Particle Tracking Model

For the purposes of the biological review, particle “entrainment” was assessed for the three scenarios: Baseline, Project Description with closed DCC gates, Project Description with open DCC gates (Table 1). Although the DSM2 particle tracking model does not currently incorporate a behavioral component, particles are considered dependable proxies for the relative effect of hydrological conditions on early-stage smelt larval movement because larvae are weak swimmers and are only minimally capable of selectively maintaining a position in the water column [*i.e.*, they tend to behave a lot like neutrally buoyant particles; see Kimmerer (2008)]. Six injection locations and seven flux locations were assessed (Figure 28). Daily entrainment flux fate at the CVP/SWP projects at the end of the model period (May 31) was considered and graphed for cumulative daily flux (Figure 29). Combined entrainment at the Projects was highest in both scenarios for particles inserted at Station 815 (near Prisoners Point on the San Joaquin River). The flux of particles past Chipps Island from all injection points are shown in Figures 30 and 31 for both the modeled Baseline and Project Description scenarios.

Status of the Species and Effects of Project Description

Status of Winter Run Chinook Salmon

A small number of winter-run Chinook Salmon (*Oncorhynchus tshawytscha*) (n=3,015; 90% CI= 2,741-3,290) returned to spawn in the upper Sacramento River in 2014. Of these 3,105 winter-run Chinook, 388 were collected at the Keswick trap for broodstock at Livingston Stone National Fish Hatchery. Assuming that 3-year old fish make up the majority of each spawning cohort, returning adults in 2014 were produced by a much smaller spawning escapement in 2011 (*i.e.*, 827 adult spawners). The effects of limited cold water storage and loss of temperature control out of Keswick Dam from mid-August through the fall of 2014 led to substantial egg and fry mortality. The mortality associated with this loss of temperature control was estimated to have affected up to 95% of the brood year 2014 eggs and fry (Doug Killam, CFDW, pers comm.). The average egg to fry mortality for brood year 2007-2012 was estimated to be 69% based on female escapement, fecundity, and the RBDD juvenile production index (Reclamation 2015).

As of March 11, 2015, approximately 408,704 juvenile winter-run Chinook Salmon were estimated to have migrated past the Red Bluff Diversion Dam (RBDD, Figures 32-33). The rotary screw traps at RBDD were operated for just 8 of 31 days during December 2014², a period when the Sacramento River flows and turbidity levels were at their highest. Very few natural-origin juvenile winter-run Chinook Salmon are hypothesized to remain upstream of the Delta and these are anticipated to migrate into the Delta and lower Sacramento River by the end of April based upon historical RBDD passage data (Tables 8-9). Monitoring data throughout the Sacramento River suggest that the majority of salmonids, including natural-origin juvenile winter-run Chinook Salmon are currently residing in the Lower Sacramento River and Delta (Figure 34, Tables 10-11). Detections of winter-run sized juveniles in the Chipps Island trawl monitoring have been low, but trending upwards, indicating that while few have migrated out of the Delta at this time, outmigration to the ocean is increasing (Figure 35). During April, the seaward migration of juvenile winter-run Chinook Salmon is likely to be completed due to changes in photoperiod and temperature, which stimulate smoltification and migratory behavior in these rearing fishes. Historical patterns indicate that the majority of out-migration typically occurs in March and is not complete until early spring (del Rosario *et al.* 2013). Discussions by the Delta Operations for Salmonids and Sturgeon (DOSS) team have estimated on March 17 that for the natural origin winter-run juveniles greater than 85% were rearing in the Delta, less than 15% had exited the Delta, and “few remaining stragglers” had yet to enter the Delta. A low level of salvage of winter-run sized juveniles has occurred during the winter, with a cumulative loss of 102 natural-origin winter-run sized juvenile Chinook as of March 20, 2015. This may be due to several factors, acting individually or in concert, including low population numbers, low exports, and low survival.

The entire production population of hatchery-origin winter-run Chinook Salmon were released into the upper Sacramento River in Redding from February 4-6, 2015. This segment of the

² Biweekly reports from RBDD are available at: http://www.fws.gov/redbluff/RBDD%20JSM%20Biweekly/2014/rbdd_jsmp_2014.html

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

winter-run population, which was released concurrently with a storm pulse, began entering the North Delta within a week after release based on monitoring data, coded wire tag recoveries, and acoustic tag detections. Detection of acoustic tags and recoveries of CWT tags have in occurred at the Sacramento I-80 receiver, in the Knights Landing rotary screw traps (RSTs), the Sacramento regional beach seines, and the Sacramento trawls occurring near Sherwood Harbor on the Sacramento River. Discussions by the DOSS team have estimated passage into the Delta to be approximately 70-85% for the hatchery winter-run Chinook salmon. A subset of this release group from LSNFH was tagged with JSAT acoustic telemetry tags (n=500) and provided another means to track the downstream migration of the hatchery-origin winter-run juveniles, in addition to the standard river, Delta, and salvage fish monitoring efforts already in place. As of March 16, 2015, approximately 27.8% of the acoustic tagged hatchery winter-run were observed to have entered the Delta at the I-80/50 bridge in Sacramento, based on at least 2 detections of each tag by the array on the bridge abutments. If only single detections are used (which could include some false positives), the percentage of the tagged hatchery fish reaching the North Delta is 39.2%. It is worth noting that the Tisdale Weir did overtop immediately following the release of these fish and adipose fin-clipped juvenile salmonids (indicative of hatchery fish which includes both winter-run Chinook Salmon released from LSNFH and late-fall Chinook salmon concurrently released from the Coleman National Fish Hatchery [CNFH]) were rescued from the downstream apron of the weir. This observation suggests that some proportion of the hatchery release groups from both the LSNFH and CNFH releases entered the Sutter Basin and took that route downstream. As of March 20, 2015, the total observed loss of hatchery winter-run, confirmed by CWT, at the salvage facilities is 8.40. The DOSS estimates for the hatchery winter-run Chinook and the detected passage of the telemetry tagged differ considerably, which could result from, in part, detections probabilities being reduced due to high turbidity and flows, differential migration rates or holding patterns.

Sacramento River Actions

Temperature operations remain under discussion by the Sacramento River Temperature Task Group (SRTTG). The recent 90% temperature forecasts provided to the SRTTG in January and February both suggest that a temperature compliance point of 56°F at the Clear Creek CDEC gaging station cannot be maintained through the winter-run Chinook Salmon egg incubation and fry rearing period. These forecasts suggest temperatures below 56°F would no longer be attainable in mid-August to early September, which would suggest no potential impact on spawning adults. These forecasts suggest similar impacts as described during the late summer of WY 2014 (Figure 36). Impacts to egg and alevin stages are more difficult to predict due to uncertainties with actual spawn timing, redd locations, and observed hydrological and temperature profiles. A temperature management plan for the upper Sacramento River continues to be developed and an appropriate biological review will be provided upon its completion. Forecasted Sacramento River flows during the Project Description do not include large weekly fluctuations, and will incorporate ramping rates, which minimize stranding and isolation of winter-run Chinook Salmon juveniles.

⁹ Temperature management and effects will be evaluated by the SRTTG.

Net Delta Outflow Index and Water Quality Modifications

The Project Description during the remainder of WY 2015 is intended to preserve storage in Shasta Reservoir and increase the cold water pool available for management of temperatures for winter-run Chinook Salmon as late into the summer as feasible. Under the Project Description, the Net Delta Outflow Index (NDOI) will be modified from a minimum monthly daily average of 7,100 cfs to no less than 4,000 cfs during the months of April through June, and no less than 3,000 cfs during the month of July. This reduction in NDOI will lead to reduced Keswick releases during these months, which may affect out migrating winter-run Chinook Salmon during the remainder of spring 2015. DOSS estimated on March 17, 2015 that <5% of natural winter-run and <15% of hatchery winter-run remain in the riverine habitat affected by these releases upstream of the Delta. Approximately 85% of each of these groups is projected to be within the Delta and subject to effects resulting from any modified operations. These effects have been described previously (NMFS 2014a, USBR 2014a, USBR 2014b), but are reviewed here again since the distribution and proportion of winter-run Chinook Salmon in the Delta and Sacramento River have changed since these prior assessments. The changes in hydrodynamics in the modeled scenarios are representative of a range of conditions possible during April and May, and do not reflect the influence of potential Delta drought barriers that may be installed in the Delta.

¹⁰ Figure supplied by CDFW on January 20, 2015.

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

Although the NMFS BiOp (2009) does not contain outflow standards, the BiOp assumed that D-1641 standards would be met, which would afford protection to listed species and their designated critical habitats. The reduction in outflow as part of the Project Description may impact juvenile salmonids migrating through the North Delta between the Sherwood Harbor and the Sutter and Steamboat slough reach, where Sacramento River flows meet the tidally-dominated western Delta. The Project Description's reduction in Delta outflow to as low as 4000 cfs may reduce survival of out migrating winter-run Chinook Salmon, migrating through the North Delta through increased predation mediated by hydrodynamic and habitat mechanisms. Once out migrating fish reach the tidally-dominated western Delta (i.e., Sutter and Steamboat slough area downstream towards Chipps Island) or San Joaquin River under the minimum outflows identified in the Project Description, they are likely to encounter daily proportion of positive velocities and mean velocity that are similar to outflow conditions observed in the Baseline modeling (see, *e.g.*, Figures 10-15). There is a moderate level of uncertainty in these conclusions.

The Project Description's reduced outflow increases tidal excursion upstream (reduced daily proportion of positive velocities) into the waterways in the North Delta region primarily in April. In April, there is a reduction in the proportion of positive daily flows passing Georgiana Slough and/or an open Delta Cross Channel compared to May in both the Baseline and Project Description DSM2 modeling (Tables 6-7). Increased reverse flows and slower mean velocities result in longer travel times for migrating fish, which has been shown to reduce outmigration survival (Singer et al. 2013, Perry 2010, and Romine et al. 2013). Georgiana Slough flows become less positive as tidal excursion causes reversal in this channel when outflow is reduced. Reducing outflow also causes a decrease in the daily proportion of positive velocities through the Sacramento River downstream of Sutter and Steamboat sloughs confluence with the Sacramento River. These increased tidal excursions may increase juvenile entrainment into Georgiana Slough and, if open, the Delta Cross Channel. When the DCC gates are open, the daily mean channel velocity becomes even less positive in these reaches (Tables 6-7, Figures 8-9). When the DCC gates are open, the daily proportion of positive velocities further decreases in the Sacramento River upstream of the DCC gates and more noticeable between the DCC gate and Georgiana Slough. When the DCC is open, there is a reduction in the daily proportion of positive flows through Georgiana Slough. There is a low level of uncertainty in this conclusion.

At low outflow, channel margin habitat becomes exposed above the surface of the water and is unavailable to juvenile salmonids present. This lack of cover may reduce juvenile survival. It is hypothesized that lower outflows may intensify the density of littoral predators into a smaller, shallower area and/or decrease the quantity of cover available to outmigrating salmonids to avoid predators. There is a high level of uncertainty in this conclusion. Decreased daily mean velocities may result in increased residence time of juvenile winter-run Chinook Salmon, which is hypothesized to result in an increased size at ocean entry if they are rearing in areas with suitable environmental metrics and food resources. There is a high level of uncertainty in this conclusion.

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

Delta Cross Channel Gates

Under the Project Description, modified Delta Cross Channel Gates operations may occur based on water quality and fish presence. At this time, it is believed that an open DCC Gate has a low potential for entraining a substantial proportion of the juvenile winter-run Chinook Salmon population through this junction and into the Central Delta. This is because a majority of the natural (>95%) and hatchery (>70-85%) juvenile winter-run population is believed to already be in the Delta; many of those may have already passed this location and are currently residing downstream of the DCC gate location or have exited the system altogether and have emigrated to the marine environment. The remaining fraction of the natural and hatchery winter-run juvenile population that may still occur above the DCC location will be vulnerable to entrainment into an open DCC gate configuration as they emigrate downriver past the DCC gate location. Because outmigration of both natural and hatchery winter-run juveniles past Chipps Island is expected to be largely complete by mid-April, the Project Description's Modification of the DCC gate operations will affect winter-run in the North Delta compared to the Baseline scenario, but only for a short time. It is uncertain whether the increase in the likelihood of entrainment into the Central Delta will result in any change to facility loss of winter-run, both because the duration of the effect is expected to be short, and because the limited exports in the Project Description scenarios may not result in greater entrainment into the South Delta and facility loss (see discussion in "Exports" section).

If the DCC gates were open Sacramento River water will flow through the DCC and into the Mokelumne River system. This may result in some level of straying of upstream migrating adult Winter-run Chinook Salmon into the Mokelumne River system. It is expected that this may delay these adults on their upstream spawning migration. Adult winter-run Chinook Salmon which have entered the Mokelumne River system should be able to re-enter the Sacramento mainstem through the open DCC gates and continue their upstream movements. A delay in reaching the spawning grounds and an increase in energy expenditure may result. This could result in lower survival of juveniles produced from straying individuals, if temperatures in the upper river become unsuitable for egg and fry survival.

