin habitats. Shallow margin habitats commonly experience naturally-low DO concentrations. In these habitats, it will be important to explore several questions: How common is low DO? Are events more severe (frequency, duration, DO deficit, spatial extent) than would be expected under natural conditions? Are the events having adverse impacts on beneficial uses? To what extent are anthropogenic nutrients contributing to or causing these events? Well-designed experiments, monitoring, and modeling may be needed in some of these systems to assess condition, and quantify the major drivers of O₂ budgets.

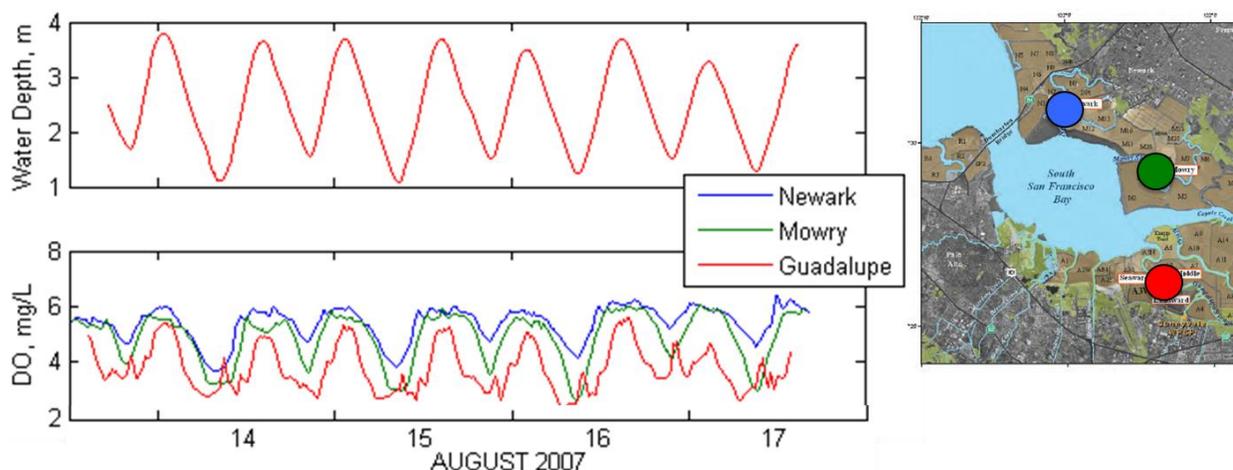

Figure 8.2 Dissolved Oxygen in three slough habitats in Lower South Bay measured using continuous monitoring sensors. Top panel shows water depth. Dissolved oxygen concentrations increase during the flood tide due to water with higher DO from LSB being tidally advected into sloughs. DO concentrations gradually decrease over the outgoing tide interval, likely caused, at least in part, by sediment oxygen demand within the sloughs, and lower DO water from up-slough moving back over the sensor. Colors of lines correspond to location denoted by circle colors in map. Source: Schellenbarger et al., 2008

8.2 Current state of knowledge

Table 8.1 summarizes major knowledge and knowledge data gaps for dissolved oxygen. The prioritizations in the rightmost two columns are related to the discussion in Section 11.

Table 8.1 Dissolved Oxygen: current state of knowledge for key processes and parameters

Process or Parameters	Importance for quantitative understanding	Current Level of confidence about magnitude or mechanistic controls	Need for <u>additional or continued</u> data collection, process studies, modeling	Priority for study in next 1-5 years
Processes or loads				
Atmospheric exchange	High	Moderate: Difficult to measure but readily modeled (albeit with substantial uncertainty)	Low	Low
Pelagic and benthic nitrification (for O ₂ budget)	Low/Moderate	Moderate: NH ₄ loads/concentrations provide an upper bound on this oxygen sink. It is not expected to be a major DO sink, or	Low	Low
Sediment oxygen demand (Benthic respiration + oxidation of reduced compounds).	High	Low: This set of processes is particularly important for understanding O ₂ budget in shallow margin environments. The mechanisms are well understood but rates are poorly constrained and likely are highly variable in space/time. Field experiments are possible. Increased (high spatial/temporal resolution) monitoring of DO will also allow “average” demand to be quantified by difference/modeling.	Very High	Very High
Pelagic and benthic primary production rates	High	Low: Benthic production rates, in particular are particularly poorly constrained and would require field surveys. Pelagic rates can be reasonably well-estimated based on phytoplankton biomass and light. As noted above, high spatial/temporal resolution monitoring of chl-a will help refine estimates	Very High	Very High
Pelagic respiration	Moderate	Moderate: In shallow areas, sediment oxygen demand will be of much greater importance than pelagic respiration. Pelagic respiration rates by viable phytoplankton can be reasonably well-estimated based on biomass. Respiration of dead OM is a function of OM abundance and quality, and water temperature. In deep channel areas of the Bay, where pelagic respiration will be more important than sediment oxygen demand, low DO does not appear to be a major issue, and thus constraining these rates are not among the highest priorities.	Low	Low
DO – Ambient concentration data				
High spatial resolution DO data in deep channel	High	Low: USGS research program provides an excellent long-term record along the Bay’s spine. This work needs to be continued.	Very High	Very High
High temporal resolution DO data in deep channel	High	Low: Limited DO data available from continuous sensors, in particular in South Bay and LSB. A network of sensors is installed in Suisun Bay and the Delta.	Very High	Very High
High temporal resolution data in shoals and shallow margin habitats	High	Low: Some special studies have been performed, and some on-going monitoring by POTWs and others (e.g., USGS studies in salt ponds). While these individual efforts have valuable information and some reports are available, a meta-analysis of this data has not been completed, and there is currently no overarching regional program.	Very High	Very High

9. Phytoplankton Community Composition

9.1. Introduction and Background

Phytoplankton community composition is highly relevant to the ecological status and function of the greater San Francisco Bay. The importance of community composition follows directly from the general conceptual model for phytoplankton biomass (Section 7), since it is the community at the level of strains, species, and functional types that in aggregate makes up the “phytoplankton biomass”. Selection pressure operates on species and has resulted in systematic phylogenetic differences between the red and green “superfamilies” (Quigg et al., 2003). These evolutionary differences in turn drive differences in nutrient assimilation, elemental composition, growth rates, and size (Irigoien et al., 2004; Irwin et al., 2006; Quigg et al., 2003). This has profound effects on ecosystem function. Phytoplankton photosynthesis drives the metazoan food webs of San Francisco Bay (Cloern et al., 2005; Jassby et al., 1993; Kimmerer et al., 2012). Changes in community composition can also alter energy flow from predominantly supporting higher trophic levels to a microbially-dominated, highly regenerating community which in turn leads to increased respiration and hypoxia (c.f. Cloern and Dufford 2005).

There are several potential ways to assess community composition (Figure 9.1). One of the simplest divisions is based on size. As a general rule, increased mean (or median) phytoplankton size is directly related to increased productivity, increased new production, and increased trophic transfer (Chisholm, 1991; Wilkerson et al., 2000). Phytoplankton size is particularly important for SFB because only phytoplankton $> \sim 5 \mu\text{m}$ equivalent spherical diameter (ESD) are available as a food source for copepods (Berggreen et al., 1988). Size-based classification is sometimes coupled with nutritional mode to separate the plankton into heterotrophs, mixotrophs, and photoautotrophs (Figure 9.2). While this is convenient conceptually, there is increasing evidence that many phytoplankton, including perhaps the majority of dinoflagellates, are facultative mixotrophs, blurring the line between these divisions (Burkholder et al., 2008).

Moving beyond size, a common approach taken when examining community composition is to group organisms into “phytoplankton functional types” (PFTs) such as diatoms, dinoflagellates, cryptophytes, etc., and/or based on trait-differentiated groupings such as high-nutrient, high light, etc. (Reynolds et al., 2002; Smayda et al., 2001). This level of analysis is often convenient for relating phytoplankton composition to ecological forcing functions (e.g. Cloern and Dufford, 2005). Continuing to a finer level of detail, community composition can also be analyzed at the species level, the basis for taxonomic classification. Finally, there is increased interest in the molecular and strain-level variability of phytoplankton. This becomes particularly important when the organism of interest is considered a harmful algal bloom (HAB) species (Burkholder et al., 2006), in part because many of the coastal HAB organisms do not fit well into classic paradigms as a function of PFT or size (Kudela et al., 2010).

For the purposes of this conceptual model, it is assumed that phytoplankton community composition can be adequately addressed using a combination of high-level metrics (size, trophic status, functional category) with the exception of HAB organisms that must be assessed at the species or strain level.

Size	Trophic Status	Functional Type	Genus/Species/Strain
Picoplankton (0.2-2.0 μm)	Heterotroph	Cyanophyte	>500 species,
		Chlorophyte	Unknown # of strains...
Nanoplankton (2-20 μm)	Mixotroph	Cryptophyte	
		Pyrrophyte	
Microplankton (20-100 μm)	Autotroph	Bacillariophyte	

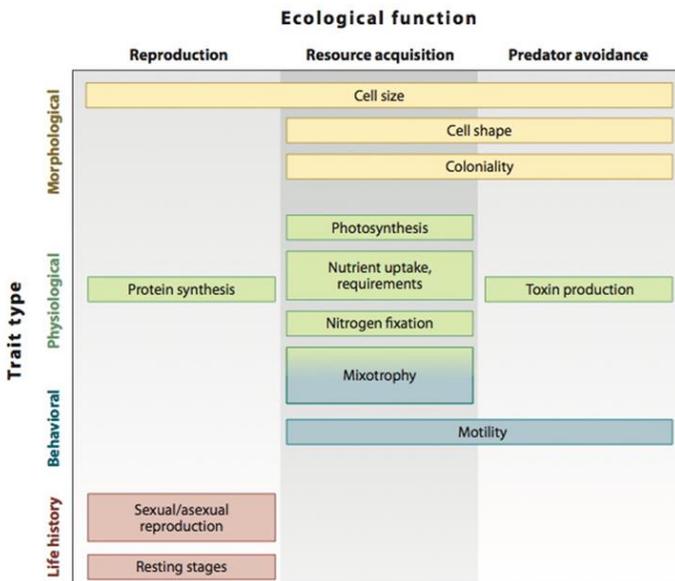

Figure 1
A typology of phytoplankton functional traits.

Figure 9.1. Examples of partitioning phytoplankton community structure. Classification can be based on phylogeny or on ecological function and traits, or some combination. Figure on right is from Litchman and Klausmeier (2008)

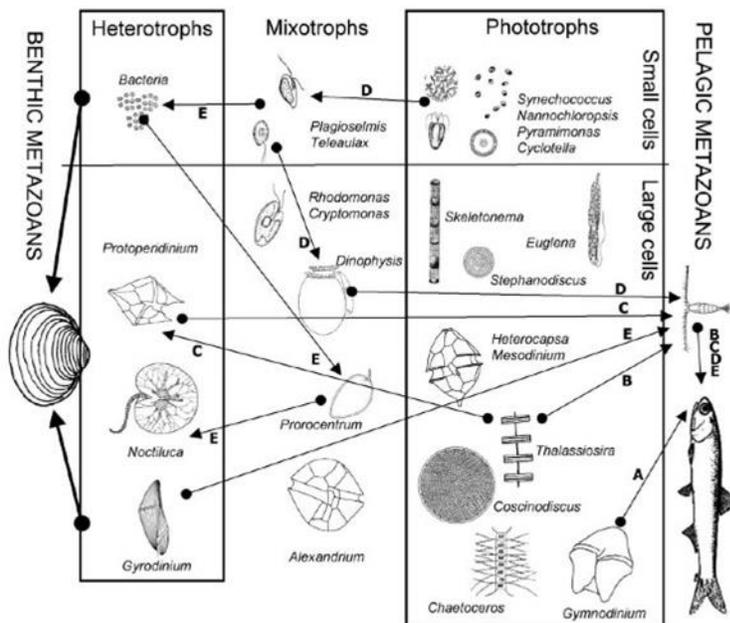

Fig. 7. Phytoplankton classification by size (small cells <15 μm) and nutritional mode that influence pathways through which energy and essential biochemicals are supplied to benthic metazoans (e.g. bivalve mollusks) and pelagic metazoans (e.g. copepods and anchovies). Trophic Pathway A is an efficient direct link from large-cell phototrophs to larval fishes. Other pathways route energy through mesozooplankton: (B) directly from large-cell phototrophs, (C) from heterotrophic algae feeding on large-cell phototrophs, or (D) from mixotrophs or (E) microheterotrophs deriving energy fixed by small-cell phototrophs and routed through the microbial loop. Some images redrawn from Tomas (1993, 1996)

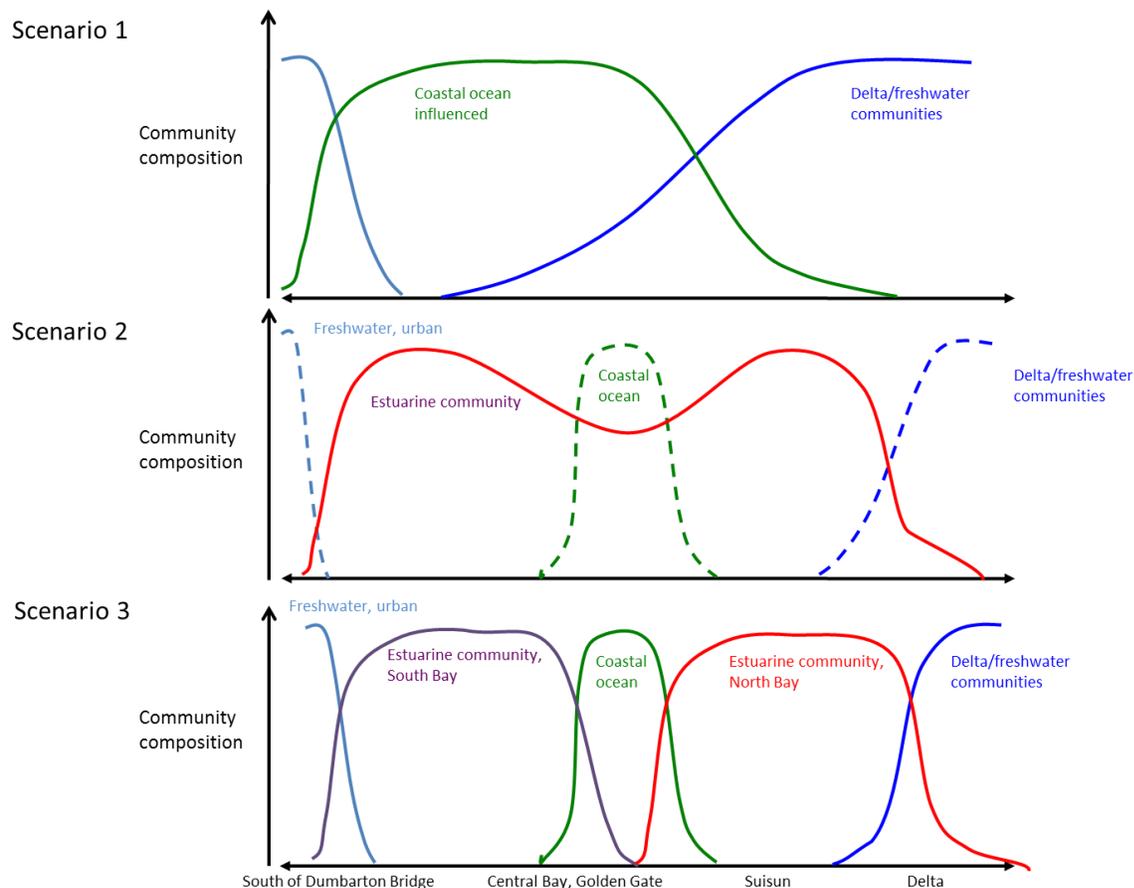

Figure 9.2. From Cloern and Dufford (2005).

2 9.2. General Conceptual Model

3 In order to use community composition as a metric for ecosystem status it is first necessary to
 4 define the spatial extent of the Bay included in the model. While the physical (geographical)
 5 boundaries are set, with the open ocean as one (external) boundary and the Sacramento/San
 6 Joaquin River and South Bay inputs as the other boundary, there are at least three potential
 7 models for describing San Francisco Bay (Figure 9.3):

- 8 1) the Bay is a mixture of the ocean and riverine end-members;
- 9 2) the Bay is a separate and distinct estuarine community, with mixing (source and sink) of
 10 oceanic and freshwater phytoplankton at the boundaries;
- 11 3) the Bay is composed of a series of basins (e.g. South Bay, Central Bay, etc.) with distinct
 12 community composition.

13
 14 Under scenario 1, community composition is largely driven by external factors that influence the
 15 oceanic and freshwater end-members. Scenario 2 assumes that the phytoplankton are dominated
 16 by a distinct estuarine community with transient “invasion” by oceanic and riverine inputs.
 17 Scenario 3 is predicated on distinct communities occupying each sub-basin, responding to
 18 location-specific forcing, such that Suisun is under fundamentally different control than South
 19 Bay (for example). These scenarios are not mutually exclusive, and could (for example) vary
 20 seasonally or interannually in response to river flow, residence time, and hydrologic
 21 modifications such as the restoration of the South Bay Salt Ponds.

22 **Figure 9.3** Conceptualization of 3 scenarios of spatial variability in phytoplankton assemblage

23 The community composition data necessary to evaluate these conceptual models do exist, and
 24 some distinct patterns have been identified between subembayments (e.g. South Bay and North
 25 Bay). However, the data are often aggregated to look at large-scale and long-term patterns
 26 (Cloern et al., 2005, 2010; Kimmerer, et al. 2012; Winder et al., 2010) unless there is an obvious
 27 end-member intrusion impacting the community composition (Cloern et al., 2005; Lehman et al.,
 28 2010). ***A first-order question that should be examined in more detail is whether a sub-basin
 29 analysis provides more or less information than the aggregate trends.*** For now, it is assumed
 30 that a simple model with oceanic, freshwater, and estuarine components is sufficient for
 31 development of a community composition conceptual model. This forms the basis for the
 32 conceptual model developed by the Phytoplankton Composition working group (Figure 9.4).
 33 Specific forcing functions are discussed in more detail below.

34 9.2.1. General trends

35 San Francisco Bay exhibits both a weak seasonal cycle and decadal trends in community
 36 composition that generally follow the trends identified for the Biomass conceptual model. Total
 37 chlorophyll in the Delta is typically high in summer (Jassby et al. 2002) while chlorophyll in
 38 south San Francisco Bay is the highest during (typically) several-week spring blooms and shorter
 39 fall blooms (Cloern et al. 2007). Like many nutrient enriched systems, San Francisco Bay is
 40 characterized by a bloom-bust cycle of larger cell species periodically dominating a more stable
 41 community of small cell species (Cloern and Dufford, 2005; Wilkerson et al., 2006; Kimmerer et
 42 al. 2012). These large-cell blooms are superimposed on a picoplankton background population
 43 composed primarily of cyanobacteria and small eukaryotes (*Nannochloropsis* sp., *Teleaulax*
 44 *amphioxeia*, *Plagioselmis prolonga*) that are found across a wide range of salinities and seasonal
 45 conditions (Ning et al., 2000; Cloern and Dufford, 2005).

46
 47 San Francisco Bay contains over 500 phytoplankton taxa. Approximately 10-20 phytoplankton
 48 species account for between 77% and >90% of the total biomass (Cloern and Dufford, 2005).
 49 Diatoms (Bacillariophyta) dominate, accounting for ~81%; dinoflagellates and cryptophytes
 50 (Pyrrophyta and Cryptophyta) made up 11% and 5% respectively (Cloern and Dufford, 2005).
 51 Picoplankton make up <15% of the Bay biomass (<2% during blooms; Ning et al., 2000; Cloern
 52 and Dufford, 2005).

53
 54 At a decadal scale several shifts in community composition are evident. Some phytoplankton
 55 taxa (*Prorocentrum aporum*, *Coscinodiscus marginatus*, *Protoperidinium depressum*, *Eucampia*
 56 *zodiacus*) have not been seen since 1996 while others (*Protoperidinium bipes*, *Pseudo-nitzschia*
 57 *delicatissima*, *Scrippsiella trochoidea*, *Thalassiosira nodulolineata*) have appeared. In addition,
 58 the benthic diatom *Entomoneis* sp. similarly was a minor component of the community from
 59 1992-2001, comprising 0.1% of the biomass and identified in about 20% of all samples (Cloern
 60 and Dufford 2005, as reported in Kimmerer 2012). Kimmerer et al 2012 suggest that, although it
 61 is not clear how much it contributes to productivity in the water column, its sudden appearance at
 62 a fairly substantial portion of phytoplankton biomass could be an indication of change in the
 63 system.

64
 65 Several studies have argued that there is also evidence for abrupt shifts in community
 66 composition from the longer time-series. Total biomass decreased substantially in 1986 (Figure
 67 9.5) as noted by many others (e.g. Lehman, 2000; Glibert, 2010; Kimmerer, 2012). Lehman
 68 (2000) described a decrease in diatom abundance from 1975-1989 and hypothesized a

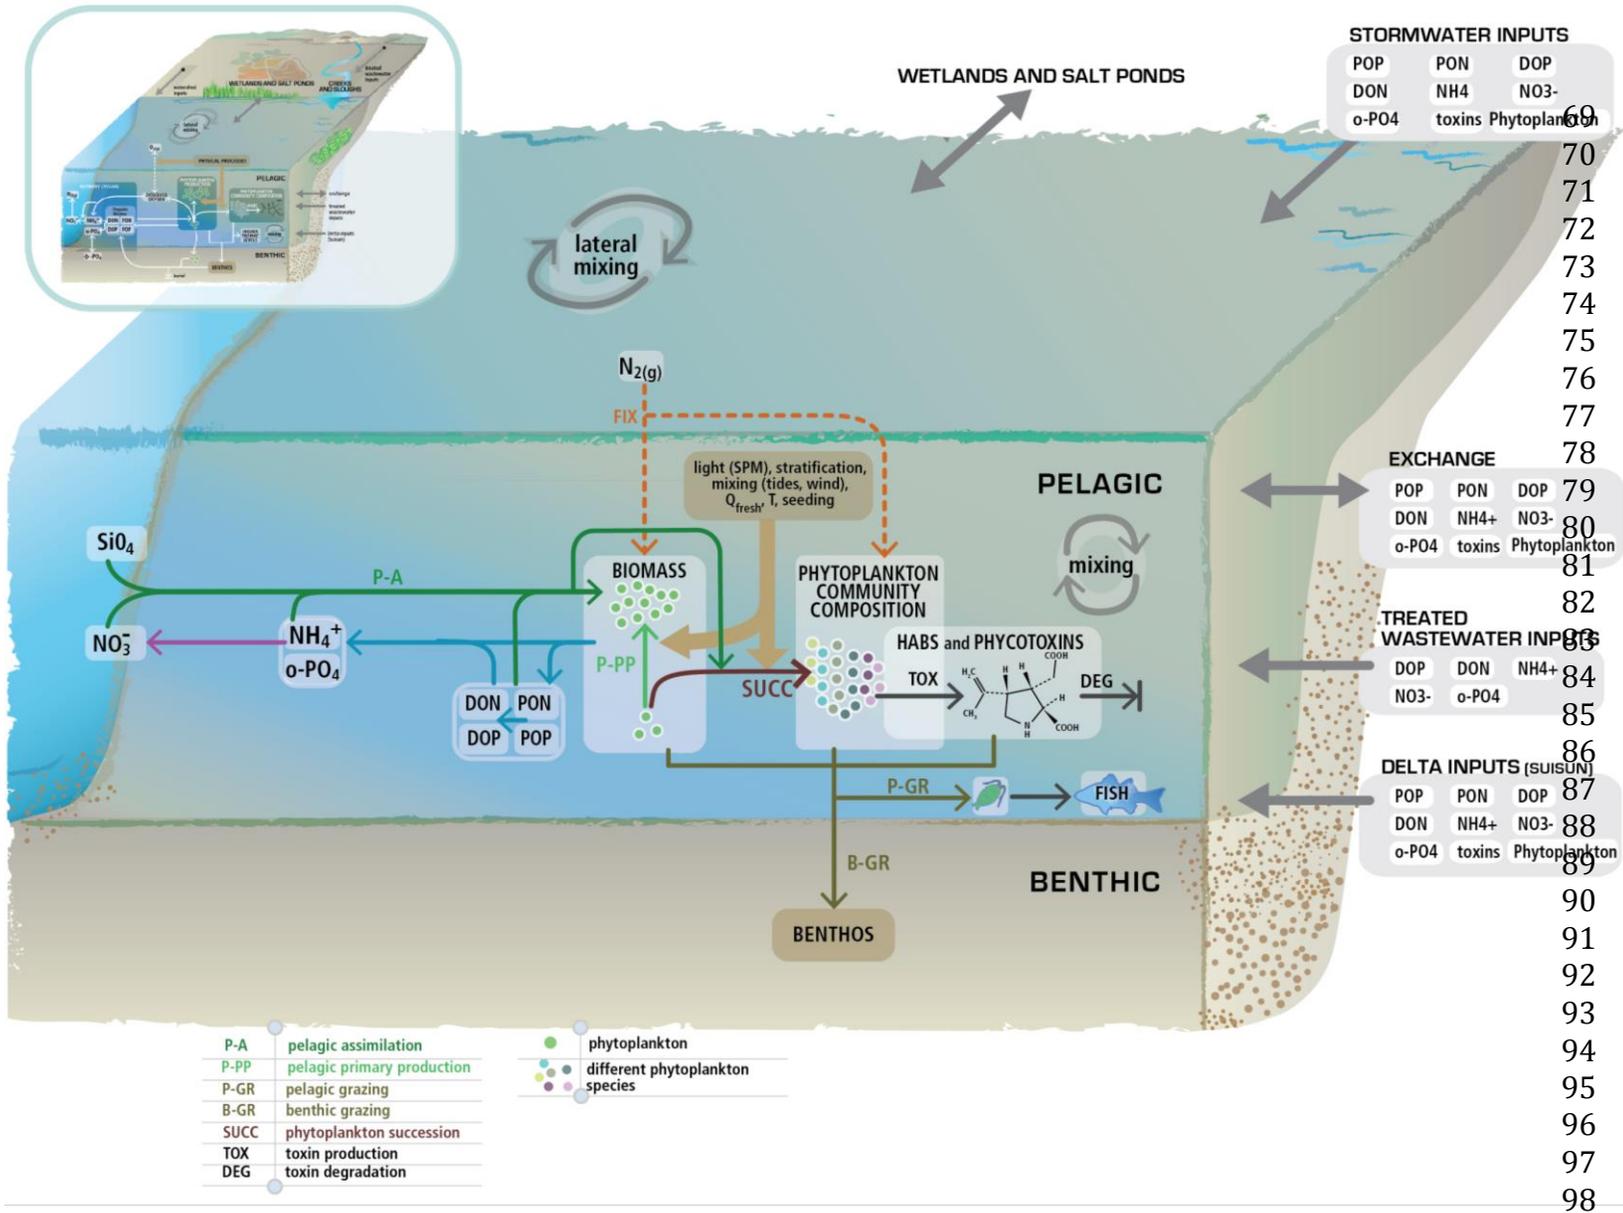

Figure 9.4 Phytoplankton community composition conceptual model

mechanistic link to the 1977 climate regime shift and El Niño, attributing the change to community shifts in high stream flow, wet years (low light, high turbulence, favoring pennate diatoms) and dry years (long residence time, favoring cryptophytes and flagellates). Using the same data, Glibert (2010) described a decline in diatoms, and increase in cryptophytes, chlorophytes, and cyanobacteria after 1986, coincident with an abrupt decline in biomass. These shifts were attributed to changes in nutrient composition and stoichiometry. The proposed phytoplankton community composition changes and hypothesized mechanisms for those trends are based on long-term monitoring data collected by DWR Environmental Monitoring Program (DWR-EMP) at multiple stations throughout Suisun Bay and the Delta from 1975-present. Considering the multi-decade and multi-station record that the EMP dataset offers and the considerable attention the nutrient-focused hypotheses have received over the past several years, the dataset has received relatively limited systematic analysis. That data is currently being reanalyzed to evaluate trends in phytoplankton assemblage and their correspondence with changes in physical, chemical, and biological drivers (Malkassian et al., in preparation; Cloern et al., in preparation).

data on chlorophyll and Secchi depth and using PAR estimated as in Fig. 7; *line* from 1975 to 1988 and *upper line* to 2004 use the mean value of Ψ determined from data of Cole and Cloern (1984), and the *lower line* and that after 2004 use the mean value of Ψ from our data for 2006 and 2007 combined (Parker et al. 2012). *Error bars* in inset give 95% confidence limits

Figure 9.5. From Kimmerer et al. 2012.

9.2.2. Bottom-Up Controls

Basin-scale oscillations

There is ample evidence that San Francisco Bay community composition responds more or less uniformly (i.e. across the estuary) to both basin-scale and climate-scale trends. As described above, Lehman (2000) identified stream flow as an important indicator of community composition. Low light, turbulence, and short residence times were associated with pennate and single-celled centric diatoms. Cryptophytes and flagellates were associated with “critically dry” periods of increased residence time, light intensity, and water temperature. Cloern et al. (1983)

similarly argued that river flow can regulate community composition by selectively retaining particles (neritic diatoms) near productive shallow bays under low flow, but promotes loss of seed populations during both high and very low flow (drought) because of changes in circulation and the position of the suspended particulate maximum. Within the Delta, low streamflow has also been associated with enhanced *Microcystis* blooms (Lehman et al. 2010), attributed to reduced turbulence and prolonged retention. Basin-scale oscillations also profoundly impact the coastal plankton assemblage. Since the oceanic end-member can serve as a seed population for the estuary, San Francisco Bay is also indirectly influenced by El Niño, the Pacific Decadal Oscillation, the North Pacific Gyre Oscillation, and other mesoscale changes (Cloern et al. 2005, 2010).

While these observed patterns suggest that community composition is regulated to some degree by bottom up controls (and therefore can be to some extent predicted; Cloern et al. 2011), a larger analysis of coastal estuaries suggests that each estuarine system is unique and responds to some combination of annual forcing, regime shifts and climate trends, and the residual (or stochastic) component (Cloern and Jassby 2008, 2010), suggesting that the low-frequency basin- or climate-scale patterns must be interpreted with caution.

Temperature

Phytoplankton species composition is strongly controlled by temperature, since each species and strain exhibits an optimal growth response to a specific temperature range (Eppley, 1972). In addition to this species-level response, PFTs also exhibit some generalized temperature optima. Diatoms generally prefer colder temperatures, and are associated with cool periods both annually and interannually in San Francisco Bay (Lehman 2000). Diatoms also exhibit optimal nitrate assimilation at lower temperatures and also reduce nitrate under cold temperatures as an electron sink to maintain optimal energy balance (Lomas and Glibert, 1999). As temperature rises some PFTs respond positively. *Microcystis* and other cyanobacteria appear to be favored by warmer conditions (Lehman et al. 2010; Paerl and Huisman 2008, 2009). Less is known about the temperature-specific response for other PFTs (flagellates, cryptophytes, dinoflagellates) but community composition generally shifts towards more of these groups coincident with increased temperature (e.g. Lehman 2000). Because temperature covaries with several other environmental factors including flow, nutrients, stratification, etc. it is difficult to determine what the impact of rising temperatures would be. ***Experimental manipulations of temperature or temperature and CO₂ would provide useful information about potential shifts in phytoplankton community composition for San Francisco Bay.***

Irradiance

San Francisco Bay productivity is generally considered to be light-limited, and is well described by a “light utilization” productivity model that uses chlorophyll, PAR, and light attenuation (Cole and Cloern 1984). Parker et al. (2012) recently re-evaluated this approach and concluded that while the general model still works, there is considerable variability in the calibration coefficient, possibly due to a shift in the carbon:chlorophyll ratio of the phytoplankton assemblage. Parker et al. (2012) noted that concurrent evaluation of the phytoplankton community composition from 2006-2007 (during their study period) by Lidström (2009) are consistent with PFT-specific shifts in both the C:CHL ratio and P_m^B (light-saturated productivity). The authors conclude that seasonal, interannual, and long-term shifts in community composition from diatoms to flagellates may be linked to changes in the modeled

productivity. It should be noted, however, that the analytical techniques for measuring production rate differed between Cole and Cloer (1984) and Parker et al. (2012), and that some or all of the apparent difference in the calibration coefficients could be the result of these analytical differences. ***In either case, these observations suggest that, if bulk productivity estimates are to be used as an index of ecosystem health, the light-utilization model should be evaluated for its sensitivity to PFT-specific response functions and potentially other factors (e.g., temperature, light levels).***

Mixing/Turbulence

As summarized in Cloern and Dufford (2005), mixing and turbulence become important for phytoplankton community composition primarily through alleviation of light limitation due to runoff-induced salinity stratification, increased light penetration (decreased turbidity), and separation of phytoplankton and benthic grazers. Classically, it is also assumed that diatoms respond positively to turbulence while ephemeral dinoflagellate blooms respond to “windows of opportunity” when environmental conditions, such as reduced grazing, enhanced stratification, and warm conditions, allow these organisms to respond rapidly (e.g. Stoecker et al. 2008; Cloern et al. 2005). As noted above, there is also evidence for shifts between diatoms and flagellates/cyanobacteria linked to changes in retention and mixing (e.g. Lehman et al. 2010). It should be noted, however, that Cloern and Dufford (2005) noted niche-separation of a small number of marine and riverine species, but also noted that a large fraction of the phytoplankton community were “generalists”, doing equally well across a broad range of conditions (Figure 9.6). This suggests that canonical descriptions of PFT response to environmental conditions such as mixing are potentially useful but should not be over-interpreted.

9.2.3 Physiological Factors: Nutrients

San Francisco Bay is generally considered to be nutrient-replete. This has been corroborated several times (e.g. Mallin et al. 1993), and is supported by the lack of response between productivity and river flow (Kimmerer 2005; Kimmerer et al. 2012). While this perspective is useful for examining forcing of phytoplankton biomass, this general nutrient-replete condition can mask considerable variability at the species or PFT level of community composition. It is generally assumed that dinoflagellates exhibit low affinity for N-substrates relative to diatoms (Smayda, 1997, 2000) and that nutrient uptake kinetics scale as a function of cell size (larger size equals lower affinity; e.g. Irwin et al., 2006; Litchman et al., 2007), although Collos et al. (2005) argue that at high-nutrient concentrations, such as in upwelling systems and estuaries, multiphasic kinetics may be quite common among a diverse array of phytoplankton species. Kudela et al. (2010) summarized the measured kinetics responses for N-uptake in several algal groups, focusing on harmful algal bloom species from upwelling systems (Figure 9.7). While the general canonical pattern of lower K_s for diatoms and higher for dinoflagellates, there is considerable overlap and the number of recorded species is quite low. It is particularly striking that there appear to be no phytoplankton strains isolated from San Francisco Bay in the National Center for Marine Algae (NCMA). Again, this highlights the need to be cautious when applying canonical patterns for nutrient utilization derived from global data sets.

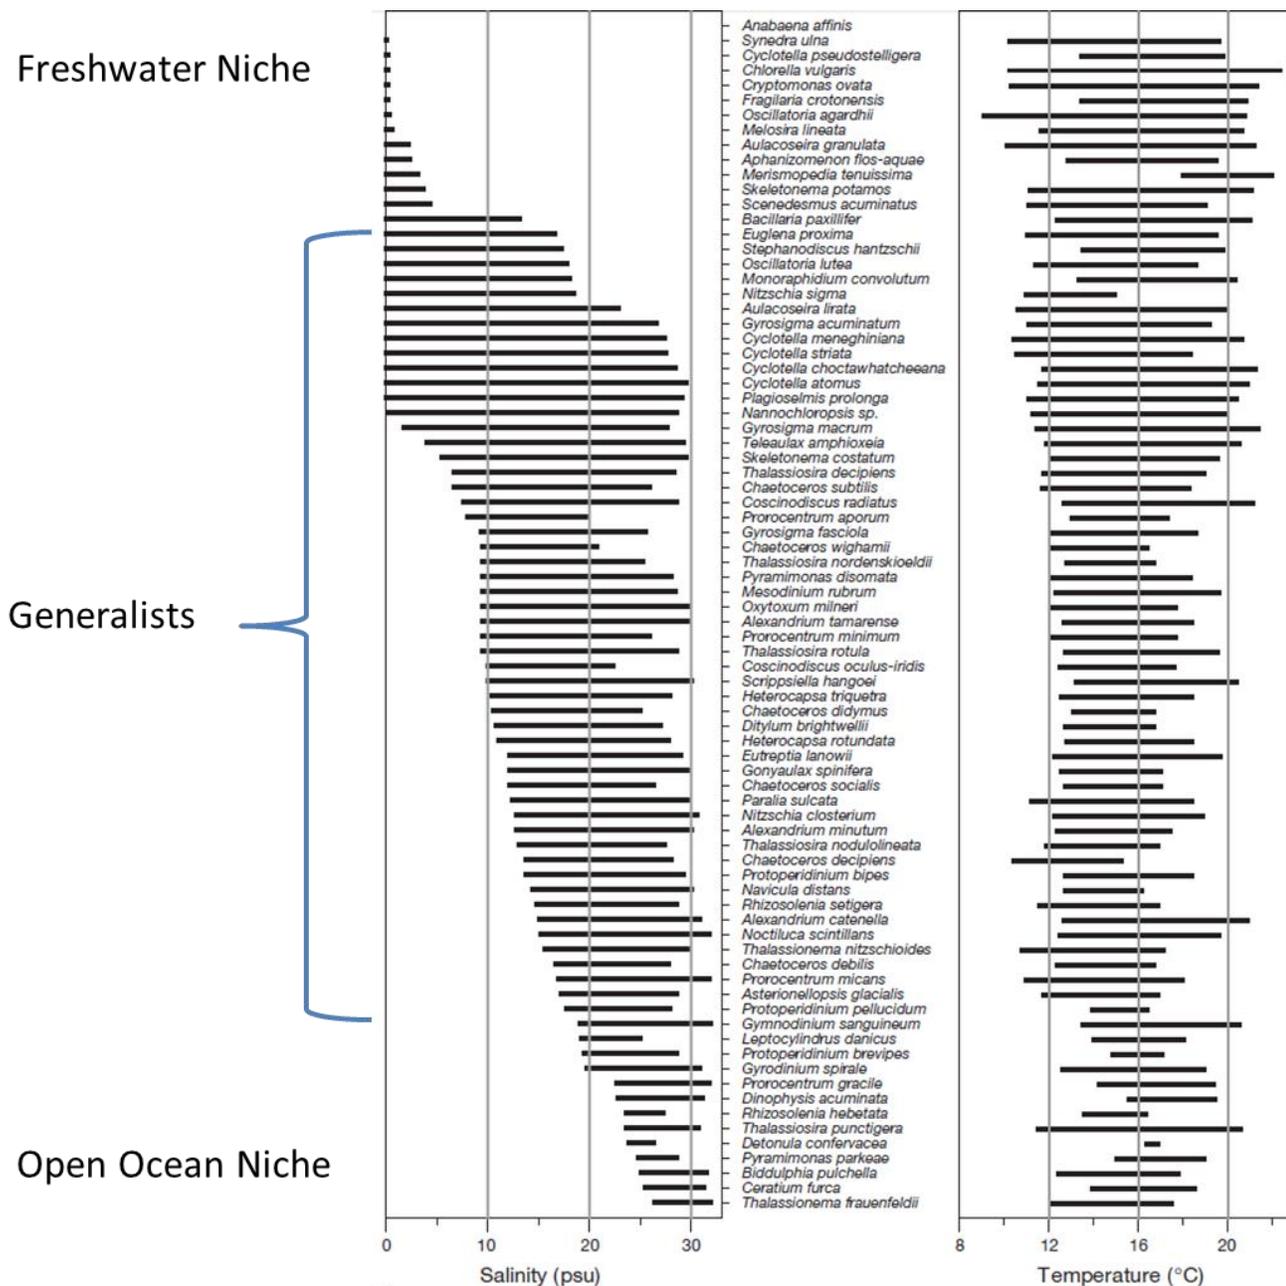

Fig. 6. Salinity and temperature ranges of selected phytoplankton species. Horizontal bars span 10th and 90th percentile salinity and temperature at which each species occurred within 599 samples distributed along salinity gradients of San Francisco Bay (Fig. 2B,C)

Figure 9.6 From Cloern and Dufford 2005.

Despite the nutrient-replete status of San Francisco Bay, several groups have proposed direct or indirect nutrient effects on phytoplankton species composition. While not specific to San Francisco Bay, vitamin B1, B7, and B12 have been implicated in controlling phytoplankton species composition in estuarine (Tang et al. 2010), coastal, and HNLC waters (Koch et al. 2011). The response is greatest in large (>2 μm ESD) cells, and in particular for dinoflagellates. There has been no published evaluation of vitamin B effects in San Francisco Bay.

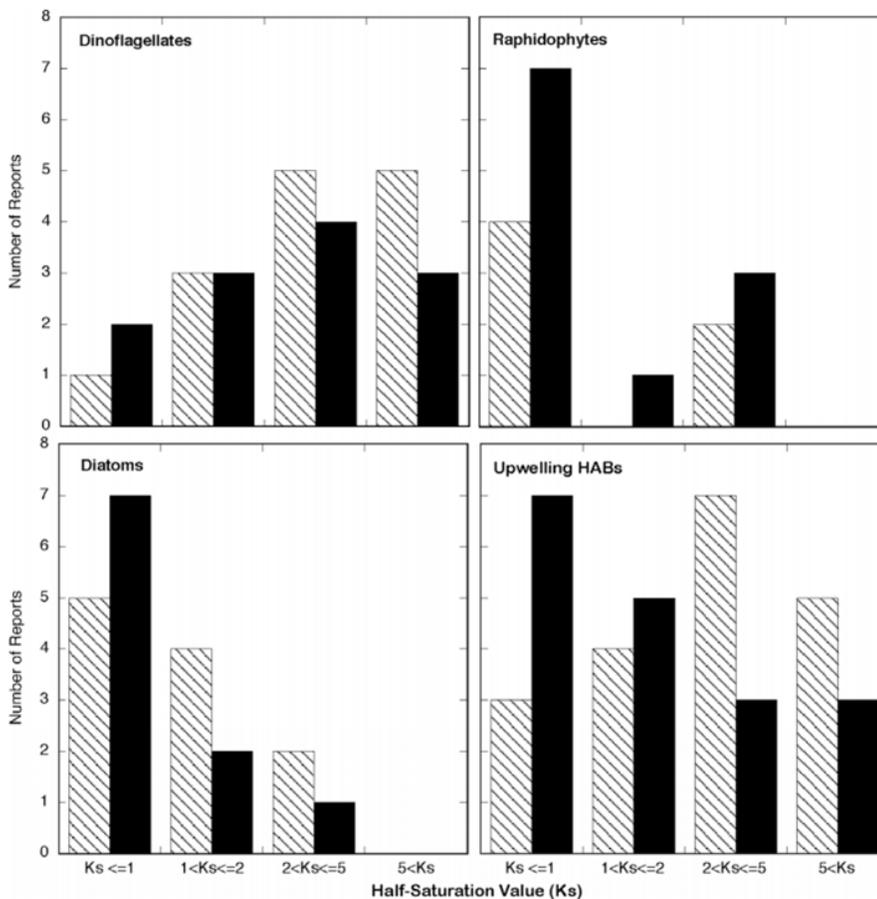

Fig. 1. Kinetics values for nitrate (solid bars) and ammonium (hashed bars) were binned based on the half-saturation (K_s) value using the same categories as Smayda (2000) for Dinoflagellates, Raphidophytes, Diatoms, and Upwelling HABs. Data were obtained from Smayda (1997, 2000), Kudela and Cochlan (2000) and Table 2. Smayda (2000) reported a general trend of low K_s values for diatoms and high K_s values for dinoflagellates, as is seen here. Note that for the Upwelling HAB group, nitrate K_s values more closely approximate the Diatom grouping, while for ammonium the pattern is similar to the Dinoflagellate grouping.

Figure 9.7 A summary of nitrogen kinetics responses reported in the literature for major algal groups, as reported in Kudela et al. 2010.

Other nutrient interactions have also been poorly defined for the estuary. For example, free copper has a strong, PFT-specific response on algae (Brand et al. 1986; Sunda and Huntsman, 1995), and elevated copper concentrations will become toxic to phytoplankton (Brand et al. 1986; Sunda et al. 1987). Brand et al. (1986) demonstrated that neritic diatoms are least sensitive, while cyanobacteria and dinoflagellates were most sensitive to copper. Copepods such as *Acartia tonsa* also exhibit more sensitivity to copper than do diatoms (Sunda et al. 1987), suggesting that copper could subtly impact both the productivity and loss terms, leading to shifts in community composition. Buck et al. (2007) recently reviewed copper trends in San Francisco Bay. They concluded that copper concentrations have declined significantly since 1993, with the North Bay declining 17% and South Bay declining 29-44%; no data were available prior to 1993, but copper concentrations were presumably elevated due to anthropogenic-driven inputs. As copper concentrations dropped, it is at least possible that inhibition of flagellates, cyanobacteria, and zooplankton has been alleviated, leading to increased competition with diatoms.

Two other nutrient relationships have been proposed as regulators of both total biomass and community composition. Dugdale et al. (2007) have proposed that elevated ammonium

concentrations from wastewater discharge is suppressing diatom productivity, while Glibert (2010) and Glibert et al. (2011) have argued that N:P ratios are indirectly controlling community composition. Dugdale et al. (2007) proposed a modified conceptual model of bloom initiation for the North Bay as follows: (1) In spring, increased irradiance and increased river flow (diluted ammonium) promote diatom growth, initially fueled by ammonium; (2) if the ammonium is drawn down to $< \sim 4 \mu\text{M}$, nitrate uptake is initiated; (3) if conditions remain suitable (increased irradiance, low ammonium, retention) a bloom develops. This hypothesis was developed primarily with direct field observations, but there are multiple ongoing projects evaluating several aspects with both field and laboratory experiments.

Elevated external NH_4^+ levels are toxic to photosynthetic organisms because the build-up of a charged molecule on one side of cell membranes results in the establishment of a high cross-membrane potential. While NH_4^+ is mostly transported into the cell via active, ATP-dependent transport (as are nearly all charged molecules) it can also passively diffuse into the cell via channels (facilitated diffusion). When external concentrations are elevated, these channels will allow a large influx of NH_4^+ as a consequence of the cross-membrane potential. The influx initiates active pumping to rid the cytosol of NH_4^+ and to prevent an intracellular pH disturbance (Bligny et al. 1997). However, the efflux of NH_4^+ maintains the cross-membrane gradient, thereby the channel influx, and necessitates continued, active efflux pumping at a great energetic cost to the cell, culminating in the cessation of growth and sometimes death of the organism (Britto et al. 2001). Some plant species have adapted to high external NH_4^+ concentrations by preventing the establishment of a cross-membrane potential, eliminating the futile NH_4^+ cycling and high respiratory cost of efflux pumping (Britto et al. 2001). Because the susceptibility to the establishment of a cross-membrane potential varies from organism to organism, susceptibility to NH_4^+ toxicity also varies greatly. For example, susceptibility to NH_4^+ toxicity is known to vary by orders of magnitude in aquatic plant species and in unicellular algae. Freshwater unicellular algae such as *Chlorella vulgaris* isolated from wastewater settling ponds can tolerate NH_4^+ concentrations up to 3 mmol/L (Berg et al. unpublished data, Perez-Garcia et al. 2011). Among marine species, diatoms also tolerate NH_4^+ concentrations in the mmol/L range (Antia et al. 1975, Lomas 2004, Hildebrand 2005, Pahl et al. 2012). In contrast, marine phytoplankton species with a large variety of NH_4^+ transport proteins encoded in their genomes, and with low half saturation constants for NH_4^+ uptake, can be susceptible to toxicity at orders of magnitude lower NH_4^+ . [update with recent papers]

While NH_4^+ toxicity at the physiological level has a response time on the order of the cell division time, it can culminate in a much greater, community-level response that builds-up over longer time scales. The community-level response is manifested through a change in phytoplankton community composition to species that are more tolerant to high NH_4^+ concentrations and to primary and secondary consumers that can feed on those species (Glibert et al. 2011). This can also lead to proliferation of Harmful Algal Blooms since many of the noxious and toxic species found in the California Current show a preference for reduced N compounds such as NH_4^+ (Kudela et al. 2010). It is this community-level response that is important for ecosystem function. But, the latter cannot occur if the former, physiological effect is not present.

To date, investigators have used a lack of chlorophyll *a* (Chl *a*) biomass or a lack of nitrate (NO_3^-) uptake as evidence of NH_4^+ stress on the phytoplankton community in Suisun Bay,

(Dugdale et al. 2007). However, both changes in Chl *a* and NO_3^- uptake may be influenced by a multitude of factors including irradiance, community composition, and season, making it difficult to use these indirect measures as evidence of NH_4^+ inhibition (e.g. Kimmerer et al. 2012). In addition, although NH_4^+ inhibition of NO_3^- uptake by phytoplankton has been widely demonstrated, there is also considerable evidence showing that phytoplankton, across the range of taxa (including diatoms), grow at comparable rates on both NH_4^+ and NO_3^- (SFEI, 2014b). Lastly, while the ammonium-inhibition hypothesis has primarily been used to explain observations from the North Bay, it remains unclear why the similar NH_4^+ concentrations found in South Bay and Lower South Bay do not inhibit blooms there. ***A direct comparison between the North and South Bay would likely help to determine whether ammonium concentrations are directly inhibiting diatoms, are indirectly shifting the community towards organisms with lower K_s and higher maximal uptake rates (Figure 9.7), or are covarying or interacting with some other variable such as irradiance, or size-selective grazing (Section 9.2.7).***

A complementary hypothesis linking nutrients and community composition has been proposed based on the stoichiometry of N and P (Glibert 2010; Glibert et al. 2011). Glibert (2010) proposed that decadal changes in phytoplankton community composition altered the food web of San Francisco Bay by favoring varying groups of organisms. Prior to 1982, the community was dominated by a nitrate-driven diatom assemblage (Figures 9.5). With the increasing ammonium loads from wastewater treatment plants the community shifted towards flagellates. As the N:P ratio continued to increase, cyanobacteria were eventually favored. This analysis is based largely on a statistical metric called cumulative sum analysis, and has been criticized by others as flawed (Cloern and Jassby et al. 2012; but also see Lancelot et al. 2012). Glibert et al. (2011) elaborated on this argument by proposing a conceptual model for how estuarine systems respond to changes in N:P ratios. They argue that even though N and P are in excess for phytoplankton growth, the ratio impacts higher trophic levels (and thus the ecological stoichiometry of the system). The authors argue that decadal changes in DIN:DIP ratios correlate with declines in diatoms and chlorophytes, and increases in dinoflagellates, because diatoms and dinoflagellates also exhibit different intrinsic N:P ratios. There are two potential issues with this argument. First, so long as N and P are saturating, the ratio should have no direct impact on species composition, other than by selecting for the organism with optimal growth. Second, Chlorophytes have a higher N:P ratio than either diatoms or dinoflagellates, suggesting that chlorophytes should be dominant under these conditions (Figure 9.8). The authors argue that this is accounted for due to the stoichiometric adjustments and feedback loops that occur between primary producers and higher consumers, and that both the Pelagic Organism Decline and the invasion of organisms such as *Potamocorbula* were triggered by bottom-up control through nutrient stoichiometry. These assertions are controversial, but the conclusion, that phytoplankton community composition is an indicator of ecosystem “health”, is nonetheless consistent with other hypotheses.

9.2.4 Top-Down controls

Grazers: *Potamocorbula*

While Glibert et al. (2011) conclude that the invasion of *Potamocorbula* was triggered by gradual shifts in ecosystem nutrient stoichiometry, others have pointed to the invasion as coincident with the rapid decline of diatoms in San Francisco Bay (Figure 9.5). The long-term shift in phytoplankton from diatoms to flagellates and cyanobacteria and the timing of declines in apparent silica uptake in Suisun Bay (Kimmerer 2005) and in abundance of anchovies in the Low Salinity Zone (Kimmerer 2006) are consistent with an influence of grazing by the clam

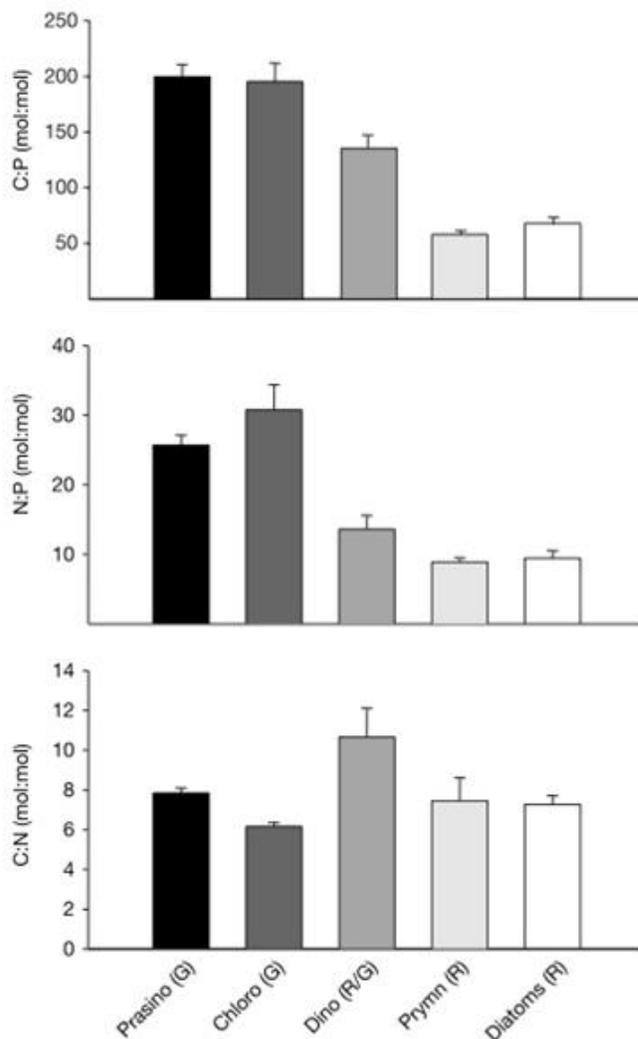

Figure 1 C:N:P composition varies between phyla and superfamilies. Phytoplankton C:P, N:P and C:N (mol:mol) ratios are grouped phylogenetically—Prasinophyceae (Prasino) and Chlorophyceae (Chloro) are members of the green (G) plastid superfamily whereas Dinophyceae (Dino), Prymnesiophyceae (Prymn) and Bacillariophyceae (Diatoms) are members of the red (R) plastid superfamily. Error bars indicate standard errors.

Figure 9.8 Intrinsic C:P, N:P, and C:N ratios for major phytoplankton groupings. From Quigg et al. 2003

shift in phytoplankton from diatoms to flagellates and cyanobacteria and the timing of declines in apparent silica uptake in Suisun Bay (Kimmerer 2005) and in abundance of anchovies in the Low Salinity Zone (Kimmerer 2006) are consistent with an influence of grazing by the clam

Potamocorbula amurensis.

Potamocorbula exhibits lower feeding rates on bacteria (typically $<1 \mu\text{m}$) than on phytoplankton (Werner and Hollibaugh 1993). Thus, the phytoplankton biomass available to many grazers is considerably lower than indicated by bulk chlorophyll values. The combination of low productivity and a high proportion of small cells offers poor support to the food web of the upper estuary, likely resulting in shifts in diet and food limitation and contributing to the poor condition of some fish species (Feyrer et al. 2003; Bennett 2005) and the general pattern of decline across species and trophic levels (Kimmerer et al., 2012). This direct modulation of phytoplankton community composition by an introduced benthic predator presents a conceptual model of trophic interactions that is strikingly different from the bottom-up, stoichiometrically driven scenario described above. As detailed below, *Potamocorbula* grazing could also have other indirect impacts on community composition in addition to the size-selective removal of PFTs.

Other grazers

Winder and Jassby (2011) document both abrupt and gradual changes in zooplankton composition, abundance, and occurrence in San Francisco Bay. Major shifts coincide with the extended drought from 1987-1994 and the invasion by *Potamocorbula*. The calanoid copepod *Limnithona tetraspina* increased rapidly in the 1990s to become the numerically abundant zooplankton, presumably due to predator avoidance, low respiration, and a dietary preference for bacteria and mixotrophic ciliates, which were in turn stimulated by the shift from diatoms to flagellates and cyanobacteria (Figure 9.9). Rollwagen-Bollens et al. (2011) also noted the importance of microzooplankton as both a consumer of small autotrophs and a link to metazoans. Microzooplankton grazing is classically assumed to differentially impact small autotrophs, suggesting that microzooplankton grazing has increased in importance as a biomass sink with the decrease in diatom abundance. This could also lead to more stochastic bloom events of other organisms as proposed by Irigoien et al. (2005) and Stoecker et al. (2008), who argued that blooms occur when a particular species of PFT exploits a “loophole” in grazing pressure. This is also consistent with Greene et al. (2011) who reported high mortality rates of microzooplankton due to *Potamocorbula* grazing, thus potentially disrupting trophic transfer and stimulating more nano- and picoplankton by removing grazing pressure on these smaller organisms, even though the nano- and picoplankton are not efficiently grazed by *Potamocorbula* directly. This highlights the potential complex interactions between top-down and bottom effects in relation to the use of phytoplankton community composition as an index of ecosystem health.

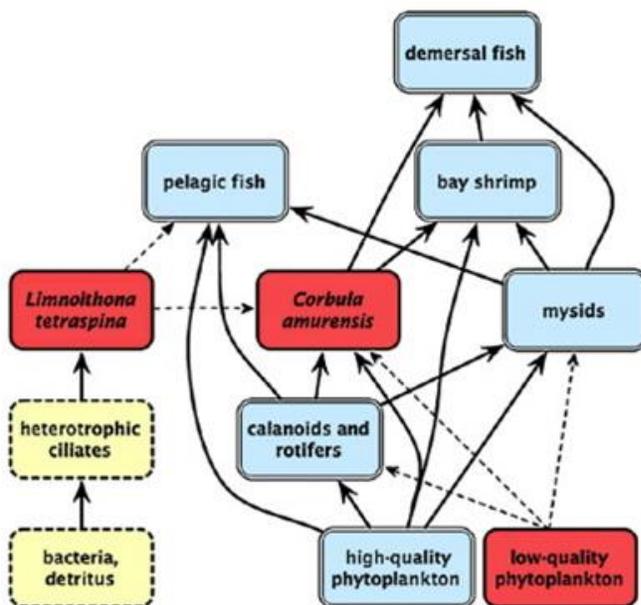

Fig. 11 Trophic interactions of the pelagic food web in the upper San Francisco Estuary at the “suisun” subregion. Arrows indicate major energy flow based on gut content analysis or literature data. Solid lines represent strong and dashed lines weak trophic interactions. Box colors reflect long-term taxa trends: red are increasing taxa, blue decreasing taxa, and yellow taxa of unknown trends over the last four decades. Phytoplankton is separated into groups of high (group I; e.g., diatoms) and low (group II; e.g., cyanobacteria, chlorophytes) food quality and/or availability for herbivorous organisms. Biomass trends

Figure 9.9. Shifts in phytoplankton community composition are associated with shifts in grazing pressure. Source: Winder and Jassby 2011

9.2.5 Interactive Effects

Several of the previous sections allude to interactive effects between multiple drivers. For example, water flow in the Northern Bay regulates turbidity, water clarity, residence time, nutrient concentrations and ratios, and benthic-pelagic coupling. Trace metals and vitamins can have subtle influences on phytoplankton community composition, leading to shifts in trophic efficiency as well as shifts in dominant phytoplankton assemblages. The ecological stoichiometry hypothesis proposed by Glibert et al. (2011) assumes a series of interactive effects, ultimately stemming from changes in nutrient forms and ratios. A conceptual model (or models) of phytoplankton community composition must be flexible enough to allow for these interactive effects, and for differential responses spatially and temporally.

A specific example of the potential for interactive effects focuses on light-nutrient-photosynthesis interactions. There is clear evidence for light limitation of phytoplankton productivity in San Francisco Bay, while it is generally accepted that macronutrients are not limiting to productivity. The interactive effects of these processes are rarely examined, but can have a direct impact on phytoplankton community composition. After carbon assimilation, nitrogen metabolism is the second largest sink for photosynthetic reductant (ATP, NADPH) in most photo-autotrophs. Under light limitation (e.g. San Francisco Bay), it is often assumed that ammonium will be a preferred N source compared to nitrate because of the large differential in energy required, since nitrate must be reduced first to nitrite and then to ammonium before being metabolized in the cell. As noted above, diatoms will also reduce nitrate as an electron sink under rapidly changing light environments (such as occurs in a turbulent estuary). Much of this N is subsequently effluxed as ammonium. This could conceivably lead to a scenario where (1) diatoms are initially light-limited in a heterogenous, rapidly mixing environment, leading to (2) efflux of ammonium, nitrite, and DON as an electron sink; as the water column stabilizes, (3) physiological energy balance is restored, ammonium efflux stops, and N is assimilated to produce more biomass, leading to (4) depletion of ammonium followed by depletion of nitrate as a diatom bloom develops. While there is no direct evidence for this occurring in San Francisco Bay, Kimmerer et al. (2012) noted that productivity was positively correlated to light availability and negatively correlated with ammonium concentrations, while Parker et al. (2012) noted a shift towards lower C:N ratios, both of which are consistent with this scenario.

These potentially complex interactions are not limited to diatoms. A previous field study of a “red tide” of the dinoflagellate *Lingulodinium polyedrum* in Southern California demonstrated that, to maintain the bloom, the dinoflagellates had to be using urea, possibly in some combination with other nitrogen sources (Kudela and Cochlan, 2000). This observation would not be evident from direct measurements of nutrients, photosynthetic carbon fixation, or ¹⁵N-labeled nitrogen uptake, but could be inferred by comparing the elemental ratio of the algae with nutrient kinetics curves, nutrient versus irradiance uptake curves, and photosynthesis versus irradiance curves (Figure 9.12). In contrast to typical paradigms, the bloom could also maintain balanced growth at very low or very high irradiances using only nitrate, while the classic Michaelis-Menten kinetics would suggest the bloom was using NO₃>NH₄>Urea. While these complex interactions are presumably common in dynamic environments, simultaneous evaluation of these interactive effects is rarely performed. Since every species (and probably strain) of algae has a potentially unique combination of light, nutrient, and carbon assimilation capabilities there is plenty of opportunity for seemingly stochastic selection of species or PFTs in the real world.

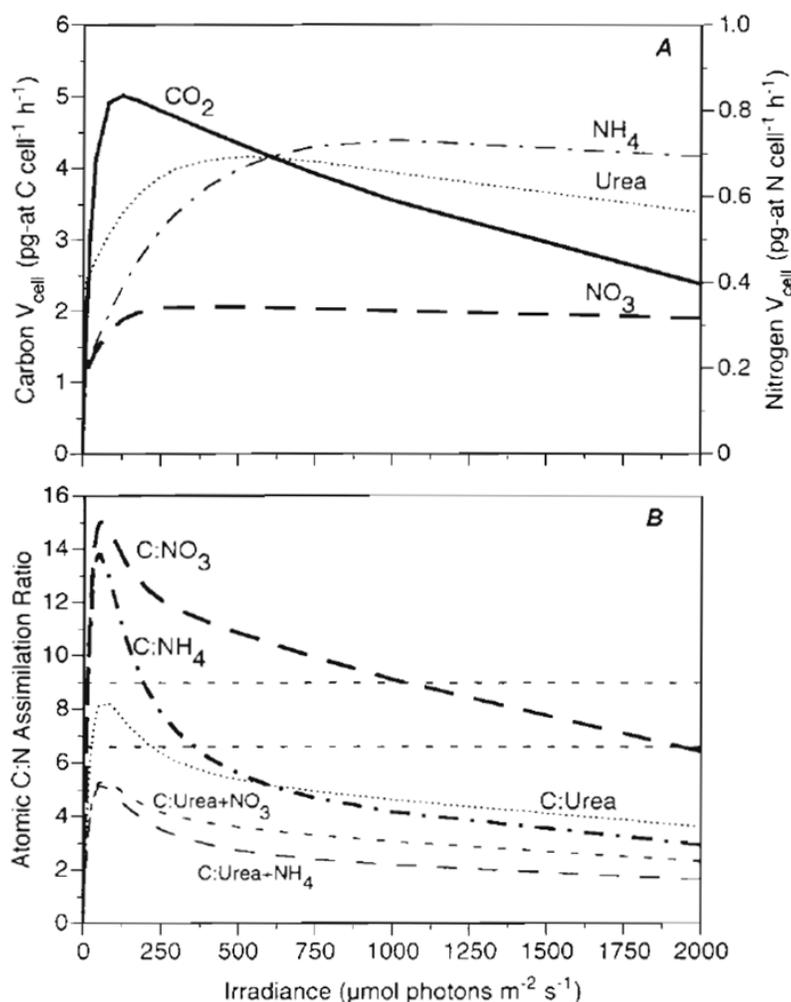

Figure 9.10 The interactive effects of light, nutrient assimilation, and the energetic requirements for N-metabolism (see Figure 9.11) can result in unexpected patterns of nutrient utilization. Panel A shows uptake versus irradiance for a red tide comprised of the dinoflagellate *Lingulodinium polyedrum*, indicating more efficient utilization of ammonium and urea compared to nitrate. Panel B shows the C:N assimilation ratio for different combinations of C and N. The lower dashed line is the Redfield ratio, the upper dashed line is the measured C:N ratio of the algae. At very low light, the observed C:N ratio could be maintained with any source of N. At moderately low light (up to 250 μmol photons m⁻² s⁻¹) urea is almost certainly utilized, and urea could sustain balanced growth (if sufficiently available) across the full range of irradiances. Note that nitrate alone could only sustain balanced growth at both extremely low and extremely high light levels. In contrast, uptake kinetics (not shown) would indicate preference as NO₃>NH₄>Urea (based on K_s values). At the time of collection, ambient nutrients were approximately at the K_s value or higher throughout the water column. From Kudela and Cochlan, 2000.

9.2.6 Harmful Algae

A special case within the larger framework of phytoplankton community composition are those organisms classified as harmful algal blooms. This provides perhaps the most direct metric of ecosystem health since sufficiently elevated numbers of these algae and their associated toxins is a clear indication of impacted ecosystem health. HAB organisms are well studied at the species level in terms of both physiological parameters and ecological patterns. Despite the persistent nutrient enriched status of San Francisco Bay, few harmful algal blooms have been reported recently for the estuary. A lack of monitoring, especially for toxins, may play a role, given the large number of potentially harmful algae present in San Francisco Bay (Cloern and Dufford, 2005; Table 3.1 and Figure 3.9). However, there have been historical occurrences (see Cloern et al., 1994 referenced in Cloern, 1996), and recently cyanobacteria and dinoflagellate blooms have been documented. For example, blooms of the cyanobacteria *Microcystis aeruginosa* have been occurring in the late summer/autumn in the northern Bay and Delta since 1999 (Lehman et al., 2005), the raphidophyte *Heterosigma akashiwo* created a red tide in the Central Bay in summer 2002 (Herndon et al., 2003), and the dinoflagellate *Akashiwo sanguinea* caused a red tide in the Central and South Bay areas during September 2004 (Cloern et al., 2005).

Microcystis aeruginosa blooms have occurred in the Delta and the North Bay during July through November of each year since 1999. The colonial form of *M. aeruginosa* is the first recorded toxic phytoplankton bloom in the northern reach of SF Bay and may have been recently introduced because it was not recorded in historic samples taken between 1975 and 1982 (Lehman et al., 2005), although sampling technique during that period may have been suboptimal for detecting *Microcystis* (samples collected at 1m depth, as opposed to surface samples/horizontal tows). *M. aeruginosa* can form surface scums and is a nuisance to recreational users; reduce aesthetics and oxygen; and produce microcystin, a hepatatoxin to humans and wildlife (Lehman et al., 2005; Lehman et al., 2008). Several surveys of *M. aeruginosa* blooms in the Delta have documented that the blooms can be widespread, often with microcystin concentrations that exceed World Health Organization guidelines for risks to humans and wildlife (e.g., Lehman et al. 2005; Lehman et al., 2008). *M. aeruginosa* may also produce cascading effects on the food web (Brooks et al. 2012).

The other well-studied HAB organisms within California waters, *Alexandrium catenella* (causes paralytic shellfish poisoning) and *Pseudo-nitzschia spp.* (causes domoic acid poisoning) are also present in the estuary. Indeed, sampling in South Bay Salt Pond A18 during 2006 (Thébault et al. 2008) revealed the presence of six phytoplankton taxa that can potentially cause harmful algal blooms (HABs): dinoflagellates *Alexandrium sp.* and *Karenia mikimotoi*, pelagophyte *Aureococcus anophagefferens*, raphidophyte *Chattonella marina*, and cyanophytes *Anabaenopsis sp.* and *Anabaena sp.* Microscopic analysis of samples collected by USGS monitoring in 2006 and 2008 revealed seven additional species of phytoplankton (e.g., Figure 3.9 and Table 3.1) that, when present at bloom abundances, have disrupted aquatic food webs, caused mortality of invertebrates, fish and birds, or human illness in other shallow marine ecosystems. In 2007 and 2008 the USGS water-quality sampling program also found HAB species in South San Francisco Bay, including *Karlodinium (Gyrodinium galatheanum) veneficum* (November 2007), *Chattonella marina* (March 2008), and *Heterosigma akashiwo* (September 2007). Appearances of these taxa are surprising because they were not detected previously in 3 decades of sampling (Cloern and Dufford 2005). These observations, all made after the first salt ponds were opened in 2004, suggest that the salt ponds might function as incubator habitats and a source of toxic phytoplankton to San Francisco Bay as they are opened to tidal exchange. Dinoflagellates, flagellates, and pelagophytes form HABs in other shallow marine ponds that are enriched in organic matter and have long hydraulic residence time (e.g. Gobler et al. 2005). Shallow, semi-isolated systems (such as the salt ponds) can also serve as “biological capacitors”, providing inocula for large-scale blooms in nearby bay and coastal waters (Vila et al., 2001). Actions to open these habitats might pose an unanticipated risk to the water quality and living resources of San Francisco Bay and to tidal-ponds created by the South Bay Salt Pond Restoration Program, particularly for water birds and fish assemblages.

Given the prevalence of HAB organisms in the Bay, the dramatic increase in blooms of Microcystis, and the potential linkages between ecosystem health and HABs (Kudela et al. 2008), it would be prudent to more closely monitor HAB organisms and associated toxins within San Francisco Bay as indicators of water quality.

9.3 Summary of Major Conceptual or Data Gaps

San Francisco Bay is somewhat unique in that it is well studied for both physical/environmental parameters, and for phytoplankton community composition. Despite this wealth of information, any attempt to develop a conceptual model of community composition runs into the fundamental

issue identified by Cloern and Dufford (2005): "...the problem is hyperdimensional, whereby communities are assembled by selective forces operating on variation in algal size, motility, behavior, life cycles, biochemical specializations, nutritional mode, chemical and physiological tolerances, and dispersal processes...our knowledge base is therefore insufficient for constructing reliable numerical models of phytoplankton population dynamics at the species level, in spite of our recognition that the functions provided by the phytoplankton vary among species." While this issue is not intractable, it is unlikely that we will be able to predict or fully understand the species-level variability in San Francisco Bay in the near future. We can, however, identify important components of a conceptual model for phytoplankton community composition at the level of traits and ecosystem function (Figure 9.4). The immediate challenge is to identify the relative importance of these sometimes conflicting conceptual relationships. A long-term goal should perhaps be the development of sophisticated numerical-biological models that incorporate "evolution" and natural selection. This approach is being increasingly applied to oceanic ecosystems with some success (Follows and Dutkiewicz 2011) and has recently been used to test fundamental questions about community assembly and stability (Barton et al. 2010a,b). Applications of such models in the near term – as synthesis tools for examining multi-dimensional parameter space – may allow us to rule in or rule out hypotheses, evaluate potential drivers of phytoplankton community shifts, and identify the highest priority experimental studies. Several gaps in our ability to develop or apply a conceptual model of phytoplankton community assembly include the following specific issues:

- It is unclear how many spatio-temporal compartments need to be included for San Francisco Bay. The estuary could be modeled as single unit, as North Bay versus South Bay, or as a series of sub-basins. While many authors recognize that algae are both imported and exported from the ocean and riverine end members, it is still very common to describe the mean patterns for the estuary or develop conceptual models based on data from particular locations. The estuary clearly responds to forcing from the oceanic and riverine end-members; any conceptual model of community assemblage for San Francisco Bay must be linked to models of the coastal ocean and the watershed.
- The estuary is generally considered to be nutrient-replete, but there is little or no information available about vitamins, trace-metals, and the influence of anthropogenic contaminants such as pesticides that may be influencing community composition. Several of these factors would likely co-vary with more easily measured parameters and could easily be overlooked.
- Very little is known about the species-specific physiological properties of the community, nor about the potential interactions between (e.g.) light, nutrients, photosynthesis, etc.
- The presence of HABs and toxins has been largely ignored in San Francisco Bay. The prevailing assumption is that the Bay is resilient to these impacts, but this may simply be a lack of monitoring and measurement. Large-scale restructuring such as the opening of the salt ponds has the potential to suddenly and dramatically alter this perspective.
- Several conceptual models have been proposed that could account for the abrupt and long-term trends in community composition, and are diametrically opposed. Similar to the classic paradigm of top-down versus bottom-up control in marine systems, reality is probably somewhere in between, and may change spatially and temporally.

Tables 9.1 summarizes the current state of knowledge and knowledge/data gaps related to phytoplankton community composition. The prioritizations in the rightmost two columns are related to the discussion in Section 11.

Table 9.1 Phytoplankton community composition and HABs: current state of knowledge for key processes and parameters

Process or Parameters	Importance for quantitative understanding	Current Level of Certainty about magnitude, composition, or controls	Need for additional or on-going data collection or process studies	Priority for study in next 1-5 years
Processes				
Pelagic grazing rates (size-selective)	High	Low: No systematic zooplankton sampling in LSB, South Bay, Central Bay. Only 1 station in San Pablo.	Moderate	Moderate
Size-selective benthic grazing rates	High	Low: Good data to support estimates in Suisun Bay. Limited data in LSB South Bay. Monitoring of benthos abundance would inform this.	Very High	Very High
Temperature, light, and nutrient (concentration, N:P, form of N) preferences of phytoplankton PFTs specific to SFB subembayments	High	Low: Limited understanding of how these factors/preferences may shape phytoplankton community composition, in particular in a light-limited nutrient-replete system.	Very High	Very High
Effects of trace metals, organics or pesticides	Moderate/Uncertain	Low: Limited information on vitamins, trace-metals, and the influence of anthropogenic contaminants such as pesticides that may be influencing community composition. competition with diatoms.	Moderate	Moderate
Effect of physical forcings, including exchange between subembayments, oceanic and terrestrial (including wetlands, salt ponds) end-member inputs, large scale climate forcings	High	Moderate: Data on community composition over the past 20 years (Bay wide) and up to 40 years (Suisun and Delta) to explore different explanations.	Very High	Very High
NH ₄ inhibition: diatom productivity	High/Uncertain	Low: Several studies completed, others underway.	Very high	Very high
Ambient composition data				
Size-fractionated chl-a	High	Low: Provides a coarse measure of in which classes phytoplankton biomass resides, which is a useful albeit coarse surrogate for food quality. Not currently being collected but could be easily added to monitoring.	High	High

Process or Parameters	Importance for quantitative understanding	Current Level of Certainty about magnitude, composition, or controls	Need for additional or on-going data collection or process studies	Priority for study in next 1-5 years
Phytoplankton community composition, monthly time-scales, at sufficiently high spatial resolution, and higher temporal/spatial resolution to test mechanisms	High	Moderate: 20 year near-monthly Bay-wide record from USGS and ~40 year record for Suisun and Delta. But few higher resolution data sets or special studies.	Very high	Very high
Frequency and magnitude of detection of HABs or HAB toxins	High	Low: Limited data on HABs and toxins, and	Very high	Very high
Phytoplankton community composition in salt ponds, particularly HAB-forming species	High	Low: Limited data to date, but of high concern.	Very High	Very High
Surrogate measures for phytoplankton composition	Low	Low: The use of phytoplankton pigments or digital image recognition approaches could be piloted that would eventually increase the amount of composition data that could be collected	Very High	Very High

10 Other proposed adverse impact pathways

While other potential nutrient-related adverse impact pathways - including those that have impacted other estuaries or have been hypothesized in SFB – are possible, this report focused on a subset considered to be most relevant or most important in SFB (Figure 3.1, Table 3.2 AI.1-AI.6). Other adverse impact pathways, listed below, may need to be considered at a later date if observations indicate that they are indeed important in some habitats of SFB.

- Loss of submerged aquatic vegetation (SAV) habitat due to shading from phytoplankton or periphyton growth
- Excessive growth of macroalgae
- Excessive macrophyte growth, in particular invasive species
- Nutrient-induced changes in the composition of individual phytoplankton cells that cause adverse outcomes on primary consumers (Glibert et al., 2013)
- Direct NH_4^+ toxicity to copepods (Teh et al., 2011)

11 Priority Science Questions and Knowledge/Data Gaps

11.1 Introduction

The overarching questions that the Nutrient Management Strategy aims to address seem straightforward at first glance (Table 11.1 Column A). But those questions barely scratch the surface. Below the surface, the number of questions, and the information needed to answer those questions, grow exponentially (Table 11.1 Column B), because:

- San Francisco Bay is a large and complex estuary, comprised of distinct habitats that receive different nutrient loads, and that process and respond differently to those loads.
- A broad array of potential adverse impacts (Table 3.2) needs to be considered, and many of those paths have unique knowledge and data gaps;
- There are numerous important physical/chemical/biological processes along the pathways between nutrient loads and response (the conceptual model presented in Sections 5-9), and considerable knowledge and data gaps.

Table 11.1 Overarching Management Questions and next-layer more specific questions for SFB NMS

A. Overarching Questions	B. Next layer of more specific questions
1. Is SFB experiencing nutrient-related impairment under current conditions, or is it likely to in the future?	1.a Which impairment pathways (Figure 3.1 and Table 3.2), and what “conditions” constitute impairment?
	1.b What subembayments?
	1.c Which habitats (deep subtidal, intertidal, margins)?
	1.d What plausible future scenarios need to be considered, how would conditions differ under those scenarios, and would impairment develop?
2. What are the major nutrient sources?	2.a What are the magnitudes of the major nutrients sources, and how do those magnitudes vary temporally: POTWs; stormwater; agriculture; upstream inputs from the Delta; other perennial streams/rivers?
	2.b How do those individual loads contribute to ambient nutrient concentrations as a function of space and time throughout the Bay, considering temporal variability in the physical, chemical, and biological factors that influence their fate and transport once entering the Bay?
3. What nutrient loads or concentrations are protective of ecosystem health?	3.a What is/are the most important or sensitive endpoint(s), which nutrient forms cause or contribute to that adverse impact, and what loads or concentrations would be protective?
	3.b After considering fate and transport, what loads, from the combination of sources, would be protective?
4. What are efficacious and cost-efficient nutrient management options for ensuring that Bay beneficial uses are protected?	4.a What management actions - load reductions and other actions - will protect ecosystem health?
	4.b What actions mitigate or prevent impairment, and do so at the most reasonable cost and/or by delivering the greatest set of multiple net benefits?

When considering both the breadth and depth of monitoring, modeling and special studies that would be needed to address all the issues, it is clear that trying to tackle it all, in-depth, and in parallel would be impossible. Some degree of prioritization is needed to focus effort on the most important issues first.

The goal of this section is to inform the direction of scientific inquiry and monitoring by taking an initial step toward identifying the highest priority issues, the related science questions, critical knowledge and data gaps, and the types of investigations that would most directly target those gap and allow well-informed nutrient management decisions to be made. In Section 3, we explored the following question: *What would nutrient-related problems look like in San Francisco Bay if they were occurring now or in the future?* In response to this question, 8 adverse impact categories were identified (Table 3.2, Figure 3.1). In this section, using the conceptual model as a guide, we identify scenarios (current conditions, future environmental change, management actions) under which those adverse impacts could occur (or may already be occurring), and examine those scenarios to identify highest priority issues warranting further exploration. Based on the set of highest priority issues related we then identify key science questions, major knowledge gaps or data gaps (based on the assessments in Tables 6.2, 7.1, 8.1, 9.1), and identify the types of studies needed to address those questions and gaps.

11.2 Identifying priority scenarios for further consideration

Scenarios were identified and explored as follows:

Current Conditions or Current Trends:

These ‘scenarios’ address the question: *Based on current observations – current conditions or current trends – are some subembayments or habitat-types already experiencing, or heading toward experiencing, adverse impacts from nutrients?*

In considering the conditions and trends, the analysis does not aim to assess whether impairment is occurring, but rather to frame and present the issue, and its priority level, for comparison with other issues. Four broad categories were encountered: i. Existing data suggest do not suggest a major problem; ii. Existing data may be suggestive of a potential problem but are currently insufficient to definitively answer this question; iii. There is currently little or no data, but adverse impacts are highly plausible based on the conceptual model; and iv. mechanistic-studies are needed to address key conceptual gaps;

Environmental change scenarios

N and P are abundant in SFB, but physical and biological drivers severely limit their conversion into phytoplankton biomass, and generally prevent SFB from experiencing exceedingly high biomass and low dissolved oxygen. Some of those same regulating factors may help prevent potentially harmful phytoplankton, which are regularly detected at low numbers in SFB, from developing into full-blown HABs/NABs. This set of scenarios focuses on uncontrollable environmental change and was developed through exploring the following questions:

What could cause a relaxation of the physical or biological controls that regulate the Bay’s response to high nutrients, and thereby contribute to, cause, or worsen adverse impacts?

Future scenarios require serious consideration for several reasons. First, SFB boasts multiple examples of unexpected and substantial environmental changes over the past 20-40 years that have had major impacts on ecosystem response and ecosystem health (see Sections 3, 7, and 9;

e.g., biomass increases in South Bay over the past 20 years; 30-50% decrease in suspended sediment concentrations Bay-wide over past 20-30 years; *Potamocorbula* invasion in Suisun in 1987; shifts in zooplankton community composition and abundance in Suisun Bay due to invasions and other drivers; decline in benthos-feeding organisms in South Bay). Second, the potential effects of climate change need to be evaluated. Third, it will take many years, even multiple decades, to implement major management actions. Taking action only once a problem arrives means years or decades of impairment before ‘the fix’ can be implemented. If future problems are to be averted, impairment scenarios need to be anticipated, evaluated, and, if deemed necessary, managed in advance of their onset. Lastly, implementing management actions while a problem is still over the horizon, as opposed to already upon us, will allow time for planning, and for a broader range of management options to be considered. Planning ahead will increase the likelihood and feasibility of implementing “the best solution” – a set of management actions that achieve multiple benefits (beyond just nutrients) and are the most cost-effective.

To identify environmental change scenarios requiring further analysis, we first used the conceptual model to identify changes to regulating factors that could lead to, or exacerbate, the adverse impacts identified in Section 3 (Table 3.2; Figure 3.1). Figure 11.1 illustrates how shifts in various regulating factors could adversely influence ecosystem responses. Next, we identified environmental change scenarios under which those shifts could occur. Those scenarios are summarized Table 11.1, and mapped to changes in regulating factors in Figure 11.2.

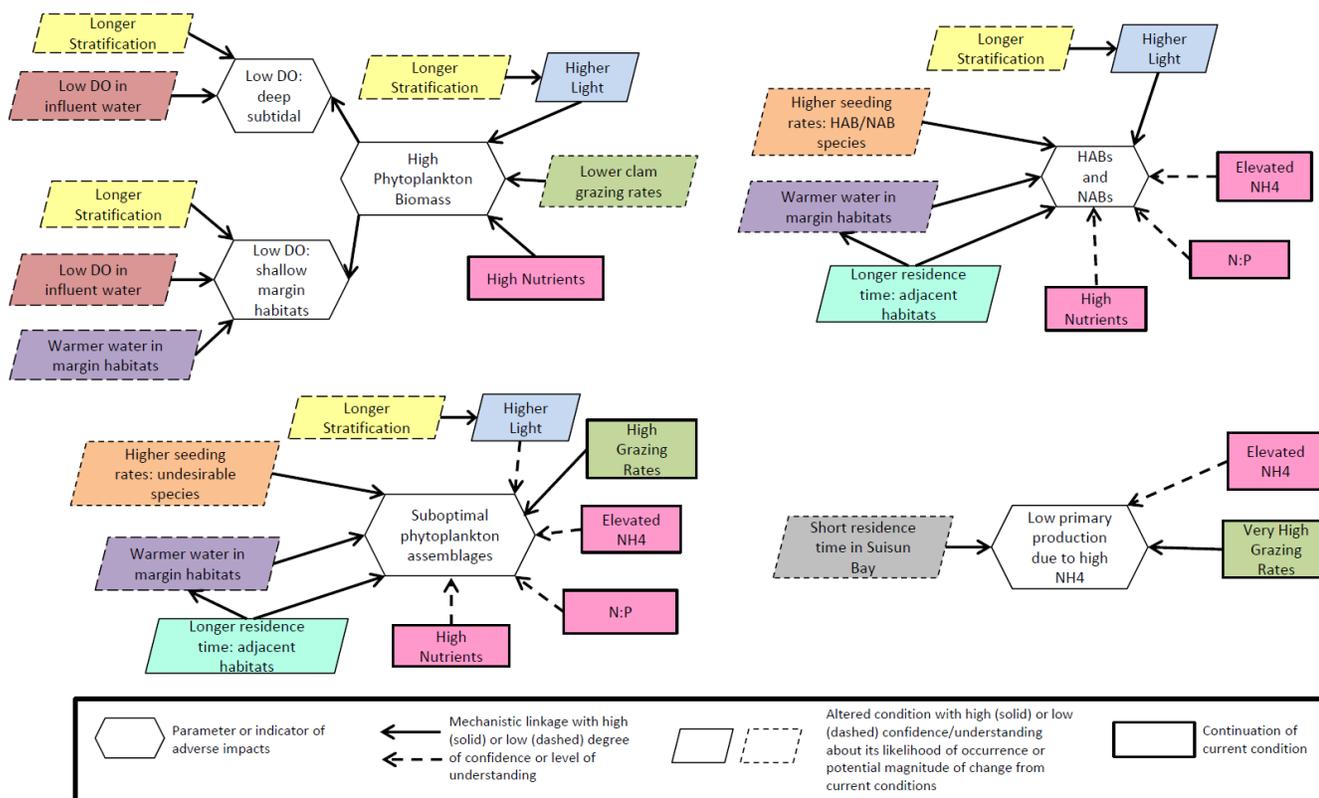

Figure 11.1 Changes to underlying drivers of response that could contribute to adverse impacts.

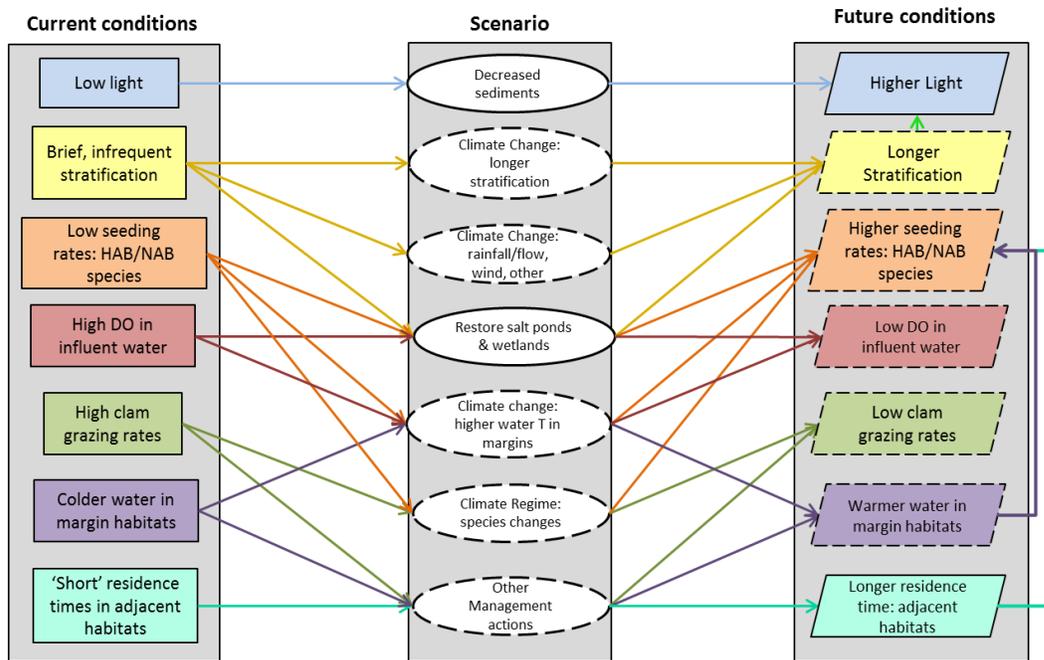

Figure 11.2 On the left, Current Conditions within SFB that have thus far provided resistance to harmful effects of high nutrient loads. In the middle, potential environmental or management scenarios that could create future conditions with weaker resistance to nutrient-related adverse impacts. Likelihood of a scenario is indicated by a solid line (more certain) or a dashed line (unknown likelihood of occurrence, or unknown magnitude or direction). Dashed lines for Future Conditions indicate uncertainty about degree to which condition would change in response to scenarios

Management action scenarios

We considered two broad categories of management actions: management actions that would specifically target nutrient-related problems; and management actions being implemented for other reasons that could have unintended (positive or negative) effects with respect to nutrients (e.g., large-scale habitat restoration projects (SBSP, Deltaplans, BEHGU); flow rerouting in the Delta (ref); shoreline redevelopment (ref)). Similar to the approach followed for environmental change scenarios, we used the conceptual model to identify junctures along the path between nutrient loads and adverse impacts where a change to regulating factor could substantially influence ecosystem response (positive or negative). We then identified specific or more general management actions that could act on those factors, which are also summarized in Table 11.2.

Subembayment-Scenario-Response matrix

To organize the numerous issues requiring consideration into a single graphic and facilitate the systematic comparison of issues and their importance, we developed the matrix in Figure 11.3. Figure 11.3 depicts subembayment-scenario-response combinations. Columns represent scenarios, organized into their three categories. Rows represent potential ecosystem responses based on the adverse impact categories in Table 3.2, grouped by subembayment. For each combination, we assessed whether it would result in worsened conditions; would result in improved conditions; or was not highly relevant with respect to nutrients.

Table 11.2 Major scenarios considered

Environmental Change (EC) or Management Scenario (MS)	Description
EC.1	Continued decreasing suspended sediment concentrations in SFB due to a continuation of lower external loads and depletion of the erodible sediment pool.
EC.2	Increased frequency or duration of stratification due to climate change, in particular thermal stratification in fall
EC.3	Climate-change related changes in precipitation patterns (timing, intensity) and timing of snow melt. Potential effects include: altered timing/intensity of freshwater flows from the Central Valley and Sierras that could change stratification duration and residence time in the Delta, Suisun, and other subembayments; changes in freshwater flows from watersheds adjacent to subembayments and influence stratification in particular in LSB and South Bay.
EC.4	Climate regime shifts (el Nino/La Nina, PDO) that cause shifts in biota, such as introducing new phytoplankton species, or changes in abundance bottom feeding macrobiota that have top down controls on food web (e.g., similar to the loss of clams in South Bay, and their eventual return)
EC.5	Climate-change related increases in water temperature in margin habitats
EC.6	Dramatically decreased <i>Corbula</i> abundance due to environmental factors (disease, increased predator abundance)
MS.1	N-P load reductions at POTWs discharging directly to SFB subembayments or adjacent watersheds (not including those east of Suisun Bay)
MS.2	Nitrification with no further nutrient removal at POTWs discharging directly to SFB subembayments or adjacent watersheds (not including those east of Suisun Bay)
MS.3	Stormwater load reductions through the use of best management practices, low impact development, etc.
MS.4	Wetland restoration around the Bay margins. Largest scale planned changes in LSB and South Bay, but large areas for potential for restoration in San Pablo Bay and Suisun Bay (See Figure 5.2)
MS.5	Salt pond restoration and reconnection. Largest scale planned changes in LSB and South Bay, but large areas for potential for restoration in San Pablo Bay and Suisun Bay (See Figure 5.2)
MS.6	Managed shellfish beds to increase water column filtration rates to maintain low phytoplankton biomass
MS.7	Sac-Regional upgrades: Nitrification, N-removal
MS.8	Other Central Valley load reductions
MS.9	Delta flow changes, due to changes in water withdrawals or flow routing, or due to restoration

We then ranked the combinations from low to high priority, in terms of the need for further investigation, based on the following factors:

- The combination was considered to be among the most plausible or probable issues to develop into a substantial problem, or among the most feasible mitigation approaches;
- Major gaps in knowledge or data exist that limit our current ability to make further assessments (in terms of determining if there is currently a problem, high likelihood of a future problem, or whether a management action would mitigate impacts), and severely limit the confidence with which science-based decisions can currently be made;
- The combination was a tractable issue to explore, and highly relevant to management decisions. In other words, resources directed toward exploring these issues (monitoring, special studies, modeling) could yield a large return on investment in terms of the knowledge/data gaps filled and scientifically-informed decision-making.

A subset of these combinations is discussed below. First, Section 11.2 explores combinations that represent adverse impacts. Next, Section 11.3 discusses combinations under which adverse impacts would be mitigated or prevented adverse impacts from nutrients. Based on a consideration of the full scenario set, Section 11.4 identifies a subset of highest priority combinations (Section 11.4) and Section 11.5 discusses the related priority science questions and knowledge/data gaps.

11.3 Adverse impacts

The discussion below is organized around the adverse impact pathways (i.e., from Table 3.1). For each pathway, current conditions/trends are discussed first, followed change scenarios that could cause or exacerbate impacts along that pathway.

High biomass and low DO in deep subtidal areas

Current Conditions or Current Trends: Phytoplankton biomass has increased in all SFB subembayments over the past 20-30 years, and small but statistically significant decreases in DO have also been noted (J Cloern, pers. comm.). Biomass increases have been greatest in LSB and South Bay. Current phytoplankton biomass levels in LSB and South Bay do not appear to be having pronounced impacts within deep subtidal areas, since DO concentrations have generally tended to remain above 5 mg/L. However, the rate of change in biomass in South Bay between the mid-1990s and 2005 was rapid (Figure 3.5). Recent data from the past several years suggest that biomass may have reached a new plateau. Nonetheless, the underlying causes of the biomass change over the 20 year, and indeed why it plateaued as opposed to continued increasing, remain highly uncertain, and therefore so does its future trajectory. When conditions are appropriate, LSB and southern South Bay can also experience large and long-lived blooms (50-100 µg/L, 1-2 months; Figure 7.5). High phytoplankton biomass and low DO in deep subtidal areas of LSB and South Bay are thus considered high priority issues based on current conditions and trends. Determining whether LSB and South Bay are trending toward experiencing adverse impacts due to high biomass and low DO in deep subtidal habitats requires identifying the causes of recent change, forecasting future biomass and DO, and comparing present and future conditions to numeric criteria (being developed separately as part of the SFB Assessment Framework).