Exports

The Project Description scenario is expected to result in minimal additional entrainment of juvenile winter-run Chinook. Exports, barring a precipitation event substantial enough to produce natural and abandoned flows resulting in an NDOI greater than 5500cfs and closure of the DCC gates, if open, will be limited to combined 1500 cfs. The PTM for the Baseline and Project Description scenarios with Sherwood Harbor as the injection location (Figure 29) indicates that ~3% more particles are entrained at the export facilities in the modified scenarios (5% for Project Description (DCC Closed), 5.1% for Project Description (DCC open)) compared to the baseline (2%). The exposure to the increased risk of facility loss will occur in early April, after which the majority of juvenile winter-run Chinook are located further west and are exiting the Delta past Chipps Island. Considering that the majority of natural origin and hatchery winter-run are currently still rearing in the Delta and salvage of fish at the CVP/SWP fish collection facilities has occurred this season, concern for the entrainment risk at the projected export ranges would be a moderate risk of entrainment in early April, and low (for Winter-run) from mid-April onward.

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

Summary of Effects on Winter Run Chinook Salmon

The proposed operational modifications to the D-1641 flow and operational criteria may reduce through-Delta survival of migrating juvenile winter-run Chinook Salmon by the reducing the transit rate for these migrating salmonids, which may increase the predation potential. The timing of Delta exit appears to be fairly consistent over time and while less than 15% have been projected to have migrated out of the Delta, the remaining portion should exit during April and possibly into May (del Rosario 2013). While salvage of listed juvenile Chinook is projected to remain moderate due in part to the migratory behavior being displayed by winter-run Chinook Salmon juvenile and the low levels of exports, if exports increased during the Project Description in April and May, a measure to reduce the risks associated with entrainment loss would occur by shifting exports from the SWP to the CVP.

Status of Spring-Run Chinook Salmon

The 2014 spawning run of spring-run Chinook Salmon returning to the upper Sacramento River Basin was lower in four of seven locations compared to the 2013 escapement, with markedly lower escapement observed in Clear Creek, Butte Creek, and Feather River Hatchery (Table 13).

Table 13. Spring-run Chinook Escapement in 2013 and 2014

Tributary	2013	2014	Percent Change	Source
Battle Creek	608	429	-29	Laurie Earley, USFWS
Clear Creek	659	95	-86	
Antelope Creek	0	7	-	Matt Johnson, DFW
Mill Creek	644	679	+5.4	
Deer Creek	708	830	+17	
Butte Creek	16783	4815	-71	Clint Garman, DFW
Feather River Hatchery	4294	2825	-34	Penny Crenshaw, DWR

Spawning of spring-run Chinook salmon in the Sacramento River Basin occurs approximately from mid-August through mid-October, peaking in September. In 2014, this peak in spawning activity corresponded with the high Sacramento River temperatures downstream of Keswick Dam resulting in an elevated potential for high egg and alevin mortality. It is believed that spring-run Chinook salmon eggs in the Sacramento River underwent significant, and potentially complete mortality due to high water temperature downstream of Keswick Dam starting in mid-August when water temperatures downstream of Keswick Dam exceeded 56°F (see water temperatures in August through October in Figure 36) in WY 2014. Spring-run Chinook

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

Salmon eggs spawned in the tributaries to the Sacramento River may also have experienced warmer temperatures in 2014 due to low flows through late October, as well as scouring or sedimentation during rain events from late October through December.

Juvenile spring-run Chinook salmon begin emigration from Clear Creek soon after emergence, with passage near the mouth peaking in November through December and continuing to around May. Recent year passage indices are shown in Table 14. For BY 2014, extremely few juvenile Spring-run Chinook Salmon were observed migrating downstream past RBDD (Figure 37) during high winter flows, when spring-run Chinook Salmon originating from the upper Sacramento River, Clear Creek, and other northern tributaries are typically observed to outmigrate. As of March 11, 2015¹¹, only 35,435 BY 2014 spring-run Chinook Salmon were estimated to have passed Red Bluff Diversion Dam, and these low RBDD passage estimates are a concern. A second pulse of juvenile spring-run Chinook Salmon typically migrate past RBDD in the springtime (Poytress et al. 2014). However, this second pulse appears to positively bias estimates of spring-run Chinook passage due to the presence of millions of unmarked fall-run Chinook salmon hatchery fish released from the Coleman National Fish Hatchery on Battle Creek. These hatchery production fish typically overlap with the spring-run Chinook salmon category based on the length-at-date run assignments (Poytress et al. 2014).

Table 14. Passage Indices of Juvenile Spring-run Chinook Salmon with 90% and 95% Confidence Intervals for Brood Years (BY) 2003-2013 Captured by the Upper Rotary Screw Trap at River Mile (RM) 8.4 in Clear Creek, Shasta County, California, by the U.S. Fish and Wildlife Service. In fall 2014, yearling spring-run Chinook Salmon from Mill and Deer creeks experienced flow and temperature conditions typically associated with the outmigration of this life history expression from these tributaries. Although not currently monitored with RSTs, these tributaries have experienced flows (Figures 38-39) exceeding “First Alert” thresholds identified in the NMFS BiOp Action IV.1.2. Recent analyses of multiple years of RST data have determined that 99% of outmigrating yearlings are captured at flows greater than 95 cfs (Kevin Reece, DWR, pers. comm.).

Spring-run young-of-the-year (YOY) sized Chinook Salmon juveniles have been observed at the Tisdale Weir and Knights Landing RSTs since early December 2014 (Table 9). Likewise, juvenile YOY spring-run Chinook have been observed in the catch from multiple Delta beach seine regions, and in the standard trawling and special drought monitoring trawling surveys, including those in the Central Delta (Tables 10-11). Monitoring data suggest that the majority of surviving BY 2014 natural origin YOY juveniles are currently residing in the Delta, downstream of Knights Landing. No yearling spring-run Chinook Salmon have been caught in 2014 Delta monitoring, however, yearling spring-run observations are expected to be rare because of their relatively large size and strong swimming ability (associated with gear avoidance), and relatively low densities relative to YOY. The majority of YOY, yearling, and surrogate (hatchery late fall) spring-run are currently rearing in the Delta. This estimate is based on the best professional judgment of the biologists participating on the DOSS work team. No natural or hatchery origin spring-run Chinook Salmon have been salvaged at the fish collection facilities as of March 15, 2015.

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

Adult spring-run Chinook salmon will be entering the upper Sacramento River and Clear Creek during spring and continue into the summer of 2015, then holding until they start spawning in mid-August, with peak spawning occurring in September and completing by mid-October. Spring-run Chinook salmon spawning in Clear Creek occurs primarily upstream of a barrier weir installed at river mile 7 that separates spring-run and fall-run Chinook salmon spawning based on timing of entry into the tributary and protects spring-run Chinook salmon eggs from superimposition by fall-run Chinook salmon spawners later in the year. Table 15 shows spring-run Chinook Salmon spawning distribution in Clear Creek. Distribution has shifted upstream somewhat through the years after removal of McCormick-Seltzer diversion dam (approximately RM 6.2) in 2000 and with repeated gravel additions.

Spring-run Chinook Salmon may spawn in the Sacramento River between RBDD and Keswick Dam in very low densities with only a total of 449 redds documented from 2001 to 2014 (average 37/year; range= 0-105; no data available for 2009 or 2011; CDFW unpublished data). Most spring-run Chinook Salmon redds (93 percent) have been documented upstream of Jelly's Ferry Bridge (river mile [RM] 265.9).

Table 15. Distribution of Spring run Chinook Salmon Redds in Clear Creek, 2003–2013. River miles (RM) Begin at the Confluence at RM 0, and End at Whiskeytown Dam at RM 18.3. Both RM 7 (0.6 miles) and RM 18 (0.3 miles) are Incomplete Miles. RM 7 was Not Available for Spring run Spawning in 2003-2005, and 2011 When the Weir Was Located at the Lower Site

Delta	Yes	N/A	No Change	No Change

Sacramento River Actions

Temperature operations as part of the Project Description remain under discussion by the SRTTG. The 90% temperature forecasts provided to the SRTTG in January and February both forecast a temperature compliance point of 56°F at the Clear Creek CDEC gaging station cannot be maintained during September when peak spring-run Chinook salmon spawning and egg incubation occurs. Impacts to egg and alevin stages are more difficult to predict due to uncertainties with actual spawn timing, redd locations, and observed hydrological and temperature profiles. A temperature management plan for the upper Sacramento River, including Clear Creek, continues to be developed and an appropriate biological review will be provided upon its completion. Forecasted Sacramento River flows during the Project Description include

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

reduced releases from Shasta during September, which may cause some spring-run Chinook redd dewatering. Chinook redd dewatering at multiple locations was documented during Fall 2014 when Keswick flows were reduced below 5,000 cfs.

Net Delta Outflow Index and Water Quality Modifications

Drought operational actions impacting Sacramento River outflow proposed during the remainder of WY2015 are intended to preserve storage in Shasta Reservoir and increase the potential coldwater pool available for management of temperatures for both winter-run and spring-run Chinook Salmon. Similar to winter-run Chinook Salmon, the reduction in Keswick releases to meet modified spring D-1641 NDOI standards may affect outmigrating spring-run Chinook Salmon during the remainder of spring 2015. As of March 17, 2015, DOSS estimates that the majority (80-95%) of natural-origin YOY Spring-run Chinook Salmon are rearing in the Delta, with approximately 5-20% remaining upstream of the Delta and <5% have exited the Delta. In contrast, the entire cohort of yearling spring-run Chinook Salmon are either in, or have existed the Delta (approximately 50% each), with the exception of a few possible stragglers upstream of the Delta.

Effects to individuals remaining upstream would be similar to those described above for Winter-run Chinook Salmon upstream of the Delta. To review, reductions in Delta outflow to as low as 4,000 cfs during April and May may reduce migratory survival of any YOY spring-run Chinook Salmon migrating through the Sacramento River until reaching the tidally dominated North Delta through increased predation mediated by hydrodynamic and habitat mechanisms. Increased tidal excursions are likely to increase entrainment of any downstream migrating YOY into Georgiana Slough and, if open, the Delta Cross Channel. The reduced velocities in the lower Sacramento River due to reduced inflow is evident in the DSM2 modeling and increased tidal excursion occurs in this modeling causing less positive velocities until tides reduce the force of incoming riverine flows and mute any difference observed in the modeling from the Baseline and Project Description scenarios (Figures 2-11). The possible reductions in outflow through multiple distributaries in the North Delta may increase straying and travel time of adult spring-run Chinook Salmon in this region during April and May.

Rearing juvenile spring-run Chinook Salmon within the Delta are not expected to be affected by the Project Description's modifications to NDOI and Delta water quality standard during April and May. Flows are tidally dominated in the North Delta and Central Delta areas where rearing occurs (Figures 4-15). There is low certainty in our understanding of the juvenile salmonid biological processes affected by flow in the Delta. South Delta conditions in the Project Description scenario are similar to the Baseline scenario during April and May (Figures 22 and 23). There is moderate certainty in our understanding of how hydrodynamics and suitable habitats for rearing juvenile salmonids are affected in the Delta by the Project Description .

Clear Creek Actions

Temperature management on Clear Creek attempts to achieve a temperature compliance schedule to reduce thermal stress to over-summering steelhead and to spring-run Chinook Salmon during their holding, spawning, and incubation periods. Under the 90% Operation Forecast, monthly average flows in August and September are estimated to be 85 cfs and 150 cfs, respectively, and with those lower flows, there is a potential for temperature criteria to be

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

exceeded during these months. Adult spring-run Chinook Salmon holding when temperatures exceed 60°F may experience higher pre-spawn mortality, and those surviving may have reduced egg viability. If temperatures exceed 56°F after September 15, there will be greater mortality of incubating eggs and pre-emergent fry. There is low uncertainty in this conclusion. The temperature management for Clear Creek will be coordinated through the Sacramento River Temperature Task Group under the SWRCB 90-5 requirements and as outlined in RPA Action I.1.5.

Delta Cross Channel Gates

Under the Project Description, modified Delta Cross Channel Gates operations may occur based on water quality and fish presence as described in the Project Description. Effects to spring-run Chinook Salmon are generally similar to those discussed above for winter-run Chinook whereby an open DCC Gate has a low potential for entraining juvenile spring-run Chinook Salmon through this junction and into the Central Delta due to most juvenile (about 85-95% YOY and 95% yearling) spring-Run Chinook Salmon having already passed this location earlier this year. There is a low potential for adult straying associated with some Sacramento River water flowing through the DCC and into the Mokelumne. Additionally, there is a low potential for temporary adult migration delays and associated lower egg viability due to physiological stress from increasing energy expenditures or increasing exposure to high water temperatures.

Exports

The Project Description scenario is expected to result in minimal additional entrainment of juvenile spring-run Chinook Salmon. Exports, barring a precipitation event substantial enough to produce natural and abandoned flows resulting in an NDOI greater than 5500cfs, and closure of the DCC gates, if open, will be limited to combined 1500 cfs. These low export levels are not expected to appreciably affect survival of juvenile spring-run Chinook Salmon emigrating through the Delta. The PTM run with Sherwood Harbor as the injection location (Figure 29) indicates that ~3% more particles are entrained at the export facilities in the modified scenarios (5% for Project Description (DCC Closed), 5.1% for Project Description (DCC open)) compared to the baseline (2%). Since export levels are the same between the Project Description and Baseline scenarios, the change in the risk of loss at the export facilities is likely unchanged between scenarios for fish in the interior delta, but, due to the expected increase in entrainment of fish into the central/south Delta, more fish might reach the interior Delta under the actions in the Project Description (even if, though to a lesser extent, if the DCC is closed). Therefore, the cumulative effect of exports due to the Project Description is uncertain, since that effect will depend on distribution of outmigrating spring-run Chinook salmon. The majority of natural origin Spring run Chinook Salmon are currently rearing in the Delta, yet as of March 15, 2015, no Spring run Chinook Salmon juveniles have been salvaged at the pumping plants. This is likely due to the very low juvenile productivity. The entrainment risk at the minimum export levels described in the Project Description is similar to the Baseline scenario, and remains low-to-moderate through April and May based on their current distribution and rarity.