Change scenarios: Bay-wide, several scenarios could lead to increased rates of primary production, increased biomass accumulation, and low DO in deep subtidal areas, including (see also Table 11.1 and Figure 11.3): i. continued decreases in suspended sediment concentrations;

ii. increased frequency of climatic conditions that allow stratification to occur more frequently or persist for longer periods of time; iii) changing rainfall patterns that strengthen and lengthen spring salinity stratification; iv.) wetland or salt pond restoration dampening turbulent mixing energy, which would allow stratification to persist longer during its current spring and fall periods, and also outside those times; v. wetland/salt pond restoration and reconnection to the open Bay, and elevated nutrients being more efficiently converted to biomass that is tidally-transported to deep subtidal habitats vi.) loss of benthic grazers (in Suisun Bay). Suisun Bay currently has extremely low phytoplankton biomass. High biomass and low DO would only occur in Suisun if there was an abrupt loss of the *Potamocorbula* clam (e.g., due to disease, predator introduction). Prior to the *Potamocorbula*'s establishment, Suisun was highly productive. With the substantial light level increases in Suisun Bay and its higher nutrient concentrations since pre-1987, greater biomass accumulation than pre-1987 would be expected now if *Potamocorbula* disappeared. Further declines in suspended sediment or more frequent or longer stratification would amplify this effect. Indeed, baseline phytoplankton biomass has increased in Suisun Bay over the past 15 years (Figure 3.8), although levels remain far below pre-1987 concentrations.

High Biomass and Low DO in shallow margin habitats

Current Conditions or Current Trends: LSB, South Bay, San Pablo Bay, and Suisun Bay have large shallow margin habitat areas that provide critical ecosystem services (Figure 2.1). To date, these habitats have received limited systematic monitoring. The available data that has been analyzed to date indicate that low DO occurs periodically in LSB's shallow margin habitats, i.e., as sloughs, creeks, and salt ponds undergoing restoration (Figures 3.13 from earlier in report; SFEI 2014c). Low DO is also commonly observed in Suisun Marsh (Tetra Tech 2013). However, it is unknown how the severity (spatial extent, DO concentration, duration, and frequency) of low DO compare to what would be expected under natural conditions. In addition, the impacts of this low DO on habitat quality is unknown, but would depend on both the severity of low DO and how it effects the biota utilizing (or who would otherwise utilize) that habitat. Lastly, if adverse impacts are occurring, the degree to which anthropogenic nutrient loads cause or contribute to those impacts needs to be determined. Given the severe data limitations, limited investigation to date, and the disproportionately high-value of these habitats to biota, current conditions related to low DO in margin habitats emerged as a high priority issue for all subembayments that have substantial areas of shallow margin habitat.

Change scenarios: Many of the same change scenarios that would lead to high biomass and low DO in deep subtidal habitats would similarly affect DO in margin habitats. For example, decreases in SPM concentrations would increase light levels and production rates. Any changes filter-feeding benthos abundance would have an even greater effect on phytoplankton biomass in margin habitats than in deep subtidal areas because of the shallower depth. Reconnection of wetlands and salt ponds through restoration could deliver low DO water or high BOD loads (in the form of reduced compounds or phytoplankton biomass) to sloughs.

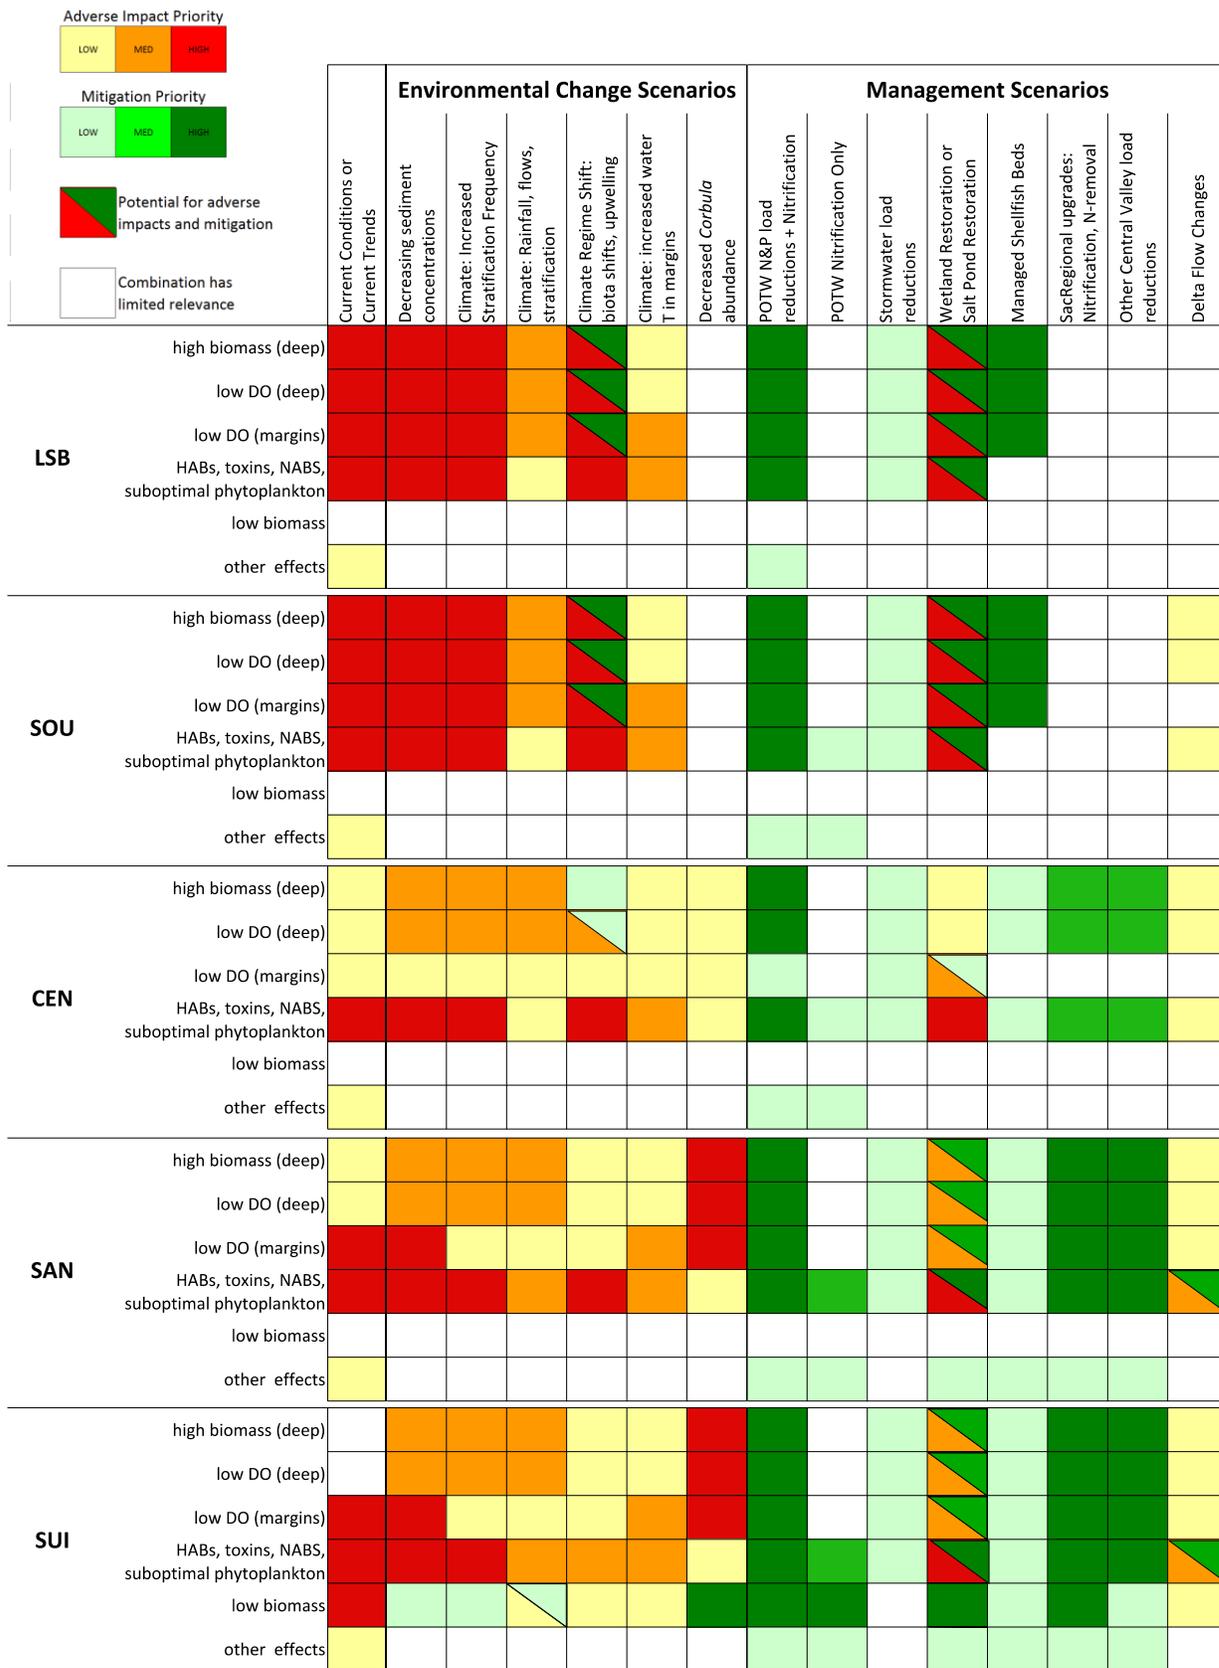

Figure 11.3 Prioritization of subembayment specific response. Columns represent scenarios and rows represent potential ecosystem responses based on the adverse impact categories in Table 3.2

HABs/NABs and phycotoxins

Current Conditions or Current Trends: Recent measurements indicate that HAB toxins, or phycotoxins, occur year-round in all SFB subembayments, plus the Delta (Figure 3.9). The current ecological significance of the observed phycotoxins in SFB is unknown. HAB-forming species are frequently detected throughout the estuary at low abundances (Table 3.1, Figure 3.10), and have been observed in salt ponds undergoing restoration (Thebault et al., 2008). The underlying mechanisms or triggers that determine when a HAB may form, when high levels of phycotoxins are produced, and the relationship with nutrients are among the most poorly understood. Yet the Fall 2004 nuisance red tide bloom in Central Bay and South Bay clearly demonstrated how an undesirable organism can readily take advantage of SFB's high nutrient concentrations when favorable physical conditions allow (Figure 3.11). That bloom was the first of its kind in nearly 40 years of observations, and it remains unknown whether it was a low-probability event that occurred by pure coincidence during that year, or if the underlying factors that contributed to its occurrence in 2004 are related to broader patterns of changing ecosystem response in SFB.

Given the potential magnitude of problems that HABs/NABs can cause when they do occur, the currently poor understanding of the mechanisms that may lead to HAB/NAB blooms and phycotoxin production, and the potential for major blooms that current high nutrient concentrations provide, HABs/NABs and phycotoxins need to be considered among the highest priority issues Bay-wide.

Change Scenarios: Future scenarios that would lead to increased light levels (lower SPM) or longer periods of stratification would favor HABs/NABs through allowing for increased growth rates and fuller utilization of abundant nutrient supplies. In addition, restored salt ponds and wetlands (LSB, South Bay, and San Pablo Bay) have the potential to be HAB and NAB incubators, due to their relatively long residence times, warm water temperatures, high light levels, and abundant nutrients. The potential linkage between large-scale salt pond restoration efforts and increased HAB frequency and elevated toxins need to be examined. Increased water temperatures in margin habitats due to climate change or longer water residence time could also favor HABs/NABs. Lastly, changes in large-scale climate forcings could change – increase or decrease - the seeding-rate of HAB-forming species from the coastal ocean to SFB.

Suboptimal phytoplankton community compositions

HABs/NABs are one category of undesirable shifts in the phytoplankton community. However, other manifestations of nutrient-driven community shifts, such as toward compositions of poor nutritional quality for supporting food webs, have also been proposed. While they are addressed separately in this section, HABs/NABs and other shifts in phytoplankton community compositions are combined in Figure 11.3, and to some degree the knowledge and data gaps related to current and future conditions are similar.

Like HABs and NABs, the combination of factors, including nutrients, that would cause undesirable compositional shifts are poorly understood in SFB. On the one hand, it can be argued that since nutrients seldom limit phytoplankton growth that – from phytoplankton succession viewpoint – nutrients are not a major determinant of which species thrive (Sections 9.2.6 and 9.2.9). On the other hand, it has been hypothesized that nutrients concentrations, forms, and ratios alter phytoplankton community composition through different mechanisms (Glibert 2010;

Glibert et al., 2011; Glibert et al., 2013). If nutrient-related suboptimal phytoplankton composition will be included among the potential adverse impacts that management decisions will aim to address, more investigation is needed into the hypothesized underlying mechanisms and the potential importance of their effects relative to other factors regulating ecosystem response. Mechanisms need to be explored in controlled experiments. Ecosystem-scale observations are also needed, requiring a well-designed and targeted program to collect high-quality data on phytoplankton taxonomy and ancillary data over a wide range of conditions (physical, chemical, and biological).

Low phytoplankton biomass caused by elevated NH_4^+

Current Conditions or Current Trends: In Suisun Bay and the Delta, phytoplankton biomass levels are extremely low and blooms rarely occur (Figure 3.8), and food limitation is considered to be among the factors contributing to fish declines (Baxter et al., 2011). Elevated NH_4^+ concentrations have been hypothesized to play an important role in preventing phytoplankton blooms and maintaining low biomass in Suisun Bay (Dugdale et al., 2007; Parker et al., 2012a,b; Dugdale et al. 2012). However, there remains uncertainty and disagreement within the scientific community, including among this report's authors, about the mechanism and its importance relative to other processes that regulate biomass accumulation (Section 7.2.3; see also SFEI 2014X). Similar to suboptimal phytoplankton community compositions, if NH_4^+ inhibition will be included among the potential adverse impacts that management decisions will aim to address, more investigation is needed into the hypothesized underlying mechanisms and the potential importance of their effects relative to other factors regulating ecosystem response. Focused experiments are needed to test key aspects of the hypothesis (see SFEI 2014b for further discussion), and modeling is needed to compare the magnitude of any NH_4^+ -related effect to other factors that regulate phytoplankton biomass accumulation (e.g., light limitation, clam grazing rate, residence time).

Change Scenarios: Only one of the future scenarios considered in this report could potentially exacerbate low productivity due to elevated NH_4^+ in Suisun Bay: shifts in rainfall patterns that cause increased flows from the Delta which in turn flush phytoplankton from the system faster at a rate faster than they can grow. This future scenario is not currently considered to be among the highest priorities.

Other food web effects

Currently there is limited field or experimental evidence that nutrients adversely affect the food web along additional pathways such as: direct toxicity to copepods (Teh et al., 2011), creating conditions that allowed *Potamocorbula* to become and thereafter remain established in Suisun Bay (Glibert et al., 2011); and changes in individual phytoplankton cell composition that adversely impact copepod populations (Glibert et al. 2013). Similar to suboptimal phytoplankton community composition and NH_4^+ inhibition, if these other nutrient-related food web effects will be included among the potential adverse impacts that management decisions will aim to address, more investigation is needed into the hypothesized underlying mechanisms and the potential importance of their effects relative to other factors regulating ecosystem response. Compared to adverse impacts, at this point were not considered to be among the current highest priorities issues.

11.3 Scenarios that could prevent or mitigate adverse impacts

Scenarios under which nutrient-related adverse impacts could be prevented or mitigated are discussed below, organized by scenarios (as opposed to Section 2's organization around adverse impact pathways)

N and P load reductions from POTWs discharging directly to SFB subembayments

Since POTWs are responsible for ~65% of the nutrients loads entering SFB (Bay-wide, annual average; Figure 6.2), reducing POTW N and P loads is an obvious management scenario to explore. Although some POTWs currently perform nitrification prior to discharge, and several carry out advanced treatment that removes a portion of N and P, most SFB POTWs do not perform nutrient removal. Substantial reductions in POTW N and P loads can be achieved with conventional, albeit still expensive, treatment upgrades (N: 2-5 fold decrease; P: >10 fold decrease; Table 6.1). If nutrient load reductions are deemed necessary, the key challenges will be to determine how much removal is necessary to protect ecosystem health, and to identify the optimal approach for achieving those reductions (including potentially through nutrient trading between POTWs), since costs could differ by billions of dollars among options.

At present, DIN and o-PO₄ seldom limit phytoplankton growth in most deep subtidal habitats of SFB and during most times of the year. Therefore, reducing POTW nutrient loads would be unlikely to result in substantially-decreased phytoplankton production - at least in deep subtidal habitats- unless the decreases are very large (e.g., 5-10 fold reduction).

Decreasing POTW nutrient loads would, however, cap phytoplankton production (and biomass) and DO deficits at levels lower than today's potential maxima by decreasing the amount of DIN and o-PO₄ available for phytoplankton growth. To the extent that HAB/NAB frequency, or suboptimal phytoplankton composition, are influenced by high nutrients or highly altered nutrient ratios, POTW load reductions would also mitigate these impacts. Direct POTW nutrient load reductions are discussed below for each subembayment. As noted in Section 6.4, this segmentation greatly oversimplifies hydrodynamics and nutrient cycling, but remains instructive for a qualitative discussion.

LSB and South Bay: POTWs are the dominant external sources of DIN and o-PO₄ to LSB and South Bay (Figure 6.2; SFEI 2014a). Reducing POTW loads would therefore substantially reduce total subembayment-scale nutrient inputs to LSB and South Bay. The San Jose wastewater treatment has already reduced its N and P loads by ~40% and ~10-fold, respectively, through treatment upgrades in the mid-1990s (SFEI 2014a,c). However, LSB has the smallest volume and slowest net flushing rate of all SFB's subembayments, allowing N and P to accumulate to higher concentrations.

The effects of load reductions may differ between deep subtidal habitats. For deep subtidal habitats in LSB and South Bay, while moderate POTW load reductions may not result in phytoplankton biomass reductions during much of the year, load reductions would create a lower-level cap on phytoplankton production and biomass. Given that the efficiency with which nutrients have been converted to biomass in South Bay and Lower South Bay has increased over the past 10-20 years (Figure 3.5 and 3.6), this may be an important consideration for preventing future potential adverse impacts. Although DO generally remains above 5 mg/L in deep subtidal habitats, recent observations suggest that DO does approaches, and occasionally dips below, 5

mg/L in LSB deep subtidal areas. If such conditions are deemed to be problematic, POTW load reductions could mitigate that impact. In addition, load reductions would presumably (depending on the decrease) have an effect on episodic major bloom events like that depicted in Figure 7.5, to the extent that such events are considered problematic. Similarly, decreased nutrient loads could help cap the magnitude of episodic HAB/NAB events. For these latter two examples, the frequency with which such events occur compared to some “acceptable frequency” (a regulatory decision) would need to be considered in determining the benefit of load reductions.

The situation may be different in shallow margin habitats. The limited data from sloughs rimming LSB indicate that DO concentrations do frequently fall well below 5 mg/L at some locations (Figure 3.14; SFEI 2014c). Based on the conceptual model, it is reasonable to hypothesize that POTW-derived nutrients contribute to low DO in shallow margin habitats, and that POTW load reductions would decrease the severity of those events (spatial extent, DO deficit, frequency, duration). At the same time, multiple factors may contribute to low DO in sloughs, including organic matter entering from adjacent watersheds, and periodic naturally-low DO; therefore, the contribution of anthropogenic nutrients to low DO still needs to be determined. The extent to which low DO in margin habitats is having adverse impacts depends to a large degree on whether it is impacting biota that utilize that habitat (other potential impacts include odor problem from sulfide production). Data on benthos and pelagic macrobiota abundances in margin habitats are extremely limited. In addition there needs to be a systematic analysis of DO tolerances of key organisms.

Suisun and San Pablo Bays: Evaluating the relative importance of direct POTW load reductions to Suisun Bay and San Pablo Bay is less straightforward than for LSB and South Bay. Suisun Bay sizable loads from POTWs discharging directly to Suisun Bay; however it also receives large, seasonally varying NH_4^+ , NO_3^- , and o-PO_4 loads from the Delta (Figure 6.3). San Pablo Bay in turn receives seasonally varying loads from Suisun Bay plus the Delta (Figure 6.3). Therefore, an evaluation of the effect that reduced direct POTW loads to Suisun Bay will have on ambient conditions within Suisun Bay needs to consider magnitudes of upstream loads. The planned ~65% N load reductions from Sacramento Regional County Sanitation District (Regional San), which should go on-line within 10 years, are expected to have a major influence on DIN loads that enter Suisun Bay from the Delta (see Figure 6.3; planned decrease at Regional San ~ 10,000 kg d⁻¹). After those reductions, direct POTW loads to Suisun Bay will represent a much larger portion of the total load, at least during low-flow months. The extent to which direct POTW loads to Suisun would mitigate adverse impacts will also depend on the time of year and the adverse impact pathway and nutrient forms that are most concerning (i.e., Figure 3.1). If, for example, the goal is to achieve reduced ambient NH_4^+ concentrations, upgraded treatment at CCCSD could be impactful, since it discharges ~4000 kg d⁻¹ NH_4^+ to Suisun, which would be the largest external NH_4^+ source once Regional San’s loads are cut. However, if cutting DIN concentrations is the goal, initial estimates suggest that Delta loads will remain a non-trivial contributor, especially during winter and spring, even after Regional San’s loads decrease (Figure 6.3; Regional San’s current DIN load is ~15000 kg/d, indicating there is a seasonally varying additional source of 5000-20000 kg/d).

Central Bay: Assessing the potential effectiveness of load reductions from Central Bay POTWs on Central Bay conditions is more complex. Central Bay receives direct POTW loads and is the

ultimate recipient of loads that enter northern and southern subembayments. A detailed modeling analysis would be needed to determine the relative contribution of loads from different sources. Coastal upwelling and exchange flows through the Golden Gate can carry oceanic-source NO_3^- and o-PO_4 into Central Bay. However, while upwelling-related loads have the potential to be large under some conditions, on average Central Bay is expected to be a net exporter of N and P to the coastal ocean (Largier and Stacey, 2014).

Nitrification of POTW effluent

Unlike reducing N and P loads from POTWs (Section 11.3.1), nitrification of POTW effluent alone does not decrease nutrient loads, but instead changes the predominant N form from NH_4^+ to NO_3^- . However, to the extent that elevated NH_4^+ concentrations favor HABs/NABs, cause shifts in phytoplankton community composition, or inhibit primary production, nitrification of POTW effluent has the potential to mitigate these adverse impacts.

South Bay and Central Bay: POTWs discharging to South Bay and Central Bay release N primarily in the form of NH_4^+ . Thus nitrifying effluent prior to discharge would substantially reduce NH_4^+ loads. The benefit of nitrification prior to discharge needs to be weighed relative to what appears to be fairly efficient *in situ* nitrification, as evidenced by NO_3^- being the major DIN form in these subembayments despite them receiving primarily NH_4^+ loads. In addition, the importance of *in situ* NH_4^+ production (release from sediments, OM matter mineralization in the water column) needs to be considered.

Lower South Bay: All POTWs in LSB have been performing nitrification since the 1980s, although nitrification efficiency at one of those POTWs (Sunnyvale) varies seasonally. So this scenario is not particularly relevant in LSB. Interestingly, though, LSB has the second highest NH_4^+ concentrations Bay-wide (Figure 6.3). Much of the observed NH_4^+ likely comes from organic matter mineralization within LSB. This suggests that nontrivial baseline NH_4^+ concentrations could continue in other subembayments after external NH_4^+ inputs cease. Note, however, that the influence of *in situ* NH_4^+ production on ambient water column concentrations may be most pronounced in LSB because of its shallow bathymetry, which causes sediment processes to have larger effects on water column concentrations.

Suisun Bay: Upgrading Suisun POTWs to include nitrification would likely have a substantial impact on ambient NH_4^+ concentrations in Suisun Bay. Suisun Bay and San Pablo Bay receive large seasonally-varying NH_4^+ loads from the Delta, much of which originates from Regional San's discharge. In evaluating the potential environmental effectiveness of upgrading Suisun POTWs to include nitrification, the seasonally-varying magnitudes of Delta NH_4^+ loads need to be considered, as do planned decreases in Regional San's NH_4^+ loads. Under current loading conditions, direct POTW discharges to Suisun Bay are the major NH_4^+ source during dry months (Figure 6.2). Regional San's NH_4^+ loads will be cut to near zero within 10 years. At that time, POTWs discharging directly to Suisun Bay would be the primary NH_4^+ source, other than NH_4^+ produced *in situ* with Suisun Bay or within the Delta and Sacramento River and transported into Suisun Bay. *In situ* nitrification appears to play an important role in shaping ambient NH_4^+ concentrations in Suisun Bay during summer/fall months (Section 6.4; SFEI, 2014b). In evaluating the benefit of upgrading POTWs to nitrification alone (i.e., no N or P removal), the incremental benefit achieved relative to *in situ* nitrification may need to be considered.

Stormwater load reductions

Stormwater and flow from perennial streams that drain directly to SFB deliver seasonally-varying N and P loads to the system. Only rough estimates of those loads are available at this point. At the subembayment scale, stormwater N and P loads have the potential to contribute substantially to total nutrient loads in Suisun Bay and San Pablo Bay during the wet season (Figure 6.2; SFEI 2014a), and are of lesser importance in other subembayments. Although more work is needed to better constrain loads from stormwater and perennial streams, it seems unlikely that stormwater N and P loads would rival POTW loads at the subcatchment scale unless the current stormwater load estimates substantially underestimate actual loads. In calculating the stormwater loads, only inorganic NH_4^+ , NO_3^- , and o-PO_4 . Recent stormwater monitoring data suggests that organic N and non-o- PO_4 forms of P commonly comprise more than 50% of total N and P (SFEI 2014d). At the same time, a portion of the organic-N and particle-complexed P pool would be less bioavailable than DIN and DIP, and would be only slowly converted to bioavailable forms. In summary, it is possible that subembayment-scale stormwater loads could be higher than initially estimated and may warrant further examination. For LSB, South Bay, Central Bay, and (to a lesser extent) Suisun Bay, even if stormwater loads were twice as large, their contribution to N loads would remain relatively small compared to POTW loads; however, stormwater P loads could prove non-trivial. Stormwater N and P cannot be discounted in San Pablo Bay.

The discussion of stormwater loads above was focused primarily on their subembayments-scale importance. Stormwater and perennial stream N and P loads have the potential to be more important in shallow margin habitats than they appear to be at the subembayment scale, and a more spatially-explicit evaluation may of their importance may be warranted.

Changes in grazer abundance due to climate forcings or other factors

In some SFB subembayments, grazing plays an important role in limiting phytoplankton biomass accumulation. Cloern et al. (2007) argue that a loss of benthic grazers due to a shift in the Pacific Decadal Oscillation (PDO) could be responsible for much of the increase in phytoplankton biomass in South Bay and LSB (Figure 7.10). A shift in the PDO back to pre-1998 conditions would presumably allow benthic grazers to repopulate South Bay and Lower South Bay, and return phytoplankton biomass to lower levels. On the other hand, a decline in *Potamocorbula* in Suisun Bay due to disease or other factors would eliminate a major sink for phytoplankton biomass, and allow for large blooms to return and better support the food web.

Wetland and salt pond restoration

Wetland and salt pond restoration efforts around the Bay's margins have the potential to reduce N (and to a lesser degree P) concentrations and potentially play a major role in an integrated nutrient management strategy. Denitrification (or annamox) converts NO_3^- to N_2 gas, thus serving as a true N sink. High denitrification rates can occur in wetlands. However, denitrification rates vary over a wide range, with strong dependence on temperature and other conditions (e.g., amount of labile organic matter in the sediments). Furthermore, sufficient hydraulic exchange needs to occur between the nitrate-replete Bay and wetlands to maximize loss by denitrification. This latter limitation could be overcome by moving deep-channel POTW outfalls to locations within wetlands so that they directly discharge effluent to wetlands. However, the issue of seasonally-varying denitrification rates would remain. Wetlands also

retain P. However, unlike N, P has no true sink other than burial, which is inherently inefficient both because of resuspension and recycling.

The largest wetland restoration efforts are currently going forward in LSB and in the southern third of South Bay (Figure 2.1). The scale of planned restoration is such that those areas could potentially serve as major nutrient sinks. Large areas that ring other subembayments are also being considered for wetland restoration. While the use of wetlands to remove nutrients holds promise, its potential to mitigate the adverse impacts of high nutrient loads would need to be carefully evaluated, initially through modeling work, and subsequently, if warranted, through pilot field studies.

Managed shellfish beds to maintain low phytoplankton biomass

Using managed shellfish beds (e.g., clams, oysters) is an alternative management option being considered in other estuaries to maintain phytoplankton biomass at acceptable levels (Rose et al., 2014). The *Potamocorbula* invasion in Suisun Bay serves as an unfortunate yet compelling example how effective shellfish can be at reducing biomass (Figure 3.8). Managed shellfish beds could be used exclusively as a phytoplankton biomass management tool, or could be a commercial venture that offsets some of the associated maintenance costs. The bed's collective filtration rates would need to be great enough to maintain baseline phytoplankton levels at acceptable levels. The beds would also need to control phytoplankton blooms, which in SFB deep subtidal habitats tend to occur during relatively short windows of time (e.g., 5-10 days). The collective filtration rate of beds would be directly related to shellfish biomass, which would in turn depend on food that had been previously available to support their growth. Pre-growing enough shellfish biomass to handle, for example, a spring bloom would require a well-coordinated program. Shellfish beds would need to be placed in appropriate locations and at appropriate densities so that they could access sufficient phytoplankton. The feasibility and effectiveness of cultivated shellfish beds as a management option could be initially evaluated through basic modeling, and explored through pilot studies thereafter. Given the large amounts of legacy bioaccumulative pollutants (e.g., methyl-Hg, PCBs) in San Francisco Bay, the suitability of shellfish for human consumption or as animal feed needs to be considered. Shellfish are primary consumers and would therefore tend to bioaccumulate lower levels of contaminants than higher trophic level organisms, especially during early life stages when they are steadily increasing their own biomass.

Load decreases from the Central Valley

To the extent that elevated nutrients are having adverse impacts in Suisun Bay along pathways other than those related to high-biomass/low-DO, reductions in the loads entering Suisun Bay from the Delta would have the potential to substantially mitigate these adverse impacts. However, there remains uncertainty and disagreement within the scientific community about several of the hypothesized mechanisms for nutrient-related adverse impacts (NH_4^+ inhibition, phytoplankton community composition, elevated NH_4^+ or N:P allowing *Potamocorbula* to become and remain established; effects on higher trophic levels of nutrient-induced changes in the N:P of individual phytoplankton cells) and their importance relative to other processes that regulate biomass accumulation. If these hypothesized mechanisms will be included among the potential adverse impacts that management decisions will aim to address, more investigation is needed into the hypothesized underlying mechanisms and the potential importance of their effects relative to other factors regulating ecosystem response.

Delta nutrient loads to SFB influence ambient concentrations most in Suisun Bay and San Pablo Bay. Initial estimates suggest that Delta loads could be the dominant nutrient source to Suisun and San Pablo Bays throughout much of the year (Figure 6.3; SFEI, 2014a,b). Delta loads would also influence ambient concentrations in Central Bay, but likely to a lesser extent than in the up-estuary subembayments. While during very high flows some freshwater from the Delta has been shown to enter South Bay and, less frequently, LSB, the Delta-derived loads likely have relatively low influence there.

Scenarios for load decreases from the Central Valley can be divided into three groups: 1. decreased loads from the Regional San POTW, which is located ~70 km upstream of Suisun Bay along the Sacramento River; 2. reductions from other POTW discharging within the Delta or in upstream watersheds; and 3. reductions in agriculturally-derived loads, originating either within the Delta or within the watersheds drained by the Sacramento or San Joaquin Rivers. As noted earlier, Regional San's current discharge of ~15000 kg d⁻¹ DIN, primarily in the form of NH₄⁺, travels along the Sacramento River's main stem, and also moves with the river into and through the Delta. During low flow periods considerable nitrification (up to 60%; Parker et al., 2012; SFEI 2014b) and likely some denitrification can occur in transit. The Sacramento River, prior to reaching Regional San's discharge, also carries a large and seasonally varying NO₃⁻ load, presumably from upstream agriculture loads (Kratzer et al. 2011). The San Joaquin River also delivers large and seasonally varying NO₃⁻ loads to the Delta (Kratzer et al., 2011), but relatively little NH₄⁺. Due to complex flow patterns within the Delta, water withdrawals that alter flow routing, and transformations, losses, and additional loads within the Delta, determining which sources contribute most to loads that eventually enter SFB will be a non-trivial undertaking. That said, it is reasonable to suggest that most of the NH₄⁺ load (and some of the NO₃⁻ due to *in situ* nitrification) appears to originate from Regional San, while other sources, including agriculture, contribute a substantial portion of the NO₃⁻ load. Recent permit requirements are requiring In response to recent permit requirements, Regional San will nitrify and carry out biological nitrogen removal before discharge, with upgrades implemented by the year 2020. Under this upgraded operation, Regional San will discharge ~5,000 kg d⁻¹ NO₃⁻ and little or no NH₄⁺, amounting to a complete shift from NH₄⁺ to NO₃⁻, and a 2/3 reduction in overall DIN load. The cessation of NH₄⁺ loads will represent a considerable reduction in overall NH₄⁺ loads to Suisun Bay during much of the year, and will also likely translate into substantial DIN loads to Suisun Bay. The feasibility and effectiveness of agricultural N and P load reductions also need to be considered. Initial estimates indicate that these loads are large during some times of the year (Figure 6.2). Any major reductions in agriculture-sourced loads could therefore have a substantial effect on nutrient concentrations in Suisun and San Pablo Bay. However, achieving those reductions is made more challenging by their nonpoint-source origins. Loads from POTWs that discharge within the Delta are relatively small at the scale of the whole Delta-Suisun system and the loads that enter Suisun. To better understand the effect that load reductions at Regional San will have on nutrient levels in Suisun Bay, nutrient fate and transport within the Delta and Suisun Bay need to be examined through modeling and field studies, since initial mass balance estimates suggest that losses of NH₄⁺ and DIN can be substantial (SFEI 2014b, Novick et al., 2014)

11.4 How would San Francisco Bay respond to changes in nutrient loads?

Carstensen et al. (2011) and Duarte et al. (2009) explored multi-decade water quality observations in 6 nutrient-impacted estuaries in Europe and North America over time courses

that included periods of eutrophication and subsequent recovery periods when nutrient loads were reduced through management actions. In all cases they found that the chl-a:nutrient relationship exhibited considerable hysteresis, and the estuaries followed markedly different and slower recovery trajectories in terms of chl-a response than than expected based on the eutrophication trajectories. Duarte et al. (2009) hypothesized that the apparent hysteresis in the chl-a response during the phase when total nitrogen decreased resulted from shifts in baseline conditions over time that made the systems more sensitive to nutrients, and/or “regime shifts” from one relatively stable system state to another. In both cases, they suggest that the altered responsiveness could have been caused or hastened by nutrients themselves or be the result of other physical or biological factors (e.g., invasive species, increased water temperature). Carstensen et al. 2011 observed that the ratio of chl-a:TN actually increased in a consistent manner across the 4 systems they studied, and argued that large-scale changes were the cause (e.g., climate change, or similar types of increased human stress on coastal ecosystems).

Based on observations in other estuaries, it is reasonable to expect that there will be hysteresis in the response:nutrient relationship (e.g., chl-a:TN, HAB-frequency:TN) in SFB during the early stages after any load reductions are implemented. That likelihood needs to be kept in mind when considering incremental management actions and adaptive management to inform next steps. It will also be important to manage expectations of regulators, managers, stakeholders, and the public by communicating the complexities of ecosystems and uncertainties, and foreshadowing the likelihood that responses to management actions may be muted or delayed. It is important to note that, although both Duarte et al (2009) and Carstensen et al. (2011) deliver discouraging news, both studies stress that nutrient load reductions were nonetheless important to have implemented: although conditions may not have improved to the degree originally expected, based on their conceptual models and empirical evidence no action would have led to worsened conditions.

11.5 High priority subembayment-scenario-response combinations

Through evaluating the full range of scenarios summarized in Figure 11.3 (Sections 11.2-11.3), a subset of scenario-subembayment-response combinations emerged as the highest priority issues to address through near-term research and monitoring (e.g., over the next 1-5 years):

Adverse Impact Combinations

1. High biomass leading to low DO or nuisance levels of phytoplankton in LSB and South Bay, based on both current trends and future conditions under several scenarios
2. Low DO, resulting from high phytoplankton biomass, in margin habitats (sloughs, creeks, wetlands, restored salt ponds), under current conditions and potentially exacerbated by several future scenarios.
3. HABs/NABs based on both current conditions/trends and on future conditions under several scenarios, including reconnection of salt ponds, longer stratification, climate regime shift, and climate change.
4. Low phytoplankton biomass in Suisun Bay under current conditions

Mitigation/Prevention Combinations

5. Reductions in nutrient loads from direct POTW discharges, and reduction in nutrient loads from the Delta
6. Reductions in stormwater nutrient loads
7. Other mitigation strategies: wetland treatment and managed shellfish beds

8. Effectiveness of nitrification (at Regional San and Suisun direct POTWs) on NH_4^+ inhibition of primary production.

11.6 Priority science questions

Based on the high priority adverse impact and management scenarios, we identified a set of high-level priority science questions and the types of investigations that are needed to address these questions (Tables 11.3 and 11.4). These questions are not necessarily intended to be an exhaustive list, but rather to serve as a starting point that can be refined as detailed science plans are developed.

Table 11.3 Highest priority adverse impact scenarios, science questions, and types of studies needed to address those questions

	Literature Review	Analysis of existing data and synthesis	Data collection and monitoring	Field or laboratory experiments	Bay Modeling: Basic	Bay Modeling: Complex or full bay	Watershed Modeling	Assessment Framework	Technology, cost-benefit analysis
1 High phytoplankton biomass and low DO in LSB and South Bay									
a. What level of phytoplankton biomass (and over what area, for what period of time) would result in adverse impacts in LSB and South Bay habitats?	x	x			x	x		x	
b. What are the relative importances of the fundamental drivers that underlie recent changes in phytoplankton biomass in LSB (decreased SPM, loss of benthic grazers, other)?		x	x		x	x			
c. What is the importance of organic matter produced in margin habitats to biomass and DO budgets in LSB and South Bay deep subtidal habitats?			x		x	x			
d. What will be the response of phytoplankton biomass and DO if suspended sediments continue decreasing at rates similar to the past 20 years? Do adverse impacts become increasingly likely at environmentally-relevant SPM values? Or are adverse impacts unlikely along this pathway under this scenario?			x		x	x			
e. What scenarios could lead to worsened conditions and adverse impacts? - Longer periods of stratification due to salt pond and wetland restoration efforts, higher production/biomass? - Changes in climate patterns, longer periods of stratification, higher T, higher production/biomass? - Salt pond and wetland restoration, greater biomass production in margin habitats that is transported to deep subtidal habitats? - Multiple changes in parallel (lower SPM, longer stratification, biomass from margins, low grazing rates)?		x	x	x	x	x			
f. Based on this analysis, what are likely future trajectories in LSB and South Bay? Will biomass concentrations level off or continue increasing? What will be the response of DO?		x	x		x	x			
g. What reductions in nutrient loads are necessary to prevent adverse impacts?			x		x	x			
2 High phytoplankton biomass and low DO in margin habitats									
a. What low DO 'severity' would cause adverse impacts: spatial extent within individual sub-habitats (e.g., %age of slough), DO deficit, frequency, duration? Individual sub-habitats vs. overall condition (e.g., individual slough(s) impacted vs. percentage of total slough kilometers impacted)?	x	x						x	
b. How common (spatially) are low DO occurrences in these habitats? What is the severity of the low DO in each sub-habitat and collectively (within individual sloughs/creeks/salt-ponds, and collectively, what is the spatial extent (e.g., small stretch vs. entire slough), frequency, duration, DO deficit, bottom layer or full water column)?		x	x						

	Literature Review	Analysis of existing data and synthesis	Data collection and monitoring	Field or laboratory experiments	Bay Modeling: Basic	Bay Modeling: Complex or full bay	Watershed Modeling	Assessment Framework	Technology, cost-benefit analysis
c. Are relevant biota adversely impacted by low DO? Field surveys, potentially controlled studies. Avoidance, stress/toxicity, death	x	x	x	x					
d. What mechanisms act to cause the periodicity of low DO, including causing it to develop and dissipate? New organic matter sources (e.g., <i>in situ</i> production within sloughs or inputs from adjacent habitats, microphytobenthos vs. phytoplankton), on-going sediment oxygen demand, residence time, stratification, freshwater inputs, tidal exchange		x	x	x	x	x			
e. To what extent do anthropogenic nutrient loads contribute to or cause increased severity (spatial extent, DO deficit, frequency, duration) of low DO?		x		x	x				
f. Based on observed (or modeled) conditions relative to conditions that have adverse impacts, are these habitats (subset or as a whole) adversely impacted by low DO?		x	x		x	x		x	
3. HABs/NABs and phycotoxins									
a. What frequency or magnitude of HABs/NABs or HAB-toxins would be considered to cause adverse impacts?	x	x			x			x	
b. How do the abundances of phycotoxins and the HAB-forming species vary in space and time within the Bay? Have there been detectable changes over time, based on existing data? What are the sources of phycotoxins (in situ production vs. transport into SFB or subembayments)?		x	x	x					
c. What causes/contributes to increased frequency or elevated abundances of HAB/NAB-forming organisms? To what extent do nutrients cause, contribute to, or enable increased abundance/blooms? Seeding rates from the coast, seeding rates from adjacent habitats (including salt ponds), role of physical drivers (T, light, mixing/stratification) and chemical conditions (nutrients) favoring higher <i>in situ</i> production specifically of <u>HAB/NAB forming organisms</u>	x		x	x	x	x			
d. What causes/contributes to production of <i>in situ</i> phycotoxins production? To what extent do nutrients cause, contribute to, or enable increased phycotoxins production? role of physical drivers (T, light, mixing/stratification) and chemical conditions (nutrients) favoring higher <i>in situ</i> production	x		x	x					
e. What future scenarios could increase the frequency or severity of HAB/NAB events or increase phycotoxin abundance? - restoration and reconnection of salt ponds/wetlands? high-light, warm, nutrient-replete incubators? - future water management practices in the Delta (withdrawals, longer residence times) ? - changes in climate patterns? How likely are those changes in the 20-30 yr time horizon?		x	x	x	x				

	Literature Review	Analysis of existing data and synthesis	Data collection and monitoring	Field or laboratory experiments	Bay Modeling: Basic	Bay Modeling: Complex or full bay	Watershed Modeling	Assessment Framework	Technology, cost-benefit analysis
h. Based on a comparison of observed conditions and conditions considered to induce adverse impacts, are regions/subembayments/habitats of SFB experiencing HAB/NAB related adverse impacts, or will they in the future?			X					X	
i. What decreases in nutrient loads or ambient nutrient concentrations would decrease adverse impacts, or the risk of adverse impacts, from HABs/NABs?					X	X			
4. Other Nutrient Impact Pathways: Low phytoplankton biomass (NH₄⁺ inhibition), Suboptimal phytoplankton community composition									
a. What is the underlying mechanism by which NH ₄ ⁺ slows or inhibits primary production? Characterize NH ₄ ⁺ concentrations and magnitude of effect. At what NH ₄ ⁺ concentrations are primary production rates substantially impacted?	X	X		X					
b. What is the relative contribution of elevated NH ₄ ⁺ compared to other factors that maintain low phytoplankton biomass in Suisun Bay (clam grazing, light limitation, flushing)?					X	X			
c. Are current NH ₄ ⁺ loads or concentrations adversely impacting biomass levels in Suisun Bay?		X	X		X	X		X	
d. What nutrient load reductions would prevent or mitigate adverse impacts due to NH ₄ ⁺ inhibition of primary production?					X	X			
e. What constitute optimal, or healthy, phytoplankton assemblages in SFB's subembayments? Conversely, what assemblages would be considered to poorly support desirable food webs?	X	X						X	
f. How have phytoplankton community compositions changed within SFB subembayments over recent years?		X	X						
g. Based on what is known from other systems or from prior experimental/field work (Bay-Delta or elsewhere), what hypothesized mechanisms are most likely to influence phytoplankton community composition in the Bay-Delta, based on ambient conditions (nutrient concentrations, light, temperature, stratification, etc.)? What controlled experiments or observations in SFB are needed to further evaluate these proposed mechanisms in SFB?	X	X							
h. What is the magnitude (or relative importance) of the role that current ambient nutrient concentrations play in shaping phytoplankton community composition?	X	X		X	X	X			
i. What changes to nutrient availability would mitigate or prevent adverse impacts of nutrients on phytoplankton community composition?	X	X		X	X	X			
i. What other adverse impact pathways may require further attention in SFB (aquatic macrophytes, macroalgae, SAV habitat)?	X	X							

Table 11.4 Highest priority mitigation scenarios, science questions, and types of studies needed to address those questions

	Literature Review	Analysis of existing data and synthesis	Data collection and monitoring	Field or laboratory experiments	Bay Modeling: Basic	Bay Modeling: Complex or full bay/Delta	Watershed Modeling:	Assessment Framework	Technology, cost-benefit analysis
5. Reductions in nutrient loads from POTWs and nutrient loads from the Delta									
a. What are the magnitudes of loads from individual POTWs?		x	x						
c. How do internal processes shape nutrient concentration within SFB, how do they vary in space/time: mixing/flushing, nitrification, denitrification, uptake/assimilation, regeneration from sediments, etc.				x	x	x			
b. What are the zones of influence and magnitude of contributions of individual POTWs and Delta loads, and how do these vary seasonally and interannually?					x	x			
d. How do Delta loads to Suisun Bay vary seasonally and interannually? What portions of the loads that enter Suisun Bay from the Delta originate from Regional San, others POTWs? What portions of the loads come from Central Valley agriculture? What are the load contributions from agriculture within the Delta?		x	x		x	x	x		
f. What will Delta loads to Suisun Bay be under future scenarios: restoration, changes to water management practices, changes in agricultural practices?					x	x			
i. Considering areas of influence, zones where impairment may be occurring, and internal processes, what combination of load reductions are needed to mitigate or prevent impairment?					x	x			
g. What is the range of options for achieving various levels of nutrient load reductions from POTWs? What are the costs and multiple benefits (nutrients + other benefits, e.g., recycled water) of individual POTW efforts, and of longer-term integrated sub-regional plans?									x
h. Given the necessary load reductions and cost-benefits, what are the best options for achieving load reductions?									x
6. Reductions in stormwater nutrient loads									
a. Are stormwater nutrient loads potentially important sources to some margin habitats in some subembayments, or at the subembayments scale, and do they warrant further consideration?		x	x		x	x	x		
b. If yes, what are the loads from priority watersheds? What is their contribution to nutrient loads, or organic matter/BOD loads, to margin habitats?		x	x				x		
c. What are the magnitudes of stormwater nutrient contributions to deep subtidal habitats in other subembayments?					x	x			

	Literature Review	Analysis of existing data and synthesis	Data collection and monitoring	Field or laboratory experiments	Bay Modeling: Basic	Bay Modeling: Complex or full bay/Delta	Watershed Modeling:	Assessment Framework	Technology, cost-benefit analysis
7. Other mitigation strategies: wetland restoration/treatment and shellfish beds									
a. What is the potential for wetland restoration/treatment to mitigate adverse impacts of nutrients?	x				x	x			
b. What is the potential for managed shellfish beds to mitigate adverse impacts of nutrients?	x				x	x			
b. If wetlands or managed shellfish beds appear to be promising nutrient management options – what do pilot studies, advanced modeling, and economic considerations suggest about their potential to be part of an integrated management program?					x	x			x
8. Influence of nitrification at Regional San and Suisun direct POTWs on NH₄⁺ inhibition of primary production or other adverse impacts									
a. What is NH ₄ ⁺ fate within the Delta and how does this change as a function of season, flow, etc.?					x	x			
b. What load reductions are necessary to reduce NH ₄ ⁺ to ambient concentrations that would not inhibit production or have other adverse impacts?					x	x			

12 Key Observations and Recommendations

12.1 Key observations

1. Changes in SFB's response to nutrient loads over the past decade, combined with the Bay's high nutrient loads and concentrations, justify growing concerns about elevated nutrients.
2. The future trajectory of SFB's response to nutrients is uncertain. One plausible trajectory is that SFB maintains its current level of resistance to the classic effects of high nutrient loads and no further degradation occurs. A second, equally plausible scenario is that SFB's resistance to nutrients continues to decline until adverse impacts become evident. The highly elevated DIN and DIP concentrations Bay-wide provide the potential for future impairment. Any major reductions in loads to SFB will take years-to-decades to implement. Thus, if future problems are to be averted, potential impairment scenarios need to be anticipated, evaluated, and, if deemed necessary, managed in advance of their onset.
3. By considering current conditions in SFB, trends of changing ecosystem response, and a conceptual model for SFB's response to nutrients, we identified the following highest priority issues:
 - a. Determine whether increasing biomass signals future impairment. This issue is most pertinent for Lower South Bay and South Bay.
 - b. Characterize/quantify the extent to which excess nutrients contribute now, or may contribute in the future, to the occurrence of HABs/NABs and phycotoxins.
 - c. Determine if low DO in shallow habitats causes adverse impacts, and quantify the contribution of excess nutrients to that condition.
 - d. Further evaluate other hypotheses for nutrient-related adverse impacts to ecosystem health, including nutrient-induced changes in phytoplankton community composition and ammonium inhibition of primary production. That evaluation – to include data analysis, additional experimentation, or modeling – should assess their potential quantitative importance, and help to determine if they should be considered among the highest priority issues.
 - e. Test future scenarios that may lead to worsening conditions through the use of numerical models.
 - f. Quantify the contributions of nutrients by sources in different areas of the Bay, considering both their transport and in situ transformations and losses.
 - g. Evaluate the potential effectiveness of various nutrient management strategies at mitigating or preventing adverse impacts.
4. Although concern related to changing ecosystem response in SFB is warranted, widespread and severe nutrient-related impacts do not currently appear to be occurring, based on existing sampling locations and parameters commonly measured. This apparent lack of current severe impacts translates into time for conducting investigations to improve understanding of SFB's response to nutrients and allows for sound, science-based management plans to be developed and implemented. That said, the considerable amount of time required to implement any management strategy raises the level of urgency such that work should move forward expeditiously.