Summary of Effects on Spring-run Chinook Salmon

The extreme drought conditions are causing increased stress to spring-run Chinook Salmon populations, with or without water project operations, in the form of low flows reducing rearing and migratory habitats, higher water temperatures affecting survival, and likely higher than

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

normal predation rates. Water management over the first portion of WY 2015 has focused on maintaining a level of reservoir storage which is generally higher than what would have been in place at this time without the planning that has gone into attempting to reduce adverse effects on resources. The current drought operations plan strives to continue to save some water resources for the future in the hopes of minimizing long-term adverse effects of the drought.

Cumulatively, the Project Description modification to the D-1641 flow and operational criteria may reduce through-Delta survival of juvenile migrating spring-run Chinook Salmon and may modify their designated critical habitat during April and May. Changes in Sacramento River outflow during April and May can possibly delay adult spring-run Chinook salmon migration. Drought conditions and current reservoir storage levels have forecasted to impact the ability to maintain suitable water temperatures in the Upper Sacramento River and Clear Creek. Temperature effects on Clear Creek and in the Upper Sacramento may lead to possible higher pre-spawn mortality of adult Spring-run Chinook Salmon and reduced egg viability if temperatures exceed 60°F during August and early September, as well as greater mortality of incubating eggs and pre-emergent fry if temperatures exceed 56°F after September 15.

Status of Green Sturgeon

Information on green sturgeon is extremely limited. Adult green sturgeon will migrate into the upper Sacramento River through the Delta in March and April. Last year, a review of telemetric data found 26 tagged green sturgeon entered the San Francisco Bay with only half migrating upstream of RBDD (M. Thomas, UC Davis, pers. comm.). Already in 2015, one acoustically-tagged adult was recorded migrating past Sacramento this winter and based on typical migration rates, has likely reached Red Bluff (M. Thomas, UC Davis, pers. comm.).

Adult green sturgeon have been observed to overwinter in the Sacramento River, and a number of tagged 2014 adults appeared to still be present in the upper Sacramento River as of January, 2015 (R. Chase, Reclamation, pers. comm.), but it is unknown if they remained in this area during the past two months (M. Thomas, UC Davis, pers. comm.). Also, adult green sturgeon exit through the Lower Sacramento River during the summer and fall following their spawning, then return to SF Bay throughout this period also. Green sturgeon exit the San Francisco Bay late in the summer through the winter.

Spawning typically occurs from April through July. Spawning in the upper Sacramento River was documented during 2014 and associated larval green sturgeons were observed at RBDD during the summer of 2014 (n=316). This was greater than the long-term average of 186 fishes, but less than the highest number observed (i.e., >3,500 in 2011; Figure 40). At RBDD, two juvenile green sturgeon were also observed in the fall of 2014, but no additional fish have been recorded as of March 12, 2015 (Bill Poytress, USFWS, pers. comm.). At GCID, ten juvenile green sturgeon (TL= 110-285) were observed from September through October 2014 and no additional fish have been recorded as of March 9, 2015. Based on Israel and Klimley (2009), BY 2014 juvenile green sturgeon have likely migrated downstream from their natal spawning areas and are overwintering in the Lower Sacramento River and Delta.

Green sturgeon observations are extremely rare in the Delta, primarily related to the use of monitoring gear types that are not designed to sample the benthic habitats where green sturgeon

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

are most likely to be found if they are present. Although the lower Sacramento and Delta fish monitoring surveys do not target benthic environments, they have captured juvenile green sturgeon in the past, but none have been observed in these surveys in recent years including during 2011 when high numbers were observed migrating downstream past RBDD. One dead green sturgeon (FL= 670mm) was removed from the SWP Fish Facility on February 9, 2015. In 2011, over a thousand juvenile green sturgeons were enumerated at RBDD and none were observed in Delta or Bay fish monitoring. While this absence in the monitoring may suggest no impact from Delta Cross Channel operations or outflow operations, it may also suggest the recruitment of juveniles may be limited before the species reaches one year old due to habitat, predation, or multiple stressors; which is a phenomenon that has been observed in other North American sturgeon species. More monitoring needs to be conducted in order to reduce this uncertainty.

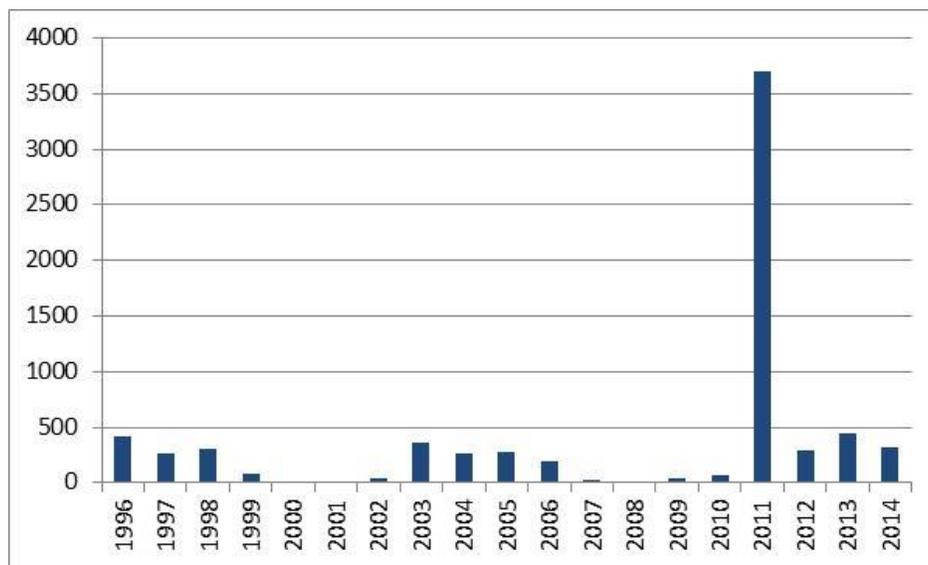

Figure 40. Larval Green sturgeon counted at Red Bluff Diversion Dam rotary screw traps¹⁵

Effects of Project Description on Green sturgeon

The predicted distribution of Green Sturgeon during the Project Description and a summary of potential effects are presented in Table 17, followed by more details per action type and location.

Sacramento River Outflow

The Project Description's reduction in upper Sacramento River CVP reservoir releases to meet modified spring and summer NDOI and Wilkin Slough standards may affect spawning green sturgeon. Although little is known about spawning habitat, these habitats do not seem limited. Adult green sturgeon spawn in specific locations presumably based on turbulent velocities, cold water temperatures, coarse substrate, presence of conspecifics, and large riverbank expansion bars likely to provide nursery habitats for larval and juveniles. The Project Description's

¹⁵ The annual average catch is 426 fish. In 2011, an egg was observed directly upstream of the rotary traps; thus, the large number of fish in 2011 represents a unique sampling of a spawning event (Josh Gruber, USFWS, pers comm.). If 2011 data is removed, the annual average of juvenile green sturgeon counted is 183 fishes.

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

reservoir release operation, described in the 90% Forecast, is unlikely to influence habitat characteristics for larval or juvenile green sturgeon. There is low certainty in our understanding of how hydrodynamics is affected in these regions by the Project Description and suitable

Net Delta Outflow Index and Water Quality Modifications

Juveniles and sub-adult green sturgeon rearing and utilizing the Delta are not expected to be affected by the Project Description's modifications to NDOI and Delta water quality standard from April through September. Over the course of juvenile green sturgeon rearing in the Delta (1 to 3 years), the fish are exposed to a wide variety of flows, depending on where they happen to be at a particular moment. In most of the Delta where green sturgeon are expected to be rearing, flows are tidally dominated. The 90% Operational Forecast characterizes Delta flow conditions in the Central Delta (OMR flows); North Delta (NDOI flows); and South Delta (exports) where tidal conditions occur. There is low certainty in our understanding of the juvenile and sub-adult green sturgeon biological processes affected by flow in the Delta. Delta conditions in the Project Description scenario are similar to the Baseline scenario during April and May, and the 90% without a modeled 90% Forecast of the Baseline summer hydrology, it is difficult to determine the summertime impacts of the actions in the Project Description. The minimal exports during the summertime between June and September may be assumed to be less than any other hydrology, which would cause more negative summertime flows in the South and Central Delta regions due to pumping greater than the minimum health and safety diversion. This suggests the actions in the Project Description would cause a reduced risk to entrainment into these regions and the CVP/SWP fish collection facilities. There is moderate certainty in our understanding of how hydrodynamics is affected in the Delta by the Project Description and suitable habitats for foraging juvenile and sub-adult green sturgeon.

Adult green sturgeon will be potentially present in the Delta throughout the Project Description as they migrate into and out of the Sacramento River and possibly forage in the Delta during the summer. The reductions in outflow through multiple distributaries in the North Delta in the Project Description may increase straying and travel time of green sturgeon in this region during April through September. During these months, a substantial portion of adult green sturgeon will

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

migrate through the North Delta. Foraging green sturgeon utilize Sacramento and interior migratory routes through the Delta, and also Steamboat slough during the summer. Since these areas are normatively used by green sturgeon, the impact of increased travel time is unlikely to negatively impact adult green sturgeon.

Delta Cross Channel

The Project Description's Modification of the DCC gate operations will have a similar, but lesser, potential effect on green sturgeon, as it potentially has on salmonids in the North Delta compared to the Baseline scenario. To review, opening the DCC gates provides an alternate outmigration route through the Central Delta for juvenile, subadult, and adult green sturgeon that may pass this location during April through September. The possible effect is less since green sturgeon utilize Sacramento and interior migratory routes through the Delta, and also Sutter and Steamboat sloughs often foraging and spend summer in the Western, Interior and Central Delta regardless of the DCC gates being open. Modeling of the Baseline and Project Description scenarios show South and Central Delta condition in May to be similar with no change in this regions' proportion positive daily flow, but some negative and positive impacts on average daily flows and velocities through these regions. Thus, while the likelihood of entrainment into the Central Delta during April and May may increase, these routes are not clearly less suitable or expose green sturgeon to greater risks at the minimum level of diversions described in the Project Description. The effect of entrainment into the Central Delta is unknown since it is hypothesized that hydrodynamic and habitat characteristics in this region are similar to those in the North Delta under the Project Description's hydrodynamic scenario.

Summary of Effects on Green sturgeon

Cumulatively, the Project Description's modifications in flow and water quality criteria should not reduce riverine or through-Delta survival of juvenile green sturgeon. The Project Description's changes in Sacramento River outflow during April and May can possibly delay juvenile, sub-adult, and adult green sturgeon migration. Modification to D-1641 Municipal and Industrial and Agricultural water quality standards in the Delta from April to September will not likely affect green sturgeon.

Status of Central Valley Steelhead

Sacramento River

Adult steelhead abundance is not estimated in the mainstem of the Sacramento River or any other waterways of the Central Valley. Much of the spawning is believed to occur in the tributaries of the Central Valley rather than in the mainstem rivers. Observed levels of catches of juvenile outmigrating *O. mykiss* at Red Bluff Diversion Dam have been low in 2014-2015 in comparison with recent past years. Peaks in juvenile downstream passage generally occur in the August/September time period; however, there was no peak emigration observed this past year. Fish emigrating during the peaks are primarily YOY *O. mykiss*. For a representation of smolt production from the upstream river and tributaries, the data need to be segregated by size. Larger fish pass mostly later in the fall and winter after the peaks in passage shown in Figure 41. A slight peak occurred in March of 2014. This peak was not present in the earlier years and may indicate a smolt emigration during one of the few significant rain events in 2014.

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

For WY2015 (as of March 9, 2015), 10 unmarked (two on 10/15/2014; five from 1/7/2015 and 1/27/2015; and three from 3/3/15-3/5/15) and 1,109 marked steelhead (from 1/7/2015 to 2/21/2015) were captured at the GCID RST. Marked fish likely originated from a Coleman Hatchery release of 688,000 brood year 2014 steelhead (100% marked with adipose clip only) in the Sacramento River at Bend Bridge (fish released in two groups: 144,700 on January 2, 2015, and 543,300 on January 5-9, 2015). For WY2015 (as of 3/8/15), three unmarked (two captured from 1/5/2015 and 1/8/2015, and one on 12/22/2014) and 33 marked steelhead (one on 11/8/14, 32 from 1/12/15-2/13/15) were observed at the Tisdale Weir RST; and five unmarked (2/10/15-2/14/15) and 117 clipped (2/8/15-2/19/15) steelhead were captured at Knights Landing RST. A low to moderate level of salvage of natural- and hatchery-origin, respectively, juvenile steelhead has occurred this winter, with a cumulative loss of 95 natural-origin and 1,754 hatchery-origin juvenile steelhead as of March 15, 2015.

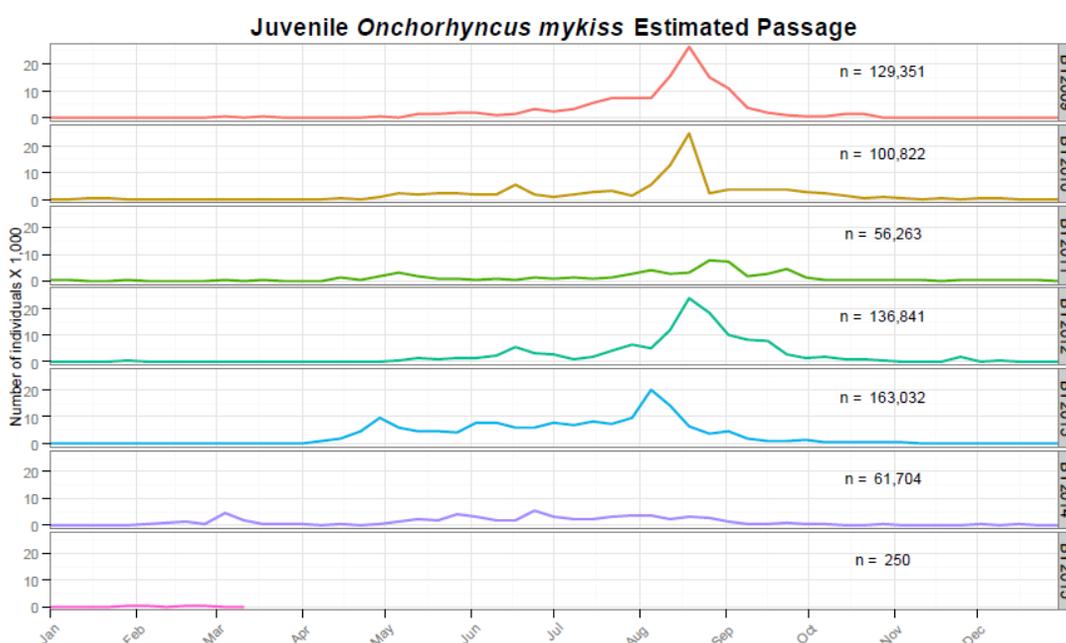

Figure 41. Weekly Estimated Passage of Juvenile Rainbow/steelhead trout at Red Bluff Diversion Dam (RK391) by Brood Year. Fish were Sampled Using Rotary-screw Traps for the Period January 1, 2009 to March 2015

Clear Creek

As of March 12, 2015, steelhead spawning surveys are underway on Clear Creek. Surveys are carried out from early December through the end of March. The preliminary steelhead redd index count for 2015 is 188 redds. Table 18 shows the redd index results through 2014. The redd index values include some mix of resident and anadromous *O. mykiss*.

The rotary screw traps on Clear Creek capture primarily YOY *O. mykiss* (not displayed here). Steelhead emigrating from Clear Creek are further monitored as they pass Red Bluff Diversion Dam in combination with other upper Sacramento River tributaries.

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

Table 18. Clear Creek Steelhead Redd Index 2003–2014

Year	Redd index
2003	78
2004	151
2005	144
2006	43
2007	165
2008	148
2009	409
2010	233
2011	218
2012	178
2013	239 ^a
2014	313 ^a

^a In survey years 2013 and 2014, an additional survey reach was added at the downstream end of the study area. An additional 40 steelhead redds were counted in 2013, and 93 redds were counted in 2014 in this reach. USFWS is in the process of determining how to include these redds in the annual index for comparison to other years.

American River

Steelhead spawning in the American River occurs from late December to about late March or early April. Reclamation conducts bi-weekly steelhead spawning surveys throughout the spawning period. The American River in-river steelhead population consists primarily of hatchery-produced fish that spawn in the river, and the steelhead return is dominated by fish that return to the hatchery or are harvested prior to spawning in the river (Figure 42). Seining surveys conducted by CDFW throughout the summer and fall have shown that summer rearing distribution for steelhead essentially mirrors the spawning distribution. Mark and recapture of rearing steelhead has shown strong natal site fidelity. Although few recaptures of marked fish occur, the recaptures that do occur all happen within close proximity to the marking site (i.e., at the same riffle or the next riffle upstream or downstream). No thermal refugia have ever been found in the lower American River. The coolest water is essentially in the faster flowing sections of the river and the steelhead rear and feed primarily in the faster water areas (riffles predominantly) of the river through the summer.

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

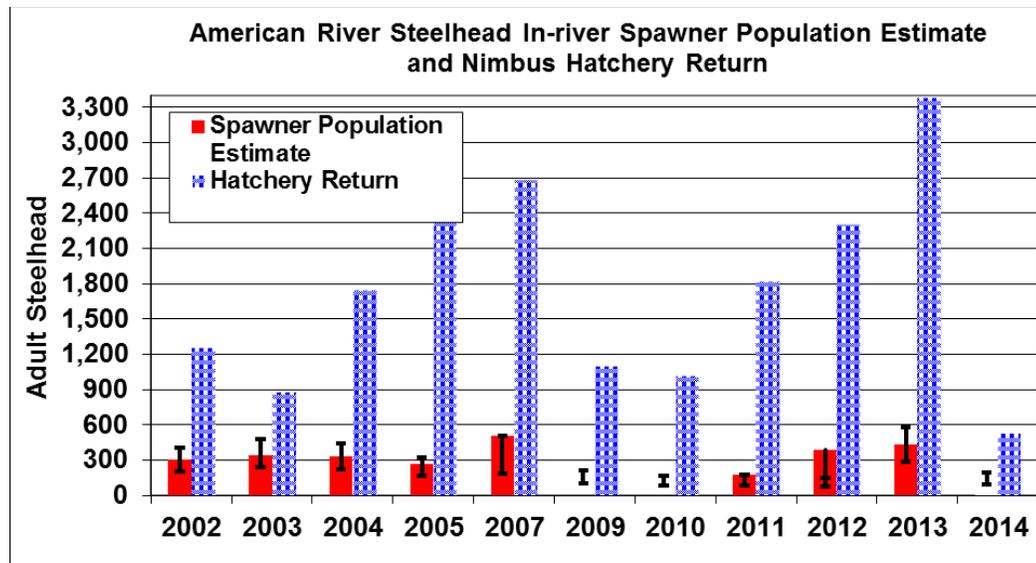

Figure 42. American River Steelhead Spawner Population Estimates Compared to Nimbus Hatchery Steelhead Return (updated from Hannon 2013). The Red Bars are Area Under the Curve Population Estimates (based on observations of adults holding on redds) and the Error Bars are the Redd Count Based Estimates. No ‘Area Under the Curve’ Based Estimates are Available for 2009, 2010, and 2014

Steelhead spawning surveys have identified few steelhead redds in the American River in 2015 from January through March 6 and hatchery returns have been near the lowest since the 1950s. The hatchery return for 2015 is 146 steelhead as of March 10 and only 46 of those were females. Nimbus flow releases have been 800–900 cfs throughout the spawning period, less than half the median flow of 2,000-3,000 cfs typically released during this time period. The majority of spawning is now complete based on the timing of spawning from past surveys (Hannon 2013). Figure 43 shows a comparison of spawning timing between the years surveys occurred. The 2015 spawning data are still draft but escapement appears to be very low. Coleman National Fish Hatchery steelhead eggs have been transferred to Nimbus Hatchery during January and February 2015 as part of a study evaluating replacing the Nimbus Hatchery steelhead broodstock with a broodstock that would be considered a part of the Central Valley steelhead distinct population segment. The low steelhead return has provided an opportunity to test an aspect of the broodstock replacement with Central Valley steelhead from Battle Creek/Coleman Hatchery. The goal of this egg transfer is to produce 150,000 steelhead smolts and evaluate their performance in the hatchery environment and in the American River following release from the hatchery.

The hatchery-produced steelhead in 2014 were all released into the river in May 2014 as YOY fish because water temperatures that supplied the hatchery raceways were anticipated to become lethal for fish reared in the hatchery over the summer.

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

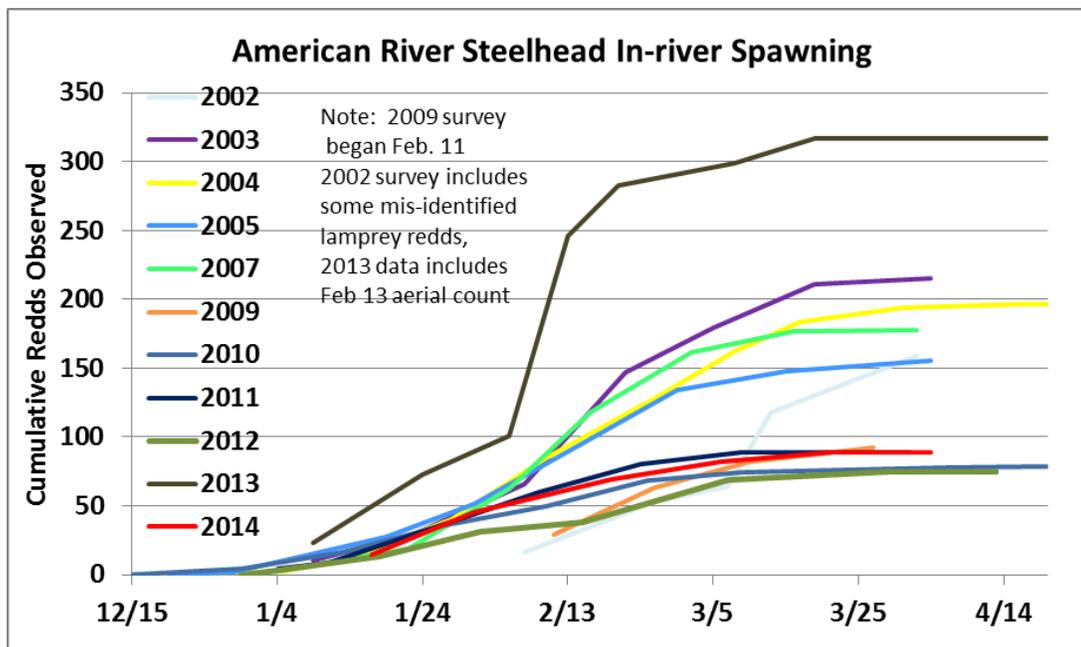

Figure 43. American River Steelhead Redd Observation Timing, 2002 - 2014

Stanislaus River

A weir on the Stanislaus River near Riverbank identifies *O. mykiss* passage using a VAKI camera. Two *O. mykiss* (> 16") and one *O. mykiss* (<16") were counted at the weir from October 2014 to December 15, 2014. Data after that have been unavailable.

Bergman et al. (2014) estimated a population of *O. mykiss* in an approximately 300 meter reach of the river immediately below Goodwin Dam to be 3,427 (SE =1,522) (95% CI = 1,492-7,873) using mark and recapture of trout identified using spot pattern recognition. This reach probably represents the highest density of trout in the river (based on snorkel survey observations) but indicates a much greater resident than anadromous component to the population. The stable cool water conditions in this tail-water area should allow at least the resident component of the population to persist through most drought conditions.

Steelhead spawn timing in the Stanislaus River is likely similar to other CVP rivers. Formal spawning surveys have not been conducted, but a trial survey was conducted by Reclamation and CDFW in February 2014 between Knights Ferry and Horseshoe Bar and near Goodwin Dam. Ten redds were found in the Knights Ferry reach and two were found in Goodwin Canyon at the cable crossing area. The redds are likely a mixture of resident and potentially anadromous *O. mykiss*. One of the redds was occupied by spawners with estimated lengths of 25 cm (10 inches) and 35 cm (14 inches). The California regulatory cutoff between steelhead and rainbow trout is 40 cm (16 inches) for anglers. The absence of abundant spawning near Goodwin Dam during this survey probably indicates mostly resident (later spawning) fish in that area.

Snorkel surveys conducted in 2003–2005 identified the first steelhead fry observations around mid-March to early April each year. Fry were observed between Goodwin Dam and Orange Blossom Bridge with observations in one year down to Valley Oak near the City of Oakdale.

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

None were observed below Valley Oak. This indicates that spawning was limited to the area mostly upstream of Orange Blossom Bridge. Higher rearing densities were always found from Goodwin Dam down to the Lover’s Leap area. This likely coincides with the area of most spawning for both resident trout and steelhead. A majority of outmigrating steelhead smolts leave the Stanislaus River during the late winter and early spring. Based on recoveries of steelhead in the Caswell and Oakdale rotary screw traps, 50% of steelhead have emigrated by March 4 and 76% smolts have exited the Stanislaus River by the end of March (Figures 44-45).