5. Given the stakes of no action - and the time required for data collection, analysis, and modeling tools to reach a useable state - work needs to move forward in parallel on implementing multiple aspects of the Nutrient Strategy. A well-coordinated program is needed to maximize the effectiveness and efficiency of this effort. That program needs to integrate seamlessly across what might otherwise be (or become) semi-independent program areas. Specifically, we recommend the following set of highly-integrated program areas:
 - a. **Monitoring:** Develop and implement a sustainably-funded and regionally administered monitoring program that continues routine monitoring, and fills newly-identified data gaps relevant to nutrients;
 - b. **Modeling:** Develop and apply linked hydrodynamic and water quality models to integrate observations, identify critical data gaps (to be addressed through monitoring or experimental studies), quantify processes at the ecosystem scale, and evaluate future scenarios (including management alternatives);
 - c. **Observational and Experimental Studies:** Undertake special studies (field investigations, controlled experiments) to address the highest priority knowledge and data gaps identified in #3; and
 - d. **Data Synthesis and Interpretation:** Analysis of existing and newly collected data (from monitoring and experimental studies), incorporating models, to improve understanding of linkages between nutrients and ecosystem response and to inform the development of an assessment framework.
6. The Delta/Suisun boundary, while an important regulatory boundary, is not meaningful from ecological and loading standpoints. Nutrient loads to and transformations within the Delta exert considerable influence over nutrient loads to and ambient concentrations within Suisun, San Pablo, and Central Bays. Furthermore, the ecology and habitat quality of the Delta and Suisun Bay are tightly coupled. A unified approach – one that spans the Bay-Delta continuum - for evaluating the impacts of nutrients on beneficial uses will best serve both ecosystem health in the Bay-Delta and the information needs of environmental managers.

12.2 Recommendations for Addressing Priority Knowledge Gaps

Section 12.2.1 provides an overview of the recommended highest priority work efforts over the next 1-5 years to address knowledge and data gaps to, in a targeted way, inform nutrient management decisions in SFB. The process we followed (outlined in Figure 1.1) consisted of

- Identifying the highest priority scenarios (Section 11) for potential impairment along one or more pathways, and high priority science questions that need to be addressed related to those scenarios (Tables 11.3 and 11.4);
- Prioritizing data or knowledge gaps related to the key processes that control ecosystem response to nutrients along the pathways of the near-term highest priority scenarios, developed within conceptual module descriptions in Sections 6-10 and identified in Tables 6.2, 7.1, 8.1, and 9.1.

Recommendations presented in Section 12.2.1 are organized around several major themes or types of work. Not all high priority data gaps are discussed below, and the reader is also referred to Tables 6.2, 7.1, 8.1, and 9.1 and Tables 11.3-11.4. Section 12.2.2 takes a broader view, and describes knowledge gaps and data needs in terms of a set of ecological and management challenges that lie ahead.

12.2.1 Recommendations

R.1 Develop a regionally-administered and sustainably-funded nutrient monitoring program

Major research and monitoring efforts in San Francisco Bay and the Delta include the USGS research program¹⁰ and the IEP Environmental Monitoring Program (Figure 5.3).¹¹ The data generated through these programs, and the related interpretations, form much of the foundation for current understanding of SFB's response to nutrients. However, the focus and mandates of these programs are not necessarily aligned with those of a program designed to inform nutrient management decisions. Furthermore, future funding of the USGS program is uncertain.

Developing a regionally-administered and sustainably-funded nutrient monitoring program needs to be a major priority. Effort needs to be directed toward developing the institutional and funding frameworks for the program, and developing its primary science goals and activities. Several initial recommendations are presented below.

R.1.1 Program development

R.1.1.1 Develop institutional and funding agreements

Developing and implementing a regional nutrient monitoring program will be a major undertaking in terms of logistics and cost, and long-term institutional support will be needed. There are several entities currently involved in ship-based and continuous (moored sensors) monitoring (e.g., USGS, IEP, CA Department of Water Resources, CA Department of Fish and Game). To avoid unnecessary duplication of effort and maximize resources, there may be considerable advantage to achieving some monitoring program goals through fostering close coordination among on-going programs, and augmenting those efforts with additional monitoring. Activities distributed across independent programs need to be well-coordinated, especially in terms of methods, QA/QC, data management and data sharing, synthesis, and reporting.

R.1.1.2 Develop the monitoring program science plan: management questions, goals, priorities, and approaches

A nutrient monitoring program science plan needs to be developed that lays out the management questions, and the program's goals and priorities relative to those management questions. Detailed plans for achieving those goals also need to be developed. A number of the goals and data needs may differ considerably from those of the current research and monitoring activities (i.e., USGS, IEP). When evaluating the future program's needs relative to current efforts, particular attention needs to be given to the following issues:

- The optimal distribution of effort and resources among broad monitoring categories (water column vs. benthos, shoals vs. channel, open bay vs. margins, physical/hydrodynamic vs. biological vs. chemical)
- Key parameters or processes to be measured within these categories;
- Spatial and temporal resolution of sampling; and
- The distribution of monitoring effort between ship-based sampling and moored sensors for continuous monitoring.

¹⁰ <http://sfbay.wr.usgs.gov/access/wqdata/>

¹¹ <http://www.water.ca.gov/iep/activities/emp.cfm>

For some of these issues, considerable data resources already exist from long-term monitoring in SFB. A major component of the monitoring program design effort should include analyzing this data to inform decisions (e.g., about the necessary spatial and temporal density of sampling). Pilot studies should also be part of planning, to inform which parameters provide important additional information, test methods that provide less expensive approaches for essential data collection, and select moored sensor sites and parameters.

R.1.2. Initial monitoring program science recommendations

Several clear monitoring program recommendations emerged through developing the conceptual model, and identifying data/knowledge gaps related to priority scenarios (Tables 6.2, 7.1, 8.1, and 9.1).

R.1.2.1 Continue ship-based monitoring along SFB's deep channel

The long-term record provided by the USGS research program has yielded important insights into the mechanisms that shape SFB's response to nutrients, including physical and biological processes that regulate that response, and how that response has changed over time. Maintaining and building upon this program will be critical for anticipating future changes, and for assessing the effectiveness of any management actions. New parameters may be needed informative, such as size-fractionated chl-a and C:chl-a, organic forms of N and P, as well as others noted below.

R.1.2.2 Develop a moored sensor sub-program for high temporal resolution data

Data collection at higher temporal resolution for chl-a, DO, nutrients, turbidity, and other parameters is needed at multiple locations to assess condition and to improve our quantitative understanding of ecosystem response to nutrients, including the processes that influence phytoplankton blooms, influence oxygen budgets, and regulate nutrient fate. High temporal resolution data will be essential for accurately calibrating water quality models. Continuous monitoring with moored sensor systems is feasible for a wide range of water quality parameters. Techniques for some parameters are becoming increasingly well-established and reliable (e.g., salinity, T, turbidity, chl-a, DO), while others are advancing (e.g., nitrate, phosphate, ammonium, phytoplankton counts and identification). Moored sensor systems can telemeter data, allowing for near real-time assessment of conditions. The data from moored sensors are not a substitute for ship-based sampling, but rather provide strongly complementary information about physical and biological processes that influence key water quality parameters (chlorophyll, DO, T, SpC) over time-scales (hours) that are too short to effectively monitor or study through ship-based sampling. While there are currently multiple stations in Suisun Bay and the Delta that measure some nutrient-related parameters, there are only 3 newly-added stations south of the Bay Bridge for measuring chl-a or nutrients (added in September 2013), and few that measure DO and other parameters (T, SpC, turbidity).

R.1.2.3 In addition to monitoring along the channel, monitoring is needed in shoal environments, including lateral transects

Sampling along the shoals is needed for improved understanding of phytoplankton and nutrient processes, and for model calibration. Most of the water quality data available in SFB is from stations along the deep channel. The shoals are important areas for phytoplankton and MPB production, and large lateral heterogeneities in phytoplankton biomass (and SPM, which influences light availability and growth rates) are common in SFB (Thompson et al., 2008; Cloern, 1995). In addition, a substantial proportion of nutrient transformations likely take place along the shoals (benthic nitrification and denitrification). Shoal monitoring can be accomplished

both through boat/ship-based transects or with moored sensors, and the best approach will vary depending on the questions being addressed. Using autonomous underwater vehicles (AUVs) outfitted with sensors may also be a possibility. AUVs are commonly employed in research studies, and some AUV-sensor systems are already commercially-available. Pilot studies that test AUVs in SFB would be useful for assessing the feasibility and cost effectiveness of this approach, and to inform planning.

R.1.2.4 Coordinated monitoring in shallow subtidal habitats.

Some agencies (e.g., stormwater, wastewater) carry out periodic monitoring in shallow habitats, and several focused studies have been conducted in Lower South Bay systems (Thebault et al., 2008; Shellenbarger et al. 2008; Topping et al., 2009). However, there is currently no systematic monitoring in shallow margin habitats either at the subembayments scale or Bay-wide. Data collection on productivity (e.g., chl-a, light levels) and DO concentrations in select systems would help inform whether adverse impacts are occurring in these systems due to low DO, and help ascertain the causes of low DO. Before embarking on this effort, it would be worthwhile to examine existing data from current or recent studies (e.g., studies in LSB) to assess the need for monitoring and identify the best approaches to pursue.

R.1.2.5 Increased focus HAB/NAB-forming species, phycotoxins, and phytoplankton community composition in general

Given the prevalence of HAB-forming organisms in the Bay and the frequent detection of phycotoxins Bay-wide, it would be prudent to more closely monitor phytoplankton composition, the occurrence of HAB-forming organisms and phycotoxins within San Francisco Bay. Composition and biovolume data collected for HAB-related work would also support assessment and improved mechanistic understanding of other hypothesized nutrient-related shifts in phytoplankton community composition. The abundance and forms of nutrient are two among many factors that can influence phytoplankton community composition and the occurrence of HABs. The relative contributions of those factors toward causing adverse shifts in composition or HAB occurrences are poorly understood. More frequent (in space and time) analysis of phytoplankton composition and phycotoxins, in combination with special studies, (see Recommendation 4.1) will be needed to better understand these mechanisms and assess potential linkages to nutrients.

Determining taxonomy and biomass by microscopy is expensive and time consuming, which limits the amount of data that can be collected. Some amount of manual microscopy ground-truthing will always be needed. However, other techniques, in combination with microscopy, may allow for increased data collection of at lower costs. Carrying out pilot studies will help inform which techniques provide valuable and cost-effective information. Measuring phytoplankton-derived pigments is one such approach. Different classes of phytoplankton have distinct pigment fingerprints. It is possible, with sufficient calibration (relative to microscopy) and training of software to quantify phytoplankton biomass within specific classes. Flow cytometers and digital imaging tools are also available. These systems - which measure optical properties and capture images of individual cells, and employ image-recognizing software to identify and count phytoplankton down to the species level - can be deployed at moored stations for continuous monitoring, used on a monitoring vessel as it cruises along a transect, or used in the laboratory. Moored applications can telemeter data, allowing for near real-time information.

One such system provided early warning of a toxic algal bloom in the Gulf of Mexico.¹² An additional advantage of digital imaging approaches is that an archive of phytoplankton image data would be developed: if a phytoplankton species eventually becomes important, the digital archive could be mined to determine when that species first appeared.

Pilot projects have been initiated recently that are measuring phycotoxins in SFB (Figure 3.8), and an algal pigment pilot study is underway. Continuation of similar pilot studies, and testing a variety of methods, will help identify the most informative and cost-effective options, all the while establishing baseline concentration data against which future data can be compared. The feasibility of measuring algal toxins in archived benthos samples should also be considered in order to generate longer time series of algal toxins and look for changes over the past decade or more (if well preserved samples exist).

R.1.2.6 Benthos monitoring to quantify spatial, seasonal, and interannual variability in grazer abundance

Grazing by benthic filter feeders is considered to be one of the main controls on phytoplankton biomass accumulation in several subembayments. To estimate the influence of the benthic grazing, and track its changes in space and time, benthos surveys are needed on a regular basis in some subembayments, most importantly Lower South Bay, South Bay, San Pablo Bay, and Suisun Bay. In recent years there has been ample benthos monitoring in Suisun Bay and the Delta (and some in San Pablo Bay), although the fate of this program is not known. There are currently no sustained programs in the other subembayments. However, there are some years during which intensive benthic sampling has taken place (e.g., Thompson et al. 2008; see Figure 7.4.B), and along with opportunistic sampling efforts (in some cases, samples have been archived but not yet analyzed for biomass; J Thompson, personal communication). Benthos monitoring could occur less frequent than water quality monitoring, e.g., three times per year (spring, summer, fall). Sorting, counting, and weighing benthos samples is time consuming and costly. A pilot study to test the feasibility of using benthic cameras may also be worth considering (alongside traditional sample collection for calibration/validation), since its use could potentially allow for more cost-effective benthos surveys.

R.1.2.7 Zooplankton abundance/composition

Monitoring data on zooplankton are needed to quantify pelagic grazing rates. Zooplankton abundance and composition may also serve as an important indicator of food supply and quality for higher trophic levels. Long term zooplankton monitoring has been carried out in Suisun Bay and the Delta. However, zooplankton abundance and composition are not currently measured in other subembayments.

R.1.2.8 Allocate sufficient funding for data interpretation and synthesis

Data analysis and data synthesis are essential components of a monitoring program. Allocating sufficient funds for these activities will allow field results to be efficiently translated into management-relevant observations that inform decisions, and allow the monitoring program to nimbly evolve to address emerging data requirements. Annual reports will be needed that not only compile and present data, but that also evaluate and interpret trends. More detailed special studies will also be needed periodically to generate scientific synthesis reports on complex data sets (e.g., spatial and seasonal trends in phytoplankton community composition).

¹² <http://www.whoi.edu/oceanus/viewArticle.do?id=46486>

R.2. Develop and implement a science plan for SFB that targets the highest priority management and science questions

The size of SFB, and the complexity and diversity of its nutrient-response issues, create a situation in which there are numerous science questions that need to be addressed to improve our understanding of the system. Addressing the management and science questions will require a combination of field studies, controlled experiments, monitoring, and modeling across the topics of nutrient cycling, phytoplankton response (biomass and community composition), and hydrodynamics. It will not be feasible to explore all the relevant science questions – that would take longer than management decisions can wait, and would outstrip any reasonable budget. To best target science efforts, there would be considerable benefit to developing and implementing a science plan that: identifies the highest priority management issues, and associated science questions; and identifies the sets of studies and data collection/monitoring needs that efficiently target those questions. In some cases, the management issues, science questions, data gaps, and studies may be similar Bay-wide. In other cases, the science questions or data gaps may be subembayment- or habitat-specific. The science questions listed in Tables 11.3-11.4 and the recommendations in this section could serve as a starting point in what would be an iterative Science Plan development process.

Analysis of existing data from SFB, combined with broader critical literature review, would be useful early steps in science plan development, to articulate what is well-understood - in other estuaries and SFB - and focus scientific studies and monitoring on addressing the most critical knowledge and data gaps.

R.3. Develop hydrodynamic, nutrient cycling, and ecosystem response models

Tables 11.3-11.4 illustrate that modeling will play a central role in addressing a wide range of science questions. Models can also be used to prioritize data collection needs. While there are multiple hydrodynamic models available for SFB, there are currently no integrated hydrodynamic-phytoplankton-nutrient models. Considerable progress could be made toward addressing several important science questions through using “simplified-domain” models that are built upon simplified (spatially-aggregated), but still accurate, hydrodynamics. Potential applications of these simplified domain models include (not an exhaustive list):

- R.3.1* Quantitative analysis of nutrient budgets (including losses/transformations of nutrients);
- R.3.2* Quantifying the relative importance of major processes that control primary production in Suisun Bay (light, clams, flushing, NH_4^+ inhibition), and explore which factors may explain the changes in phytoplankton biomass in South Bay over the past ~20 years.
- R.3.3* Performing sensitivity/uncertainty analysis, and identifying highest priority monitoring activities, process level studies, or rate measurements to minimize model uncertainty.
- R.3.4* Forecasting ecosystem response under future scenarios, and narrowing the list of high priority scenarios;

In developing such models, there is a benefit to “starting simple”, and adding complexity as needed. LSB/South Bay and South Bay could serve as good initial focus areas for basic model development and application, because of the abundance of data for those systems and since these two subembayments are where concerns about adverse impacts from nutrients are greatest. Lessons learned through applying basic models will be useful for informing larger-scale or more complex model development.

Higher spatial resolution models, or larger spatial scale models (e.g., full Bay as opposed to individual subembayments) will be needed to explore several important issues, including:

- R.3.5 Determine the zones of influence of individual POTWs under a range of hydrodynamic forcings and estimated transformations/losses
- R.3.6 Test future scenarios under which adverse impacts may develop Bay-wide or in individual subembayments
- R.3.7 Evaluate the effectiveness of different nutrient control strategies for achieving desired reductions in ambient concentrations as a function of space and time.
- R.3.8 Quantify loads from the Delta to Suisun Bay under seasonally- and interannually-varying hydrological conditions, and the influence of these loads in Suisun and down-estuary subembayments under a range of forcings.
- R.3.9 Quantify the importance of net nutrient loads from the coastal ocean to SFB under a range of commonly-occurring forcing scenarios, and explore the fate of the nutrient-rich SFB plume leaving the Golden Gate, and the potential influence of those nutrients on coastal ecosystems.

R.4. Carry out special studies to address key knowledge gaps about mechanisms that regulate ecosystem response, and inform whether or not impairment is occurring

The draft list of priority science questions in Tables 11.3-11.4, viewed alongside the data/knowledge gap priorities in Tables 6.2, 7.1, 8.1, and 9.1, present an initial picture of the types of data collection and studies that are the most important in the near term. A number of priorities have been discussed above in the context of monitoring program development (*R.1.2.1-1.2.8*) and modeling (*R.3.1-R.3.9*). An overview of special study priorities is provided below; however, the reader is also referred to the Tables 11.3-11.4, 6.2, 7.1, 8.1, and 9.1.

Nutrient cycling

- R.4.1 Controlled field/lab experiments to measure pelagic nutrient transformations (pelagic nitrification, nutrient uptake rates)
- R.4.2 Controlled field/lab experiments to measure benthic nutrient transformations (benthic nitrification, denitrification, mineralization and N and P fluxes from sediments)
- R.4.3 Quantify the importance of internal nutrient transformations using models.

Productivity of phytoplankton and MPB

- R.4.4 Controlled experiments that further test the proposed “NH₄⁺-paradox” mechanism of lower productivity when NH₄⁺ is elevated, determine relevant thresholds, and allow its effect to be better parameterized and compared to other regulating factors in models (*R.3.2*).
- R.4.5 Through analysis of existing data or through field studies, assess the variability or uncertainty in the Cole and Cloern (1987) productivity relationship due to factors such as different phytoplankton assemblages, temperature, light levels, etc.
- R.4.6 Field measurements to quantify MPB primary production rates and biomass.
- R.4.7 Compare MPB production and biomass with phytoplankton production and biomass, consider how MPB’s relative importance would change (or already has changed) due to ecosystem change (lower suspended sediments, benthic grazers), and explore how those changes influence nutrient cycling, oxygen budgets, and food webs.

Dissolved O₂

- R.4.8 Controlled field experiments to quantify sediment oxygen demand in a range of depositional environments. These can be carried out in conjunction with the benthic nutrient transformation special studies as part of the same experimental protocol (R.4.2).
- R.4.9 Monitoring and targeted mechanistic studies of DO in shallow margin habitats to assess the severity of low DO (concentration, spatial extent, frequency, duration).
- R.4.9 In cooperation with other efforts or as special nutrient-related studies, determine the degree to which low DO in margin habitats (or in open water areas of some areas of the Bay, specifically LSB) adversely impact biota. To a certain degree, this work could be carried out based on existing data from other studies on DO tolerances of key organisms. Field surveys of fish or benthos abundance may also be warranted.
- R.4.10 Through field experiments and modeling, quantify the degree to which anthropogenic nutrients contribute to occurrences of low DO.

HABs, toxins, and phytoplankton community composition

- R.4.12 Rigorous analysis of existing phytoplankton community composition data – for HAB-forming species and composition more broadly – to test qualitative and quantitative agreement with various conceptual models, and refine those conceptual models as needed.
- R.4.13 Field studies (collecting phytoplankton composition data at higher temporal or spatial resolution) to test mechanisms of HAB development and phytoplankton community succession in response to physical, chemical, and biological drivers.
- R.4.14 Field studies to evaluate the potential importance of salt ponds as incubators of HAB-forming species.
- R.4.15 Controlled experiments, using mixed cultures and monocultures from SFB, that mechanistically explore the interactive effects of nutrient availability (including variability in concentrations and forms), light, and temperature on HAB/NAB development and phycotoxins production, or other shifts toward assemblages that poorly support food webs. The goals of such studies would be to identify conditions that favor some classes or species of phytoplankton over others under the prevailing conditions in SFB (light limitation, excess nutrients), and enable predictions about assemblage response. Such information is also essential for identifying nutrient concentrations or loads that would decrease the risk of HAB occurrences or other adverse assemblage shifts.
- R.4.16 Apply the information from R.4.1.5 within models to, among other issues, evaluate the magnitude of the nutrient component of stress, and explore potential composition responses to changing conditions, including those due to potential management actions (e.g., nutrient load reductions).

12.2.2 Grand Challenges

During the conceptual model development and identification of knowledge gaps, data gaps, and monitoring needs, four so-called “Grand Challenges” emerged related to understanding and managing SFB ecosystem health. While there is overlap between the underlying management issues that motivated the more specific recommendations above and those that motivated the Grand Challenges, the Grand Challenges represent a somewhat different, more holistic perspective or framework for considering science and data collection needs. In so doing they

highlight connections between nutrient issues and other ecosystem health concerns, and provide an additional impetus for addressing those data collection needs.

Grand Challenge 1: What do we need to know in 10-20 yrs to make improved decisions related to water quality management or ecosystem health, including those related to nutrients? 1-2 decades is approximately the time scale over which large capital improvement projects are planned and implemented. 10-20 years is also a long enough time period for trends to become evident, e.g, the changes in phytoplankton biomass in South Bay and LSB since the late 1990s (Figure 3.4). What information needs to be collected now, to serve as baseline condition data, so that changes in important indicators can be confidently identified and attributed to the correct causal agent(s), whether those changes lead to improved or worsened condition?

Grand Challenge #2: The northern estuary is poised to experience major changes due to management actions and environmental change. Anticipated changes include: nitrification and nutrient load reductions at Sac Regional wastewater treatment plant; numerous large scale restoration projects and changes in water management in the Delta; changing climate patterns altering the timing, residence time, and amount of water passing through the Delta. What do we need to be measuring now in order to determine if these changes have positive, negative, or no impacts on ecological health in SFB and the Delta? How will phytoplankton respond to changes in nutrient loads/speciation? How will the food web respond?

Grand Challenge #3: Large areas along the margins of South Bay and LSB are slated to undergo restoration. Given the size of these areas compared to the adjacent water surface area (Figure 2.1), it is reasonable to expect that proposed restorations along the margins will have measurable impacts on water quality and ecological health in the open Bay. Some of these effects may be positive, including increased habitat for fish, birds and other organisms. It will be desirable to document those changes; in order to do so, baseline data is needed for these higher trophic level indicators of ecosystem health. Those changes could also encourage more denitrification and decreased N within the Bay, which could be considered within integrated nutrient management plans. As discussed earlier, there may also be unintended and undesirable consequences, including: restored/reconnected salt ponds acting as incubators for HAB-forming phytoplankton species; exceedingly high primary production rates and high biomass, causing periodic low DO in wetlands and sloughs; and increased duration of stratification due to dampening of tidal mixing energy. What hypotheses of adverse impacts need to be tested, as part of restoration planning, so that the risks of severe unintended consequences can be minimized?

Grand Challenge #4: Similar to Grand Challenges 1-3, what baseline observational data is needed to detect climate-related changes in habitat quality in SFB and to disentangle them from other anthropogenic drivers? What types of modeling simulations should be done to anticipate effects? The CASCaDE II¹³ project is exploring these issues, largely focused in the Delta. Similar studies may be warranted in the Bay.

Abstract

Background: Tidal marshes will be threatened by increasing rates of sea-level rise (SLR) over the next century. Managers seek guidance on whether existing and restored marshes will be resilient under a range of potential future conditions, and on prioritizing marsh restoration and conservation activities.

Methodology: Building upon established models, we developed a hybrid approach that involves a mechanistic treatment of marsh accretion dynamics and incorporates spatial variation at a scale relevant for conservation and restoration decision-making. We applied this model to San Francisco Bay, using best-available elevation data and estimates of sediment supply and organic matter accumulation developed for 15 Bay subregions. Accretion models were run over 100 years for 70 combinations of starting elevation, mineral sediment, organic matter, and SLR assumptions. Results were applied spatially to evaluate eight Bay-wide climate change scenarios.

Principal Findings: Model results indicated that under a high rate of SLR (1.65 m/century), short-term restoration of diked subtidal baylands to mid marsh elevations (−0.2 m MHHW) could be achieved over the next century with sediment concentrations greater than 200 mg/L. However, suspended sediment concentrations greater than 300 mg/L would be required for 100-year mid marsh sustainability (i.e., no elevation loss). Organic matter accumulation had minimal impacts on this threshold. Bay-wide projections of marsh habitat area varied substantially, depending primarily on SLR and sediment assumptions. Across all scenarios, however, the model projected a shift in the mix of intertidal habitats, with a loss of high marsh and gains in low marsh and mudflats.

Conclusions/Significance: Results suggest a bleak prognosis for long-term natural tidal marsh sustainability under a high-SLR scenario. To minimize marsh loss, we recommend conserving adjacent uplands for marsh migration, redistributing dredged sediment to raise elevations, and concentrating restoration efforts in sediment-rich areas. To assist land managers, we developed a web-based decision support tool (www.prbo.org/sfbayslr).

Introduction

Projections of sea-level rise (SLR) range from 18 cm to nearly 2 m over the next century [1,2] (and recent assessments suggest that as much as 5 m could be possible [3]), making low-lying coastal zones particularly vulnerable to climate change. The primary threats of SLR are well known: exacerbated beach and shoreline erosion, and inundation of critical infrastructure and coastal wetlands [4–6]. Uncertainty about how dynamic ecosystems such as coastal and estuarine tidal marshes (hereafter “tidal

marshes”) may respond to different aspects of climate change has prompted a large body of research exploring potential tidal marsh responses to increased rates of SLR [7–9], as well as increased temperature [10], salinity [11], and CO₂ concentrations [12].

Tidal marshes provide high-value ecosystem services such as water filtration, flood abatement, protection for infrastructure, and carbon sequestration [13–15]. They also have high ecological value, supporting a large number of specialized and endemic species [16,17] and have already experienced dramatic historical declines in area and hydrologic integrity [18]. The sensitivity of

tidal marshes to increased rates of SLR will vary depending upon factors such as mineral sediment supply [19], vegetation productivity [7], rates of subsidence or uplift [20], changes in storm frequency and intensity [21], and availability of uplands suitable for marsh migration [22]. Estuarine systems with low sediment inputs and high rates of subsidence such as the Mississippi River Delta have already experienced substantial marsh loss due to relative SLR (i.e., including the influence of subsidence) [23], while sediment-rich systems such as parts of San Francisco Bay have demonstrated resilience to rapid rates of relative SLR [24,25].

Tidal marshes are dynamic ecosystems that occupy a relatively narrow band of elevation, governed primarily by vegetation tolerance of tidal inundation, along with other factors, including hydroperiod, sediment supply, and biological dynamics [7,8,26,27]. With adequate sediment supply, the marsh plain builds to an elevation high within the tidal frame, typically around mean higher high water (MHHW) under semidiurnal tides [28]. At higher elevations, reduced tidal inundation curtails building processes through reduced mineral sediment supply and oxidation of soil organic material. At lower elevations, increased flooding frequency and duration increase mineral sedimentation and therefore enhance marsh building. In addition, vegetation plays an important role in trapping sediment and contributing organic material through above- and below-ground growth [29,30], with additional potential feedbacks between elevation and plant dynamics [7].

Under conditions where rates of SLR exceed marsh building processes the marsh plain falls in elevation relative to the tidal frame. A new steady state may be achieved, reflecting increased sedimentation at lower elevations that balances increased SLR. Alternatively, if supply of sediment is inadequate to keep pace with SLR, the marsh plain will continue to fall relative to sea level, eventually to an elevation where vegetation cannot tolerate the prolonged inundation, and the marsh will transition to a mudflat [9,31]. When topographically suitable uplands are lacking or located behind levees (as in most urbanized estuaries), marshes will not be able to migrate landward as they have done historically, resulting in marsh loss.

Previous research has shown a positive relationship between local rates of relative SLR and rates of sediment accretion [24,25,32]. However, increased sediment accretion in response to SLR is limited by mineral sediment inputs as well as plant growth and organic material accumulation, which may decrease in response to increases in salinity resulting from SLR and changes in precipitation regimes [11]. Measured rates of sediment accretion in tidal marshes have varied from 1 to 15 mm/yr, with the highest rates recorded in regions with very high rates of relative SLR driven by local subsidence, e.g., parts of Chesapeake Bay, the Mississippi River Delta, and other large delta systems [33–36]. However, the likelihood that tidal marshes can keep pace with high rates of SLR appears to diminish rapidly if rates of relative SLR are more than 10 mm/yr or increase rapidly [37,38].

With hundreds of millions of dollars invested in tidal marsh restoration and conservation, management strategies need to clearly identify and integrate thresholds and sensitivities of mineral sediment supply, organic accumulation rates, and starting elevation for marsh sustainability under various climate change scenarios. The long-term persistence of these habitats also depends on our ability to identify and protect areas where marshes can move upland as sea level rises and to identify barriers to that movement, such as levees. Conservation planners need to know where in the landscape tidal marshes will have the greatest long-term sustainability and how to prioritize restoration activities. To

address these problems, spatially explicit projections of tidal marsh sustainability and restoration potential are needed at the estuary scale.

Many modeling approaches have been implemented and have improved our understanding of marsh responses to increased rates of SLR [39]. The challenge in developing models for tidal marshes is to combine realistic local processes of sediment feedbacks with broader scale (i.e., estuary-wide) spatial dynamics. Many models have accurately represented realistic local processes, focusing on mineral and/or organic material dynamics [7,31,40]. Most of these models lack spatial variability, although recently-developed geomorphic models also incorporate channel dynamics and erosion across the marsh plain surface [41,42]. Other models, such as SLAMM (sea level affecting marshes model), have focused on broad-scale spatial patterns but have not realistically modeled feedbacks of elevation on sediment dynamics or other critical local processes [43,44]. Combining high resolution process-based models with broad-scale spatial modeling that includes hydrodynamics would be ideal; however, this is very computer intensive and is subject to potential accumulation of errors across multiple time steps. Although estuary-wide mechanistic approaches are being developed, the application of this sort of model is currently not practical.

Given the increasing interest among resource managers in spatially-explicit, estuary-wide assessments of potential SLR impacts on tidal marshes, we developed a hybrid method that involves a realistic, mechanistic treatment of marsh accretion dynamics and incorporates spatial variation across an estuary. Our approach is simple, transparent, and easily transferable and updatable, such that results can be readily accessible to land managers. At the core is a process-based model of point-based mineral accumulation based on Krone's [45] model called Marsh98 [9,46], which includes feedbacks between elevation and sediment inputs and incorporates constant rates of organic accumulation. We extended the point-based predictions to develop spatially-explicit projections of marsh sustainability based on current marsh elevation at the 5-m pixel level, and characterization of mineral (suspended sediment concentrations) and organic (relative plant productivity) inputs at the level of biogeomorphic subregions. While this approach lacks the hydrodynamic component to spatially transport sediment, it still allows for the evaluation of realistic process-based accretion dynamics and is feasible to apply across an entire estuary, over long time frames, and across multiple scenarios. It is of particular interest in the San Francisco Bay, California, USA (hereafter "Bay"), where, since European settlement, more than 90% of tidal marshes across the Bay have been destroyed or altered, primarily through agricultural and urban land development [47,48]. Many of the Bay's remaining marshes are adjacent to developed urban areas with minimal or no natural upland buffer zones. The large-scale loss of Bay wetlands has caused dramatic functional changes to the region over the last 150 years, affecting endangered and endemic species. Furthermore, over \$60 billion in infrastructure is at risk of inundation under high rates of SLR [49]; some of this loss could be prevented with tidal marsh restoration. Thus, there is considerable interest to maintain the integrity of current tidal marshes and facilitate restoration of diked baylands throughout the Bay [50].

Herein, we used our modeling approach to explore the sustainability of tidal marshes under a range of SLR and sediment availability conditions, using San Francisco Bay as a case study. In doing so, we sought to answer the following key questions: (1) What are the thresholds and sensitivities for marsh sustainability in terms of mineral sediment supply, organic material contribution, SLR rates, and starting elevations? (2) How is the Bay-wide area

and composition of intertidal habitats likely to change under varying projections for SLR and sediment availability? (3) How much space exists for new marshes to form, and how much habitat may be expected under these different scenarios? Our goal was also to deliver results to land managers in an easily accessible and interactive web-based map tool, to support conservation planning and restoration activities.

Specifically, we evaluated eight scenarios for bay-wide change over the next century, intended to capture low and high levels of potential outcomes based on a combination of factors:

- Two subregion-specific levels of suspended sediment concentration (SSC)
- Two subregion-specific levels of organic material (OM) accumulation
- Two rates of SLR (0.5 and 1.65 m/century)

We evaluated these eight scenarios over the range of actual starting elevations and estimated levels of SSC and OM accumulation found throughout the Bay.

Materials and Methods

Study area

Our study area within the San Francisco Bay, which is characterized by a mixed semi-diurnal tide cycle, includes salt water and brackish tidal marshes west of the confluence of the San Joaquin and Sacramento rivers (Fig. 1). The area has a Mediterranean-type climate, with warm, dry summers and rainy, cool winters [51]. Rain and runoff from snow pack of the Sierra Nevada mountains create lower salinity conditions in the Bay during the winter and spring, with significantly reduced freshwater influx and higher salinity during the summer and fall [52]. Plant species richness and productivity are greater in lower salinity tidal marshes [28,53].

Bay tidal marshes owe their early development to changes in sea level. During the last glacial event, San Francisco Bay was a river valley. By about 5,000 years before present, sea level had risen to an elevation adequate to flood the Bay, creating conditions for fringing tidal wetlands [54,55]. These wetlands continued to build and transgress landwards over subsequent millennia. Seasonal flows of the Sacramento River, as well as from local catchments, brought sediment to the Bay, maintaining expansive marshes and mudflats. Tidal marshes and mudflats continued to expand through the 1800 s, when hydraulic mining activities in the Sierra Nevada foothills deposited considerable sediments in the Bay, estimated to be an order of magnitude larger than pre-mining conditions [55,56].

During the 20th century, filling and levee building activities reduced tidal marshes to less than 10% of their original 220,000 ha [28] although approximately 5,000 ha have since been regained through restoration efforts [57]. Upstream activities such as dams, water diversions, riverbank protection, and altered land use limited the downstream delivery of sediment and caused erosion of subtidal habitats [58]. Since 1999, a substantial decrease in suspended sediment has been observed at long-term deepwater monitoring stations [59]. This step change is attributed to the flushing of the hydraulic mining pulse from the estuary and limitations on downstream delivery [60,61].

The current Bay wetland landscape west of the Sacramento/San Joaquin River delta is an intricate mosaic of natural and restored tidal marshes intermixed with diked baylands. Tidal marshes line the bay and river margins and, in most cases, abut levees along urban and agricultural land. We defined the bayward

limits of our study area based on the mapped edge between tidal marsh and mudflat habitats according to the San Francisco Estuary Institute's EcoAtlas (<http://www.sfei.org/ecoatlas/index.html>) and used the USGS national elevation dataset (NED) to delineate upland boundaries. The upper limit was defined as the 15.2 m (50-ft.) elevation contour line plus a 100-m horizontal buffer to account for error in the NED, resulting in a total study area of just over 186,000 ha. Mapping of study area boundaries and subregions was performed in ArcGIS 9.3.1 (ESRI, Redlands, CA, USA).

Biogeomorphic subregions

Suspended sediment concentrations (SSC) differ throughout the Bay because of variations in wave conditions, proximity to mudflats, bathymetric convergence zones, and river inputs. These subregional differences help define the morphology, extent, and resilience to SLR of Bay tidal marshes. In addition, marshes with high rates of organic matter (OM) production have been observed to accrete at faster rates than marshes composed primarily of inorganic sediments [7,40]. Marshes associated with the highest OM accumulation rates are typically found in brackish and freshwater environments.

In light of this spatial variation, we separated the Bay into 15 biogeomorphic subregions (ranging in area from 2,123 to 34,605 ha) based on sediment and salinity characteristics (Fig. 1). Each subregion was categorized according to "low" and "high" estimates of SSC and OM for that subregion, based on information described in the following sections and summarized in Table S1. These subregion-specific "low" and "high" values were used to explore scenarios of high/low SSC and OM.

Accretion model

Marsh accretion (the vertical accumulation of sediment mineral and organic material) was estimated using the Marsh98 model, which has been used widely to examine marsh response to SLR across San Francisco Bay [9]. The Marsh98 model is based on the mass balance calculations described by Krone [45]. This model assumes that the elevation of a marsh surface increases at a rate that depends on the (1) availability of suspended sediment and (2) depth and periods of inundation by high tides. Marsh98 implements these processes by calculating the amount of suspended sediment that deposits during each period of tidal inundation and sums that amount of deposition over the period of record. OM was added directly to the bed elevation at each time step at a constant rate (see below for details). Marsh98 was implemented in the Fortran programming language, and multiple runs were executed using MatLab v.2010b (MathWorks Inc., Natick, MA).

Modeling was conducted relative to the tidal datum of mean lower low water (MLLW) and converted to mean higher high water (MHHW) based on a 1.8-m tide range. The tidal boundary condition used for all model runs was a repeated tidal month that has statistical characteristics representative of the observed tides at the mouth of San Francisco Bay and in the North and Central Bays. However, the tides are naturally amplified in the South Bay such that the tide range increases by approximately 50% at the far southern end of the Bay. The tide range diminishes in Suisun Bay and eastward into the Sacramento/San Joaquin Delta.

Given the spatially-varying tide range, a sensitivity analysis was conducted testing the impact of a larger tide range on the marsh accretion rates and elevation. For cases with moderate to high SSC as are typically found in the South Bay, simulations run with a tide range of 2.8 m predicted marsh surface elevations after a century that were at most 0.2 m lower relative to MHHW than simulations using a 1.8-m

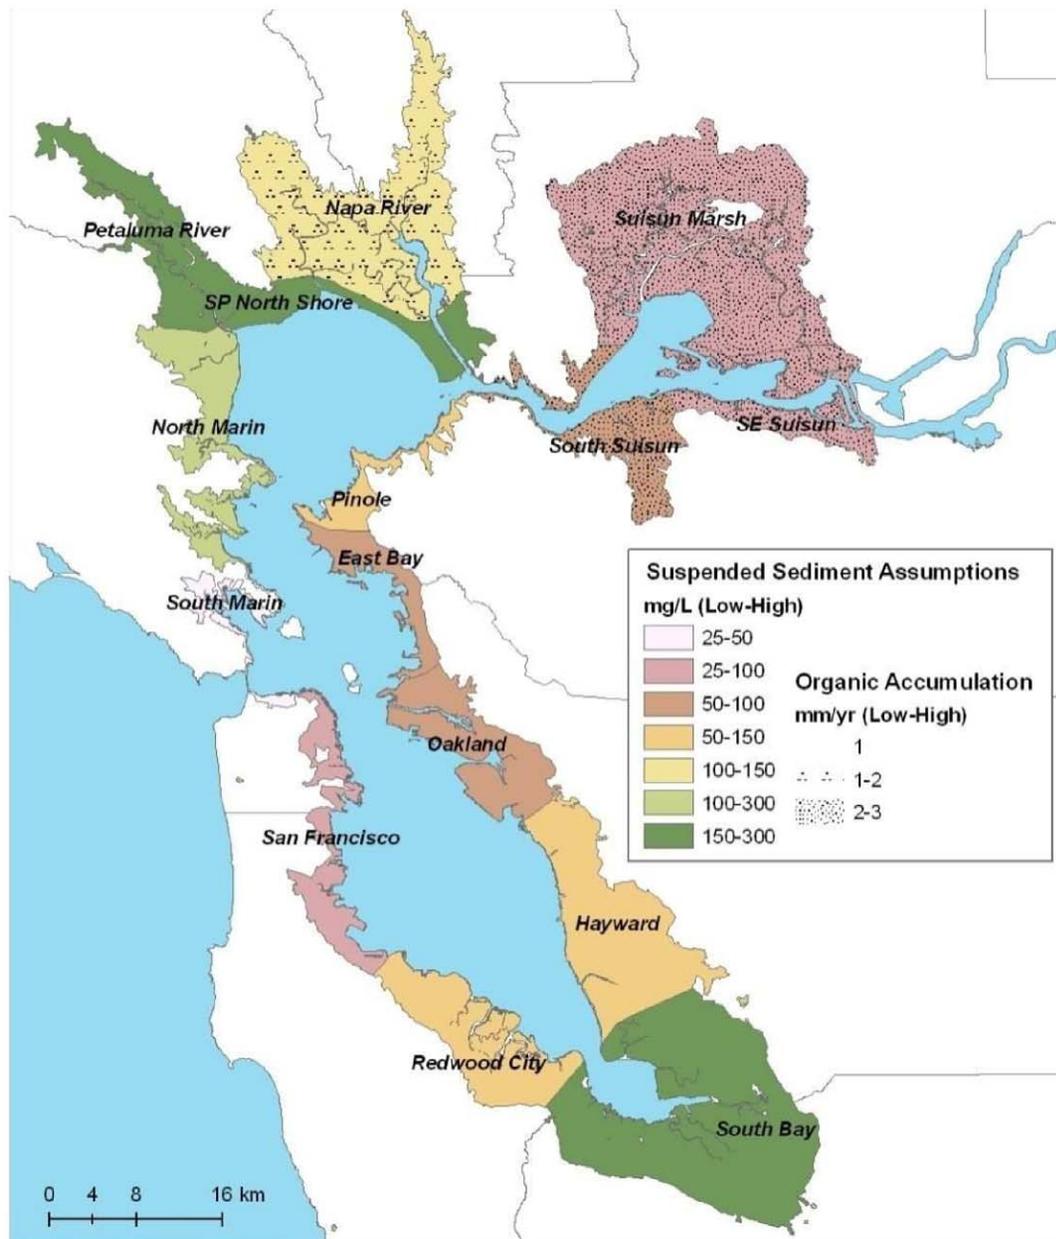

Figure 1. Biogeomorphic subregions within San Francisco Bay study area and assumptions about suspended sediment concentrations and organic matter accretion rates for climate change scenarios.

doi:10.1371/journal.pone.0027388.g001

tide range (although overall accretion was higher). In relative terms, this difference is less than 5% of the total predicted accretion for all cases. Thus, we used a single tidal range (1.8 m) to simplify the analysis.

Model input parameters

To address the range of conditions across the Bay, as well as climate change uncertainty, we considered seven SSC levels, three OM accumulation rates (except for scenarios with subtidal initial elevations, which included no OM), two rates of SLR, and three initial bed elevations, for a total of 70 model runs (90 possible—20 subtidal/OM combinations not considered). Various combinations of these 70 model runs were combined at the subregion level and interpolated to a range of starting elevations to generate six bay-wide spatial change scenarios.