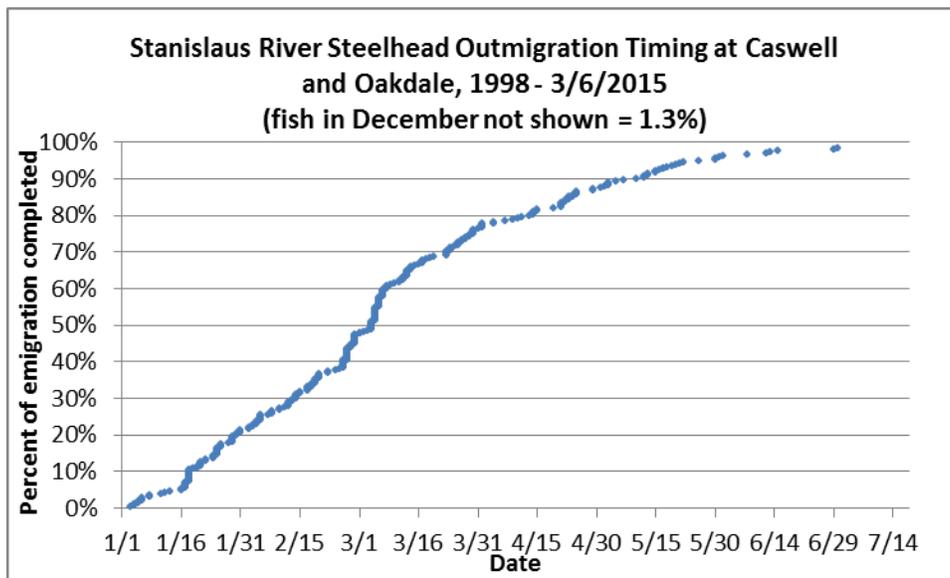

Figure 44. Stanislaus River Steelhead Outmigration Timing from Caswell Park and Oakdale Screw Traps, 1998-3/6/2015 (includes only fish rated as smolt index 5). Fish Leaving in December Constitute 1.3% of Migrants and Are Not Shown

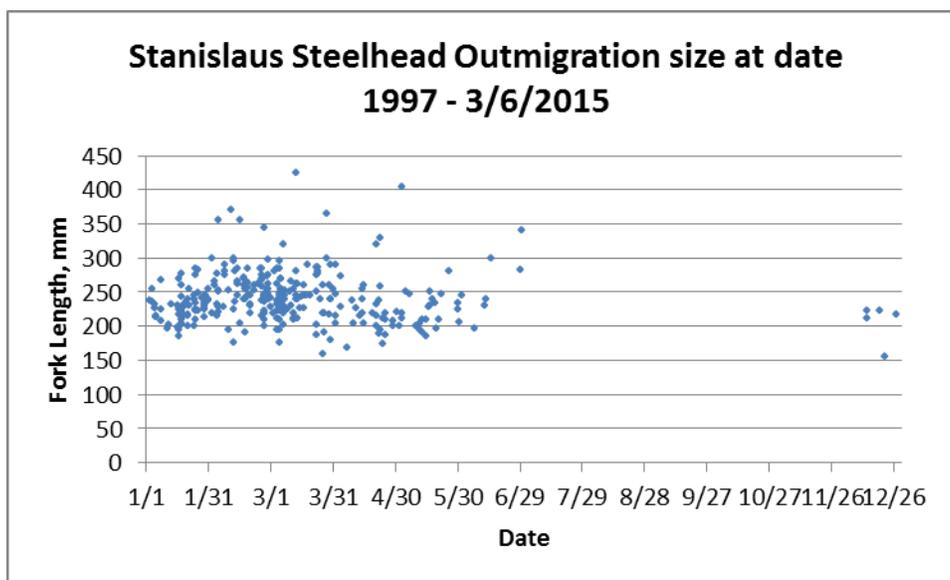

Figure 45. Stanislaus River Steelhead Outmigration Timing and Size from Oakdale and Caswell Rotary Screw Traps

Delta

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

Information on steelhead in the Delta is extremely limited. Steelhead smolts are seldom recovered in Sacramento River and Delta fish monitoring efforts due to sampling biases related to their large size and swimming ability. False negatives (*i.e.*, zero catches when the target species is present) are more likely with steelhead smolts than smaller older juvenile Chinook Salmon, but historic data can be assessed to consider their typical periodicity in Delta monitoring efforts. From 1998 to 2011, temporal observations of wild steelhead juveniles (n=2,137) collected in Delta monitoring efforts occurred less than 10% of the time in January, >30% of the time during February, and >20% of the time during March.

The temporal occurrence of Central Valley steelhead near and within the Delta is informed by recovery of natural steelhead in various monitoring surveys (Table 19). For WY2015 (as of March 9, 2015), 36 adipose-clipped steelhead and no unmarked steelhead have been recovered in various beach seine and trawling efforts in the Delta and Lower San Joaquin River. Of these, one marked steelhead was observed in the Chipps Island mid-water trawl (228 mm clipped fish on 3/2/15) and three marked steelhead were observed (one each) at Sacramento beach seine monitoring locations: Miller Park (300 mm acoustic tagged fish on 12/8/14); Sherwood Harbor (178 mm clipped fish on 2/17/15); and Verona (203 mm clipped fish on 2/17/15). Additionally, marked steelhead were observed at three Kodiak trawling locations including: Jersey Point (four clipped fish from 2/28/15-2/20/15), Prisoner's Point (fourteen clipped fish from 2/12/15-3/3/15), and Sherwood Harbor (fourteen clipped fish; one on 1/23/15 and thirteen from 2/9/15-2/20/15). No outmigrating steelhead have been observed in the Mossdale trawl yet; however, Figure 46 indicates that most steelhead are recorded at this location during April and May. Adipose clipped steelhead from Coleman National Fish Hatchery and Feather River Hatchery, are considered ESA listed Central Valley steelhead. No steelhead have been released from Nimbus Fish Hatchery to date in 2015. These fish were released in-river in May 2014 and marked with a secondary mark of a clipped pelvic fin. Fish monitoring at Mossdale on the lower San Joaquin River also encounter steelhead entering the Delta, and based on these information it is likely steelhead may still be migrating into the Delta from the San Joaquin in April and early May (Figure 46).

An expanded salvage of 22 natural origin and 450 adipose-clipped steelhead have been estimated at the state and federal fish collection facilities at the South Delta CVP/SWP export pumps. Of these, all 22 natural origin and 382 adipose-clipped fish were salvaged at the SWP and no natural origin and 68 adipose-clipped fish were salvaged at the CVP fish collection facilities. Most steelhead have been salvaged during the past month. The high ratio of clipped to unclipped steelhead (17:1) likely indicates a low abundance of naturally-produced steelhead compared to the number of hatchery steelhead.

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

Delta	Yes	No Change	No Change	No Change

Sacramento River Actions

Monthly average flows in the Sacramento River are forecast to be at the 3,250 cfs base flow in March and then increase to a high of a monthly average of 9,594 in July and then back down to

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

5,000 cfs in September. Rearing habitat limitations for steelhead have not been identified at the base flow. Water temperature management for Winter-run Chinook provides suitable conditions for the steelhead lifecycle throughout the year in habitat below Keswick Dam. During these drought conditions, the length of the suitable steelhead rearing habitat will be lower but rearing habitat availability is not expected to appreciably reduce the steelhead population in the mainstem Sacramento River. The end of the juvenile emigration period occurs during March through May. The base flows in the Sacramento River may potentially result in lower emigration survival than what would occur in wetter years. This effect of reduced emigration survival for steelhead originating from the Sacramento River basin is unquantified and is attributed to the persistent drought conditions continuing in WY 2015.

Water temperature conditions in the September time period for upstream migrating adult steelhead will be stressful and could result in delay of upstream migration through the lower Sacramento River until natural cooling with shorter day length occurs.

Net Delta Outflow Index and Water Quality Modifications

Similar to effects in the mainstem Sacramento River, the proposed lower outflow under drought conditions may result in lower survival of steelhead smolts emigrating to the ocean in the March through May period. This effect is unquantified and is attributed to the drought conditions necessitating modification of D-1641 Delta fish and environmental flow conditions. There is a high degree of uncertainty in this conclusion because this effect occurs largely in tidal areas so could be very slight.

Delta Cross Channel Gates

Under the Project Description, modified Delta Cross Channel Gates operations may occur based on water quality and fish presence. At this time, it is believed that an open DCC Gate has a low potential for entraining a substantial proportion of the juvenile Sacramento River steelhead. The remaining fraction of the natural and hatchery steelhead population that may still occur above the DCC location will be vulnerable to entrainment into an open DCC gate configuration as they emigrate downriver past the DCC gate location. Similar to Spring run Chinook Salmon, the Project Description's modification of the DCC gate operations will affect steelhead in the North Delta compared to the Baseline scenario, but only for a short time. It is uncertain whether the increase in the likelihood of entrainment into the Interior Delta will result in any change to facility loss of steelhead, both because the duration of the effect is expected to be short and because the limited exports in the Project Description scenarios may not result in greater entrainment into the South Delta and facility loss (see discussion in "Exports" section).

If the DCC gates were open Sacramento River water will flow through the DCC and into the Mokelumne River system. This may result in some level of straying of upstream migrating adult Winter-run Chinook Salmon into the Mokelumne River system. It is expected that this may delay these adults on their upstream spawning migration. Adult Winter-run Chinook Salmon which have entered the Mokelumne River system should be able to re-enter the Sacramento mainstem through the open DCC gates and continue their upstream movements. A delay in reaching the spawning grounds and an increase in energy expenditure may result. This could result in lower survival of juveniles produced from straying individuals, if temperatures in the upper river become unsuitable for egg and fry survival.

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

Clear Creek Actions

Flows on Clear Creek are forecast to range between 175 cfs and 85 cfs over the summer with the exception of springtime pulse as prescribed in the RPA to attract spring Chinook into the river. Steelhead rearing over the summer occurs in the upper reaches of Clear Creek with the downstream extent of suitable juvenile rearing habitat determined by water temperature. The extreme drought conditions will likely result in below average Trinity River diversions and thus a compressed length of the river suitable for oversummer rearing steelhead. Temperatures in the upper reaches of the stream are estimated to be suitable for rearing for the juvenile steelhead produced by the close to average number of adult spawners. A lower than average number of juvenile emigrants in 2016 per adult spawner could be expected to occur with the below normal habitat availability under the extreme drought conditions.

The temperature management for Clear Creek will be coordinated through the Sacramento River Temperature Task Group under the SWRCB 90-5 requirements and as outlined in RPA Action I.1.5. The temperature criteria are based on the Spring-run Chinook requirements and are expected to be protective of steelhead rearing through the summer. If these criteria are not met, juvenile steelhead habitat will be further restricted, predation by nonnatives may reduce survival, and disease may become more prevalent. The amount of uncertainty regarding Clear Creek effects is moderate.

American River Actions

Monthly flows in the American River are forecast to be held at 500 cfs through March and April. The lower than normal flows may enable cold water releases from Folsom to be maintained as long as possible through the summer. This will also result in a higher than normal rate of heating as water moves downstream. Flows will increase starting in May up to a peak of 3,035 cfs monthly average flows in July and then drop down to around 700 cfs in September. Reclamation will submit a draft temperature management plan to NMFS by May 1 per RPA Action II.2.

Considering the low steelhead escapement in the American River in 2015 it is hypothesized that water temperatures will be the limiting factor to the survival rate for rearing steelhead in 2015. Density dependence should not be a factor. Physical habitat and food should be less limiting than temperatures at the expected low rearing densities. However, if the Nimbus Hatchery steelhead are released in the spring or summer, as occurred in 2014, then density dependence would come into play under the low flow conditions.

American River at Hazel Avenue water temperatures were used to estimate steelhead emergence timing based on spawning timing (Figure 47). Temperatures after March 18 were estimated based on the near term weather forecast and additional warming expected to occur through April and May. The spawning timing for 2015 based on the bi-weekly spawning surveys is shown in Table 21. The emergence timing estimate used 600 accumulated temperature units to emergence (degrees C). Hazel Avenue temperatures reflect the coolest temperatures in the American River, thus emergence will be slightly earlier further downstream as water temperatures increase downstream up to a limit. The difference will be around a three to four day earlier emergence at Watt Avenue for the later season redds. High mortality is likely at over 59 F. Estimated

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

emergence of fry from current year spawners should be completed by around May 4 (Table 18). Note that redds were included on March 28 based on timing in past surveys. This March 28 survey has not occurred as of this writing so this is a guess. In addition the redd survey data are still draft and subject to change.

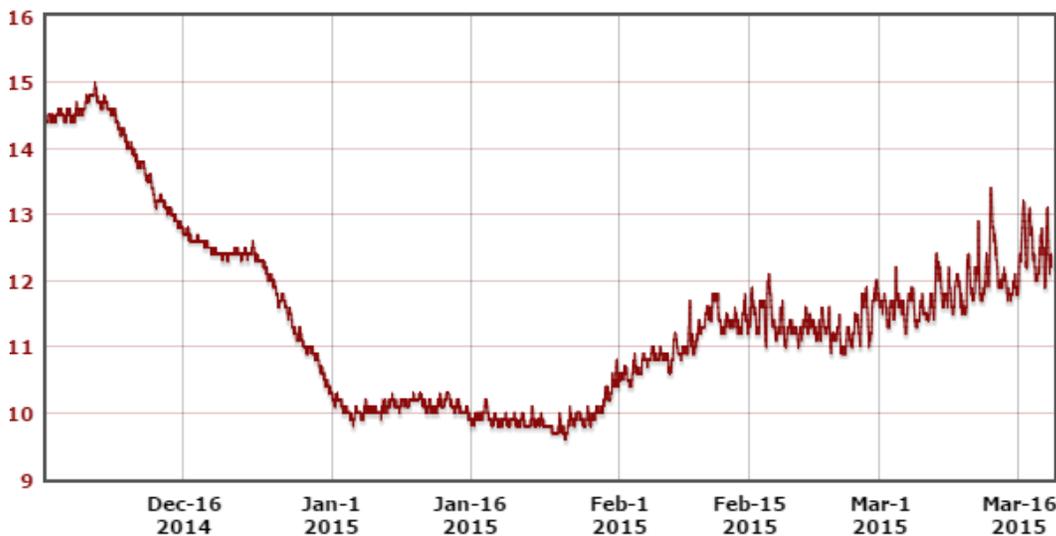

Figure 47. American River at Hazel Avenue water temperature (degrees C), December 2014 – March 19, 2015

Table 21. American River steelhead fry emergence from the gravel timing in 2015

Survey Date	Redds SH and unknown	600 ATU emergence Date	Cumulative % emerged
1/9/2015	0	3/5/2015	0%
1/23/2015	35	3/17/2015	43%
2/5/2015	35	3/27/2015	85%
2/20/2015	6	4/7/2015	93%
3/6/2015	4	4/15/2015	98%
3/28/2015 ¹	2	5/4/2015	100%

¹ The March 28 survey has not occurred so spawning on this date is a guess based on past experience.

Based on the current preliminary spawning survey results at a fecundity of 5,732 eggs/ female (based on recent past hatchery data and size of fish observed on redds in 2015) and 1.5 redds per female about 313,000 eggs would be produced by the observed redds. A 25% egg to fry survival (lower survival than typically assumed due to currently warmer water that will reach levels that will likely reduce egg to fry survival for later spawners this year) would produce about 78,250 emergent fry. Eggs from the later spawning fish may not survive to emergence. CDFW is planning to conduct juvenile steelhead monitoring during the summer. Surveys would be conducted in close proximity to spawning areas and within restoration reaches and would enable an assessment of survival in the expected stressful water temperatures over the summer.

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

The steelhead smolts leaving the American River in spring of 2015 are expected to complete emigration by around the end of April when temperatures under these drought conditions are expected to be affecting survival for fish leaving the river later. These fish are the progeny of steelhead that spawning in 2014 when water temperatures through the summer were stressful for rearing steelhead. These fish may have suffered mortality or left early. Estimates of fry to smolt survival for naturally spawned steelhead have ranged from 4% to 11% for brood years 2002 to 2010 (Table 22). The survival rate is likely to be lower under the drought conditions.

Table 22. Estimates of American River wild smolt production and hatchery smolt survival based on adult hatchery counts, spawner surveys and hatchery yearling releases (updated from Hannon 2013)

Adult Spawning Year	2013	2012	2011	2010	2009	2008	2007	2006	2005	2004	2003	2002	2001	2000

² assumes same smolt to adult survival of wild smolts as for hatchery released smolts and that 10% of in-river spawners are naturally produced fish														
³ no adjustments made for potential missed redds														

Conditions in the American River have met the criteria for a conference year under the flow management standard in compliance with the RPA. Therefore, operations will be adaptively managed in partnership with the fishery agencies and the Water Forum to best meet needs under the extreme drought conditions. There is a moderate level of uncertainty in the conclusions about American River steelhead.

Stanislaus River Actions

Stanislaus River flows under Appendix 2E of the 2009 BO are being coordinated with the Stanislaus Operations Group to provide the best conditions as feasible under the current drought situation. Mean monthly flows are projected to be around 460 cfs and 380 cfs in April and May respectively and then drop to a baseflow of 150 cfs through September. The Ripon dissolved oxygen standard of 7.0 ppm, described in SWRCB D-1422, is modified in the Project Description by moving the compliance location upstream to Orange Blossom Bridge over the project period. Given the *O. mykiss* population in the Stanislaus which has been sustained under flows of 150 cfs in past years it is hypothesized that the limiting factor to oversummer survival in 2015 will be water temperatures under the extreme drought conditions affecting conditions in the Stanislaus watershed. Summer operations on the Stanislaus may not be able to meet the temperature compliance schedule described in NMFS RPA Action III.1.2. The RPA will be followed regarding notification and Stanislaus Operations Group (SOG) advice. Under the expected flows and temperatures the oversummer steelhead rearing habitat will be confined to the area upstream of Orange Blossom Bridge. The relaxation of the dissolved oxygen standard from Ripon to 7.0 at Orange Blossom Bridge could result in dissolved oxygen levels reaching lethal levels for fish at times in the Ripon area. A DO of 7.0 is considered protective of salmonids.

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

Steelhead rearing habitat will be reduced due to temperatures and may be marginal at Orange Blossom Bridge. A dissolved oxygen level of 7.0 and greater at Orange Blossom would be protective of steelhead over the summer in the area between Orange Blossom and Goodwin as DO will be higher on average further upstream.

We expect that spawning of steelhead will be complete by the end of March based on observations in other watersheds. At a temperature of 56°F (13.3°C) emergence of steelhead fry should be completed by May 15. If water temperature becomes greater than a mean daily temperature of 56°F in the redd locations, then emergence would be completed sooner, up to a limit. Mean daily water temperatures greater than 59°F (15°C) could result in very low egg to fry survival if they occur during the incubation period. Recent water temperatures near Goodwin Dam are shown in Figure 48. Resident trout often spawn later than steelhead, so it is likely that the fry from resident fish will continue to emerge past the May 15 date. It is hypothesized that some coldwater refugia should be present, particularly in the deep pools at and upstream of Knights Ferry so that *O. mykiss* populations will persist and the resident population will continue to maintain spawner abundance and juvenile productivity of *O. mykiss* on the Stanislaus River.

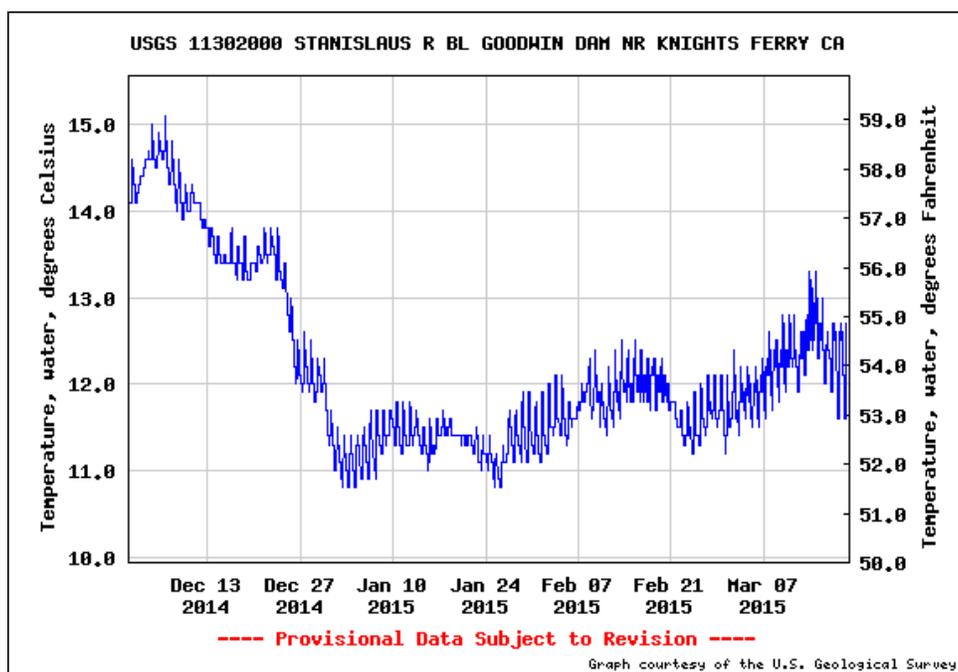

Figure 48. Stanislaus River below Goodwin Dam at the cable crossing water temperature, 12/1/2014 – 3/19/2015

Rotary screw traps in the Stanislaus at Caswell provide information on size and timing of steelhead emigrating from the Stanislaus. During late 2013 through March 6, 2015, no steelhead have been captured at Caswell. Trap calibrations are not conducted for *O. mykiss* but since capture rate is size-dependent for Chinook, larger steelhead are likely much less susceptible to capture than Chinook (Joe Merz, Cramer Fish Science, pers comm). Therefore zero steelhead captured does not represent an absence of emigration from the Stanislaus. The median date of steelhead exit from the Stanislaus based on screw trap data was March 4 for the period from 1997 to 2015.

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

A pulse flow as specified in the NMFS RPA (2011 amendment), based on SOG advice and NMFS determination, will be scheduled to occur sometime during the late March to April time period to provide migratory cues and flows for the last of the emigrating juvenile steelhead before downstream temperatures become inhospitable. The timing is being coordinated at the SOG. Dissolved oxygen concentration varies with temperature and the warming water temperatures in the spring may also result in stressful DO levels in the lower Stanislaus River in April and May.

The low quality habitat along routes to the ocean likely results in low emigration survival, especially in extreme drought conditions such as this and is likely a large contributor to why the steelhead component of the *O. mykiss* population in the San Joaquin basin is small. It is hypothesized that steelhead escapement in two years will be lower than during previous wetter years due to lower steelhead survival through the lower San Joaquin River between Durham Ferry (near the confluence of the Stanislaus River) and Lathrop than during previous wetter years as well as along the rest of the various routes to the ocean.

Adult steelhead upstream migration generally occurs in October and later in the Stanislaus River. A few may occasionally enter the river in September but this year conditions will likely be unsuitable in the lower San Joaquin and Stanislaus in September (low flows, high temperatures, stressful dissolved oxygen levels) so any steelhead that attempt to migrate early will likely be delayed.

There is a moderate level of uncertainty in conclusions regarding Stanislaus River steelhead.

Delta Exports

Delta exports are forecast to be at a low level due to the drought conditions. The low export levels are not expected to appreciably affect survival of steelhead emigrating through the delta from the Sacramento River. This emigration should be completed by early May when water temperature is likely to be warm for emigrating steelhead. Steelhead emigrating from the San Joaquin River prior to the HORB being in place are more likely to be salvaged at the CVP facility and be trucked downstream of the Delta. Under these extreme low flow conditions the steelhead that experience this route through the fish salvage facilities are hypothesized to have a better chance of survival to the ocean than those that continue down the mainstem San Joaquin River route. The degree of uncertainty with this conclusion is moderate.

No appreciable effect of the pumping levels on the early part of the adult upstream migration in September is expected to occur.

San Joaquin River I:E ratio and San Joaquin River downstream of Stanislaus River Confluence

The Project Description flows at Vernalis are hypothesized to result in less suitable conditions for steelhead emigration than would otherwise occur in the Baseline modeling. These conditions reduce survival of outmigrating San Joaquin basin steelhead downstream of the Stanislaus River confluence until tidal conditions dominate the South Delta. San Joaquin River flow limits are being reduced during the Vernalis pulse flow period and then will be no less than 300 cfs after the pulse until the end of May. Summer Vernalis flows would be no less than 200 cfs monthly

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

average. Water temperatures are likely to be unsuitable for steelhead emigration by early May due to the drought conditions. These conditions in the San Joaquin following the pulse period are expected to be lethal to steelhead so that later emigrants are not likely to survive.

The Vernalis salinity standard is modified in the Project Description. Additional flows from the Stanislaus River and San Joaquin River tributaries would be required to meet the existing standard. The change in salinity in the San Joaquin River would not affect steelhead as they would not be present in the summer. The result of the low flows over the summer in the Stanislaus, which are enabled to occur with the salinity relaxation, are discussed above in the Stanislaus River section.

If there is a precipitation event outside of the pulse period, then the Project Description modifies RPA Action IV.2.1 to allow pumping to capture abandoned or natural flows in the Delta up to the OMR limits. If precipitation occurs then that would be the same period that steelhead would likely to emigrate. Pumping will occur preferentially at the Jones Pumping Plant if condition permit, which should increase salvage rates and reduce loss, due to lower pre-screen mortality at the Tracy Fish Collection Facility. In a future year, Reclamation and DWR would make available an amount of water equal to half the volume of any increased exports realized over the April – May period for the fishery agencies to shape. This could benefit steelhead in future years but would not benefit fish this year. The degree of uncertainty with this conclusion is moderate.

Summary of Effects on Steelhead

The drought conditions are causing increased stress to steelhead populations, with or without water project operations, in the form of low flows reducing rearing and migratory habitats, above normal water temperatures affecting survival, and likely higher than normal predation on juvenile steelhead. The water management over the last year has focused on maintaining a level of reservoir storage which is generally higher than what would be in place at this time without the planning that has gone into attempting to reduce adverse effects on resources. The Project Description strives to balance spring and summer operations between Shasta and Folsom divisions of the CVP to minimize affects across CVP tributaries in WY 2015. Steelhead survival will be low in 2015 in all tributaries and migratory pathways and is likely to result in a smaller returning year class of steelhead from those juvenile steelhead emigrating this year.

Battle Creek/Coleman Hatchery experienced one of the highest adult steelhead returns that has been measured and eggs from some of those fish are being provided to Nimbus Hatchery on the American River where the steelhead currently do not contribute to the Central Valley steelhead DPS. Although an experiment at this point, if these fish are successful in surviving to emigration next spring then they could contribute to increasing the proportion of Central Valley steelhead returning to the American River in the future and improving genetic diversity for Central Valley steelhead.