Initial bed elevation. Two of the initial bed elevations evaluated span the range of regularly inundated vegetated marsh, the lower of which was based on the colonization elevation for vegetation (low marsh), assumed to be -0.5 m MHHW (mean tide level plus 0.3 m or 1.3 m MLLW) [62]. The higher initial bed elevation was based on the standard marsh plain (mid marsh) elevation around 0 m MHHW (1.8 m MLLW). The third initial bed elevation at -2.4 MHHW (0.6 m below MLLW) was used to predict the bed elevation trajectory for marsh development from subtidal conditions.

Rate of SLR

We chose two nonlinear SLR scenarios based on the guidance provided by the US Army Corps of Engineers [63], which

recommends scenarios modifying curves proposed by the National Research Council to extrapolate intermediate and high SLR scenarios (“NRC-I” and “NRC-III”, respectively). These scenarios project 0.52 m and 1.65 m of SLR over the next century (2010 to 2110) with most of this change occurring within the second half of the century (Fig. 2). The high-end rates are similar to recent estimates [1,64], and to the draft State of California planning guidelines, which recommend planning for 0.41 m of rise in the next 50 years and 1.4 m in the next 100 years [65].

Suspended sediment concentration. To represent the range of observed SSC, we modeled seven different concentrations: 25, 50, 100, 150, 200, 250, and 300 mg/L. Although observations of SSC within Bay tidal marshes are limited, several deepwater (major channel and open bay) data sources helped inform this range. The first four values are representative of observed SSC along the deepwater channel [66]. SSC at the bay-marsh boundary is thought to be higher because of wave resuspension over nearby mudflats [67]. For tributaries entering the North Bay, Ganju et al. [68] corroborate the concentrations at the high end of our range. A second line of evidence for the high SSC values comes from calibrations of the Marsh98 model to observed rates of bed elevation change at several restoration sites around the Bay [46].

Organic material. Based on data from over 30 dated sediment cores (^{137}Cs and ^{210}Pb) from multiple sites across the Bay (Callaway, unpublished data), we modeled OM accretion using constant rates of 1, 2, and 3 mm/yr for the scenarios with initial bed elevations in the vegetated marsh regime. For the scenarios with subtidal initial bed elevations, no OM accretion was included. As a sensitivity analysis, for one test run based on high SSC (150 mg/L) and high SLR, we also ran the model in two stages, adding OM from the point at which the bed elevation reached the vegetation colonization elevation; differences in final elevations were negligible.

Elevation and tidal range mapping

A seamless 5-m elevation grid for the study area was developed based on best available data sources (Figure S1). LiDAR elevation

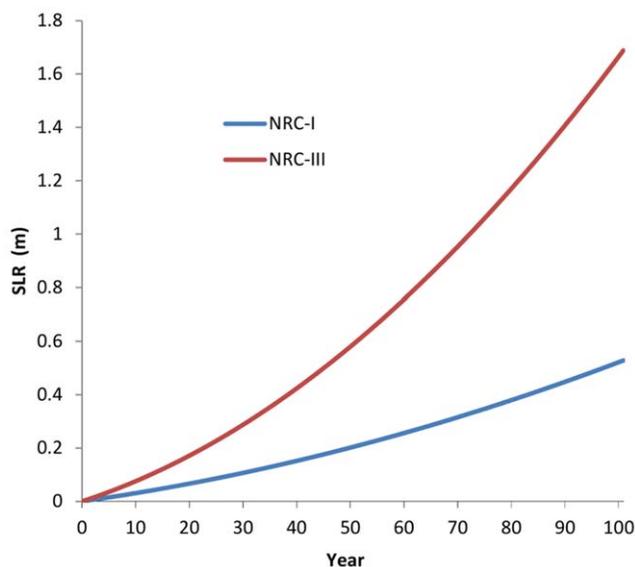

Figure 2. High (NRC-III) and low (NRC-I) sea-level rise trajectories used for climate change scenarios. Year 0 represents 2010 and year 100 represents 2110. doi:10.1371/journal.pone.0027388.g002

data were available for most of our study area and were used wherever possible. Approximately 4,300 ha of diked subtidal lands (including several former and active salt ponds) were inundated with water and thus not captured by elevation mapping efforts. All datasets were converted to the NAVD88 vertical datum (m) and resampled to a 5-m×5-m grid-cell resolution. While a comprehensive accuracy assessment was not possible, we used available real-time kinetic GPS data (horizontal accuracy: $\pm 1\text{--}2$ cm; vertical accuracy: $\pm 2\text{--}3$ cm) from four North Bay study sites to investigate potential systematic biases in the datasets. Due to obvious vegetation biases in two of these sites in Suisun Bay and the western Delta, where marsh vegetation (*Schoenoplectus* spp.) often forms particularly impenetrable mats, we used available vegetation data to develop correction factors for each general vegetation type (Table S2) and applied those correction factors throughout the relevant subregions based on available vegetation maps [69,70].

NOAA tide gauge and benchmark data (<http://tidesandcurrents.noaa.gov/>) were used to convert NAVD88 elevations to a MHHW reference more suitable for cross-bay analysis of tidal marsh habitat due to variability in tidal range across the bay. We developed a second-order inverse distance-weighted interpolation of MHHW levels (relative to mean lower low water, MLLW) across our study area ($n = 55$ tide gauges). The same procedure was repeated for NAVD88 elevations at MLLW measured for $n = 19$ benchmark locations. The two resulting grids (100-m resolution) were applied as offsets to the resulting elevation grid, corrected for vegetation bias where data were available, resulting in a bay-wide estimate of elevation (m) with respect to MHHW. Simply stated: NAVD88 elevation + MLLW offset – MHHW offset = MHHW elevation.

Spatial scenario development

Model outputs were linearly interpolated in 10-cm increments for starting elevations ranging from -3.7 to 1.7 m (relative to MHHW) such that for starting elevation x between starting elevations y and z , the future projection for a given time period t and scenario s was calculated as:

$$F(x,t,s) = F(z,t,s) - \frac{|F(z,t,s) - F(y,t,s)|}{(10 * (z-y))}$$

The lower bound for the interpolation was set at -4.0 m (MHHW), reflecting the lowest projected future elevation obtained from a model run starting at -2.4 m (MHHW). Elevations below this lower bound were assumed to remain constant (i.e., keep pace with SLR) across all scenarios and time steps. However, values are unreliable below -2.4 m due to the necessarily arbitrary lower limit for interpolation. The upper bound was set at 1.7 m (MHHW) for the high SLR scenario and 0.6 for the low SLR scenario, reflecting the area subjected to future tidal inundation. Elevations above the amount of SLR for a given scenario and time step were assumed to decrease by that amount (i.e., no accretion potential).

Interpolated model outputs were applied to a composite 5-m elevation grid for SF Bay, referenced to the MHHW tidal datum. Results for each combination of SSC, OM, and SLR assumptions were combined by geographic subregion to produce an individual scenario layer. For these scenarios, we assumed that wave- and current-induced bed shear stresses are minimal. Locations with significant wave exposure and/or tidal currents, which include much of the open bay margins, are unlikely to accrete above subtidal elevations. Thus we ignored current open bay and

outboard mudflats, and restricted our analysis to areas currently landward of the marsh-mudflat boundary. We assumed that subsided (currently diked) potential restoration sites within our study area are not large enough to be subject to erosion at levels sufficient enough to prevent vegetation colonization. Indeed, no San Francisco Bay tidal marsh restoration sites have yet failed to vegetate [71].

Analysis of marsh sustainability and restoration potential

Using the accretion model outputs for low marsh (-0.5 m MHHW) and mid marsh (0 m MHHW) starting elevations, we evaluated the potential for marsh sustainability over the next century (in 20-year increments) under each combination of SSC, OM, and SLR rate. The transition from low to mid marsh occurs approximately halfway between these elevations and mid marsh can persist at elevations lower than 0 m MHHW [62]. Thus a mid marsh area could lose elevation and still sustain marsh vegetation. However, because we were interested in the potential for a marsh to maintain its starting elevation our definition of marsh sustainability was zero elevation loss (rounded to the nearest 10 cm).

Due to the large number of planned restoration projects within subsided diked baylands, we also examined the minimum starting bed elevations required to achieve mid marsh elevations (-0.2 m to 0.1 m MHHW) over the next century in 20-year increments. This represents the potential to attain and maintain a vegetated marsh plain by restoring tidal action to currently diked (and generally subsided) areas. These calculations were based on elevation-interpolated model outputs to allow a broader range of starting elevations to be considered. Strictly speaking, we could not evaluate starting elevations lower than -2.4 m MHHW, the lowest bed elevation used in the accretion model runs. However, constantly-inundated subtidal elevations will accrete sediment very rapidly in the absence of significant erosional forces [46]. Thus, minimum starting bed elevations may be less than -2.4 m.

Area calculations for restoration scenarios

We developed a polygon GIS layer representing all diked areas within our study area to distinguish existing from potential tidal marsh habitat. Diked areas were defined as those that were separated from regular tidal inundation by dikes, levees, or roads of any height and material; additional information on levee integrity was not readily available. The layer was modified from the EcoAtlas modern baylands layer (“diked baylands” category) based on levee lines supplied by the Pacific Institute (http://www.pacinst.org/reports/sea_level_rise/data/index.htm) and manual inspection of 1-m resolution natural color and color infrared Bay-wide aerial photography flown in 2006 and 2009 by the National Agriculture Imagery Program (<http://www.fsa.usda.gov/FSA/apfoapp?area=home&subject=prog&topic=nai>). We used a 2001 urban development layer from NOAA C-CAP (<http://www.csc.noaa.gov/digitalcoast/data/ccapregional/>) to identify developed areas not available for tidal marsh restoration.

Elevation projections were classified according to marsh type and summarized by subregion, scenario, and diked/developed status. Upland was defined as >0.3 m above MHHW; high marsh was defined as 0.2 to 0.3 m above MHHW; mid marsh as -0.2 to 0.1 m MHHW; low marsh as -0.5 to -0.3 m MHHW; mudflat as -1.8 to -0.6 m MHHW; and subtidal as anything below -1.8 MHHW (i.e., 0 m MLLW). We also compared restoration potential for areas of (1) high and (2) low-intermediate sediment availability within the currently diked areas. We used results from actual study area subregions grouped as follows: (1) high sediment availability (North Bay): Petaluma River, North Marin, San Pablo

Bay North Shore; and (2) low-intermediate sediment availability (Central Bay): Redwood City, Hayward, San Francisco, Oakland, East Bay, Pinole, and South Marin (see Fig. 1 and Table S1). We selected these particular regions because they represent the range of sediment availability within the Bay, and because they have tide ranges similar to the 1.8 -m value used in our accretion models.

Web-based map viewer and decision support tool

To make our results easily accessible to land managers and decision-makers, a web-based map viewer and decision support tool was created that allows users to view projected changes in tidal marsh extent and location at varying spatial scales, over multiple time frames, and under various SLR, SSC, and OM scenarios [72]. Users can view maps of current and future marsh extent together with data overlays (diked areas, public lands, and urbanization) to assess restoration opportunities and impediments.

Results

Thresholds and sensitivities

Marsh sustainability. According to accretion model outputs, marshes in areas with very low suspended sediment concentrations (25 mg/L) would not sustain their current elevation for more than 40 years under either SLR rate (Fig. 3). However, with high OM accumulation rates (3 mm/yr) and slightly higher SSC (50 mg/L), low marsh elevations would be sustained for up to 100 years under a low rate of SLR. Under a high SLR rate, marshes with 50 mg/L SSC would not be sustainable for 20 years regardless of OM (Fig. 3).

Under a low rate of SLR and intermediate SSC (100 mg/L), low marsh elevations would be sustained for 100 years, while mid marsh would last up to 80 years with high OM accumulation rates (Fig. 3). Under a high SLR rate and intermediate SSC, low marsh elevation loss would be expected within 40 years. With 150 mg/L, mid marsh sustainability throughout the next century was projected for a low SLR rate; only low marsh with at least 2 mm/year OM accumulation would be sustainable under a high rate of SLR. At 200 , 250 , and 300 mg/L, mid marsh was sustainable under a high rate of SLR for progressively longer periods of time (up to 80 years with 300 mg/L SSC), but not over the full 100-year period. Higher OM accumulation rates (2 – 3 mm/year) would not extend sustainability for more than a 20-year period.

Restoration potential and initial elevation. Under a low rate of SLR and high SSC (≥ 150 mg/L), our models show that mid marsh restoration (i.e., establishment and maintenance of a vegetated marsh plain) could be achieved over the next century with initial bed elevations at least as low as -2.4 m MHHW (i.e., subtidal) (Fig. 4). With very high SSC (300 mg/L), mid marsh habitat could be expected within 20 years at subtidal locations, while close to 100 years would be necessary with 150 mg/L. For low-intermediate sediment concentrations (≤ 100 mg/L), successful mid marsh restoration would be expected only from marsh starting elevations. Higher rates of organic accumulation (2 – 3 mm/yr) would allow somewhat lower starting elevations, but could not (by definition) make a difference of more than 20 cm per century.

Under a high rate of SLR, however, mid marsh restoration could only be achieved over a 100-year time period given starting elevations above MHHW (current upland areas), or very high sediment concentrations (Fig. 4). With very high SSC (250 – 300 mg/L), mid marsh habitat could be restored even in areas that are currently subtidal. At lower sediment concentrations, mid marsh could initially be restored from low- and mid-marsh starting

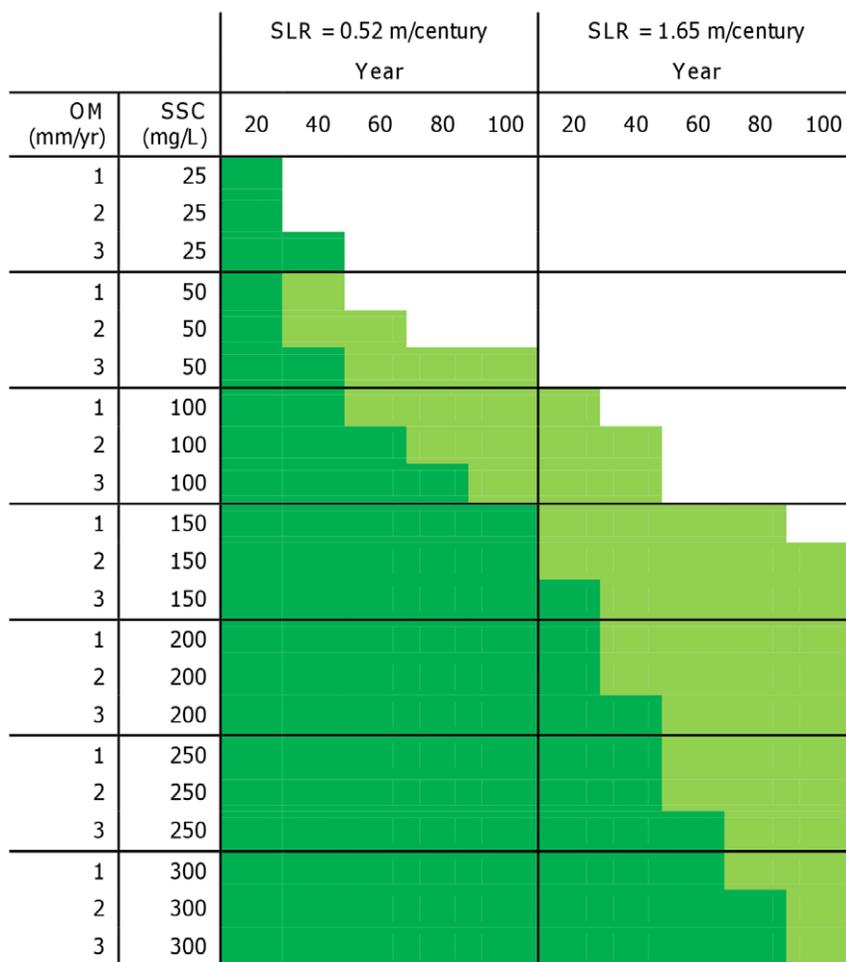

Figure 3. Sustainability (no elevation loss) of low marsh (light green) and mid marsh (dark green) areas under different sea-level rise scenarios, suspended sediment concentrations (SSC) and organic material contribution (OM). Blank cells represent no marsh sustainability.

doi:10.1371/journal.pone.0027388.g003

elevations below MHHW but would not persist more than 80 years (40 years at very low SSC).

Bay-wide habitat change

Based on mapping of current elevations and barriers to tidal inundation, there are currently ~2,500 ha of high marsh, 7,600 ha of mid marsh, and 3,000 ha of low marsh in San Francisco Bay (Table 1, Fig. 5a). An additional 7,500 ha of marsh (plus up to 4,300 ha of unmapped diked subtidal areas) could exist if existing dikes, levees, roads, and other barriers to tidal inundation were removed (Fig. 5b). 4,300 ha of potential tidal marsh are considered un-restorable due to urban development (Table 1). Below we detail projected changes over the next 100 years by habitat type. Subregional details are available in Table S3.

Habitat change trajectories. Across most scenarios examined, intertidal habitats (mudflat through high marsh elevations) were projected to increase over the next century, reflecting the combined expansion of wetlands into current upland areas and sedimentation of currently subtidal areas. Lower rates of increase, or slight decreases, were projected toward the end of the century, as topographic limitations to marsh expansion become more important and, for the most pessimistic scenario (high SLR, low SSC), subtidal elevations increase (Fig. 6). Restoration

potential for intertidal habitats (within currently diked areas) showed a similar pattern, although the area of urban development at elevations potentially subject to tidal inundation (in the absence of levees), was projected to increase even more rapidly (Fig. 6).

Only under the most optimistic scenario (low SLR, high SSC), however, was mid marsh habitat projected to continue increasing until the end of the century, both in terms of currently tidal and potential restoration areas. Under the other scenarios, mid marsh habitat was projected to increase through mid-century (2040–2080, depending on the scenario) but start declining in area thereafter. Low marsh habitats had similar projections, but would decline in existing area and increase in restoration potential under the most optimistic scenario (Fig. 6). Vegetation trajectories for potential low marsh restoration were fairly stable by the end of the century. Current areas of high marsh were projected to decrease under all scenarios, more rapidly under high rates of SLR (Fig. 6). However, restoration potential for this habitat type remained constant over time across all scenarios.

High marsh. The area of high marsh was projected to decrease dramatically over the next century across all scenarios examined – more than any other habitat type (Table 1, Fig. 7). With a high SLR rate, the area could be reduced to just over 100 ha bay-wide by 2110; with a low rate of SLR the total projected

doi:10.1371/journal.pone.0027388.g004

area was just over 500 ha under both high and low SSC scenarios. While most of the future potential for this habitat would occur in areas that are already urbanized, approximately 700–900 ha are possible in undeveloped areas that are currently behind levees, dikes or roads (hereafter “diked areas”) (Table 1, Fig. 8).

Mid marsh. Future (100-yr) spatial habitat projections for mid marsh were highly dependent upon SSC and SLR assumptions. Under all but the most pessimistic scenario (high SLR and low SSC) the total bay-wide area of mid marsh was projected to increase to between 8,300 and 18,700 ha over the next century, as sites that are newly restored or planned for restoration in the near future (primarily former salt ponds) continue to accrete sediment and build elevation (Table 1, Fig. 7). Under the most optimistic scenario (low SLR, high SSC), 25,200 ha in currently diked areas could potentially become mid marsh habitat with new restoration efforts (Table 1, Fig. 8). However, under the more pessimistic scenario (high SLR and low SSC), the total area of mid marsh was projected to decrease dramatically, to less than 600 ha bay-wide in narrow fringes along bay margins (current upland areas). Up to 2,600 ha in currently diked upland areas (also along the bay margins) could potentially be obtained through new restoration efforts (Table 1, Fig. 8). The creation of new mid marsh habitat on up to 10,700 ha of land with potentially suitable elevations under a high rate of SLR is prevented by existing urban development (Table 1).

Low marsh. Low marsh habitat was projected to increase—due to a combination of mid marsh loss in some areas and new habitat creation in others—under all scenarios except for high

SSC and low SLR (Table 1, Figs. 7 and 8). In this case, the decrease represented primarily a conversion to mid marsh, as low elevation areas would continue to accrete sediment.

Upland. The area of natural uplands projected to be reclaimed by tidal inundation (and thereby available for marsh expansion) by 2110 ranged from approximately 2,000 ha under a low rate of SLR to 3,300 ha under a high rate of SLR, as more uplands would be inundated (Table 1). Undeveloped diked uplands could provide an additional 2,300 (low SLR) to 7,000 (high SLR) ha for marsh expansion if barriers to tidal inundation were removed (Table 1). The projections for currently upland urban areas that would become tidally inundated without levee protection ranged from 2,900 (low SLR) to 13,200 (high SLR) ha.

Restoration potential. Comparing restoration potential (for currently diked areas) between regions with low-medium sediment supply (Central Bay) and regions with high sediment supply (North Bay), future habitat trajectories were dramatically different across all scenarios examined (Fig. 9). Despite higher starting elevations, the Central Bay had lower mid marsh restoration potential than the North Bay across all scenarios. Although more mid marsh habitat could initially be restored in low sediment areas due to higher elevations (in this case), models projected an overall loss of habitat by the end of the century in all but the most optimistic scenario (Fig. 9). Conversely, the North Bay was projected to experience a net gain in mid marsh habitat by the end of the century under all scenarios.

Under the most pessimistic scenario (high SLR, low SSC), models projected initial increases in marsh area, followed by

To demonstrate restoration potential, the potential future marsh area for currently diked lands reflects the assumption that all barriers to inundation are removed in 2010. Suspended sediment availability (SSC) high and low assumptions vary by Bay subregion. Sea-level rise (SLR) assumptions were developed by the National Research Council (low = 0.52 m/century; high = 1.65 m/century). Values for the urban category represent areas that are considered un-restorable due to urban development.

doi:10.1371/journal.pone.0027388.t001

widespread marsh drowning, with the conversion of mid marsh to low marsh in high sediment areas, as shown in an example from the Petaluma River region in the North Bay (Fig. 10), and to mudflat or subtidal habitats in low sediment areas. Projections can be further explored online (www.prbo.org/sfbayslr).

Discussion

By applying results from a mechanistic accretion model [9] to spatial variation in sediment, salinity, and current elevations, we were able to develop spatially-explicit projections of marsh response to a set of plausible SLR scenarios for 15 San Francisco Bay subregions. When model runs were combined across subregions with different estimated SSC and OM values, Bay-wide projections of mid marsh habitat area varied substantially, depending primarily on SLR and SSC assumptions. Across all scenarios evaluated, however, our models projected a shift in the mix of intertidal habitats, with a loss of high marsh and gains in low marsh and mudflats within the study area. We found that the minimum SSC that would be required for 100-year mid marsh sustainability (i.e., no elevation loss) is greater than 300 mg/L for a high rate of SLR (1.65 m SLR/century), and between 100 and

150 mg/L for a low rate of SLR (0.5 m/century). High rates of OM accumulation had minimal impacts on this threshold in a SLR context because the maximum rate of OM accumulation that we evaluated (3 mm/year) was swamped by SLR.

Given that suspended sediment concentrations above 300 mg/L are rare in the Bay, and considering the projected acceleration of SLR beyond the 100-year timeframe examined here, our model suggests a bleak prognosis for long-term natural marsh sustainability under a high-SLR scenario. However, results also indicated that under a high rate of SLR (1.65 m/century), short-term restoration of diked subtidal baylands to mid marsh elevations (-0.2 m MHHW) within the next century could be achieved with SSC greater than 200 mg/L (100 mg/L under a low rate of SLR). Thus, even under a high-SLR scenario, opportunities for sustainable tidal marsh restoration and conservation within the next century may be found, but are limited to certain high-sediment regions of the Bay. Under a low-SLR scenario, the potential for long-term marsh sustainability and successful marsh restoration should remain high, depending on future sediment supplies.

The approach we have developed can theoretically be applied to any estuary to provide a rapid evaluation of future marsh sustainability and expansion potential. The model is an improve-

Figure 7. ment on other available spatial models that predict wetland sustainability in the face of SLR because it incorporates a feedback between mineral sediment inputs and elevation [45]. Without this feedback, simple SLR projection models typically overestimate wetland loss because vertical accretion is constant at the relatively low rate that is found in high elevation, relatively mature tidal marshes. Evidence from field studies and process-based models indicates that vertical accretion rates are likely to increase in response to increases in inundation rates [7,32,35,40] as long as suspended sediment concentrations are sufficient. Our model incorporates this process to create more realistic projections of marsh sustainability, which may be used to assess the vulnerability to SLR and restoration potential of individual marsh sites. An additional important contribution is the development of a user-friendly web-based mapping tool to display our results [72]. This on-line tool will allow users to compare scenarios at multiple spatial scales, to evaluate the sustainability of particular locations, and to identify potential restoration sites. Managers and decision-makers can use the tool to improve the long term effectiveness of conservation strategies by maximizing the amount of tidal marsh in high-sediment regions, identifying and prioritizing key upland transitional sites, prioritizing sediment placement, and planning for future high marsh refugia.

Restoration and management implications

Importantly, even the most pessimistic scenario (low SSC, high SLR) resulted in projections of a Bay-wide increase in habitat until

nearly 2050, indicating that large-scale effects of SLR on tidal marsh may not be seen until near the end of the century. Furthermore, due to the rapidly increasing rate of SLR projected near the turn of the next century, the trajectory of marsh loss is likely to continue at accelerated rates after 2100, with anticipated severe consequences if high rates of SLR continue. This pattern, and the potential for rapid marsh plain loss once marsh drowning begins [42] indicates the importance of proactive marsh conservation planning, via the application of sediment to raise elevations at vulnerable sites before marsh loss occurs, the prioritization of more resilient (high sediment) sites for restoration, and the protection of key upland sites as future marshland. Although our results suggest that sites with low SSC may not be sustainable regardless of starting elevation, the strategic repeated delivery of sediment could potentially be used to sustain a site indefinitely. This requires a shift in sediment management strategies to capture and redistribute excess sediment, especially clean dredge materials. Collaborative efforts to maximize the beneficial reuse of dredge materials are already underway among San Francisco Bay jurisdictions and stakeholders. Because sediment contamination is a major concern [73,74], an approach using multiple lines of evidence to assessing sediment quality has been developed in part to inform sediment reuse decisions and minimize ecological impacts [75]. Due to regional variability in sediment availability, marsh resilience was projected to be much lower in some subregions (e.g., Central Bay) than others (e.g., North and South Bay systems). Thus, when restoration choices are

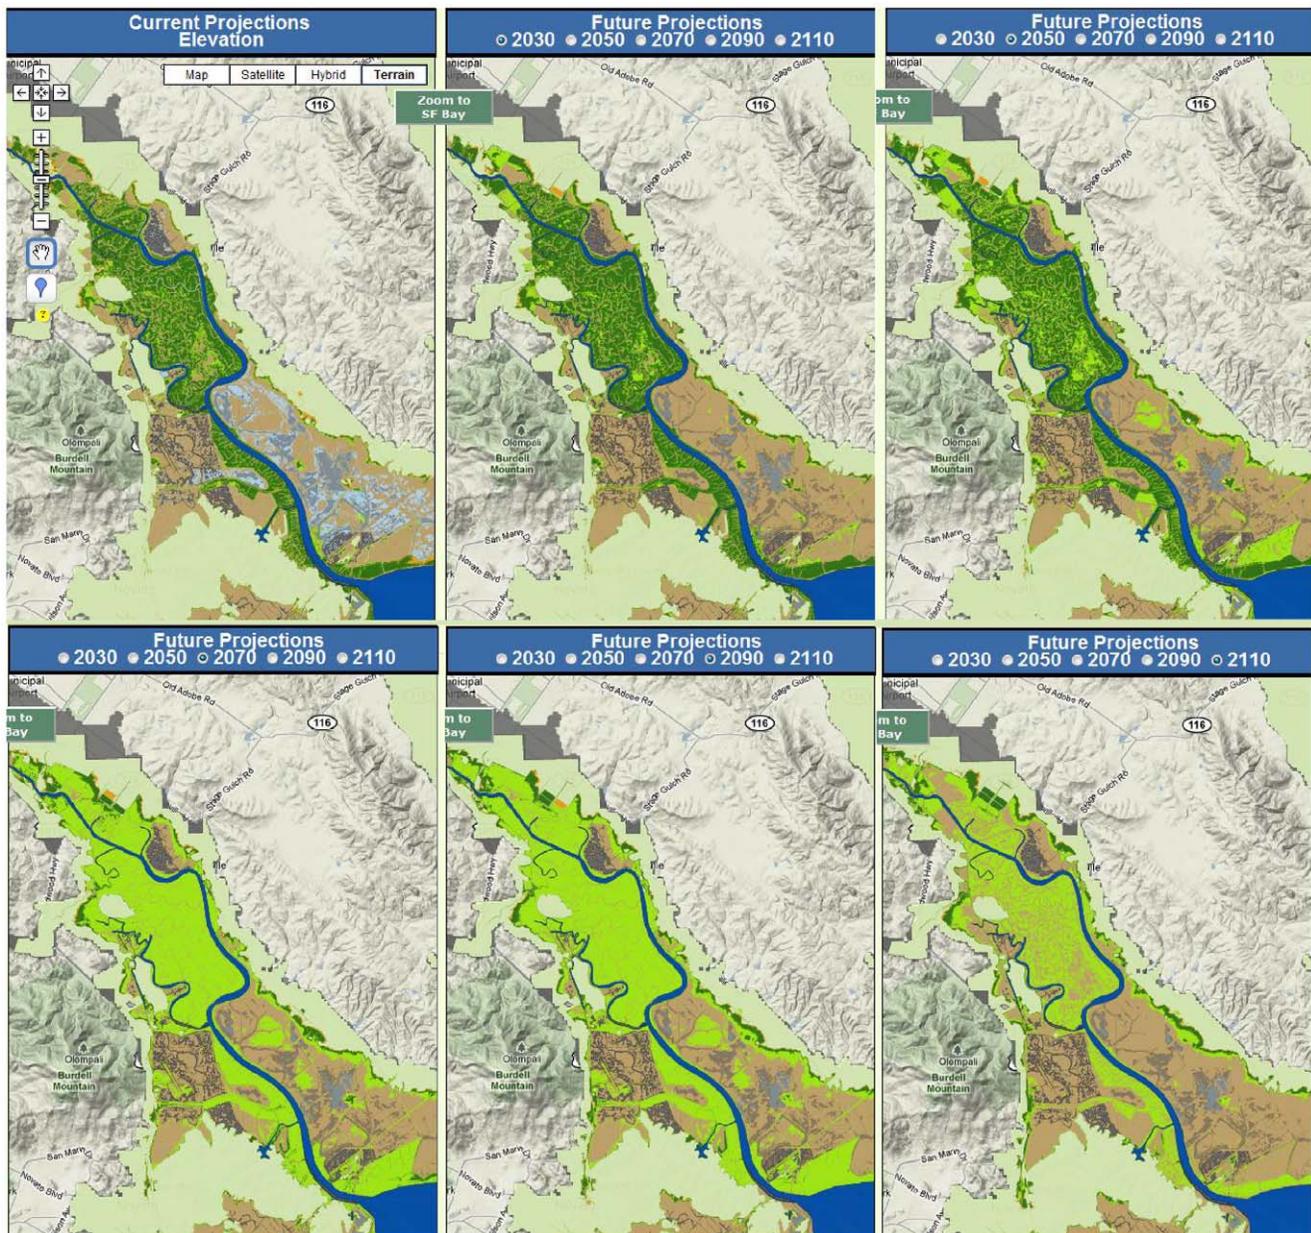

Figure 10. Projected elevation change for the most pessimistic scenario (low sediment, high SLR), using the on-line tool to zoom into the Petaluma River area. Maps assume an absence of levees, roads, and other barriers to tidal inundation. Maps demonstrate the increase in low and mid marsh through mid-century, followed by a decline as SLR accelerates and outpaces accretion rates. Note the limited amount of landward marsh expansion (See Table S3 for area summaries).
doi:10.1371/journal.pone.0027388.g010

explicit, efforts should be concentrated in sediment-rich areas with better prospects for long-term sustainability. However, high-vulnerability (low-sediment) subregions should be closely monitored and may provide early opportunities for validation of marsh sustainability projections. Although it would be easy to dismiss these areas, certain sites may be more amenable to intervention, and could be maintained either by restoring natural sources of sediment or by strategically applying dredge materials [71]. The relative viability of different sites would depend on factors such as wind-wave exposure, proximity to sediment sources, and accessibility, and may also be evaluated with respect to ecological values, e.g., presence of special status and endemic species.

Furthermore, future restoration priorities also should be informed by the availability of adjacent upland sites that are suitable for lateral marsh expansion or migration (i.e., undeveloped sites with very gradual slopes). Although our spatial analysis revealed relatively little area naturally available to accommodate future marshes (up to 3,300 ha under high SLR), we found that more than twice as much area (up to 7,000 ha) could be reclaimed by removing levees and other barriers to tidal action. In some of these areas, managed realignment of barriers to tidal inundation could be useful to facilitate marsh expansion while continuing to provide flood control benefits [76,77]. Unfortunately, the large majority of areas with elevations suitable for marsh expansion within the Bay (>13,000 ha) are already urbanized and thus

unavailable. The existing opportunities for marsh expansion into upland areas within particular subregions may be evaluated using our web-based tool.

Model limitations

While we believe that the results summarized here represent the most realistic assessment currently feasible, several limitations must be emphasized. In particular, the model does not include influence of waves, which become more important as site size increases and availability of sediment diminishes [46]. Sites that are more vulnerable to waves include those with bed elevations between vegetation colonization elevation and MLLW. At these sites, wind-wave erosion may result in marsh retreat at the bay edge, and conversion of low marsh to mudflat [42]. In this respect, the projected habitat areas are most likely an overestimate of future habitat potential, especially for low marsh habitat. Conversely, future high marsh areas are likely underestimated, as we did not consider the influence of storms or other factors that may result in the deposition of new sediment above MHHW.

In addition, we had limited data from which to estimate the relative contribution of organic material to the accretion model. The organic matter calibrations were based on data from salt marshes and rates are likely higher in slightly brackish to freshwater tidal marshes. Thus, higher rates of organic accretion may currently occur, or may occur in the future due to higher temperatures for C4 plants and higher CO₂ concentrations for C3 plants that may increase plant productivity [12,78]. Furthermore, the predicted increase in low marsh area would bring with it a shift in dominant species that may influence organic accretion rates resulting from different morphologies (e.g., volume of below-ground biomass) [7]. Thus, it is possible that we underestimated the potential future contribution of vegetation and organic matter inputs to marsh development, and thus future habitat potential. Additionally, although we considered decreased rates of organic accumulation as a proxy for increases in salinity that are projected to occur with SLR [79,80], we did not explicitly consider the adverse effects of increased salinity on plant productivity and survival, which in turn could reduce the organic contribution to accretion [11]. Similarly, effects of changing inundation on organic matter processes were not included in our model.

Finally, there is some uncertainty in the range of sediment and salinity assumptions used for each subregion, as well as spatial variability within those subregions. This is especially true for more distant future time periods, given that sediment concentrations have decreased in some parts of the Bay and are likely to continue to decrease in the future [61,80]. Although our low sediment scenario was intended to encompass such future declines, the magnitude and timing is highly uncertain. If our scenarios encompass most of this range of uncertainty, Bay-wide discrepancies are likely to be small. But for an individual site, results could change dramatically depending on actual available sediment concentrations.

Critical future uncertainties

The large disparity across scenarios highlights the importance of future sediment supply and SLR rates in determining the fate of Bay tidal marshes. Importantly, the effects of these critical variables are not linear. There are key thresholds beyond which marshes are not sustainable, with lower rates of SLR having lower thresholds for SSC requirements.

Sediment inputs to San Francisco Bay are controlled by precipitation patterns but also upstream land use decisions and water storage and diversion practices. All of these factors have high levels of future uncertainty [81–83]. With the reduced precipita-

tion that is projected for California by most general circulation models, water may become more tightly managed and thus reduce flows to the Bay, particularly during dry summer months [79,80]. Alternatively, increased precipitation, especially when delivered by high severity storms, may bring more large pulses of fresh water and sediment to the Bay, especially during winter months. Future SLR rates are also highly uncertain, but may become more precise in the near future as models and empirical data improve.

Unfortunately these key uncertainties will be difficult to address, especially over the long term, when estimates of sediment supply and SLR become increasingly variable. In the short term, however, SLR rates can be projected with a higher level of confidence, and sediment availability can be better understood through data collection and hydrodynamic modeling. Thus, by (1) collecting better data on current suspended sediment concentrations in marshes, (2) monitoring rates of marsh accretion, and (3) proactively managing sediment within an estuary, we can improve and manipulate short-term projections of marsh sustainability. In the meantime, future SLR projections may be refined, and potentially modified via societal actions to reduce greenhouse gas emissions.

Ecosystem ramifications

Across all scenarios evaluated, our model projections suggest a shift from high to low elevation marsh habitat, which will certainly affect vegetation composition, and will likely have cascading effects on ecological communities. The high marsh zone is high in plant diversity, relative to mid and low marsh, and hosts several endangered plant species, including soft birds-beak (*Chloropyron molle*, formerly *Cordylanthus mollis*), and many endemic species [84]. Much of this habitat has already been lost or degraded due to urban and agricultural development, restriction of tidal exchange, and the erection of levees, contributing to the endangered status of the plant and animal species that depend upon it [50,85].

Mid marsh comprises the majority of current vegetated tidal marsh, and the primary breeding habitat of several specialized bird species, including endangered rail species, as well three endemic subspecies of tidal marsh song sparrow (*Melospiza melodia*) [86–88] and the endemic San Francisco common yellowthroat (*Geothlypis trichas sinuosa*) [89]. While future projections for this habitat are highly variable and dependent on sediment supply and SLR rates, its large-scale loss would have wide-reaching impacts on marsh vertebrates, which generally use low marsh to a much more limited extent (or only for foraging).

Marsh drowning will result in an increase in unvegetated intertidal habitat (i.e., mudflats), as will the inevitable erosion of low marsh habitat, especially along bay margins. This may or may not counteract expected mudflat losses within the open bay [90] but should at least provide new foraging habitats for shorebirds, waterfowl, and other waterbirds. Thus, although the loss of vegetated marsh would have negative consequences for marsh-dependent species, there are likely to be benefits for other species. As a result, restoration and conservation planning in the face of SLR will necessarily involve an evaluation of ecological trade-offs, as is already the case for current restoration planning efforts [91].

Conclusions

Our model indicates at least two critical implications for tidal marsh habitat in the next century. First, the most optimistic scenarios for marsh habitat sustainability in the next century involve high availability of mineral sediment. However, sediment loads are physical inputs into the system that are largely controlled by upstream land use decisions and water storage and diversion practices and thus are very uncertain and likely to be dynamic over

the next 100 years. Second, with high SLR and SSC less than 150 mg/L, barring the significant transfer of sediment from other areas, upland habitat will have to be captured for restoration purposes in order to make up for mid marsh habitat loss. This is a challenging scenario due to the many physical barriers currently in place that prohibit wetland migration and the complexity of land ownership surrounding the Bay.

In light of these and other challenges posed by SLR for wetland managers, realistic, spatial projections must be made available quickly and clearly to inform critical conservation prioritization and restoration planning decisions. We hope the models and results presented herein and the supporting web tool (<http://www.prbo.org/sfbayslr>) provide such a contribution.

Abstract

The loss of genetic and life history diversity has been documented across many taxonomic groups, and is considered a leading cause of increased extinction risk. Juvenile salmon leave their natal rivers at different sizes, ages and times of the year, and it is thought that this life history variation contributes to their population sustainability, and is thus central to many recovery efforts. However, in order to preserve and restore diversity in life history traits, it is necessary to first understand how environmental factors affect their expression and success. We used otolith ⁸⁷Sr/⁸⁶Sr in adult Chinook salmon (*Oncorhynchus tshawytscha*) returning to the Stanislaus River in the California Central Valley (USA) to reconstruct the sizes at which they outmigrated as juveniles in a wetter (2000) and drier (2003) year. We compared rotary screw trap-derived estimates of outmigrant timing, abundance and size with those reconstructed in the adults from the same cohort. This allowed us to estimate the relative survival and contribution of migratory phenotypes (fry, parr, smolts) to the adult spawning population under different flow regimes. Juvenile abundance and outmigration behavior varied with hydroclimatic regime, while downstream survival appeared to be driven by size- and time-selective mortality. Although fry survival is generally assumed to be negligible in this system, >20% of the adult spawners from outmigration year 2000 had outmigrated as fry. In both years, all three phenotypes contributed to the spawning population, however their relative proportions differed, reflecting greater fry contributions in the wetter

year (23% vs. 10%) and greater smolt contributions in the drier year (13% vs. 44%). These data demonstrate that the expression and success of migratory phenotypes vary with hydrologic regime, emphasizing the importance of maintaining diversity in a changing climate.

Introduction

Life history diversity is often cited as a crucial component of population resilience, based on theoretical and empirical evidence that asynchrony in local population dynamics reduces long-term variance and extinction risk at both regional and metapopulation scales [1]. Pacific salmon are recognized for their complex life histories, having evolved alongside the shifting topography of the Pacific Rim [2]. In the California Central Valley (CCV), four runs of imperilled Chinook salmon (*Oncorhynchus tshawytscha*) coexist, exhibiting asynchronous spatial and temporal distributions that allow them to exploit a range of ecological niches [3,4]. The maintenance of multiple and diverse salmon stocks that fluctuate independently of each other has been shown to convey a stabilizing ‘portfolio effect’ to the overall the stock-complex [5,6]. Such ‘risk spreading’ can also act at finer scales [7,8], such as within-population variation in the timing of juvenile emigration. Preserving and restoring life history diversity remains an integral goal of many salmonid conservation programs [9], yet baseline monitoring data with which to detect and respond to changes in trait expression are scarce and difficult to relate directly to population abundance.

The expression and success of certain traits can be largely driven by hydroclimatic conditions experienced during critical periods of development [10]. CCV Chinook salmon are at the southern margin of their species range, and are subjected to highly variable patterns in precipitation and ocean conditions [4,11]. It is also a highly modified system, with >70% of spawning habitat lost or degraded as a result of mining activities, dam construction, and water diversions [4,12]. The majority of salmon rivers in the CCV experience regulated flows according to ‘water year type’ (WYT). Optimization of reservoir releases presents considerable challenges, given often limited availability and multiple uses of the water resource, inability to predict annual precipitation, and uncertainty surrounding the direct and indirect effects of flow on salmon survival [13]. Such challenges are particularly critical for the more southerly San Joaquin basin, whose salmon populations fluctuate considerably with river flows experienced during juvenile rearing (Fig 1).

Juvenile Chinook salmon exhibit significant variation in the size, timing and age at which they outmigrate from their natal rivers [3,14]. Selection for one strategy over another may vary as a function of freshwater and/or marine conditions [10,15]. In the CCV, fall-run juveniles typically rear in freshwater for one to four months before smoltification prompts downstream migration toward the ocean [16]. In this system, contributions of the smaller fry and parr outmigrants to the adult population are often assumed to be negligible, as survival tends to correlate with body size [17,18] and there is little evidence for downstream rearing in the San Francisco estuary [19]. However, this has never been explicitly tested for smaller size classes. Indeed, salmon fry are frequently observed rearing in tidal marsh and estuarine habitats in other systems [3], and have been observed in non-natal habitats in the CCV, such as the mainstem Sacramento and San Joaquin Rivers, freshwater delta, and estuary [20]. Juvenile salmon that enter the ocean at a larger size and have faster freshwater growth have demonstrated a survival advantage when faced with poor ocean conditions [18]. Yet intermediate size classes can be better represented in the adult population [21,22], and size-selective mortality can be

moderated by a variety of other processes [23]. In a regulated system such as the CCV, identifying the relationships between observable traits, hydroclimatic regime and survival would be invaluable for reducing uncertainty and predicting how populations may respond to climate change and management actions related to water operations.

Quantifying the relative contribution of fry, parr and smolt outmigrants to the adult population has, until now, been largely limited by the methodological challenges associated with reconstructing early life history movements of the adults. Mark-recapture studies using acoustic and coded wire tags (CWT) have provided empirical indices of juvenile survival through stretches of the Sacramento-San Joaquin River Delta (hereafter, “the Delta”) [24,25], but are hindered by low rates of return and tend to utilize hatchery fish that may exhibit different rearing behavior and sea-readiness to their wild counterparts [26]. Furthermore, ‘fry pulses’ tend to be dominated by individuals <45mm FL, which are difficult to mark externally without causing damage or behavioral modifications. No study to date has tracked habitat use of individual salmon over an entire lifecycle to estimate the relative success of juvenile outmigration phenotypes under different flow conditions. Previous studies have tended to rely on correlations between environmental conditions (e.g. flow) experienced during outmigration and the abundance of returns (Fig 1) [27]. Recent advances in techniques using chemical markers recorded in biomineralised tissues provide rare opportunity to retrospectively “geolocate” individual fish in time and space [28]. Given their incremental growth and metabolically inert

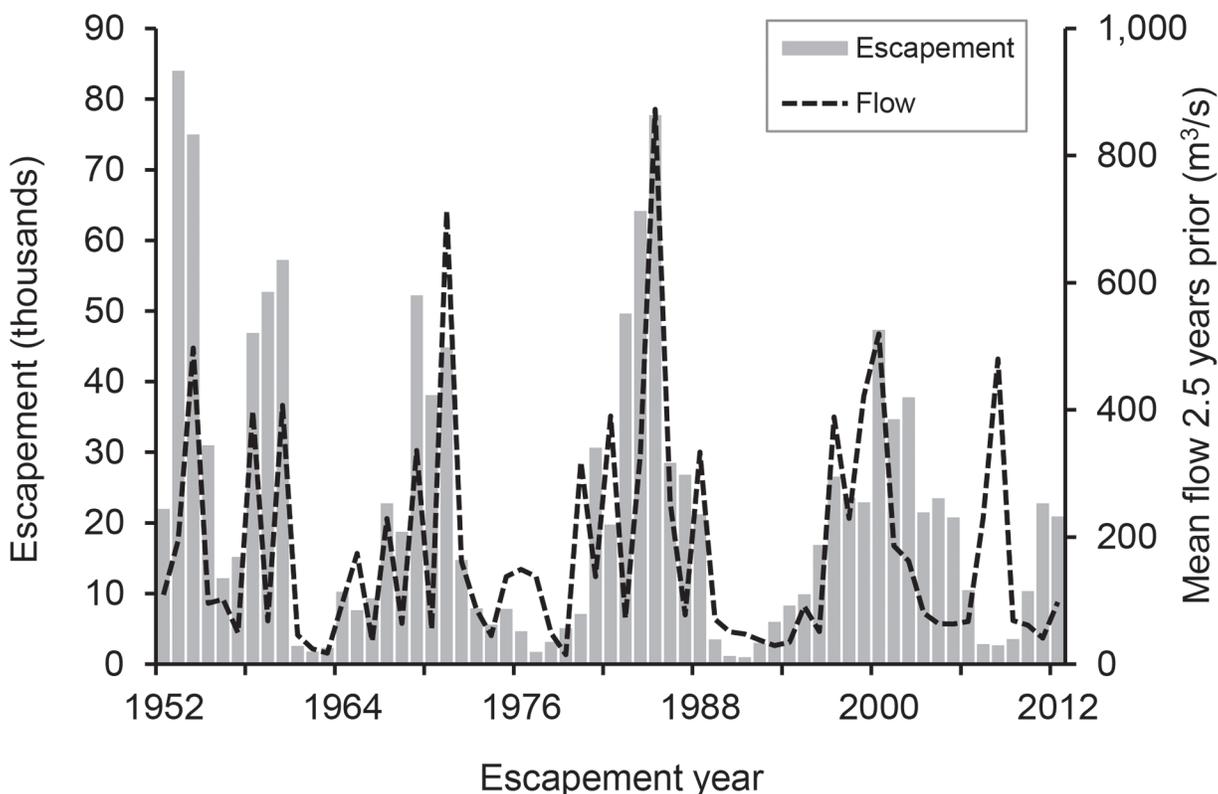

Fig 1. Relationship between adult salmon returns to the San Joaquin basin and the river flows experienced as juveniles. Fall-run Chinook salmon returns (‘escapement’) to the San Joaquin basin from 1952 to 2011 (CDFW GrandTab, www.CalFish.org) relative to mean flows at Vernalis (USGS gauge 11303500, <http://waterdata.usgs.gov/nwis>) for the January to June outmigration period they experienced 2.5 years previous. Note that adult abundance estimates have not been corrected for age distributions (we assumed that all adults returned at age 3), inter-annual variation in harvest rates or out-of-basin straying. The large deviation in 2007 reflected poor returns that were attributed to poor ocean conditions [96] and resulted in the closure of the fishery. Adapted from [97].

doi:10.1371/journal.pone.0122380.g001

nature, otoliths ('ear stones') represent a unique natural tag for reconstructing movement patterns of individual fish [29]. The technique relies on differences in the physicochemical environment producing distinct and reproducible "fingerprints" in the otolith. In the CCV, strontium isotopes ($^{87}\text{Sr}/^{86}\text{Sr}$) are ideal markers because the water composition varies among many of the rivers and is faithfully recorded in the otoliths of Chinook salmon [30–32]. Changes in otolith $^{87}\text{Sr}/^{86}\text{Sr}$ values can be used to reconstruct time- and age-resolved movements as salmon migrate through the freshwater and estuarine environments [33]. Furthermore, otolith size is significantly related to body size [34,35], allowing back-calculation of individual fork length (FL) at specific life history events [36].