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

Status of Delta Smelt

As California enters a fourth year of drought, abundance of Delta Smelt has continued to decline. The 2014 Fall Midwater Trawl (FMWT) annual index for Delta Smelt was 9, which is the lowest reported fall index since the beginning of this survey in 1967, and approximately one half of the previous lowest index values of 17 (2009) and 18 (2013). These results and a detailed account of the spatial distribution of the adult population based on survey data at that time were described in the Biological Review of the Feb-Mar 2015 TUCP (Reclamation, 2015c). The third Spring Kodiak Trawl (SKT) survey for March 9 – 12, 2015 (Figure 49) yielded six adult Delta Smelt, a record low number for March (Figure 50) and a number that has only occurred over the period of record at this level once before in May surveys, when catches typically tail off because of post-spawn mortality. These winter survey results provide additional evidence that the Delta Smelt population is likely at an all-time low. The recent catch data also indicate most adult Delta Smelt may be in the Sacramento River and outside the influence of the export facilities.

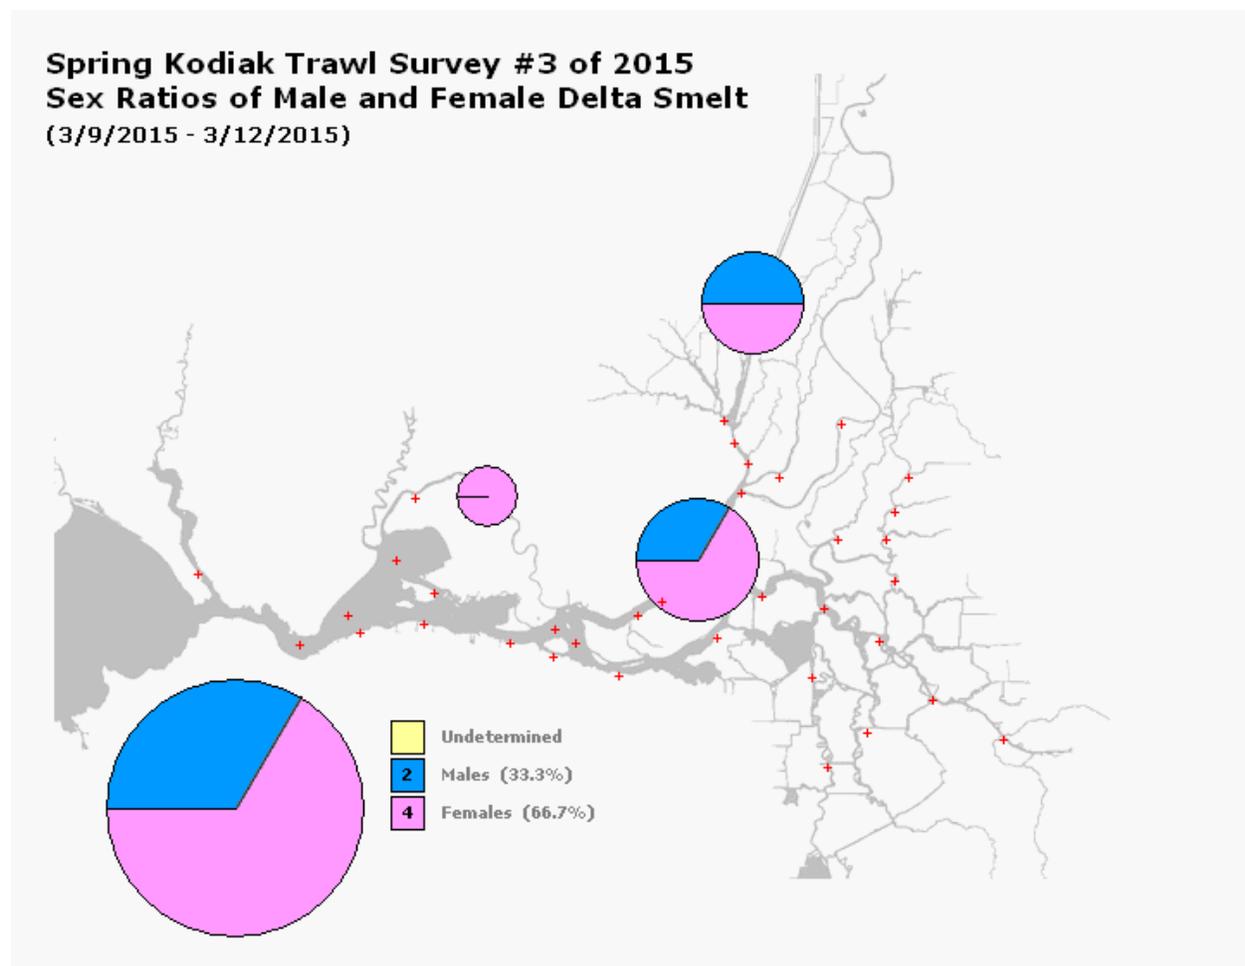

Figure 49. March distribution of adult Delta Smelt from Spring Kodiak Trawl #3

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

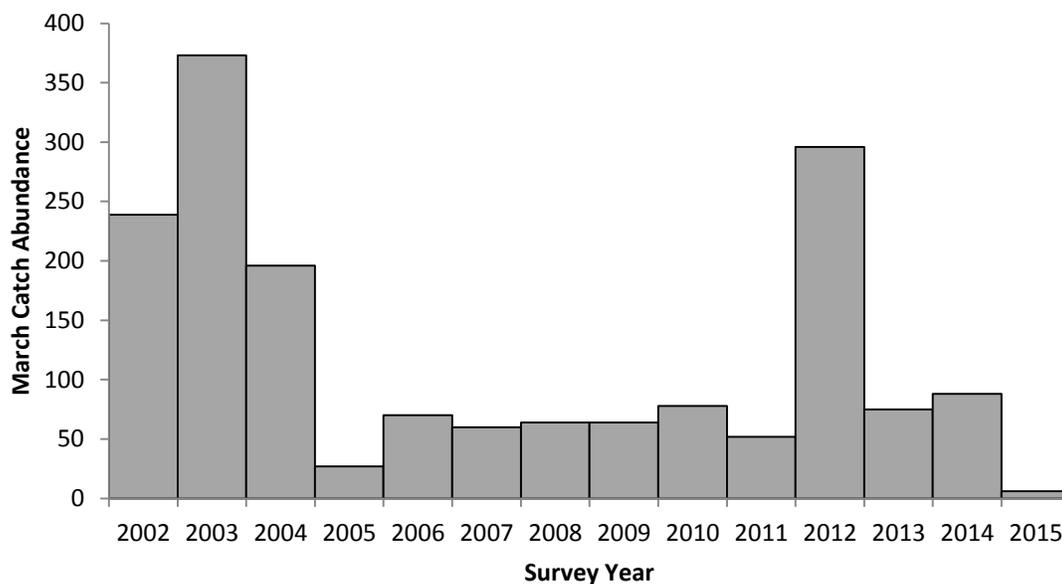

Figure 50. The number of Delta Smelt collected in March for Spring Kodiak Trawl surveys from 2002-2015

Drought Impacts

Research presented at the Interagency Ecological Program (IEP) workshop (March 18-20, 2015) showed that drought impacts Delta Smelt a number of ways. It can reduce the area of low salinity habitat to which they migrate for spawning and thereby reduce food availability for adults and for juveniles moving there to rear. Drought can indirectly impact reproductive potential by lowering the number of oocytes females produce (Hammack, 2015). This is brought about by a link between low outflow and elevated water temperature. Warming temperature shortens the spawning window, which causes fewer clutches to be produced per female (Jeffries, 2015). Both of these mechanisms combine with low adult abundance to impair population fecundity. Lower outflow also tends to reduce turbidity. Delta Smelt use turbid water to avoid predators and they also use it as foraging habitat (Hasenbein, 2015a). Otolith analysis has revealed that Delta Smelt, since 1999, experienced an 8% decline in growth between dry and wet years and spawning is more successful the north Delta during drought (Hobbs, 2015). The quality of their habitat is further compromised by concentrations of herbicides such as Diuron and Hexazinone, which increase with reduced outflow and have synergistic effects that reduce food availability for juveniles (Hasenbein, 2015b). Furthermore, warm, slow moving water characterized by drought promotes conditions in which parasites like Ich (*Ichthyophthirius multifiliis*;) and cyanobacteria like *Microcystis* thrive. Ich causes skin lesions to form on a variety of fish and has an increased prevalence among captive Delta Smelt above 17°C (Frank *et al.*, 2015). *Microcystis* is a toxic hepatotoxin that became established throughout the Delta in 2000 and also thrives in water above 17°C with low turbulence (Lehman, 2015). Because of the extended high water temperatures associated with drought, *Microcystis* blooms extended into December of 2014 (Lehman, 2015). This highly toxic cyanobacteria is known to kill phytoplankton, zooplankton and compromise fish health (Acuña *et al.*, 2012). Finally, the abundance of non-native Delta Smelt predators, such as black bass, increased in the Delta in response to the drought in 2014, mainly because it expanded their preferred habitat (Barnard, 2015). The same pattern was found for non-native

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

competitors, such as clams like *Corbicula*, which seem to be expanding throughout the Delta despite the drought (Thompson, 2015).

Salvage

The estimated cumulative season total for adult Delta Smelt salvage is 68. No salvage has been reported since February 21st. The State Water Project (SWP) and Central Valley Project (CVP) initiated larval fish monitoring on March 2nd and February 24th, respectively. The frequency of larval fish samples at the CVP has been reduced at times due to heavy debris load in the salvage collections. Regardless, no larval Delta Smelt have been reported at either facility to date. However, pre-screen loss of all life stages (e.g., predation) may decouple entrainment at low densities so that fish entrained at low densities are not observed in salvage.

This is further supported by regular presence of adult Delta Smelt at Jersey Point and Prisoners point surveys for most of the winter indicate likely presence of larvae in the central Delta in spring. Daily “early-warning” sampling resumed during the week of February 2nd at Jersey and Prisoners Point in anticipation of storm conditions. Weekly sampling resumed the week of March 9th and no adult Delta Smelt have been caught at Jersey Point since March 16th (when one individual was caught) and no Delta Smelt have been caught at Prisoners Point since February 15th.

The 3-station average water temperature threshold of 12°C (Action 3 of the 2008 Biological Opinion (BO)) was first exceeded on February 2nd and was reported on March 15th to be 17.8°C. This suggests Delta Smelt spawning has occurred early this year. On March 16th, the Smelt Working Group (SWG) suggested the most likely reason for steep decline in catch of Delta Smelt in the SKT #3 survey (Figure 2) was fish may not have survived after a first spawn (SWG notes from 3/16/15) or they could have been avoiding the gear (Baxter). This hypothesis is partly supported by poor condition of the few mature fish caught in SKT #3. Hatching will likely continue over the next few weeks, although the peak of the spawning season has likely passed. As water temperatures rise, larvae are beginning to recruit to juvenile size, and a broader distribution in the central Delta may become evident by way of larval field surveys. Intermittent salvage of adult Delta Smelt indicates the likely presence of larvae in the central and southern Delta within the vicinity of the SWP and CVP pumps. Those larval and juvenile Delta Smelt hatching in the central and southern Delta are vulnerable to entrainment; however, exports are currently at minimum levels, resulting in favorable Old and Middle River (OMR) flows (SWG-notes from 3/16/15). A temperature off-ramp occurs when water temperature at Clifton Court Forebay reaches 25°C for three consecutive days (BO). This off-ramp typically occurs in late June or early July, although present unseasonably warm water temperatures may suggest an earlier temperature off-ramp (the calendar-based off-ramp is June 30th).

Effects of Proposed Action on Delta Smelt

The following discussion is based on DSM2 particle tracking model (PTM) simulations described earlier. When reviewing this section, it is important to remember that adult Delta Smelt do not behave as neutrally-buoyant particles so a literal translation of results into changes in entrainment or entrainment risk is not advisable. In particular, the model predictions of westward advection are not relevant. It is the changes in central/south Delta hydrodynamics that are of interest because these flow conditions may affect tide-surfing fishes seeking turbid fresh water.

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

To estimate the effects of the Proposed Action on Delta Smelt, a PTM from April to June was compared to baseline hydrological conditions, assuming an equally distributed population between injection points (Figure 28). Only particles located between Railroad Cut and the pumping facilities experienced flux towards the pumps. Throughout the rest of the Delta, particles either remained in the Delta or eventually moved west regardless of the outflow scenario.

The Baseline scenario represents a constant North Delta Outflow Index (NDOI) of 7100 cfs, while the Project Description scenarios (Hydrology 2 and 2') reduces NDOI to 4000 cfs, and in 2' an open DCC Gates. The Project Description uses the February 90% Operational Forecast for Central Valley hydrologic and operation conditions during the remainder of the Project Description's period. March exceedance forecast is under development and appears to be trending drier than the February 90% exceedance forecast. Reclamation and DWR are petitioning the State Water Board to adopt a Delta outflow standard of a minimum monthly NDOI for April, May and June to be no less than 4000 cfs and for July to be no less than 3000 cfs with a 7 day running average no less than 1000 cfs below the monthly average. Other input values remained constant and reflected the best information available to Department of Water Resources (DWR) modelers when models were run on March 17th, but it should be noted that particles were injected on April 1st and tracked through May 31st. The modeled conditions of the proposed reduction in NDOI resulted in slight overall increase in the final fate of particles at the facilities compared to baseline conditions (Figure 29).