Here, we document metrics of juvenile life history diversity (phenology, size, and abundance) of fall-run Chinook salmon as they outmigrated from the Stanislaus River during an 'above normal' (2000) and 'below normal' (2003) WYT. We used otolith $^{87}\text{Sr}/^{86}\text{Sr}$ and radius measurements to reconstruct the size at which returning (i.e. "successful") adults from the same cohort had outmigrated, then combined juvenile and adult datasets to estimate the relative contribution and survival of fry, parr and smolt outmigrants. Our main objectives were to determine (1) if a particular phenotype contributed disproportionately to the adult spawning population, (2) whether this could be attributed to selective mortality, and (3) if patterns in phenotype expression and success varied under contrasting flow regimes.

Study Area

The Stanislaus River (hereafter, "the Stanislaus") is the northernmost tributary of the San Joaquin River, draining 4,627 km³ on the western slope of the Sierra Nevada (Fig 2) [37]. The basin has a Mediterranean climate and receives the majority of its annual rainfall between November and April. Contrasting with the Sacramento watershed in the north, the hydrology of the San Joaquin basin is primarily snowmelt driven [4]. There are over 40 dams in the Stanislaus, which collectively have a capacity of 240% of the average annual runoff [38]. Historically, the Stanislaus contained periodically-inundated floodplain habitat and supported spring- and fall-run Chinook salmon; however, spring-run salmon were extirpated by mining and dam construction, reducing habitat quality and preventing passage to higher elevation spawning grounds [4].

Materials and Methods

Ethics statement

This research was conducted in strict accordance with protocols evaluated and approved by the University of California, Santa Cruz Institutional Animal Care and Use Committee for this specific study (permit number BARNR1409). Otolith and scale samples were collected by California Department of Fish and Wildlife (CDFW) staff from adult salmon carcasses (i.e. already expired) as part of their annual carcass survey, permitted under the State legislative mandate to perform routine management actions. No tissue collections were taken from any state- or federally-listed endangered or protected species for this study.

Juvenile sampling and hydrologic regime

Typically, fall-run Chinook salmon return to the San Joaquin basin from September to early January, and their offspring outmigrate the following January to June [16,39]. Juveniles were sampled as they left the Stanislaus using rotary screw traps (RST) at Caswell Memorial State Park (Fig 2, N 37°42'7.533", W 121°10'44.882). Sampling was terminated when no juveniles had been captured for at least seven consecutive days in June or July [40]. Here, we focused on

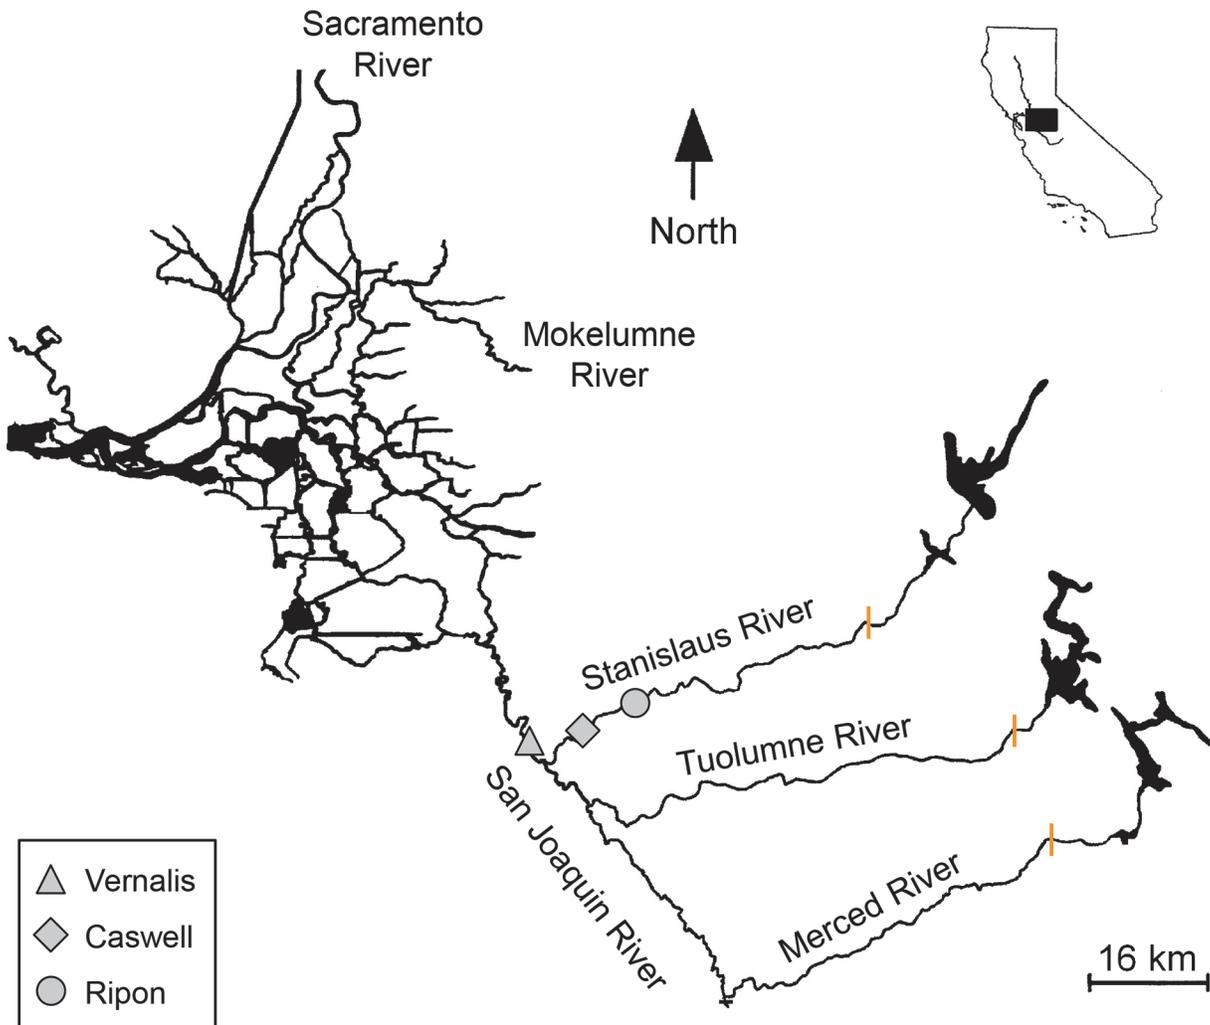

Fig 2. The San Joaquin basin of the Central Valley, California (inset). Map showing the major rivers in the San Joaquin basin, and the location of the rotary screw trap site at Caswell Memorial State Park and USGS gauges at Ripon and Vernalis. The upstream barriers to salmon migration in the three main tributaries are indicated by orange bars.

doi:10.1371/journal.pone.0122380.g002

an ‘above normal’ (2000) and ‘below normal’ (2003) WYT, and defined the outmigration period as January 1 to June 30, inclusive. When traps were checked, all fish were counted and up to 50 were randomly selected for fork length (FL) and weight measurements. Given potential subjectivity in visual staging criteria [41], we defined migratory phenotypes (fry, parr and smolt) by size: ≤ 55 mm, >55 to ≤ 75 mm, and >75 mm FL, respectively (after [21]). Unmeasured fish were assigned to phenotype using the observed proportions in the measured fish for the same date. For each phenotype, we interpolated missing catch values with a triangular weighted mean [42].

Marked fish were periodically released to develop a statistical model of trap efficiency, which was used to expand counts of fry, parr and smolt-sized outmigrants. Trap efficiency was estimated using a GLM with a quasibinomial error distribution because of overdispersion in capture probabilities. We used the same efficiency model as [42], only using phenotype (fry, parr, smolt) to characterize fish size, rather than FL. We propagated uncertainty by deriving estimated expanded counts from repeated Monte Carlo draws ($n = 2000$) from the estimated

sampling distribution of the estimated coefficients from the logistic efficiency model using R package `mvtnorm` [43]. Daily flow observations (USGS gauge no. 11303000 at Ripon, www.waterdata.usgs.gov/nwis) were used with the randomly-sampled model coefficients to simulate daily trap efficiency. Passage estimates were then simulated using daily catch and simulated trap efficiencies. We incorporated extra-binomial variation by generating simulated daily catch values from a beta-binomial distribution (based on the simulated efficiencies and passage estimates, as well as the dispersion estimated from the efficiency model). Finally, new daily passage estimates were calculated using simulated catch and trap efficiencies. Thus the final passage estimates incorporate both sampling error (catch) and estimation error (efficiency model). Annual passages estimates and confidence intervals (2.5% and 97.5% quantiles) were generated by summing daily passage estimates for the 6 month outmigration period (i.e. $n = 2000 \times 180$ days).

Measured daily size-frequency distributions were applied directly to the expanded abundance estimates, then grouped into 2mm FL bins. We attempted to produce passage estimates by FL, but the distribution used in the uncertainty propagation procedure (see above) is asymmetric at low catches, resulting in zero-inflation and the median of the resampled distribution often being lower than the observed raw catch.

Turbidity was measured at Caswell using a LaMott turbidity meter [40]; mean daily flow and maximum daily temperature were measured at Ripon (gauge details above). Daily passage estimates, turbidity, flow and temperature were \log_{10} transformed, then averaged for the 6-month outmigration period and compared among years by ANOVA, adjusting for temporal autocorrelation using the Durbin-Watson (DW) test [44]. Pearson's chi-squared test was used to identify differences in the proportion of phenotypes among years. Fry, parr and smolt phenology was summarized using three metrics associated with their date of passage past the trap: the range, interquartile range (IQR), and median (or "peak") outmigration date. Phenotype "migratory periods" were defined as the maximum IQR for both years combined.

Adult sampling and cohort reconstruction

To track outmigration cohorts 2000 and 2003 into the adult escapement, sagittal otoliths were extracted from Chinook salmon carcasses (aged 2–4 years, 45–112 cm FL) collected in the 2001–2006 CDFW Carcass Surveys (Table 1). Unmarked fish were sampled randomly, but in earlier years, known-hatchery fish with CWTs and clipped adipose fins ("adclipped") were preferentially sampled to assess the accuracy of age estimations. We utilized all otoliths collected from all unmarked fish, but included a subset of CWT fish from outmigration year 2000 ($n = 27$), which we analyzed blind to assess the accuracy of our natal assignments. Ages were estimated by counting scale annuli [45,46]. Each scale was aged by at least two independent readers and discrepancies resolved by additional reading(s).

Table 1. Adult sample sizes, age structure and collection periods.

Age	Outmigration cohort 2000 (wetter)			Outmigration cohort 2003 (drier)		
	N	%	Collection period	N	%	Collection period
2	6	7%	11/20/01–12/06/01	2	2%	11/08/04–11/12/04
3	80	87%	10/07/02–12/12/02	56	67%	11/02/05–12/15/05
4	6	7%	11/12/03–12/04/03	25	30%	11/15/06–12/06/06

Otoliths were analyzed from salmon carcasses belonging to adults that had outmigrated in 2000 and 2003, including 27 known-origin fish included as a blind test of our natal assignments.

doi:10.1371/journal.pone.0122380.t001

Otolith $^{87}\text{Sr}/^{86}\text{Sr}$ analyses

Otolith strontium isotope ratios ($^{87}\text{Sr}/^{86}\text{Sr}$) were measured along a standardized 90° transect [47] by multiple collection laser ablation inductively coupled plasma mass spectrometry (MC-LA-ICPMS; Nu plasma HR interfaced with a New Wave Research Nd:YAG 213 nm laser). Spot analyses were used to allow coupling of chemical data with discrete microstructural features, but otherwise preparation and analysis methods followed those of Barnett-Johnson et al. [32,48]. In brief, otoliths were rinsed 2–3 times with deionized water and cleaned of adhering tissue. Once dry, otoliths were mounted in Crystalbond resin and polished (600 grit, 1500 grit then 3 μm lapping film) until the primordia were exposed. Depending on sample thickness and instrument sensitivity, a 40–55 μm laser beam diameter was used with a pulse rate of 10–20 Hz, 3–7 J/cm^2 fluence, and a dwell time of 25–35 seconds, resulting in individual ablations roughly equivalent to 10–14 days of growth. Where individual ablations exhibited isotopic changes with depth (e.g. at habitat transition zones), only the start of the ablation was used (e.g. S1 Fig). Helium was used as the laser cell carrier gas (0.7–1.0 L/min) to improve sample transmission and was mixed with argon before reaching the plasma source. Krypton interference (^{86}Kr) was blank-subtracted by measuring background voltages for 30 s prior to each batch of analyses, and ^{87}Rb interferences were removed by monitoring ^{85}Rb . Isotope voltages were integrated over 0.2 s intervals then aggregated into 1 s blocks. Outliers ($>2\text{SD}$) were rejected. Marine carbonate standards ('UCD Vermeij Mollusk' and *O. tshawytscha* otoliths) were analyzed periodically to monitor instrument bias and drift, producing a mean mass-bias corrected $^{87}\text{Sr}/^{86}\text{Sr}$ ratio (normalized to $^{86}\text{Sr}/^{88}\text{Sr} = 0.1194$) within 1SD of the global marine value of 0.70918 (0.70922 ± 0.00008 2SD).

Strontium isotopes to reconstruct natal origin and size at outmigration

The baseline of natal $^{87}\text{Sr}/^{86}\text{Sr}$ signatures described in [32] was updated and expanded upon to increase sample sizes and among-year representation, resulting in an 'isoscape' that encompassed all major CCV sources, with many sampled across multiple years and hydrologic regimes. Linear discriminant function analysis (LDFA) was used to predict the natal origin of the sampled adult spawners, assuming equal prior probabilities for all sites (S1 Text). Differences in natal $^{87}\text{Sr}/^{86}\text{Sr}$ values were tested between years and sites (S1 Text, S1 Table and S2 Fig), and the performance of the LDFA was assessed using known-origin reference samples (S2 Table). Adults in this study were considered strays (not produced in the Stanislaus) when their natal $^{87}\text{Sr}/^{86}\text{Sr}$ were closer to other sources in the isoscape, and were excluded from further analysis.

For adults that had successfully returned to the Stanislaus, we monitored the change in $^{87}\text{Sr}/^{86}\text{Sr}$ across the otolith to identify the point at which they had outmigrated as juveniles. The Stanislaus has a significantly lower isotopic value (0.70660 ± 0.00008 SD) than the mainstem San Joaquin River immediately downstream from it (0.70716 ± 0.00013 SD), resulting in a clear increase and inflection point in otolith $^{87}\text{Sr}/^{86}\text{Sr}$ at natal exit (e.g. Fig 3B). If the inflection point was unclear, sequential spot analyses were analyzed by LDFA, and exit was defined as a >0.3 decrease in posterior probability of Stanislaus-assignment to a probability <0.5 . Deviation from the mean $^{87}\text{Sr}/^{86}\text{Sr}$ Stanislaus value was assumed to reflect considerable time spent in non-natal water, as (1) the Stanislaus $^{87}\text{Sr}/^{86}\text{Sr}$ signature shows minor variation in otoliths (S1 Table) and water samples collected immediately upstream of the confluence, (2) the RST location is 13.8 km upstream of the confluence (Fig 2) and (3) the length of time integrated by each laser spot is ~ 12 days. Therefore, the distance used to back-calculate exit size was from the otolith core to the last natal spot. To improve resolution and accuracy, additional ablations were performed around the transition zone, typically resulting in sub-weekly resolution.

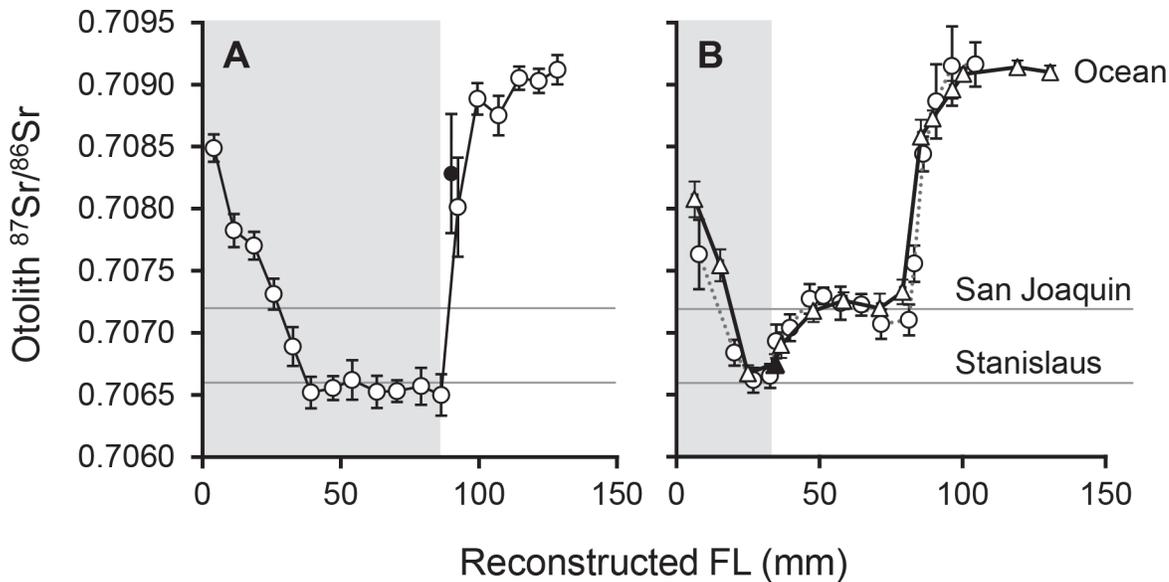

Fig 3. Otolith $^{87}\text{Sr}/^{86}\text{Sr}$ reconstructions of a smolt and fry outmigrant. Otolith $^{87}\text{Sr}/^{86}\text{Sr}$ profiles against back-calculated FL for two adult Chinook salmon that returned to the Stanislaus River having outmigrated as (A) a smolt and (B) a fry. The shaded box indicates the time spent rearing in the natal river. The fry outmigrant reared for several weeks downstream in the San Joaquin River before migrating out to the ocean, as indicated by both the left (triangles, solid line) and right (circles, dashed line) otolith (back-calculated FL = 33.3mm vs. 34.9mm). Mean $^{87}\text{Sr}/^{86}\text{Sr}$ signatures for the Stanislaus and San Joaquin Rivers, and modern-day ocean are displayed. Black filled symbols indicate 're-spots' carried out to improve sampling resolution. Error bars = 2SE.

doi:10.1371/journal.pone.0122380.g003

Reconstructed size at outmigration in the returning adults

The relationship between otolith radius (OR) and FL was first calibrated using juveniles collected from multiple sites in the CCV (S3 Table). All individuals belonged to the same Evolutionarily Significant Unit, which is critical for producing unbiased back-calculation models [49]. As there was no difference in the OR of paired otoliths from single individuals ($n = 30$, $\bar{x}\Delta = 2.5\mu\text{m}$, 95% CI = -5.6 – $10.6\mu\text{m}$), left and right otoliths were used interchangeably. OR was measured along the same 90° transect used for isotope analyses, using a Leica DM1000 microscope and Image Pro Plus (7.0.1).

Reconstructed sizes were grouped into 2mm FL bins and categorized as fry, parr or smolt outmigrants based on the criteria of [21]. Size-frequency distributions were compared between the juvenile and adult samples to identify trends indicative of size-selective mortality. The error around the OR-FL calibration line was used to estimate 95% CI around the proportions of fry, parr and smolt outmigrants using random resampling ($n = 5000$) of the residuals. This allowed us to derive the relative contribution of each phenotype to the adult spawning population.

Survival of juvenile migratory phenotypes

To generate survival indices, we normalized the contribution of each phenotype to the adult population by their abundance within each outmigration cohort based on RST sampling. To estimate spawner abundance ("natural escapement"), we removed adclipped strays from total escapement estimates (GrandTab, available at www.calfish.org) using river- and year-specific tag recovery rates (S4 Table), then separated cohorts using annual age distributions [50] and removed unmarked strays using our otolith natal assignments (see results and S4 Table). We evaluated the use of spawner abundance vs. "adult production" (after [51]). While production accounts for different harvest rates among years [52], the two metrics produced similar trends

in survival ($r^2 = 0.98$), and we found that escapement, which includes harvest, bycatch and natural mortality between outmigration and spawning, to be more intuitive to interpret.

The otolith-derived proportions ($\pm 95\%$ CI) of phenotype i in the escapement (β_i) were applied to our natural escapement estimates (E_n) to estimate the number of fry, parr and smolt spawners (E_i), then E_i was compared with the number of outmigrants of phenotype i (J_i) to estimate their relative survival (S_i):

$$E_i = E_n \beta_i \quad S_i = E_i / J_i$$

To estimate 95% CI for S_i we combined error in β_i and J_i using the delta method. The 95% CI for S_i depends on the estimate and its standard error (SE): \hat{S}_i , $SE(\hat{S}_i)$. Assuming independence of β_i and J_i , we estimated variance as $SE(\log(\hat{S}_i)) \cong \sqrt{(\frac{1}{J_i})^2 SE^2(\hat{J}_i) + (\frac{1}{\beta_i})^2 SE^2(\hat{\beta}_i)}$. From this, we derived 95% CI for S_i as $(e^{\log(\hat{S}_i) - 1.96 \times SE(\log(\hat{S}_i))}, e^{\log(\hat{S}_i) + 1.96 \times SE(\log(\hat{S}_i))})$. Note that uncertainties in adult escapement were not incorporated into these confidence intervals; however, the RST-expansions used to estimate J_i were deemed likely to introduce the largest amount of error.

Results

Juvenile outmigration relative to hydrologic regime

Mean flow and turbidity for the 6 month outmigration period were higher in 2000 than 2003 (DW-adjusted $F_{1, 361} = 7.52$, $p = 0.006$ and $F_{1, 257} = 14.53$, $p = 0.0002$, respectively) (Fig 4). In the drier year (2003) the river was warmer during the smolt migratory period (Apr 15-May 18: DW-adjusted $F_{1, 60} = 4.54$, $p = 0.037$) and peak daily temperatures first exceeded 15°C three weeks earlier (Fig 4).

Peak flows were about five times higher in 2000 than 2003, and accompanied by spikes in turbidity and juvenile migration (Fig 4). The number of outmigrants was an order of magnitude higher in 2000 (Table 2), reflecting significantly higher daily abundances of fry, parr and smolt outmigrants (DW adjusted $F_{1, 161} = 11.23$, $p < 0.001$; $F_{1, 196} = 47.99$, $p < 0.001$; $F_{1, 199} = 6.45$, $p = 0.0118$, respectively). While fry dominated in both years, phenotype contributions differed significantly between years ($X^2 = 223,683$, $p < 0.001$), with parr approximately twice as abundant as smolts in 2000, but vice versa in 2003 (Table 2). One yearling (FL = 140mm) was

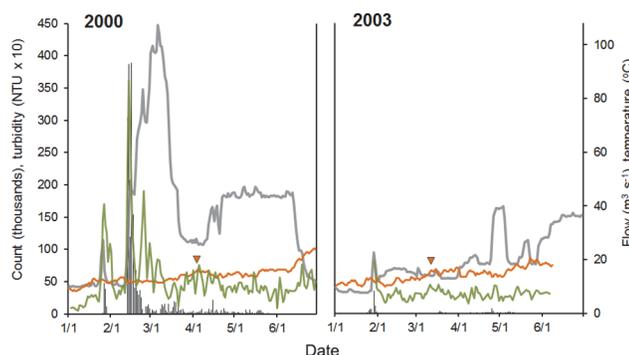

Fig 4. Daily abundance of juvenile salmon outmigrating in 2000 and 2003 relative to ambient environmental conditions. Juvenile salmon were sampled by rotary screw traps at Caswell as they outmigrated from the Stanislaus, and raw counts were expanded into daily abundance estimates (vertical bars) based on trap efficiency models. River flow (grey line) and maximum daily temperature (orange line) were measured at Ripon (data available at <http://cdec.water.ca.gov/>). Turbidity (green line) was measured at Caswell [40]. The first instance of temperatures reaching 15°C is indicated by an arrow on each plot.

2003 (drier)	Fry	79,862 (59,795– 103,916)	0.50	80 d (Jan 23–Apr 12)	4 d (Jan 27–Jan 30)	Jan 29
	Parr	25,729 (17,889– 36,282)	0.16	118 d (Feb 5–June 2)	27 d (Mar 18–Apr 13)	Mar 21
	Smolt	55,465 (38,415– 76,289)	0.34	107 (Feb 24–Jun 10)	21 d (Apr 18–May 8)	Apr 25
	TOTAL	161,056 (119,868– 209,151)				

The abundance and proportions of fry, parr and smolt outmigrants sampled by rotary screw traps, and the timing of their outmigration from the Stanislaus River in 2000 and 2003.

doi:10.1371/journal.pone.0122380.t002

captured in the RST in 2000, but none in 2003, otherwise the size range of outmigrants was similar between years (25–115mm in 2000 vs. 27–115mm in 2003).

Phenology varied between phenotypes and years (Table 2 and Fig 5). In general, migratory windows were shorter and earlier in the drier year, with smolt outmigration ceasing 15 days earlier in 2003 than in 2000. The peak migratory periods were similar across years for fry and parr, the former exhibiting a compressed interquartile range (4 d) that was tightly correlated with the start of winter flow pulses (Fig 5).

Natal origin of unmarked adults

The unmarked adults from outmigration cohorts 2000 and 2003 comprised 18% and 51% hatchery strays, respectively, primarily from the Mokelumne, Merced, and Feather River

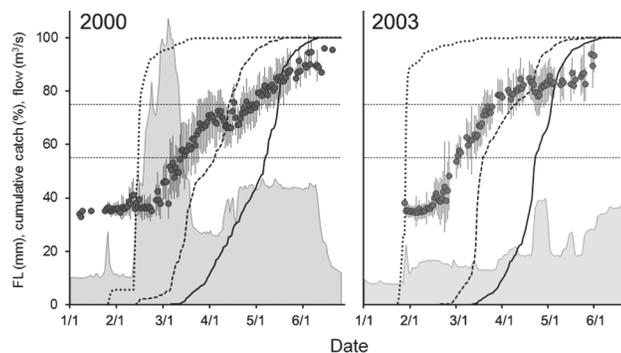

Fig 5. Size and phenology of juveniles outmigrants relative to river flow in 2000 and 2003. Mean (\pm SD) daily fork length (FL) of juveniles outmigrants, and cumulative percentage of fry (short dashed line), parr (long dashed line) and smolt (solid line) outmigrants relative to flow (filled area). Reference lines indicate the size categories used to define the migratory phenotypes: fry (\leq 55mm), parr (55–75mm) and smolts ($>$ 75mm).

Hatcheries (Table 3). These individuals were removed from subsequent analyses, ensuring that size back-calculations were calculated only for Stanislaus-origin fish that had experienced the same outmigration conditions as the RST-sampled juveniles.

Back-calculation of size at outmigration

A strong, positive relationship was observed between OR and FL ($r^2 = 0.92$, $n = 224$, $p < 0.001$; $\text{FL} = 0.171 (\pm 0.003 \text{ SE}) \times \text{OR} - 12.76 (\pm 1.54 \text{ SE})$), remaining linear across the full range of FLs reconstructed in the current study. This relationship was used to reconstruct FLs for individual $^{87}\text{Sr}/^{86}\text{Sr}$ profiles (e.g. Fig 3). The back-calculated size at which returning adults had outmigrated from the Stanislaus ranged from 31.3mm to 86.6mm in 2000, and 46.0mm to 90.5mm in 2003 (Fig 6). No yearlings were detected in the adult returns in either year.

To explore reproducibility of the method, paired left and right otoliths were analyzed from a subset of adults ($n = 3$ fry and $n = 1$ smolt outmigrant). All fish were assigned to the same migratory phenotype using either otolith, and the mean difference between back-calculated FLs was 2.3mm (e.g. Fig 3B).

Contribution and survival of juvenile migratory phenotypes

The relative abundance of the migratory phenotypes in the escapement differed significantly to the outmigrating juvenile population in both 2000 ($X^2 = 20,931$, $p < 0.0001$) and 2003 ($X^2 = 1,381$, $p < 0.0001$). The phenotype composition of the adult population also differed significantly between years ($X^2 = 749$, $p < 0.0001$), reflecting higher fry contributions in the wetter year (23% in 2000 vs. 10% in 2003) and higher smolt contributions in the drier year (44% in 2003 vs. 13% in 2000). Despite representing only 10–16% of the outmigrating juveniles (Table 2), parr were the most commonly observed phenotype in the surviving adult populations (46–64%, Table 4), although parr and smolt contributions to the escapement were near-identical in 2003 (46% vs. 44%, respectively). Conversely, fry outmigrants represented 10–23% of the adult escapement, despite representing 50–85% of the juvenile sample (Tables 2 & 4). The lowest survival was observed in individuals $< 45\text{mm}$, particularly in 2003, when the smallest outmigrant in the adult sample had left the river at 46mm FL, while the smallest individual captured in the RST was 27mm FL (Fig 6). Conversely, in 2000, 11% of the adults had left at FLs $\leq 46\text{mm}$ (the smallest at 31.3mm), compared with 80% of the original juvenile population (the smallest at 25mm; Fig 6).

In both years, fry survival downstream of the Stanislaus (S_{fry}) was significantly lower than parr or smolt survival ($p < 0.05$). S_{parr} was approximately double S_{smolt} in both years, but the confidence intervals were overlapping (Table 4). Generally, outmigrant survival downstream of

Discussion

In this study we document the expression of juvenile salmon migratory phenotypes under two contrasting flow regimes and provide new insights into their contribution to the adult spawning population and ultimate survival. We observed variable expression and survivorship of fry, parr and smolt life histories within and between years, yet all three phenotypes consistently contributed to the adult spawning population. This result challenges the common perception in the CCV, that smolt outmigrants are the dominant phenotype driving adult population abundance. Our key findings in the context of the salmon life cycle in order to link the datasets, methods, and processes examined in the study (Fig 7). Overall, the wetter year (2000) was characterized by higher numbers of juvenile outmigrants and adult returns, despite fewer adult spawners contributing to the cohort the previous fall. Using the number of parental spawners as a coarse proxy for juvenile production, these trends suggest higher in-river mortality in the drier year (2003). Given similar downstream (outmigration-to-return) survival rates, these data suggest that for the two focus years of the study, cohort strength was primarily determined within the natal river, prior to juvenile outmigration.

Juvenile outmigration behavior and phenotype expression

Juvenile outmigration timing in salmonids is inextricably linked to large-scale patterns in hydroclimatic regime and local-scale patterns in the magnitude, variation, and timing of flows [14,42]. In the Stanislaus, increases in flow were accompanied by pulses of outmigrants in both years, though greatly amplified during the turbid storm events of 2000. Correlations between fry migration, flow, and turbidity are commonly reported in the literature [14,53,54], and are suggested to have evolved as a result of reduced predation from visual piscivores [14,27,55,56]. The peak in migration in late January 2003 contained 85% of the year's total fry outmigrants and coincided with a managed water release that resulted in mean river flows of 28.4 m³ s⁻¹ [57]. This pulse flow appeared to stimulate fry migration, but comprised relatively clear water (~8 NTU) and contained outmigrants almost entirely <40mm FL (Fig 5). In both years, the larger parr- and smolt-sized fish also appeared to respond to instream flows, exhibiting smaller migration pulses from March through May, coincident with both natural and managed flows (Fig 4) [58,59].

The date and periods of peak migration were generally earlier and shorter in 2003, particularly for smolts. While warmer conditions can result in faster growth rates [60], smoltification in juvenile Chinook salmon is significantly impaired at temperatures above 15°C [61] and this critical temperature was reached at Ripon three weeks earlier in 2003, prior to the onset of peak parr migration. As the reduction in juvenile abundance in 2003 occurred in spite of greater

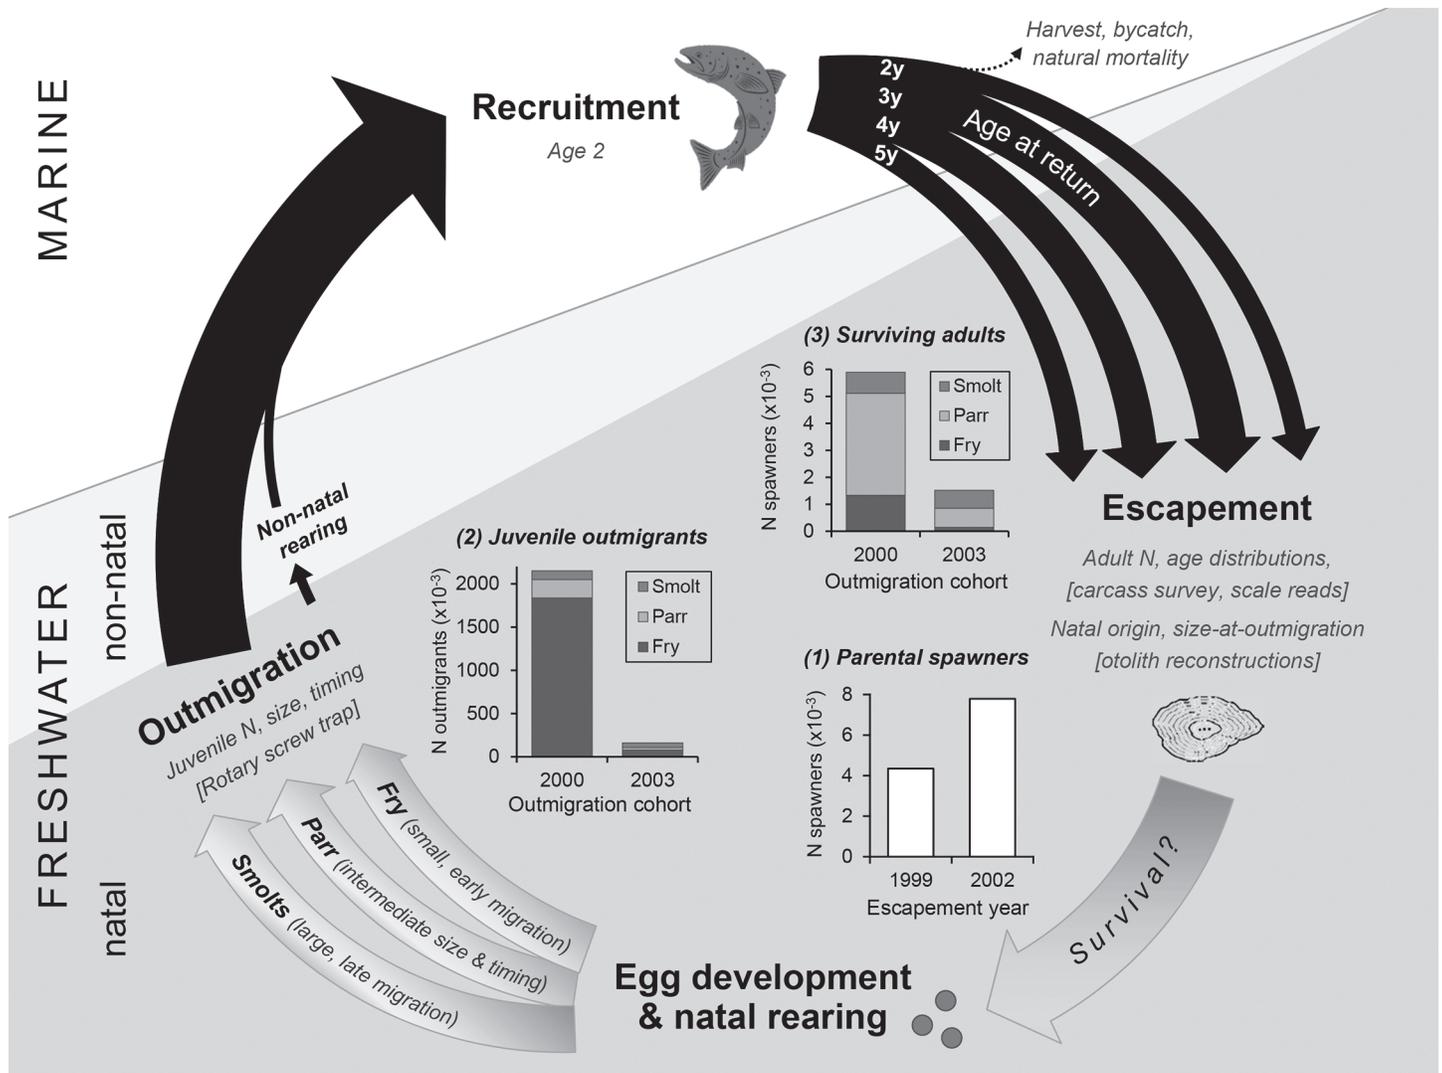

Fig 7. Schematic to conceptualize the data sources, methods and results presented in this study. This figure outlines the life cycle of fall-run Chinook salmon in the California Central Valley. Inset plot (1) demonstrates the abundance of parental spawners in the 1999 and 2002 escapement that contributed to the two focus years. Inset plots (2) and (3) illustrate the abundance and proportions of migratory phenotypes (fry, parr and smolts) observed in the juvenile sample (based on RST sampling) and in the adult escapement (based on otolith reconstructions), respectively. Arrow widths (not to scale) illustrate the typical proportions of 2, 3, 4 and 5 year olds observed in the adult escapement; note that age 5 fish tend to comprise <1% of the returns [50].

doi:10.1371/journal.pone.0122380.g007

numbers of parental spawners (Fig 7), we hypothesize that the truncation of migratory periods was driven by in-river mortality rather than altered migration timing or faster transitions between size classes. Juveniles tend to encounter less floodplain habitat, and increased predation rates and physiological stress in warmer, drier years [62], which likely resulted in a lower carrying capacity in the natal tributary [63] and increased density dependent mortality [64,65].

Survival of migratory phenotypes

Although lower flows and warmer temperatures in the Stanislaus may have contributed to the lower outmigrant production observed in 2003, our results suggest that after exiting the natal river, there was no significant difference in juvenile survival. Survival rates were, if anything, marginally higher in 2003, contradicting many tagging studies which find reduced salmon

survival through the freshwater delta during low flow conditions [24,66–68]. This discrepancy is likely due to differences in the sampling design and the time period represented by the different indices. Tagging studies generally release larger hatchery fish in similar sized batches during the later months of the outmigration season, when warmer conditions likely increase their vulnerability to predation [62]. Conversely, our survival estimates were based on variable numbers of fish over a larger size spectrum and broader migratory window, incorporating mortality events in all habitats downstream of the natal river, including the mainstem river, delta, estuary and ocean. However, we assume that differences in our survival indices would be driven by selective mortality events occurring during outmigration and early ocean residence. In support of this, there was no relationship between back-calculated size at outmigration and return FL ($r^2 < 0.01$, $p > 0.05$), implying that size-selective mortality did not vary by phenotype in the adult fish. However, marine distributions of adult salmon can be non-random [69], and if driven by timing at ocean entry, the migratory phenotypes could have been subjected to different ocean processes and mortality rates even as adults.

Parr and smolt outmigrants. Life history theory predicts selection to favor different phenotypes under different hydrologic regimes, maintaining behavioral and phenotypic diversity [70]. Yet in the current study, parr consistently exhibited the greatest contribution to the adult population and the highest survival rates. Greater representation of intermediary-sized juveniles has also been observed in some years in the ocean fisheries of Chinook [21] and Atlantic salmon [22], contradicting the expected directionality of size-selective mortality. Generally, larger or faster-growing individuals within a population are thought to have a selective advantage as a result of greater feeding opportunities, lower vulnerability to predation and greater tolerance of environmental perturbations [71]. However, the strength of size-selection in juvenile CCV Chinook salmon can vary as a function of ocean productivity [18], highlighting the importance of maintaining life history diversity in outmigration strategies. Without large-scale field experiments, it is not possible to definitively ascertain why smolts were not the most successful phenotype, however the San Joaquin basin is at the southernmost reaches of the species distribution [3] and its salmon populations are exposed to high temperatures, poor water quality, and significant water diversions [72,73]. This frequently results in river conditions that could impair growth and smoltification, and increased vulnerability to predation and disease [62], particularly at the end of the season when smolt-sized fish are most prevalent. Thus, the survival advantage of parr is likely attributable to both size and migration timing, analogous to the marine-orientated “critical size and period hypothesis” proposed by Beamish and Mahnken [74]. Furthermore, current flow practices in the San Joaquin basin include managed releases in April and May, intended to improve the survival of smolts [75]. These managed flows typically occur after most parr have left their natal tributaries, potentially selecting for this phenotype by providing downstream benefits as they migrate through (or rear in) the San Joaquin River and freshwater Delta.

Fry outmigrants. Little is known about the factors driving fry behavior or survival, yet the numbers that outmigrated during the wetter year (2000) were orders of magnitude higher, when they also contributed more than double the number of adult survivors (23% in 2000 vs. 10% in 2003). While fry consistently exhibited lower survival rates than their conspecifics (Table 4), reflecting the typical direction for size-selective mortality [71], the fact that any survived to contribute to the adult population, let alone contributing >20% of the adult returns, is a significant finding. Based on these data, their sheer abundance during high flow conditions at least partially helps to explain the increases in returns following wet outmigration conditions in the San Joaquin watershed (Fig 1). Early-migrating fry and parr may represent a significant portion of the population that can access favorable downstream rearing habitats in high flow years and survive to contribute to the adult population. Indeed, our otolith reconstructions

indicated that all of the smallest (≤ 46 mm FL) fry outmigrants in the surviving adult population ($n = 4$ in 2000, $n = 1$ in 2003) had spent several weeks rearing in the San Joaquin mainstem prior to leaving freshwater (e.g. Fig 3B). These data corroborate the extended transit times of CWT-tagged fish released in the San Joaquin basin and freshwater Delta in wetter years (averages of 16 d in 2000 vs. 6 d in 2003), although their mean size also differed (81mm vs. 87mm, respectively) [58]. Fry are observed in downstream freshwater and estuarine habitats in the CCV [20,76], and were probably more common when the Delta was a large tidal wetland [14,24,53]. This study confirms that these individuals can survive and contribute meaningfully to adult returns.

Currently there are no genetic data to support or refute a heritable component to early out-migration behavior, but it could otherwise meet the criteria of an adaptive trait, given that its expression is associated with “differential survival” and there is evidence for “a mechanism of selection” [77]. There is still some debate as to whether fry pulses during high flow events represent displacement due to reduced swimming ability or a deliberate behavior that might be considered a ‘strategy’ [3,14]. While catastrophic floods undoubtedly result in riverbed scouring and some fry displacement, not all individuals outmigrate during these events. Conversely, some fry migration is observed during periods with no pulse flows [78]. Given the frequency with which this phenotype is reported and the considerable rearing potential of downstream habitats, it is conceivable that fry dispersal is a heritable strategy, representing a ‘migratory contingent’ within the population [79,80]. Indeed, their consistent contribution to the adult population (observed here and in [21]) conclusively demonstrates that fry migration can be successful. If, however, early outmigration is purely an expression of phenotypic plasticity, it is likely that multiple factors are involved in stimulating the behavioral switch, including hydrology, intraspecific interactions [3] and density dependent mechanisms [65,81–83]. Irrespective of the underlying mechanisms, quantifying the relative success of migratory phenotypes across a broader range of hydrologic regimes is fundamental to understanding how environmental conditions and water operations contribute to salmon population dynamics.

Otolith strontium isotopes and sources of uncertainty

One of the most significant advances of the current study was the pairing of RST sampling with otolith reconstructions. This process enabled us to compare fish size at a specific time and location across life stages, and provided a unique method for generating survival estimates into adulthood. CWT studies and acoustic telemetry have provided valuable insights into survival through particular stretches of the CCV [25,75], but tend to focus on larger fish and provide no information about the long-term success of particular traits. In addition, acoustic tags have focused on understanding flow-survival relationships for smolts, which are physiologically ready for seaward migration and likely use the mainstem rivers, delta, and estuary differently than fry or parr, which may exhibit prolonged rearing. Otolith $^{87}\text{Sr}/^{86}\text{Sr}$ ratios are an ideal natural tag as they vary among many of the rivers in the CCV, resulting in high classification scores for natal assignments (S1 and S2 Tables) [30,32,84]. Sr isotopes also represent a unique and sensitive marker for reconstructing downstream movements and non-natal rearing patterns in the freshwater system (e.g. Fig 3B). While seasonal variation in $^{87}\text{Sr}/^{86}\text{Sr}$ values have been reported in certain systems [85] and interannual variations were detected for some sites (S1 Table), these were minor compared with most of the geographic differences, with the majority of sites exhibiting classification scores $>70\%$ even when pooled across years (S2 Table). Importantly, the Stanislaus exhibited a stable and distinct isotopic signature; with 96% of juveniles correctly classified using jack-knife resampling (S2 Table). Identification of natal origin represents a significant advantage of using otolith Sr isotopes over element concentrations. This was critical

for pairing RST- and otolith-derived datasets and providing confidence that our size reconstructions were not skewed by hatchery smolts.

A high occurrence of straying of fall-run Chinook salmon occurs between the San Joaquin and Sacramento basins [86–88], potentially due to the relative outflows during the return migration as well as hatchery release practices [89]. However the extent to which hatchery fish are functioning to sustain the San Joaquin salmon populations has gone largely undetected until recently [86,87]. In the current study, hatchery strays represented 18–51% of the unmarked fish, reducing the number of samples available to inform outmigration strategies of wild fish and increasing analytical costs. However, the removal of strays was vital to ensure that FL reconstructions were only performed on individuals that had experienced the same conditions as the RST-sampled juveniles. The implementation of 100% visual identification of hatchery fish [90] would increase the feasibility and efficiency of future life history diversity studies in this system.

We attempted to reduce and account for sources of uncertainty, but the low number of focus years and sample sizes, and the potential for error propagation limit the strength of our inferences. With greater representation of 2 and 4 year olds in our adult sample, a more sophisticated analysis using age-specific natal assignments could have been carried out. While no yearlings were detected in the surviving adults, their rarity in the RST-sampled outmigrant population indicate that larger sample sizes would be required to ascertain the success of this strategy with any confidence. Similarly, our approach for assigning natal origin based on otolith chemistry following yolk sac absorption means that individuals that outmigrated as yolk sac fry could have been misclassified as strays. However, yolk sac fry are rarely observed in the outmigrant population (0.1% of the 2001–2011 RST catch at Caswell), so this was deemed unlikely to significantly influence our results.

Management implications

The complex biophysical properties of freshwater systems have led to the evolution of dynamic habitat mosaics [91] and diverse salmon life histories and distributions. The observed life history diversity likely provides within-population buffering, an as yet understudied component of the portfolio effect [5,6]. These data add to the mounting evidence that managing and conserving life history diversity is necessary to support resilient salmon populations, particularly in the face of climate change and projected human population growth [9,10]. Diversity in phenotypic traits is thought to produce a more stable population complex by decoupling population dynamics and buffering variance [6]. However, population resilience does not necessarily immediately translate into population abundance. In a highly regulated system such as the CCV, there is debate as to whether environmental unpredictability dictates a need to manage salmon stocks for diversity and resilience, or whether our understanding of (and control over) the relevant processes is sufficient to manage purely for abundance. Such topics are complicated by socio-economic and ecological trade-offs, however, by improving our understanding of how juvenile life history strategies are expressed and respond to different flow regimes, we may be able to optimize both. Currently, the portfolio effect for CCV salmon stocks is weak and deteriorating [92] and San Joaquin populations face serious future challenges, given predicted 25–40% reductions in snowmelt by 2050 [93]. CCV salmon exhibit diverse outmigration timings that have evolved over geological time scales in response to the unpredictable hydroclimatic conditions characteristic of the region [11]. Yet modern-day water and hatchery management practices tend to constrain outmigration timing. For example, alterations to the natural hydrograph, such as suppression of winter pulse flows, likely to truncate migratory windows, reduce the variability in outmigration timing, and significantly suppress the fry life history type. Such

simplification and truncation of life history diversity could significantly reduce the resiliency of the stock-complex and exacerbate the risk of a temporal mismatch with favorable ocean conditions [94]. Indeed, the only clear deviation from the flow-driven relationship in Fig 1 was attributed to juveniles entering the ocean during a suboptimal period and resulted in the closure of the fishery in 2008. Perhaps with more diverse, resilient stocks, the consequences would have been less extreme. Largely without direct empirical support, hatchery and flow management practices tend to focus on optimizing the success of the largest, smolt-sized juveniles that are assumed to contribute the most to adult returns [14,21,24]. Here, we found that all phenotypes contributed to the reproductive adult population, with smolts comprising less than half of the surviving adults following two contrasting flow regimes. Without otolith reconstruction data for additional years, species, and watersheds, the broader inferences one can make regarding the influence of hydroclimatic regime on juvenile salmon survival are limited. However our data and a previous study [21] indicate that assumptions regarding size-selective mortality and smolt-focused management schemes need to be tested on a species, system and hydroclimatic basis.

This study has demonstrated the value of a combined RST and otolith geochemistry study to reconstruct patterns in the expression and survival of salmon migratory phenotypes. The results show that under paired years of low and high flow conditions, parr outmigrants comprised a significant portion of the returning adult population, while fry made smaller, but substantial contributions. Future efforts should focus on reducing the error in juvenile production estimates in order to produce more meaningful survival estimates, and understanding the demographic role that fry and parr play in salmon population dynamics. Management actions that promoted the expression and survival of fry in natal and downstream rearing habitats could result in demographic and genetic benefits to the population. Recognition of the importance of hydrodynamic regime and life history diversity should provide guidance to system managers when reassessing goals and future management strategies [5,95]. It is also important that management actions consider carefully-designed monitoring programs to detect changes in stock abundance and life history diversity at appropriate temporal and spatial scales.

Supporting Information

S1 Text. Testing the performance of the Sr isotope.

(DOCX)

S1 Fig. Time-resolved plot of a single spot ablation at a habitat transition. This plot (macro developed by C. Donohoe) shows how the isotopic composition of the otolith can change with sample depth (equivalent to analysis time). Typically we would use ~20 seconds of data per spot (A), but in cases like this we would use only the surface material (B) to avoid signal attenuation and to ensure consistency between otolith $^{87}\text{Sr}/^{86}\text{Sr}$, microstructure and distance analyses.

(DOCX)

S2 Fig. Median $^{87}\text{Sr}/^{86}\text{Sr}$ natal values for major sources of Chinook salmon in the California Central Valley. Values are based on juvenile otoliths and/or water samples. The mainstem San Joaquin River (SJR) isotopic signature is displayed, but was not included as a potential natal source. Boxes represent 25-75th percentiles, whiskers represent 5-95th percentiles. Site codes are defined in S1 Table. Isotopic signatures not significantly different ($p > 0.05$, Tukey's test) are joined by brackets. Mean ocean $^{87}\text{Sr}/^{86}\text{Sr}$ is indicated by a dashed line.

(TIF)

S1 Table. $^{87}\text{Sr}/^{86}\text{Sr}$ isoscape used to train the LDA and assign unknown adult otoliths to natal location. Data based on known-origin otolith (O) and/or water (W) samples. Interannual differences were tested by ANOVA or Welch's Test when data exhibited unequal variance. Differences among sites are shown in [S2 Fig](#) Underlined years represent water samples collected Oct 1997 to Apr 1998 that were pooled into a single water year (1998). (DOCX)

S2 Table. Natal assignments and correct classification scores of known-origin samples. Assignments based on $^{87}\text{Sr}/^{86}\text{Sr}$ values and jackknife resampling. Site codes are defined in [S1 Table](#). Equal prior probabilities were given to all sites and sites are ordered by increasing mean $^{87}\text{Sr}/^{86}\text{Sr}$ value. The training dataset ($n = 290$) comprised both juvenile otoliths and water samples. Counts are for actual rows by predicted columns. Samples from the Stanislaus River (STA) are highlighted in bold, while groups of sites with statistically overlapping $^{87}\text{Sr}/^{86}\text{Sr}$ signatures ($p > 0.05$, Tukey's test) are shown in italics and [S2 Fig](#) (DOCX)

S3 Table. Reference samples used to calibrate the fork length back-calculation model. (DOCX)

S4 Table. The number of adult spawners produced by the 2000 and 2003 outmigration cohorts ("natural escapement") (DOCX)

Acknowledgments

This study was prepared by AMS under USBR Agreement R09AC20043. Work at LLNL was performed under the auspices of the U.S. Department of Energy, Contract DE-AC52-07NA27344. The statements, findings, conclusions, and recommendations are those of the author(s) and do not necessarily reflect the views of the Bureau of Reclamation (USBR), US Fish & Wildlife Service, California Department of Fish and Wildlife (CDFW), or the US Department of the Interior. We are grateful to the staff at CDFW who collected the otoliths and read the scales, particularly C. Sinclair and G. Murphy. We are also grateful to everyone who provided juvenile otoliths, particularly C. Watry. We thank Doug Threlhoff and all the staff at Cramer Fish Sciences who have operated the Caswell RST for so many years and provided one of the most robust time-series of juvenile production in the Central Valley. Special thanks to Elizabeth Vasquez and Patricia Clinton (USBR) for their continued support of this project. We thank S. Carlson and S. Nusslé (UC Berkeley) for their insightful comments on the manuscript and statistics, respectively, C. Donohoe (UC Santa Cruz) for the use of his excellent macro, and F. Loge and M. Miller for providing laboratory space and use of equipment at UC Davis.

University of California Santa Cruz
Assessing SPATT in San Francisco Bay
SFEI Contract 1051

Final Report

This project involves using Solid Phase Adsorption Toxin Tracking (SPATT) to detect and quantify microcystin and other phytotoxins in San Francisco Bay, and to undertake controlled experiments using SPATT whose goal is to improve the ability to translate SPATT-derived measurements into average ambient concentrations of phytotoxins.

In **Task 1**, SPATT was deployed on San Francisco Bay cruises in a flow-through configuration and at fixed sites as part of on-going monitoring work for phycotoxins in San Francisco Bay. As discussed with SFEI, one SPATT was deployed per basin in the surface-sampling flow-through system during the monthly *Polaris* cruises. Based on adjustments to cruise schedules and cruise types, SPATT were routinely deployed on all available cruises.

In **Task 2** controlled experiments were conducted in the laboratory to better characterize partitioning of phytotoxins out of solution and into the SPATT. Experiments were designed to evaluate measurement reproducibility, and whether reproducibility can be optimized by adjusting SPATT configuration. Options include:

- a. Controlled experiments carried out in simulated flow-through systems in which SPATT will be exposed to brackish water and seawater containing concentrations of a surrogate compound for toxins, e.g., microcystin-RR or similar. Toxin will be quantified as a function of both dissolved concentration and exposure time. This “calibration” information will allow for more accurate back-calculations of average ambient concentrations in natural systems.
- b. Time-series “bottle” experiments in which SPATT will be exposed in containers holding brackish water with known concentrations of a surrogate compound for toxins (e.g., microcystin-RR). SPATT will be removed at multiple time points and toxin uptake will be measured. This information will aid in characterizing the uptake kinetics of microcystin under conditions simulating deployments at a single site.

Research priorities for Task 2 were identified collaboratively by Kudela and SFEI, and a project plan was developed that is feasible within the available budget.

Results—Task 1

We have processed 155 SPATT samples from USGS cruises, between October

2011 and November 2014. Additional samples (through April 2015) have also been obtained and processed, but were not included in a recent analysis as part of a separate SFEI effort. For convenience, data presented here are limited to the 155 SPATT, but we continue to process the samplers.

While we anticipated 60 SPATT per year, several of the USGS cruises were canceled or reduced in geographic range in 2013 due to ship issues. For each SPATT we have analyzed for domoic acid (DA) and microcystins LR, RR, YR, and LA. These four congeners are identified by OEHHA as the primary microcystin toxins in California, and are considered to be of equivalent toxicity. We therefore sum the congeners to report “total microcystin”.

Preliminary data analysis was conducted on the SPATT and USGS underway data for presentation at several meetings:

- Kudela, RM, C Mioni, M Peacock, T Schraga. San Francisco Bay acts as a reservoir and mixing bowl for both marine and freshwater toxins. Coastal and Estuarine Research Federation, 3-7 November 2013, San Diego, CA.
- Kudela, RM, C Mioni, M Peacock, T Schraga. San Francisco Bay acts as a reservoir and mixing bowl for both marine and freshwater toxins. Eastern Pacific Oceans Conference, Fallen Leaf Lake, California, September 17-19, 2013.
- Kudela, R, Peacock, M, Schraga, T, Senn D. 2014. Does San Francisco Bay have a harmful algal bloom problem? 2014 Bay-Delta Science Conference, 28-30 October 2014, Sacramento, CA.

Those presentations are used as the basis for this interim report.

Between 2011-2014, 25 Full Bay and 28 South Bay cruises were analyzed. From those samples, 71.5% were positive for microcystins and 96.5% were positive for domoic acid (Figure 1). Concentrations ranged from 0-400 ng/g domoic acid, and 0-25 ng/g microcystins (Figure 2). Peaks in both toxins were coincident in time, and appear to be related to river flow. Moderate river flow is associated with the highest toxin concentrations. Spatially, toxins were fairly uniformly distributed throughout the four basins (Figure 3). During some periods there was clear separation based on temperature-salinity (T-S) properties, with domoic acid associated with “marine” waters and microcystins associated with “fresh” waters. However at other times toxins were distributed without a clear pattern through the Bay (Figures 4, 5).

The range of toxin concentrations, range of environmental parameters, and length of the time-series (3+ full years of data) make this dataset conducive to statistical modeling to identify relationships between toxins and environmental drivers or correlates (see Recommendations below).

Results—Task 2

We have conducted several “bottle” experiments to evaluate SPATT adsorption under representative conditions. In particular, we recently expanded the SPATT methodology to include anatoxin-a. This is a potent neurotoxin also known as “sudden death factor”. While there are no reports of anatoxin-a for San Francisco

Bay, we have routinely seen elevated levels in the Eel River, and occasionally get positive hits in nearby Pinto Lake. We recently concluded a laboratory calibration for anatoxin-a, looking at adsorption and recovery efficiency, effect of different source waters, and effect of temperature on adsorption.

We can now quantify SPATT (using HP20 resin) characteristics for domoic acid, microcystins, and anatoxin-a. Excitingly, we can use a single extraction method to analyze all three toxins from the same SPATT. We can also analyze for okadaic acid (Diarrhetic Shellfish Poisoning), extending our capability to 4 toxins that cover the majority of compounds expected in San Francisco Bay.

Because SPATT and grab samples (or indicator organisms) are fundamentally different measurement methods, we do not recommend a direct calibration factor between the various toxin detection methods. Rather, we provide ranges of SPATT concentrations that correlate to management action levels. For example, OEHHA recommends an alert or action level of 0.8 ppb total microcystins. Based on the large comparative dataset, this would be equivalent to a threshold concentration of ~1-4 ng/g for SPATT (see below). Based on that criteria, San Francisco Bay appears to approach this alert level seasonally (Figure 2).

Additional Analyses

We requested an extension to the contract to more fully characterize SPATT. We proposed to complete the following:

- SPATT deployment/analysis through 2014, providing a full 3-year record
- Finish characterization of toxin uptake in a simulated flow-through system
- Prepare a peer-reviewed publication describing the presence of toxins in San Francisco Bay

We further recommended the following. These five recommendations are beyond the scope of the current contract, but could be implemented within a 12-18 month contract at a similar cost to this contract.

- 1) Continue SPATT deployment beyond the scope of this contract;
- 2) Analyze matched filter samples from the USGS cruises for particulate toxins, to further calibrate the SPATT data; this could also be compared to an existing dataset of HPLC pigments and microscopy samples;
- 3) Analyze archived mussel tissue provided by the RMP as a pilot dataset, to determine whether additional sample analysis is warranted. This would directly link toxins to trophic accumulation.
- 4) Develop a method for saxitoxins. This is the only toxin group that we know is in SFB that is not currently included in our analysis. It requires some personnel time to set up the method, and supplies costs.
- 5) Analyze archived SPATT for anatoxin-a and okadaic acid.

Results from the Contract Extension

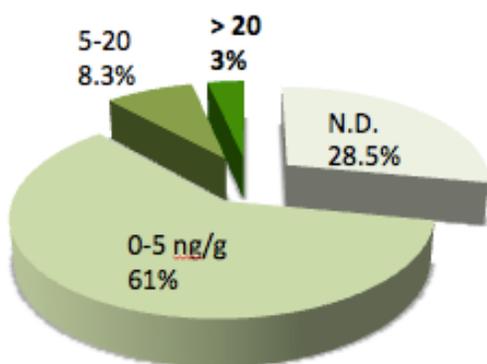

Following this document, we provide a separate write-up for the laboratory characterization (the second bullet from the proposed contract extension). Analysis of SPATT through 2014 was also completed, and an initial write-up with peer-review is ongoing as part of the following report and manuscript:

Sutula, Martha , Raphael Kudela, James Hagy, Gry Mine Berg, Suzanne Bricker, James E. Cloern, Richard Dugdale, Lawrence W. Harding, Jr., and David Senn. 2015 (in prep.). Scientific Basis for Assessment of Nutrient Impacts on San Francisco Bay.

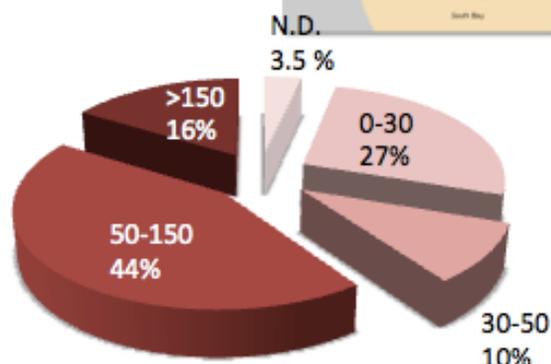

2011-2014: USGS Deployment of SPATT

October 2011 – July 2014

- 25 Full-Bay cruises
- 28 South Bay cruises

Microcystins

Domoic Acid

Figure 1. Summary results from the USGS cruises.

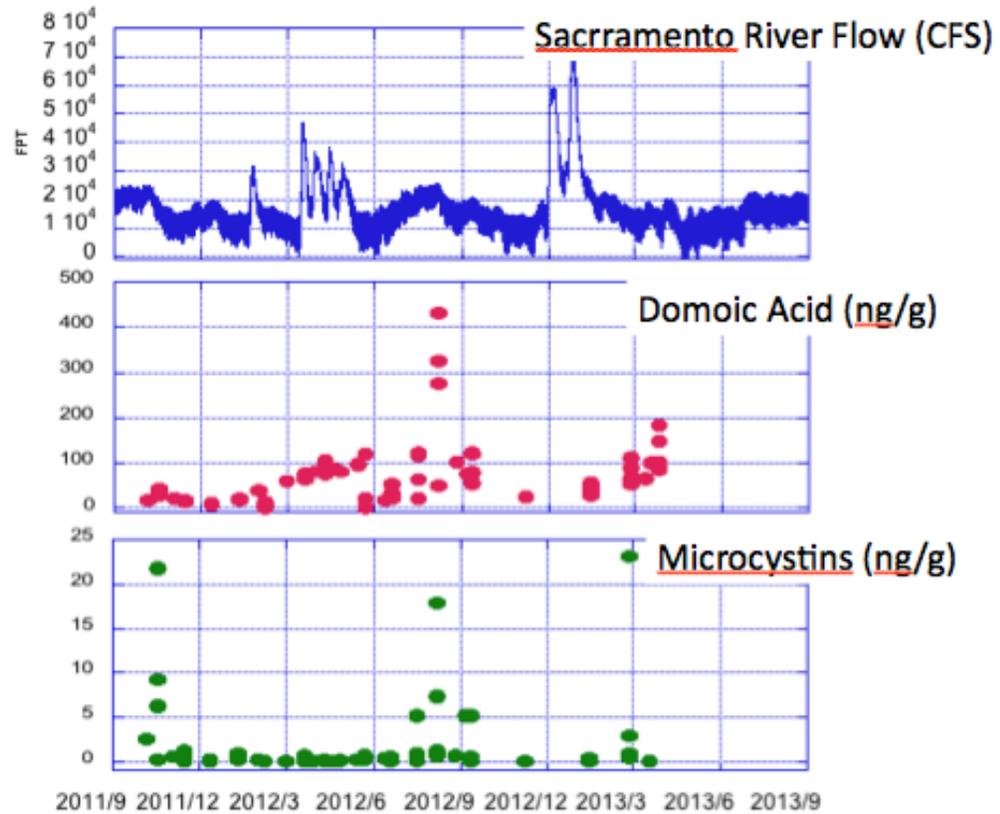

Figure 2. Toxin data shown as a time-series, with river flow (top). Toxins are generally associated with moderate flow in the autumn. The two peaks in autumn 2011 and summer 2012 are shown in more detail in Figures 4-5.

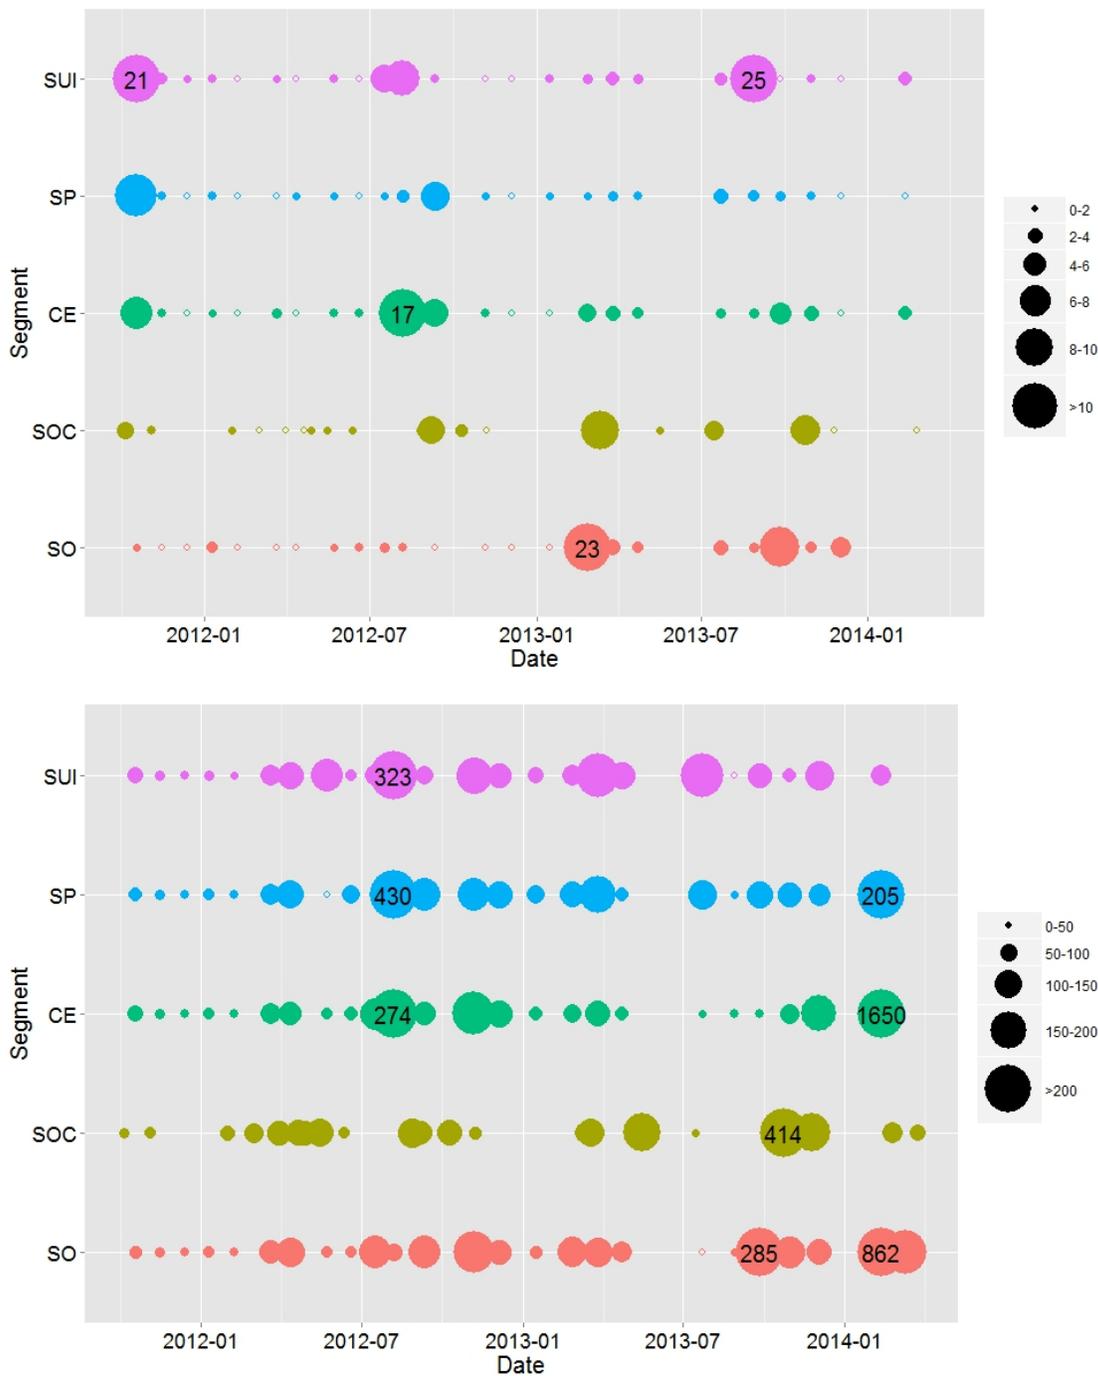

Figure 3. All of the SPATT data shown as concentration (larger circle equals more toxin). Note that microcystins are easily detectable, but fairly low. DA values are fairly high. Letter codes refer to subembayment: SO=South Bay, SOC=South Central, CE=Central, SP=San Pablo, SUI=Suisun.

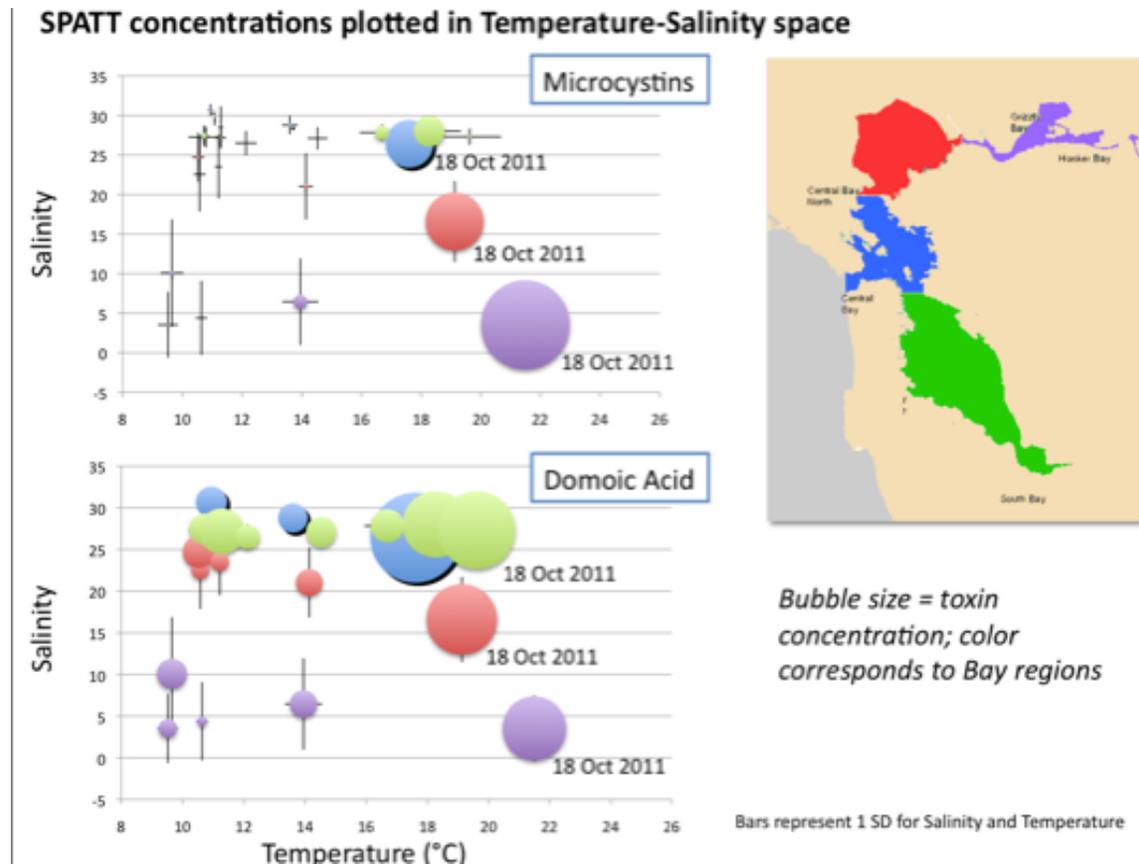

Figure 4. Toxin data plotted in T-S space. For this period, microcystins are clearly coming from the Delta, and spreading into the rest of the Bay, while DA is coming from Central Bay and spreading into the rest of the Bay, suggesting that sometimes, it's simply conservative mixing that is moving the toxins around.

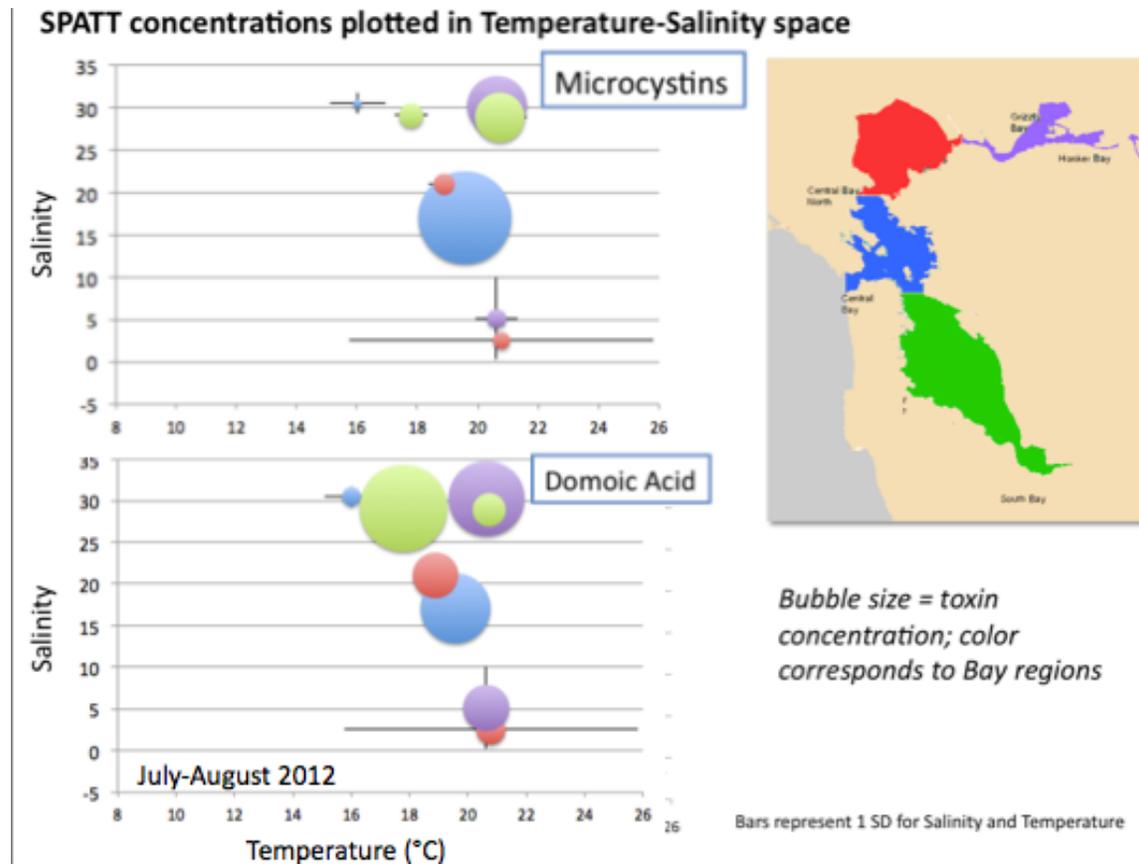

Figure 5. Another example, from July-August 2012. It is not as clear how the geographic patterns relate to environmental forcing. Highest microcystins are in Central Bay, with moderate levels in South Bay and the Delta. There is evidence (not shown) that microcystins are coming in from a separate South Bay source, possibly the sloughs and salt ponds. The DA is highest in South Bay, and pretty high in the Delta, suggesting transport of cells that eventually release toxin.

Results from Contract Extension Calibration of SPATT—Background

A primary objective of this project was to intercalibrate SPATT toxin data for microcystins and domoic acid such that data from the USGS underway mapping aboard the R/V *Polaris* can be qualitatively related to regulatory limits. OEHHA recommended 0.8 ppb for the sum of total (particulate and dissolved) microcystin LR, RR, YR, and LA. There are no formal guidelines for domoic acid, but regulatory limits for fish and shellfish is 20 ppm in tissue.

It is not possible to *directly* compare SPATT values to the regulatory guidance because (a) SPATT measures dissolved, and not total toxin; (b) SPATT toxins and grab samples for domoic acid are not equivalent to toxin levels in tissue; (c) SPATT integrates spatially and temporally. Additionally, SPATT is generally considered to be more sensitive than grab samples (Lane et al. 2010, 2012; Kudela 2011; Gobble and Kudela, 2014). Given these caveats, it is still desirable to relate SPATT concentrations to regulatory limits/guidelines.

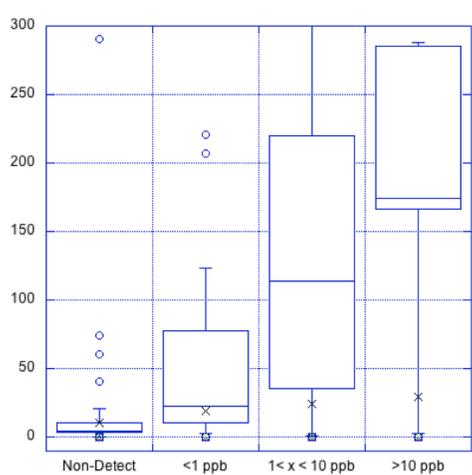

Figure 1. SPATT data from Pinto Lake, showing the correspondence between grab sample bins and SPATT values.

An initial attempt to provide an intercomparison used environmental data from long time-series at the Santa Cruz Municipal Wharf (Lane et al. 2010) and from Pinto Lake, California (Kudela 2011). For both of those programs SPATT, using the HP20 resin, are deployed weekly, with matching samples for dissolved and particulate domoic acid, and mussel tissue (SCMW), and dissolved and total microcystins (Pinto Lake). Using those data, SPATT values were binned into ranges corresponding to grab samples or mussel samples: non-detect, < 1 ppb, 1-10 ppb, and > 10 ppb for microcystins, and 0-5, 5-10, 10-20, and >20 ppm domoic acid in mussel tissue. Ranges were determined by binning the corresponding SPATT data

an calculating the median, mean, and standard deviation. These data are depicted graphically for microcystins in Figure 1 and the ranges are provided in Tables 1-2.

As part of laboratory characterization, resin capacity and equilibration times were evaluated when SPATT were developed (Lane et al. 2010; Kudela 2011). Since then, adsorption/desorption of microcystin LR was more rigorously evaluated (Zhao et al. 2013) and HP20 was again identified as the optimal resin for environmental use, with linear absorption characteristics over several days. HP20 was also identified as the best resin for use with lipophilic toxins in seawater for prolonged (days) deployment, with reasonably linear uptake and a combination of good adsorption

and desorption capabilities; other resins performed better under some circumstance, but were found not to be as universally applicable to a broad range of toxins, deployment times, and recovery methods (Zendong et al. 2014). Thus there is growing acceptance of HP20 resin as a “universal” SPATT resin, with the best overall combination of characteristics.

Table 1. SPATT concentrations corresponding to total microcystins from matching grab samples.

Microcystin Grab Sample (ppb)	SPATT (ng/g)
Non-Detect	5-13
< 1 ppb	20-50
1 < x < 10 ppb	50-200
> 10 ppb	175-275

Table 2. SPATT concentrations corresponding to mussel tissue domoic acid concentrations from matching mussel samples (SPATT were deployed weekly; mussels samples were collected weekly).

Domoic Acid Mussel (ppm)	SPATT (ng/g)
0-5 ppm	0-30
5-10 ppm	30-50
10-20 ppm	50-75
>20 ppm	>150

Calibration of R/V *Polaris* Underway Measurements

In order to translate the general characteristics of HP20 SPATT, a simulation was set up in the laboratory to mimic conditions on the R/V *Polaris* cruises. The following assumptions were made:

- 1) Transects include fresh, brackish, and marine waters;
- 2) Individual SPATT deployments are for no longer than 12 hours;
- 3) SPATT adsorption may differ when using a flow-through system compared to passive (static) water bodies such as Pinto Lake and Santa Cruz Wharf;

- 4) Temperature and salinity vary over the transects, potentially influencing toxin adsorption;
- 5) SPATT samplers are stored frozen prior to analysis.

Given these assumptions, the laboratory experiment was designed to mimic typical field conditions. A large volume (~16 L) of low-salinity water (Sacramento River water with Monterey Bay water mixed in, final salinity ~10). A recent study (Fan et al. 2014) showed HP20 adsorption varies with salinity, but not significantly so compared to other sources of variability, so it was assumed that salinity did not need to be directly tested again. The water was spiked with an initial concentration of ~34 ppb MC-LR, and 82 ppb domoic acid (a trace amount, ~3 ppb, of MC-YR was also present). The water was subsequently diluted to create a series of toxin concentrations for testing SPATT adsorption.

Adsorption kinetics should also be sensitive to temperature, since adsorption is a physical-chemical interaction between the resin and the sorbents (toxins). This was tested as part of the laboratory trial by testing adsorption at 3 temperatures (22°C, 15°C, 4°C) and three time periods (20 minutes; 1 hour; 2 hours). For each time point 2-3 SPATT were soaked in a large (~2 L) volume, with the ambient toxin concentration tested before and after each SPATT exposure to account for uptake.

For the SPATT adsorption tests (other than temperature), two methods were employed. First, SPATT were exposed for 15 minutes in a glass, 2L container with spiked water at 5 concentrations. This was designed primarily to calibrate SPATT uptake using the method employed by Peggy Lehman (DWR) in a previous field experiment. For that study, Bay and Delta water were collected into a container and SPATT were added for 15 m. Second, the large (~16L) carboy was connected to a peristaltic pump and water was recirculated through a 2L glass container (about 1.5L was in the container), using a flow rate of 2.5 L/min, which is a typical flow rate for underway mapping systems. The SPATT were prepared/deployed following the same methods as for the USGS cruises. For each time point, the SPATT were removed, allowed to drain, placed in 50 mL plastic centrifuge tubes, and frozen. The SPATT were subsequently thawed and toxin was extracted using the standard UCSC protocol (10 mL 50% MeOH, 20 mL 50% MeOH, 20 mL 50% MeOH with 1M ammonium acetate). An additional step, collection of the Milli-Q rinse water, was added to test for loss of toxin during processing. As per UCSC protocol, each eluate fraction was run separately on an Agilent 6130 LC/MS, and the total toxin per SPATT sampler was calculated based on volumes and concentrations of extract (see also Lane et al. 2010; Kudela 2011; Gobble and Kudela 2014). Pictures of the flow-through setup are provided in Figure 2.

For the flow-through experiment, replicate (2-3) SPATT were placed in the flow-through container and allowed to absorb for 20 minutes to 24 hours. The spiked water was then diluted to adjust the toxin concentration, and additional SPATT were tested. This was repeated for 4 concentrations. Additional SPATT were tested

during the transitions, to determine how quickly SPATT exposed to high toxin concentrations would equilibrate to a lower concentration.

Figure 2. Laboratory setup for the flow-through testing of SPATT. Upper photo shows the carboy, receiving container, and pump. Lower photo shows SPATT (in embroidery hoops) within the receiving container.

Calibration of SPATT--Results

Temperature: There was no significant difference (ANOVA, $p > 0.05$) for SPATT toxin concentrations of both microcystin and domoic acid as a function of temperature. This is consistent with previous laboratory experiments conducted when SPATT methodology was first developed.

Milli-Q Rinse: For standard processing of SPATT, the Milli-Q (deionized water) rinse is not tested for toxin. As part of these experiments Milli-Q volumes and toxin concentrations were measured. While toxins were detected in the rinse water, it was a few percent of the total extracted toxin (for both microcystin and domoic acid), as previously reported (Lane et al. 2010, Kudela 2011). While this lost toxin could be important for cases where very low toxin levels are of interest, SPATT is already more sensitive than grab samples so this is considered to be an acceptable loss.

Microcystins, 15 minute exposure: Adsorption of MCY-LR and MCY-YR was linear as a function of concentration. Toxins were easily detected after 15 minutes of exposure. Previous comparison of SPATT to grab samples exhibited a calibration factor of about 10-50x (SPATT is 10-50x more sensitive than grab samples), as exhibited in Table 1. Shorter exposure resulted in a calibration factor of about 5x, as seen in Figure 3. Given typical underway mapping speeds, 15 minutes would roughly correspond to spatial scales of about a kilometer, and assuming exposure to toxin occurred for 0-15 minutes at a given concentration, the SPATT factor would be 1-5x.

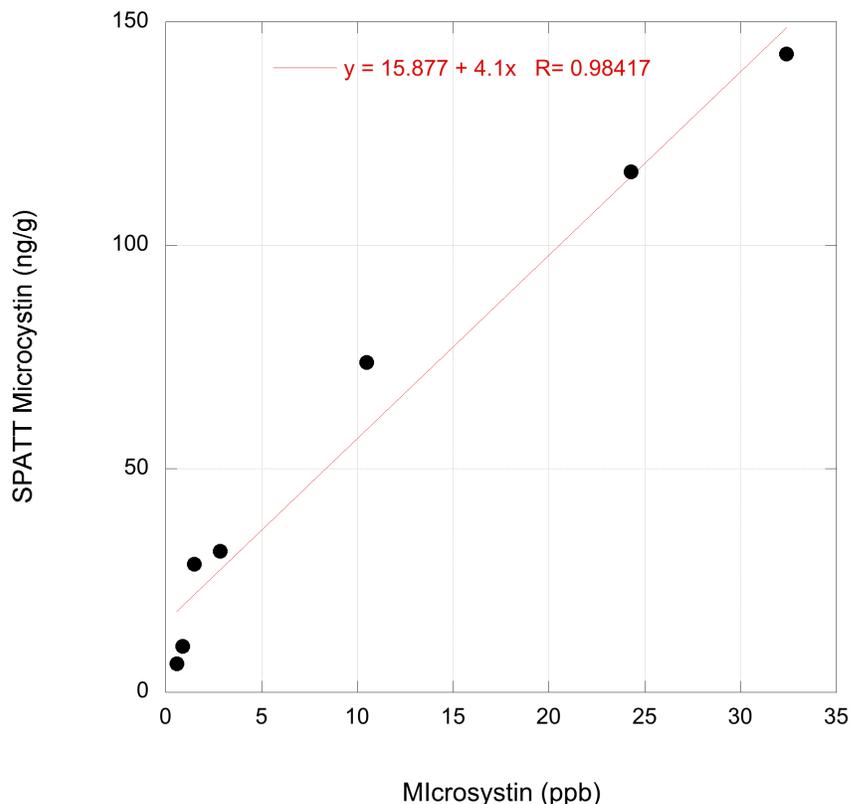

Figure 3. SPATT versus ambient water concentration for microcystins for SPATT exposed to constant concentration of toxin for 15 minutes. When forced to a zero-intercept, the calibration factor is 4.97x.

Microcystins, > 1 hour exposure: Testing of SPATT showed that microcystins equilibrate in approximately 1 hour. The calibration of toxin versus SPATT was therefore recalculated using SPATT exposed for 1-24 hours to estimate the upper-limit calibration factor. Results are presented in Figure 4. Linearity is excellent, and the calibration factor increases considerably compared to the 15 minute exposure, with a calibration factor of 271x.

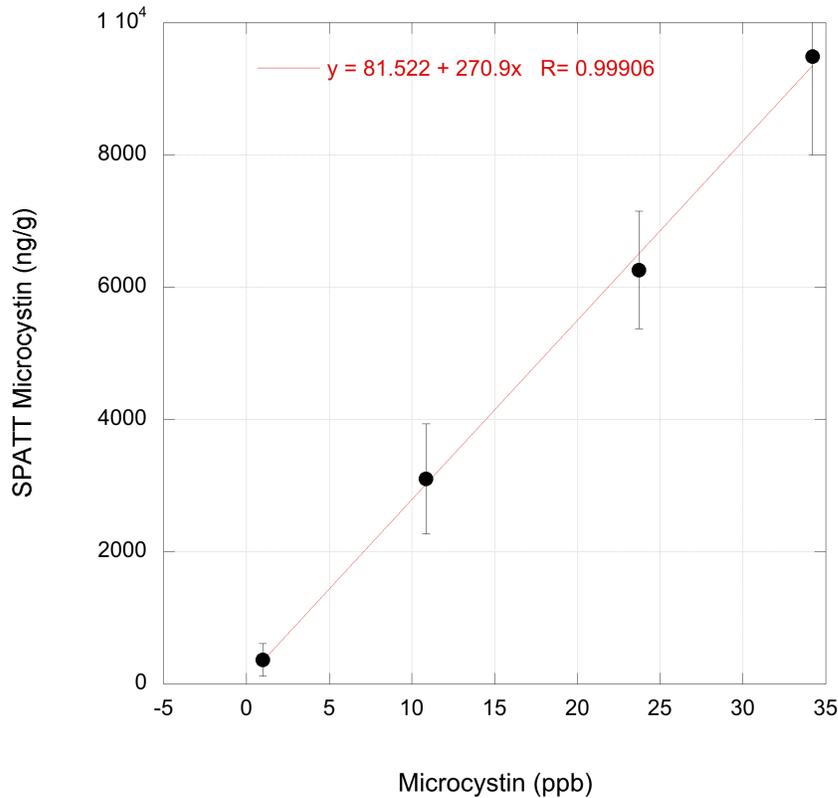

Figure 4. SPATT versus ambient water concentration for microcystins with SPATT exposed to a constant concentration for >1 hour.

Microcystins, transferred to lower concentration: When SPATT were allowed to equilibrate at a higher toxin concentration and were then exposed to water of lower concentration, similar kinetics were observed (not shown) with equilibrium occurring in ~1 hour, and a linear decrease over the first 60 minutes observed.

Field Calibration of SPATT Microcystins: the laboratory data for adsorption kinetics (time) and toxin levels (concentration) were used to develop a matrix showing the relationship between field SPATT observations and potential ambient toxin concentrations. The matrix is shown in Figure 5, together with statistics showing the total microcystin concentrations observed from October 2011- November 2014 for San Francisco Bay. The suggested “alert level” of 1 ng/g microcystins is indicated, along with the estimated non-detect limit.

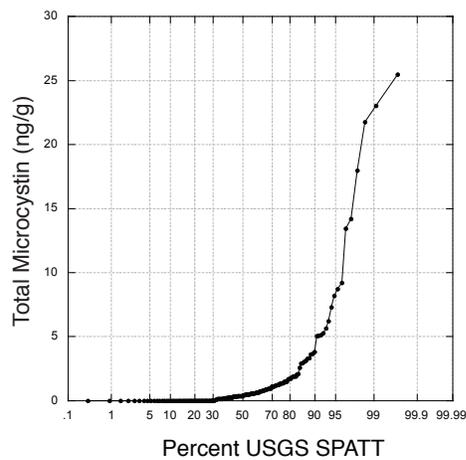

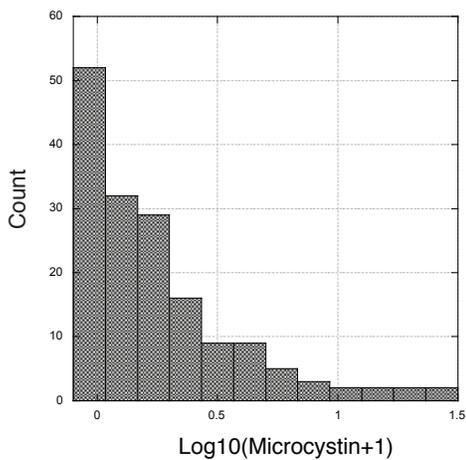

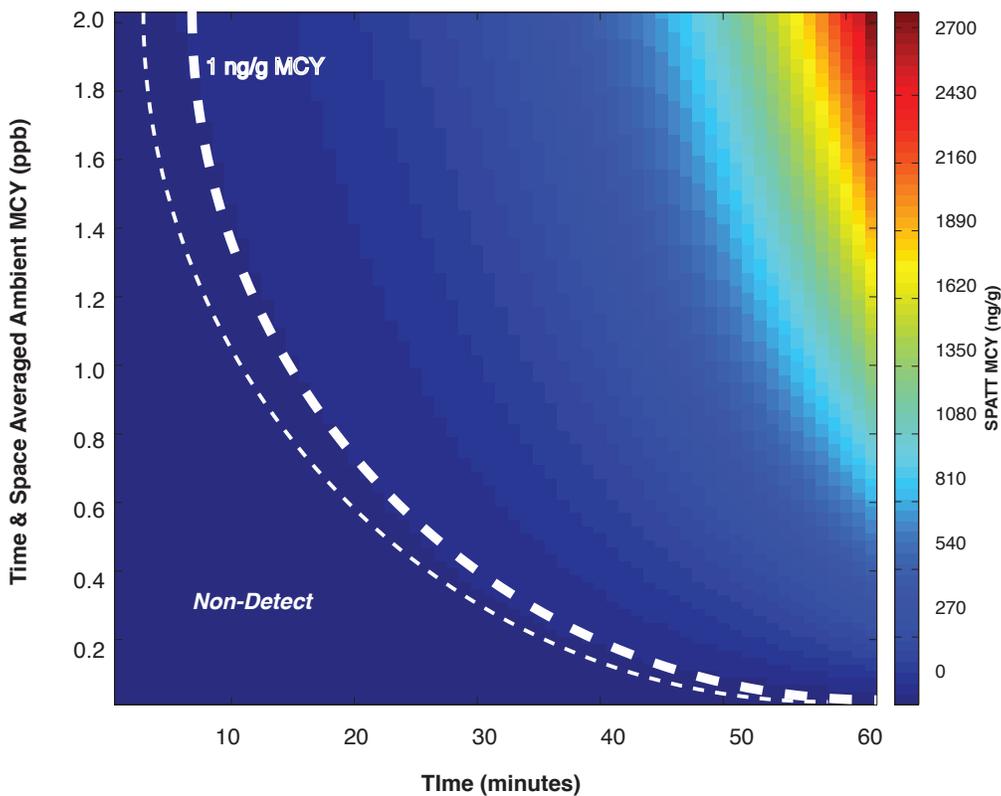

Figure 5. The top graph shows the SPATT concentrations that would be measured as a function of exposure time versus concentration. Note that toxin levels would increase/decrease in response to exposure (x-axis) to water with higher/lower concentration, with an equilibrium time of ~1 hour. The lower panels show the histogram of toxin concentrations observed in SFB (left) and cumulative percent (lower right).

Domoic Acid, 15 minute exposure: Adsorption of DA was exponential rather than linear (as seen for microcystins). Toxins were easily detected after 15 minutes of exposure. This makes calibration of SPATT more difficult, since it strongly depends on how long the SPATT are exposed. Data are presented in Figure 6.

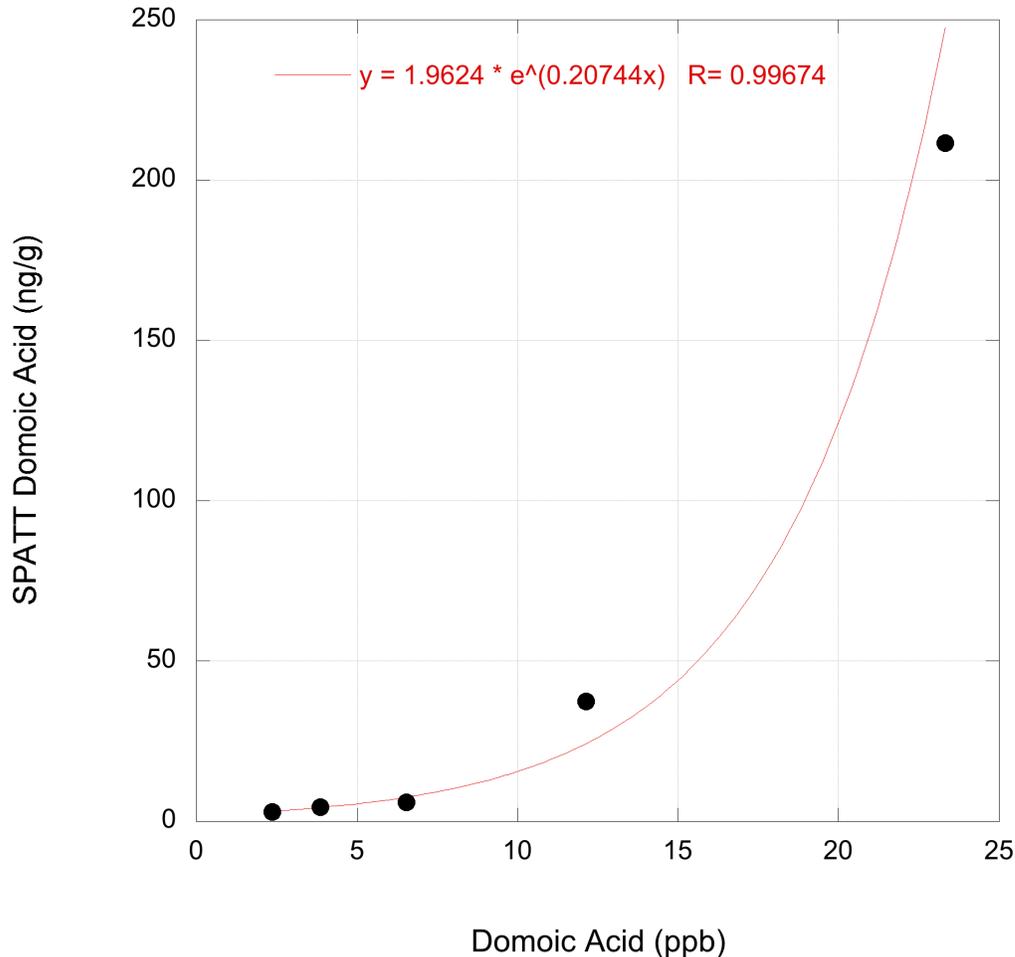

Figure 6. SPATT versus ambient water concentration for domoic acid for SPATT exposed to constant concentration of toxin for 15 minutes.

Domoic Acid, > 20 hour exposure: Testing of SPATT showed that domoic acid continues to be adsorbed for up to 24 hours, while other studies (Lane et al. 2010, Zendong et al. 2014) shows that SPATT continues to adsorb toxins for multiple days, but is quasi-linear when multiple days are included. Results for up to 24 hour exposure for varying concentrations of domoic acid are presented in Figure 7. As with 15 minute exposure the data fit an exponential curve, suggesting that SPATT concentrations of domoic acid may underestimate low values and overestimate high values, compared to what would be assume using a linear relationship.

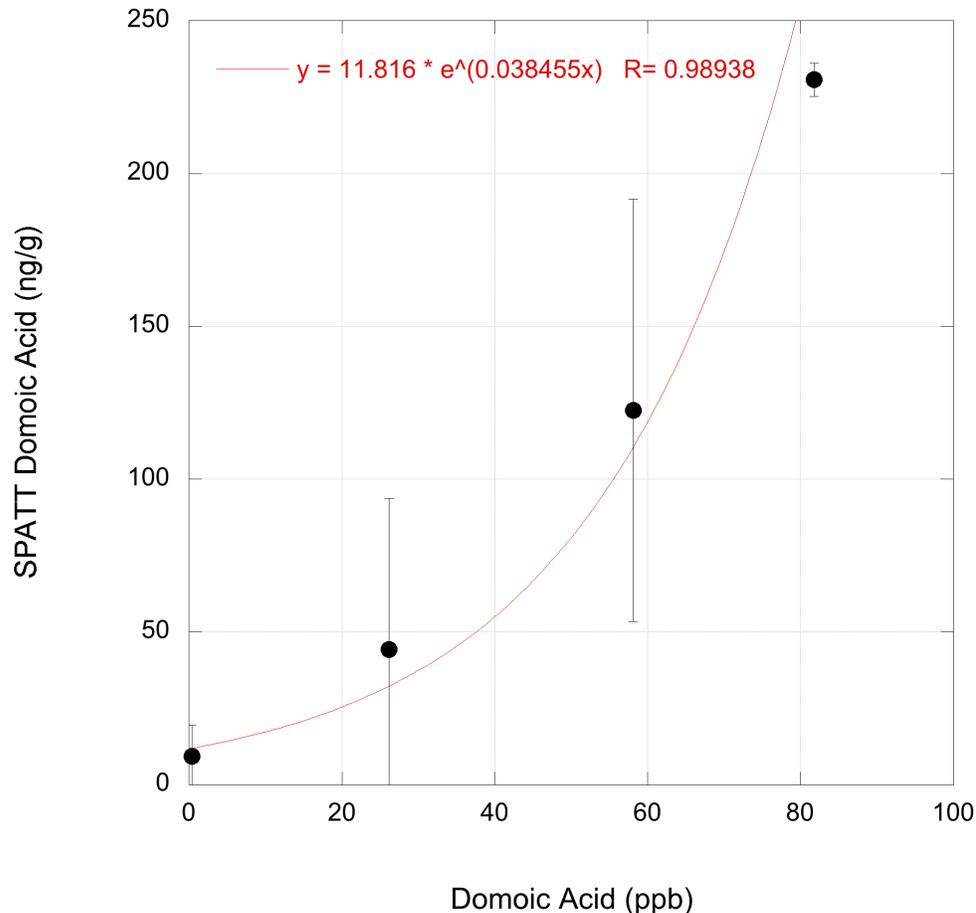

Figure 7. SPATT versus ambient water concentration for domoic acid for SPATT exposed to constant concentration of toxin for >20 hours.

Domoic Acid, transferred to lower concentration: When SPATT were allowed to equilibrate at a higher toxin concentration and were then exposed to water of lower concentration, similar kinetics were observed (not shown) with equilibrium initially fast, and then slowing down. The net result would be to (again) overestimate concentrations when exposed to high levels of domoic acid, compared to a linear response for time-averaged concentrations.

Field Calibration of SPATT Domoic Acid: the laboratory data for adsorption kinetics (time) and toxin levels (concentration) were used to develop a matrix showing the relationship between field SPATT observations and potential ambient toxin concentrations. The matrix is shown in Figure 8, together with statistics showing the total domoic acid concentrations observed from October 2011- November 2014 for San Francisco Bay. The suggested “alert level” of 75 ng/.g domoic acid is indicated, along with the estimated non-detect limit.

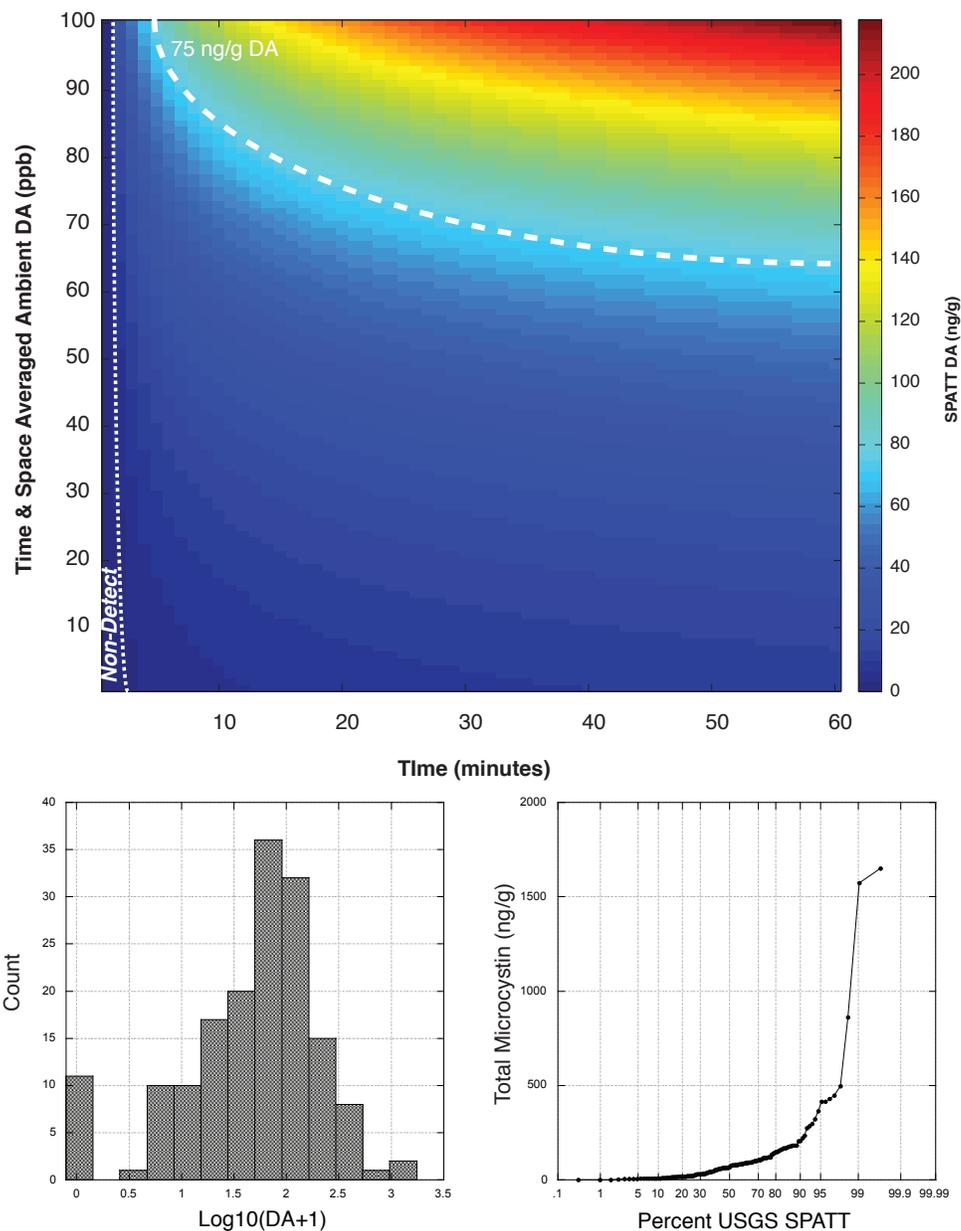

Figure 8. The top graph shows the SPATT concentrations that would be measured as a function of exposure time versus concentration. Note that toxin levels would increase/decrease in response to exposure (x-axis) to water with higher/lower concentration, with an equilibrium time of ~several days. The lower panels show the histogram of toxin concentrations observed in SFB (left) and cumulative percent (lower right).

Calibration of SPATT—Comparison to Mussels

Mussel samples were obtained from the RMP monitoring program for 2012 and 2014. This provides a direct comparison between a regulatory measurement (tissue samples) and SPATT from approximately the same time period and location, keeping in mind that the SPATT are deployed in surface water on a subembayment scale for a few hours, while mussels are deployed at depth for ~6 months.

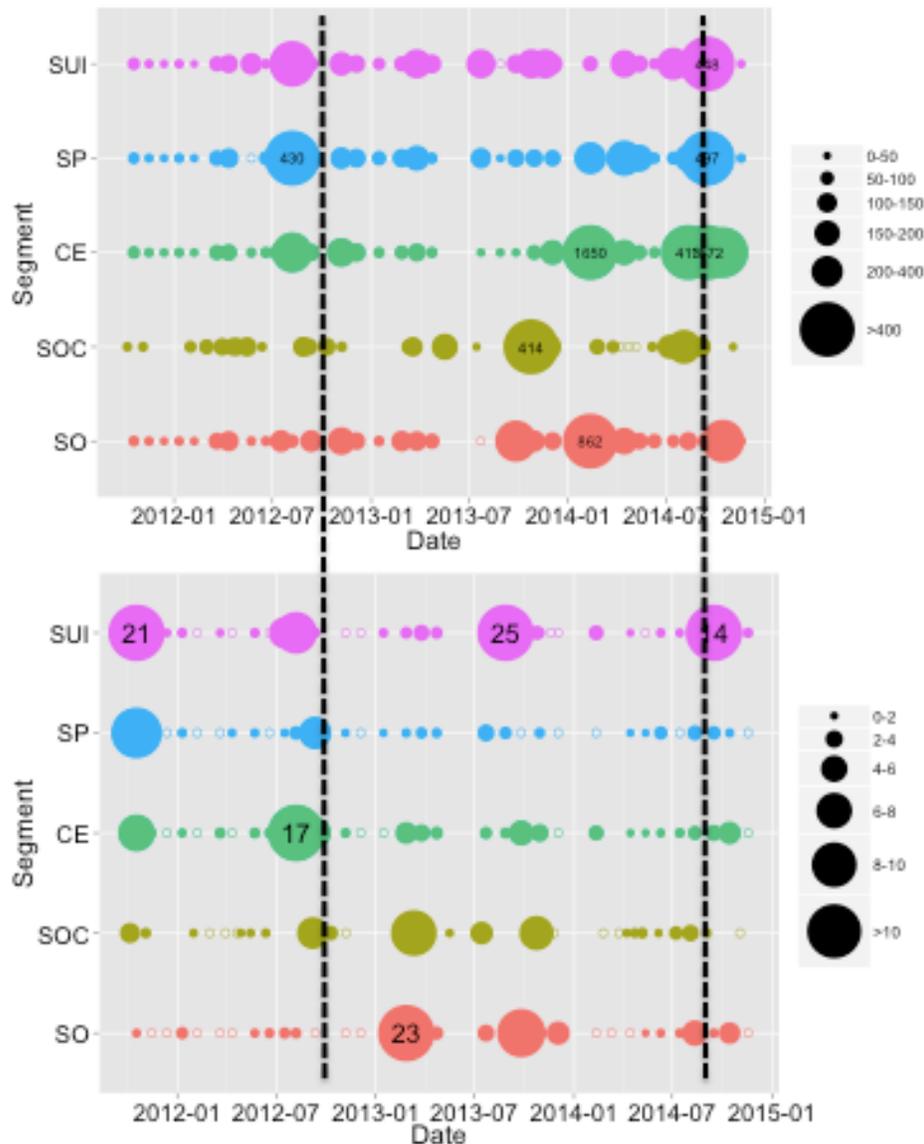

Figure 9. SPATT time-series, with bivalve retrieval dates overlaid as dashed lines. Note that bivalves were retrieved shortly after widespread toxin throughout the Bay for both DA and microcystins.

Figure 9 shows the SPATT time-series for microcystins and DA, with the mussel collection. Note that toxin was detected in mussels immediately following periods when SPATT indicated widespread presence within the Bay. For the mussel samples, 100% of sites had detectable domoic acid, while 82% (2012) and 100% (2014) of mussels had detectable microcystins. Of the two, the microcystins were closer to regulatory closure, with a maximum value of $\sim 22 \mu\text{g}/\text{kg}$ (WHO guidelines recommend closure at $24 \mu\text{g}/\text{kg}$). Comparison of SPATT with the mussel data suggest that a microcystin level of 10-20 ng/g SPATT would be too conservative, so more recent recommendations have lowered this to 1 ng/g. Similarly, presumably because of the non-linearity in uptake, DA values of 30-50 ng/g are probably too conservative, and the new recommended value is 75 ng/g (these values are reported in Sutula et al., in prep; "Scientific Basis for Assessment of Nutrient Impacts on San Francisco Bay").

Calibration of SPATT--Recommendations

Based on this initial pilot study of field-deployed SPATT and laboratory calibration, it seems clear that the SPATT time-series should be continued as part of the USGS cruises. Discussions with USGS and SFEI have explored the possibility of further dividing the Bay into subembayments consistent with the analysis performed by Sutula et al. (in prep.). This would primarily mean adding a Lower South Bay SPATT sampler, and separating Central Bay and North Central Bay. It is also recommended that, if possible, additional mussel samples be collected since this is the most unambiguous comparison between SPATT and ecosystem impairment. As part of separate SFEI funding, analysis is also underway to compare discrete filter samples with SPATT, but this will be subject to sampling variability (in previous comparisons, $>50\%$ of grab samples were negative while SPATT was positive) and to issue with limits of detection using filters due (primarily) to the heavy sediment load encountered when filtering whole water. It would also be useful to conduct a statistical analysis of SPATT relative to environmental conditions, to identify likely drivers of variability. Finally, additional laboratory testing of SPATT adsorption/desorption (for example, in response to salinity) could be carried out.

Ranking these recommendations by feasibility, cost, and impact, the following is proposed (from highest to lowest), with the recommendation followed by comments [in brackets]:

- 1) Continue SPATT time-series.

[SPATT is ongoing, primary limitation is availability of funds for both deployment and analysis of the data].

- 2) Collect additional mussel (or other invertebrate) samples for toxin analysis compared to SPATT. Ideally, deploy SPATT co-located with mussels.

[Feasible, but RMP currently conducts experiments every 2 years. So costs increase considerably if more frequent sampling is desired].

- 3) Add Lower South Bay and North Central Bay to the existing SPATT time-series.

[Minimal additional effort; would require permission from USGS, and would increase current costs by about 25%].

- 4) Collect/analyze discrete plankton samples for toxins to compare with SPATT.

[This is underway as part of separate funding; it's not clear that it will provide a direct intercalibration, given the past issues with comparing grab samples and SPATT].

- 5) Conduct retrospective analysis of SPATT versus environmental conditions to identify drivers of variability.

[This is probably a high priority, but the longer the time-series, the more valuable the analysis; analyzing now would primarily capture the drought period. Consider waiting until the drought ends, or anticipate analyzing again in the future. This could be a task for SFEI via the funded project for Blakely in 2015-16].

- 6) Conduct additional laboratory intercalibration.

[This could be done, but given the data already presented and the recent publications on SPATT, the chemistry is reasonably well-constrained. It would be a low priority compared to intercalibration with field samples].

Final Recommendation for interpreting SPATT: as documented in the Sutula et al. (in prep.) document, current recommendations based on statistical analysis, comparison with other field sites, and comparison with limited mussel samples is to consider "elevated" toxin concentrations equivalent to 1 ng/g total microcystins or 75 ng/g domoic acid for SPATT deployed by subembayment in San Francisco Bay. Values should be considered as "ranges" rather than absolute concentrations. For example, reasonable ranges, based on these updated thresholds, would be <1, 1-10, >10 for microcystins (no threat, moderate threat, high threat), and <50, 50-150, >150 for domoic acid. These ranges could be improved with additional mussel sampling, using logistic regression to define probability ranges (e.g. Lane et al. 2009; Anderson et al. 2011).

Sacramento, California 95825

DEPARTMENT OF WATER RESOURCES
1416 Ninth Street, Room 1115-1
Sacramento, California 95814

March 24, 2015

Mr. Thomas Howard
Executive Director
State Water Resources Control Board
1001 I Street
Sacramento, California 95814

Dear Mr. Howard:

The Department of Water Resources (DWR) and the U.S. Bureau of Reclamation (Reclamation) request a modification of the Revised Order that Approved a Temporary Urgency Change in License and Permit Terms and Conditions Requiring Compliance with Delta Water Quality Objectives in Response to Drought Conditions (dated March 5, 2015) (Order). The CVP and SWP Drought Contingency Plan (DCP), submitted to the State Water Resources Control Board on January 15, 2015 provides a description of the hydrologic conditions as of that date and actions proposed to balance multiple needs in a fourth consecutive dry year. The DCP serves as an initial framework to develop proposed modifications for conditions contained in Water Rights Decision 1641 (D-1641). DWR and Reclamation request the proposed modifications in the attached TUCP to be effective from April through the end of September.

Reclamation and DWR worked collaboratively with state and federal fish and wildlife agencies to prepare the DCP, as well as the Interagency Drought Strategy (Draft December 11, 2014). These documents outline the strategic goals of operations for this fourth year of drought, which serve as the context for the modifications the Projects are requesting. These overarching goals and objectives include:

1. Operating the CVP and SWP during the continuing drought to meet essential human health and safety needs and lessen critical economic losses.
2. Controlling of salt water intrusion in the Sacramento-San Joaquin Delta.
3. Preserving cold water pools in upstream reservoirs for temperature management to maintain cool water temperatures for salmon and steelhead.
4. Maintaining adequate protections for state and federally endangered and threatened species and other fish and wildlife resources.
5. Providing an overview of biological monitoring to improve water deliveries while also meeting water quality and species requirements.

BUREAU OF RECLAMATION
2800 Cottage Way, E-1604
Sacramento, California 95825

DEPARTMENT OF WATER RESOURCES
1416 Ninth Street, Room 1115-1
Sacramento, California 95814

The current Order allows Reclamation and DWR the following D-1641 modifications for CVP and SWP operations for the months of February and March:

1. The minimum daily Delta outflow of 7,100 cfs or equivalent salinity (2.64 millimhos per centimeter (mmhos/cm) at Collinsville), plus the requirement to meet higher flows of 11,400 cfs or equivalent salinity (2.64 mmhos/cm at Chipps Island) for a specified number of days depending on hydrology, was reduced to a minimum Delta outflow requirement of 4,000 cfs;
2. A minimum level of exports from the Delta when outflow is between 4,000 cfs and 7,100 cfs was approved at 1,500 cfs; authorized the use of an intermediate export rate under very limited conditions. The intermediate export rate could be increased up to 3,500 cfs when Delta outflow is between 5,500 cfs and 7,100 cfs, the DCC Gates are closed, DWR or Reclamation determined additional water is necessary to meet minimum public health and safety needs, and notifying the Executive Director of the State Water Resource Control Board;
3. The minimum San Joaquin River flow requirement at Vernalis was reduced from between 710 cfs or 1,140 cfs, depending on hydrology, to 500 cfs; and
4. The requirement to close the DCC Gates was changed to allow the gates to be open under certain circumstances.

The intent of the proposed modifications included in this letter, and the attached TUCP modification, for April to September operations is to continue the focus on conserving as much water as possible in upstream reservoirs in order to protect aquatic species, water quality, and water supplies in this fourth consecutive dry year. The conservation of storage will help meet fall Sacramento River temperature requirements and minimize potential impacts from a continuation of drought including for the benefit of Chinook salmon. The proposed suite of operational modifications from April 1 through September 30 includes continuation of provisions in the current TUC Order regarding compliance specifications for outflow requirements.

Because of the severity of drought impacts to water users south of the Delta, Reclamation and DWR are revising and resubmitting their previous request for approval of a step in intermediate export rate for the period between April, May and June. As with the previous proposal, the intermediate export is a contingency to improve south of Delta water supply in the event that hydrologic conditions remain dry and sporadic precipitation events occur. This requested Export Limit modification would only be implemented when Delta Outflow is within the range of 5,500 cfs to 7,100 cfs, and is intended to give the Projects the flexibility to capture increased natural and abandoned flows resulting from a sporadic storm event. Given the current dry hydrology and continuing dry forecast, the Projects anticipate that exercising this modification is unlikely.

BUREAU OF RECLAMATION
2800 Cottage Way, E-1604
Sacramento, California 95825

DEPARTMENT OF WATER RESOURCES
1416 Ninth Street, Room 1115-1
Sacramento, California 95814

For clarity, this is a request for regulatory flexibility. If a storm event creates hydrologic conditions that would allow for this modification to be implemented, Reclamation and DWR would consult with RTDOT to consider real-time conditions, including water quality and latest fisheries survey information. If consensus is obtained at RTDOT that any additional exports can be implemented without causing unreasonable harm to fish and wildlife, Reclamation or DWR would notify the State Water Resource Control Board Executive Director and seek final approval.

This request was conditionally approved in the revised March 5, 2015 Order, to apply only when Reclamation or DWR determines that additional water is necessary to meet minimum public health and safety needs. Due to the severity of drought conditions in the SWP and CVP south of Delta service areas and the limited amount of water that might be exported under this modification in April, May and June, Reclamation and DWR believe it would be impractical to attempt to track this increment of water separately from other project deliveries.

Specifically, and as described in more detail in the attached TUCP, Reclamation and DWR request the following modifications:

1. The minimum monthly Net Delta Outflow Index (NDOI) described in Figure 3 of D-1641 during the months of April, May and June to be no less than 4,000 cfs; for the month of July, the monthly requirement for NDOI shall be no less than 3,000 cfs. The 7-day running average shall be no less than 1,000 cfs below the monthly average.
2. The San Joaquin River at Airport Way Bridge, Vernalis river flow requirement during the 31-day pulse flow period to be no less than 710 cfs. For the period following the 31-day pulse flow through May 31st, the San Joaquin River flow at Vernalis river flow to be approximately 300 cfs. For June, the San Joaquin River flow Vernalis river flow to be approximately 200 cfs.
3. The minimum level of exports from the Delta when outflow is between 4,000 cfs and 7,100 cfs to be 1,500 cfs; and the use of an intermediate export rate under very limited conditions. The intermediate export rate could be increased up to 3,500 cfs when Delta outflow is between 5,500 cfs and 7,100 cfs under certain conditions.
4. The minimum monthly Sacramento River flow requirements measured at Rio Vista for September to be no less than 2,500 cfs, with the 7-day running average no less than 2,000 cfs.
5. The critical year D-1641 Agricultural Western Delta Salinity Standard at Emmaton (14 -day running average of 2.78 millimhos per centimeter) compliance point to be moved to Three Mile Slough from April to August 15.
6. The San Joaquin River at Vernalis Salinity requirement to be modified to 1.0 EC from April to August.

BUREAU OF RECLAMATION
2800 Cottage Way, E-1604
Sacramento, California 95825

DEPARTMENT OF WATER RESOURCES
1416 Ninth Street, Room 1115-1
Sacramento, California 95814

These proposed modifications reflect the elements included in the DCP 99% hydrology (without installation of Emergency Drought Barriers) as well as additional concepts for potential water operations. Currently DWR and Reclamation are closely monitoring and analyzing the need to install rock barriers in the Delta to protect water quality and minimize impacts on stored water supplies. If it is decided that Emergency Drought Barriers must be installed this water year, the Projects will submit a subsequent TUCP, based on most recent hydrology, to request additional modifications to D-1641 requirements. A preliminary evaluation in the DCP, as well as recent modeling, indicates the following D-1641 requirements could need modification:

1. The minimum monthly NDOI described in Figure 3 of D-1641 during the months of June through October.
2. The critical year D-1641 Agricultural Western Delta Salinity Standard at Emmaton (14-day running average of 2.78 millimhos per centimeter through August 15).
3. The mean monthly Rio Vista flow standard in September, October, and November.
4. The salinity standards for Eastern and Western Suisun Marsh beginning in May.

Urgent Need, Effects on Other Uses, Reasonable Protection of Fish and Wildlife and Protective of the Public Interest

The "urgent need" described in the previous change requests continue to exist. So far this year, the hydrology has been extremely dry with minimal precipitation events. The lack of precipitation events in 2015, combined with the past three dry year conditions have resulted in diminishing water supplies throughout the state. San Luis Reservoir and DWR's and Reclamation's reservoirs north of the Delta remain critically low. As a result, the proposed change remains urgent. This TUCP request adds additional measures to help address critically low storage levels in San Luis Reservoir and DWR's and Reclamation's reservoirs north of the Delta and associated water supply needs of those reservoirs.

This action should also not have an unreasonable impact to fish and wildlife. Reclamation and DWR have conducted a Biological Review and are seeking concurrence from National Marine Fisheries Service and U.S. Fish and Wildlife Service that these actions are consistent with the federal Endangered Species Act (Attachment A). DWR will also plan to consult with the California Department of Fish and Wildlife to determine if the existing Consistency Determination would remain in effect.

The attached analysis indicates that legal users of water will not be injured by this action (Attachment B). Delta water quality objectives protective of municipal/industrial and agricultural uses remain in place and the proposed combination of outflows and export levels are expected to continue to provide water quality adequate to meet the needs of beneficial uses. However, hydrologic conditions indicate that sufficient water may not be available in upstream reservoirs to maintain a cold water pool and also meet the Emmaton standard. Additionally, as occurs in the South Delta when water quality objectives are met, there may be an exception in achieving the agricultural objective for Old River at Tracy Road.

BUREAU OF RECLAMATION
2800 Cottage Way, E-1604
Sacramento, California 95825

DEPARTMENT OF WATER RESOURCES
1416 Ninth Street, Room 1115-1
Sacramento, California 95814

By conserving reservoir storage through the remainder of this year, providing protections for aquatic species, water quality and water supply, and thereby avoiding the severe consequences associated with depletion of reservoir capacity, the proposed changes are in the public interest. This request has been considered and is supported by the RTDOT established to recommend additional changes to the Order necessary to address risks presented by the ongoing and severe drought.

Sincerely,

David Murillo
Regional Director
Bureau of Reclamation

Mark W. Cowin
Director
Department of Water Resources

Date: 3/24/2015

Date: 3/24/2015

TUCP for April – September Draft Outline of Proposed Changes

This proposed suite of modifications includes continuation of a number of provisions in the current TUCP Order and other elements of D-1641 that could be modified.

I. Requested Changes

1. Modification of Net Delta Outflow Index

D-1641 requires a Delta outflow minimum monthly average Net Delta Outflow Index (NDOI) of 7,100 cfs 3-day average and salinity requirements during the months of April, May and June. Reclamation and DWR petition the State Water Board to adopt a Delta outflow standard of a minimum monthly NDOI during the months of April, May and June to be no less than 4,000 cfs; for the month of July, the monthly requirement for NDOI shall be no less than 3,000 cfs. The 7-day running average shall be no less than 1,000 cfs below the monthly average.

These modifications are necessary because of the extraordinarily dry conditions of the past several years in combination with the forecasts of limited future precipitation, low reservoir storage, and the competing demands on water supply of fish and wildlife protection, Delta salinity control, and critical water supply needs.

2. Modification of San Joaquin River Flow

D-1641 requires a San Joaquin River at Airport Way Bridge, Vernalis minimum monthly average flow. D-1641 also requires a 31-day pulse flow period in April and May. The Projects petition the State Water Resource Control Board to adopt the following San Joaquin River at Airport Way Bridge, Vernalis river flow requirements:

- During the Vernalis 31-day pulse flow period, the monthly average flow to be no less than 710 cfs.
- For the period following the 31-day pulse flow through May 31st, the SJ River flow at Vernalis would be no less than 300 cfs on a 30-day running average.
- In June, the SJ River flow at Vernalis would be no less than 200 cfs average for the month.

This modification is necessary because of the extraordinarily dry conditions of the past several years in combination with the forecasts of limited future precipitation, extremely low reservoir storage, high water temperatures, and the competing demands on water supply of fish and wildlife protection, Delta salinity control, and critical water supply needs.

3. Modification of Export Limit

Table 3 of D-1641 describes export limits. Generally, exports are limited to 35% of Delta inflow from February through June of each year, and 65% of Delta inflow from July through January of each year. Reclamation and DWR petition the State Water Resource Control Board to adopt the following, modified from the maximum Export Limits included in Table 3 of D-1641, for the months of April, May, and June.

- When precipitation and runoff events occur, and the DCC Gates are closed, and Footnote 10 of Table 3 of D-1641 is being met [3-day average Delta outflow of 7,100 cfs, or electrical conductivity of 2.64 millimhos per centimeter on a daily or 14-day running average at the confluence of the Sacramento and the San Joaquin Rivers (Collinsville station C2) if applicable], but any additional Delta outflow requirements contained in Table 4 of D-1641 (“Chippys days” or “Port Chicago days” requirements) are not being met, then exports of natural and abandoned flows are permitted up to Export Limits contained in Table 3 of D-1641 at the SWP Banks Pumping Plant and at the CVP Jones Pumping Plant, subject to other applicable laws and regulations including the federal Endangered Species Act (ESA) and California ESA (CESA).
- When NDOI of at least 7,100 cfs is not being met as specified above, or the DCC Gates are open, then the combined maximum exports at the SWP Banks Pumping Plant and the CVP Jones Pumping Plant shall be no greater than 1,500 cfs with one exception. DWR and Reclamation may export up to a combined 3,500 cfs of natural and abandoned flows, on a 3-day running average, provided that NDOI is greater than 5,500 cfs and the DCC Gates are closed. Before implementing this action, DWR and Reclamation will consult with RTDOT to confirm that real-time conditions are consistent with the conditions evaluated as part of this petition. If consensus is obtained at RTDOT, Reclamation or DWR would notify the SWB Executive Director for final approval.
- During the effective period of any issued Order, if precipitation events occur that enable DWR and Reclamation to fully comply with the Delta outflow, river flows, and DCC Gate Closure requirements contained in D-1641, then D-1641 requirements shall be operative, except that any SWP and CVP exports greater than 1,500 cfs shall be limited to natural or abandoned flow, or transfers as specified in condition 1e of the March 5, 2015, modified Order.

4. Modifications of DCC Gate Operations

D-1641 and the NMFS Biological Opinion require the closure of the DCC gates from February 1 through May 20. Reclamation and DWR petition the State Water Resources Control Board to modify the DCC gate operation requirements contained in Table 3 of D-1641 such that the DCC gates may be opened during April and May as necessary to

reduce intrusion of high salinity water into the Delta while preserving limited storage in upstream reservoirs and reducing impacts to migrating Chinook salmon. The DCC gate triggers matrix (as described in Appendix G of the April 2014 Drought Operations Plan and Operational Forecast) will be used by the Projects to determine operation of the DCC gates. If the Projects determine that the DCC gates must open to provide for salinity management in the Delta during a period that requires closure under D-1641 or the NMFS Biological Opinion then the Projects, through the RTDOT process, will provide at least a 5-day notice to the fish and wildlife agencies so that enhanced monitoring can begin. The Projects will implement enhanced monitoring and triggers to open and close the gates, as needed for protection of listed species.

5. Modification of Rio Vista Flow Requirement

D-1641 Table 3 dictates a minimum monthly Sacramento River flow requirement measured at Rio Vista of 3,000 cfs in the months of September (for critically dry water years). This requirement also states that the 7-day running average Sacramento River flow measured at Rio Vista shall be no lower than 2,000 cfs during this time. Reclamation and DWR petition the State Water Resource Control Board to modify the D-1641 Table 3 Sacramento River at Rio Vista flow requirements to be no less than 2,500 cfs on a monthly average in September. The 7-day running average shall not be less than 2,000 cfs.

6. Modification of Western Delta Salinity Compliance Point

In a critical year, D-1641 requires the Agricultural Western Delta Salinity Standard at Emmaton have a 14-day running average of 2.78 millimhos per centimeter from April 1 to August 15. Reclamation and DWR petition the State Water Resource Control Board to modify this requirement by moving the compliance location from Emmaton to Three Mile Slough on the Sacramento River beginning April 1.

7. Modification of San Joaquin River Salinity Requirement

In all year types, D-1641 requires a San Joaquin River at Vernalis Salinity limit of 0.7 EC from April through August. Reclamation petitions the State Water Resource Control Board to modify the San Joaquin River at Vernalis Salinity requirement from 0.7 EC to 1.0 EC from April to August.

Methods and Modeling

Conceptual models of impacts from drought management actions were presented in the Biological Review for the February-March Project Description (Figure 1, Reclamation 2015). The potential effects of the proposed April through September 2015 operational actions are considered in the context of these conceptual models. Additionally, the biological opinions (NMFS 2009, USFWS 2008) were reviewed regarding biological linkage to the considered actions.

Figure 1 Conceptual model of drought contingency plan elements and their biological linkage to salmonids and assessment information available for evaluation.

Operational Forecast Model

The February 90% Operational Forecast provides potential tributary and Delta operational conditions. In particular, this information is useful for evaluating potential Central Valley Project and State Water Project (CVP and SWP) tributary operations during April through September. The reservoir releases in this forecast include implementation of RPA actions from the NMFS Biological Opinion on the Long Term Coordinated Operations of the CVP and SWP for Clear Creek, American River, and Stanislaus River. These are described in the Project Description, which includes some modifications of these actions. When these monthly average flows assume implementation different from the RPA, a qualitative description of habitat-related impacts are described. Temperature related impacts of the forecast related to divisions of the CVP are not included at this time, since the Sacramento River Temperature Task Group (SRRTG) is actively meeting to provide advice and review of the temperature forecast modeling to support development of the seasonal Sacramento Temperature Management Plan. Temperature

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

management for the American River Group will be considered by the American River Group (ARG).

DSM2 Model

Delta Simulation Model II (DSM2) simulations were performed and evaluated for three operational management scenarios (Table 1). These simulations were designed to evaluate potential effects of the Project Description's reduced Sacramento and San Joaquin River outflow and other operational modifications on potential Delta hydrodynamics for the months of April through May when listed salmonids are most likely to be present in the Delta and hydrology forecasts are more foreseeable. These scenarios were concatenated to look at a 31-day pulse flow period ("April") and post-pulse period ("May") to evaluate DSM2 results. The Baseline scenario (Hydrology 1) represents an unmodified set of D-1641 standards for NDOI, Vernalis flows, and Delta Cross Channel Gate operations, while a Project Description scenario (Hydrology 2) included a modified NDOI and Vernalis flows.

The April modeled Vernalis average monthly flow, which were inclusive of an Appendix 2e pulse flow volume is likely positively biased compared to the predicted Vernalis average monthly flow during the pulse flow period, which in the TUCP is proposed to be no less than 710cfs. According to the modeled flows at Channel 6 (Mosssdale, downstream of Vernalis but likely to have similar flow) summarized in Table 4 and 5, the modeled monthly average flow during April and May was 951 cfs, 241 cfs more than the 710 cfs proposed in the current TUCP order. Whether realized flows at Vernalis will more closely match the modeled flows or the proposed flows will depend on accretions and depletions during April and May. This uncertainty suggests modeled flows under the Project Description are likely greater than what will actually be observed, which influences the interpretation of any possible impacts on fishes resulting from the Project Description. Additionally, results from a hydrodynamic scenario with similar NDOI and Vernalis flows and an open DCC gate for two months are presented (Hydrology 2'). Other input values remained constant and reflected the best information available to DWR modelers when models were run on March 13, 2015. These flows do not necessarily reflect current forecast information and actual conditions have and will differ from the modeled scenarios. The modeled scenarios represent minimum values, yet provide the best evaluation approach to describing the worst conditions likely to be observed for the flow measures. These issues increase the uncertainty of assessments of impacts to all species reviewed.

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

Table 1. DSM2 Model Input for Scenarios Evaluated in the Biological Review. DSM2 Run Name is Listed Parenthetically for Each Scenario

Scenario	NDOI		Freeport flow (cfs)		Vernalis flow (cfs)		Combined Exports (cfs)		DCC Status
	April	May	April	May	April	May	April	May	
Baseline (Hydrology 1)	7,100		7,100- (VNS +export)		710 +3100 cfs (4/1 -5/1)		1,500		Closed
Project Description – DCC Gate Closed (Hydrology 2)	4,000		4,000-(Lower VNS +export)		300+App. 2e flow (4/1 – 5/1) ¹		1,500		Closed
Project Description -- DCC Gate Open (Hydrology 2')	4,000		4,000-(Lower VNS +export)		300+App. 2e flow (4/1 – 5/1) ¹		1,500		Open for 2 months

DSM2 modeling outputs for each scenario were used to evaluate the distribution of 15-minute flow and velocity values for multiple channels, including:

- Upstream of Head of Old River on San Joaquin (Channel 6)
- Downstream of Head of Old River on San Joaquin (Channel 9)
- Upstream of Stockton Deepwater Shipping Channel (Channel 12)
- Jersey Point on San Joaquin River (Channel 49)
- Sherman Island on San Joaquin River (Channel 50)
- Downstream of Head of Old River on Old River (Channel 54)
- Old River south of Railroad Cut (Channel 94)
- Old River at San Joaquin River (Channel 124)
- Middle River north of Railroad Cut (Channel 148)
- Three Mile Slough near San Joaquin River (Channel 310)
- Sacramento River near Sherwood Harbor (Channel 412)
- Sacramento River at Sutter Slough (Channel 388)
- Sacramento River upstream of Delta Cross Channel (Channel 421)
- Sacramento River downstream of Delta Cross Channel (Channel 422)

¹ The TUCP identifies proposed modification of the average monthly flow during the Vernalis 31-day pulse flow period to be no less than 710 cfs.

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

- Sacramento River upstream of Georgiana Slough (Channel 422)
- Sacramento river downstream of Georgiana Slough (Channel 423)
- Sacramento River near Cache Slough (Channel 429)
- Sherman Island on Sacramento River (Channel 434)

Hydrodynamic Metrics

Hydrodynamic metrics, such as daily mean velocity and flow were calculated (Tables 2-5). Additionally, mean daily proportion positive velocity, daily mean velocity, and daily mean flow were used to assess changes in the Delta at these locations. These were calculated over the separate April and May periods (Tables 6-7).

These data are also visualized spatially at both temporal steps to assess regional impacts and more complex hydrodynamics around the Delta Cross Channel and Head of Old River under each scenario. Daily proportion positive velocity is the percentage of the day that river flows have a positive velocity value (flows in downstream direction). Daily mean velocity and mean flow are the average of all values summed over the 24 hour period, which takes into account the effects of tidal stage on velocity magnitudes. These daily values are then averaged for the period of interest. The difference in the values of these hydrodynamic metrics between the Baseline and Project Description model run was calculated to assess how the metric was affected by the Project Description. We also calculated the difference in the values of these hydrodynamic metrics between the Project Description and Project Description with DCC gates open scenarios.

Density plots of DSM2 modeled 15-minute velocity data were developed for the eighteen channel nodes modeled for the two scenarios. Figures 2-23 show nodes showing variation between modeled scenarios in April and May periods for the different hydrology scenarios. These plots show low levels of change in the 15-minute velocity plots and in the lower river reaches tidal hydrodynamics and channel morphology drive channel velocities to a greater extent than the operational differences evaluated in the modeled scenarios. Figures 24-27 show spatially key channel nodes through the Delta during April and May for a few of the hydrodynamic metrics.

Differences in the river inflow between the Project Description and Baselines modeled scenarios are seen in the velocity plots at the upper extent of the tidal influence on the Sacramento near Sherwood Harbor (Figure 2-3) and San Joaquin river near Head of Old River (Figures 16-17). In the May portion of the model runs, there is a larger difference between the Baseline and Project Description modeled velocities due to reduced San Joaquin River contribution to the NDOI and thus greater flows at Freeport in May than April (Figures 2 and 3). At all other channel nodes during May and all nodes for the April portion of the model runs, the influence of these river inflows quickly dissipates as tides begin to dominate on the Sacramento (Figures 4-15). An open DCC gates during these months also impacts velocities upstream of the DCC gates (Channel node 421, Figures 6-7), and modeled results show a greater range of velocities, both negative and positive in this reach, due to increased flows rates downstream on an ebbing tide and upstream on a flooding tide. Modeled channel velocities in the Sacramento River near the DCC and Georgiana Slough differ between the Baseline and Project Description scenarios. Modeled results from the Project Description with an open DCC show a reduction in daily mean velocities in April and May downstream of the DCC (Channel node 422; Figures 8-9). At locations in the

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

North Delta further south, tidal conditions dominate and the range and magnitude of velocities observed in the modeling are similar into the western Delta (Figures 10-15).

Difference between the Project Description and Baseline model run influence the velocity along the San Joaquin River more during the modeled April period than May period (Figures 16-21) from upstream of Head of Old River to downstream of the Stockton Deepwater Ship Channel. These differences influence the proportion of daily positive flow (Tables 6-7), daily velocities (Tables 2-3), and daily flows (Tables 4-5). In the South Delta along Old and Middle River corridor, these changes are less significant due to the low export levels in the Baseline and Project Description model run. The modeled daily average hydrodynamic changes resulting from the proposed operations for both the April and May periods are small (Tables 4-5, approximately 62cfs for channel 148 in April and 152cfs in May) and do not show substantive differences in daily average velocities (Tables 2-3, Figure 22-23) between Baseline period at channel node 148 (Middle River north of Railroad Cut).