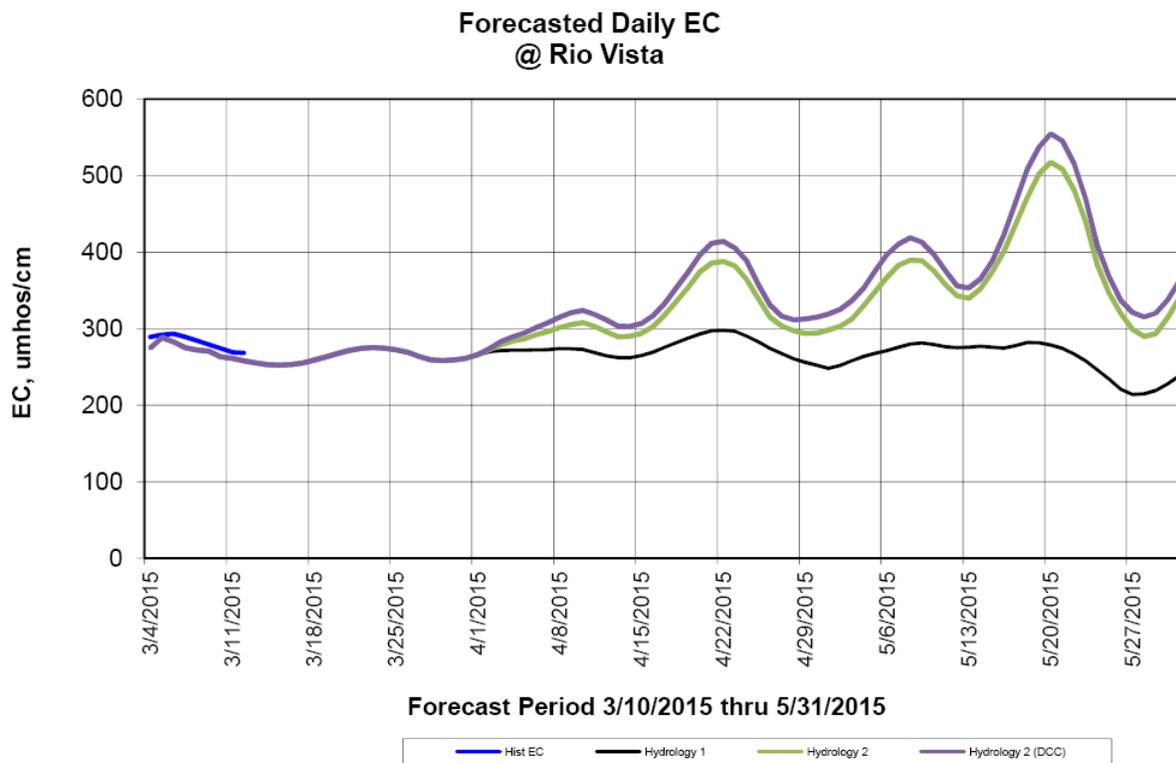

Figure 51. Forecasted electrical conductivity (EC) under different hydrologic scenarios from March – June, 2015 at Rio Vista

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

Similar to the effects review from 2014 (Reclamation, 2014), if such changes would remain through the summer, the 2 ppt isohaline (X2) will shift upstream and, given the general decrease in habitat suitability when the low-salinity zone moves upstream of Suisun Bay, is assumed to result in higher predation rates, and greater exposure to contaminant effects, losses in irrigation diversions, water temperatures stress, etc. (Feyrer et al., 2007). Similar to the effects review from 2014 (Reclamation, 2014c), if such changes would remain through the summer, the 2 ppt isohaline (X2) will shift upstream and, given the general decrease in dynamic habitat with movement upstream of the low-salinity zone, would result in reduced spawning and rearing habitat (Feyrer et al., 2007). Further constraints on habitat for juvenile Delta Smelt towards upstream spawning areas in the lower Sacramento/San Joaquin Rivers and the Cache Slough Complex/Sacramento Deep Water Ship Channel will reduce the quantity of available habitat, but will be within the range of salinity generally occupied by Delta Smelt during the summer and fall. As Sommer and Mejia (2013) noted, Delta Smelt are not confined to a narrow salinity range and occur from fresh water to relatively high salinity, even though the center of distribution is consistently associated with X2 (Sommer et al., 2011). However, Nobriga et al. (2008) found the probability of occurrence of Delta Smelt was highest at low EC (1,000-5,000 $\mu\text{mhos/cm}$), and declines at higher EC. EC forecasts for Rio Vista and Emmaton (Figures- 51-52) and locations upstream are within this range during the period modeled. Therefore we conclude that while changes in salinity in the lower Sacramento River are within the physiological tolerances of Delta Smelt, the proposed modifications are expected to shift the Delta Smelt population further upstream. There is a relatively high level of uncertainty in these conclusions when compared to Reclamation (2014c) due to a lack of temporally projected data.

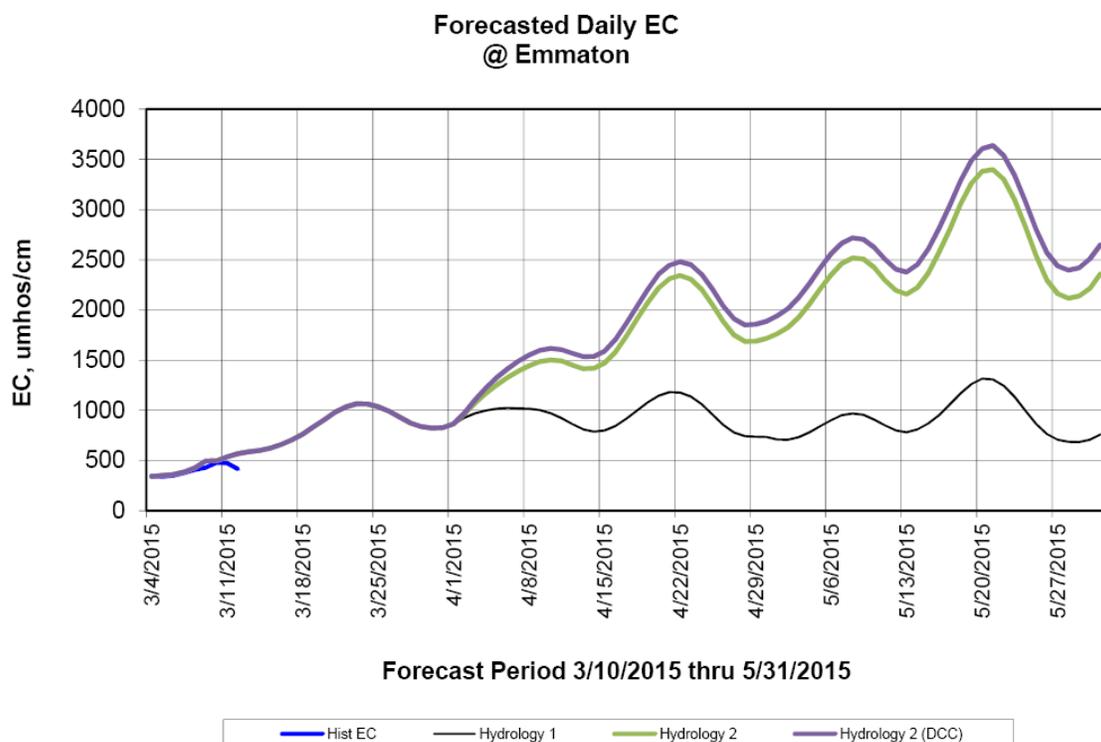

Figure 52. Forecasts of electrical conductivity (EC) under different hydrologic scenarios from March – June, 2015 at Emmaton

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

The upstream shift of Delta Smelt distribution on the Sacramento River will increase the potential for stochastic events to exacerbate mortality and density-dependent effects on the population (Feyrer *et al.*, 2011). As an example, there may be water temperature increases during prolonged heat waves that would pose risks to Delta Smelt. In general, summer temperatures are higher in landward channels (Wagner, 2012), so reduced inflow is expected to shift the distribution of Delta Smelt into these warmer regions. In addition, with the shifting of X2 above the Sacramento-San Joaquin confluence, salinities may be too high downstream for juvenile Delta Smelt to move substantially seaward, where the maritime influence and larger water bodies maintain cooler water temperatures.

In the San Joaquin River, modeling suggests EC at Jersey Point will increase given the proposed action although it is similar to historical EC values (Figure 53). Regardless, it is inferred there would be little physiological effect on Delta Smelt from changes in salinity in the lower San Joaquin River, as ranges are well within the physiological tolerance level for the species (Nobriga *et al.*, 2008). However, the increase in salinity may alter the distribution of Delta Smelt into less favorable areas within the lower San Joaquin (*e.g.*, Franks Tract).

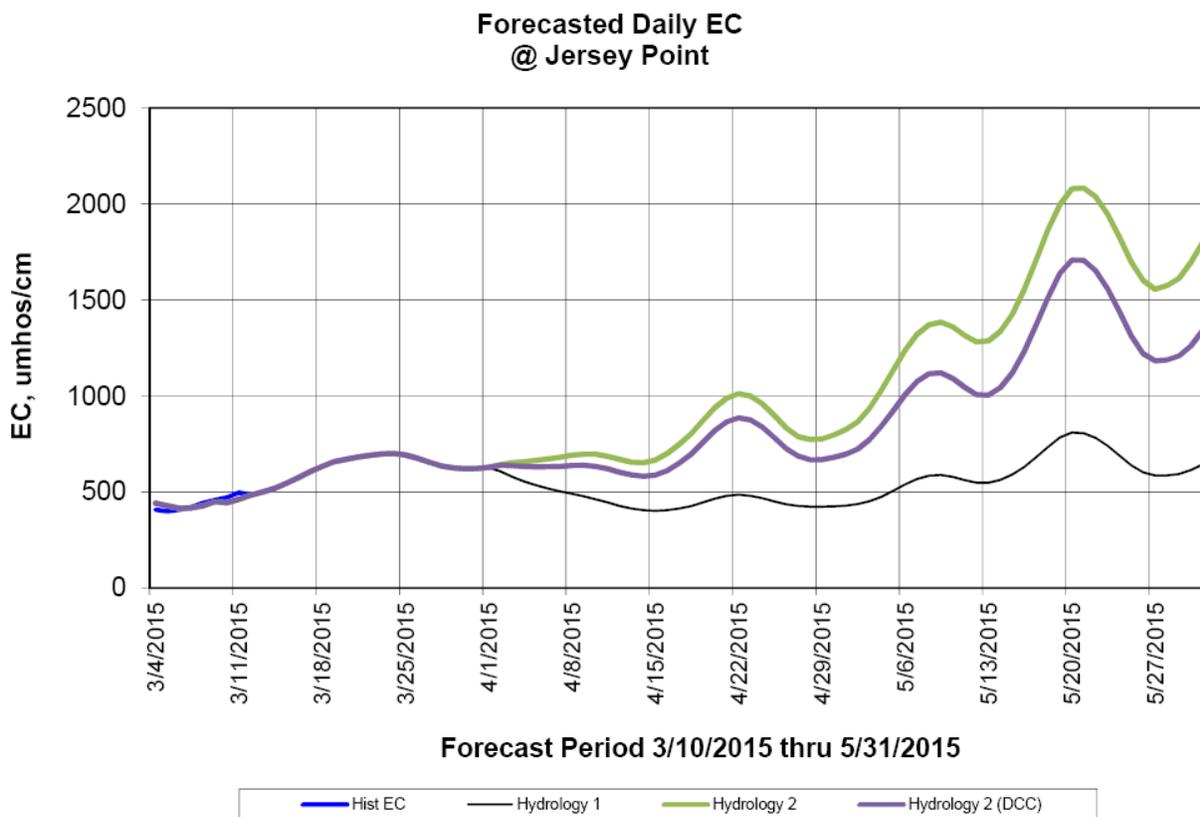

Figure 53. Forecasts of electrical conductivity (EC) under different hydrologic scenarios from March – June, 2015 at Jersey Point

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

Hydrodynamic Effects on Entrainment

The proposed modifications will result in lower outflows that may reduce survival of migrating young-of-year Delta smelt that are currently in the Interior Delta. For example, lower flows may expose them to loss at the CVP/SWP export facilities, and increase their travel time and exposure to degraded habitats and predators described above. For Delta Smelt residing in the north Delta, reduced outflow, while limiting available habitat, is not expected to result in additional entrainment. Modeling outputs suggest effects from the actions in the Project Description by reducing outflow are negligible through the end of May (Table 23). There is a low level of uncertainty in this conclusion.

Table 23. Presence of Delta Smelt During the Project Description Period and Potential Effects, based on the most recently available survey data¹⁶

Delta Smelt	Life stage Affected	Change in Risk of Lowered Recruitment	Change in Risk of Entrainment at Facilities	Certainty
Eggs	Attached to substrate with very low risk of entrainment			
Larvae	Presence has been established based on Smelt Larva Survey #5 and 20 mm Survey #1. This life stage has not yet recruited to most sampling gear			
Juvenile	Juvenile Delta Smelt (>20mm) have not yet been detected this year			
Adults	Distribution based on February 2015 Spring Kodiak Trawl survey and salvage at SWP/CVP export facilities			
No detections in South Delta	Yes	Not Applicable	Reduced	Moderate
Present in San Joaquin River	Yes	Not Applicable	Reduced	Moderate
Present in Sacramento River	No	Not Applicable	Not Affected	Moderate
Present in Confluence and down	No	Not Applicable	Not Affected	High

Food Availability

Prey availability is constrained by habitat use, which in turn affects what types of prey are encountered. Larval Delta Smelt are visual feeders. They find and select individual prey organisms and their ability to see prey in the water is enhanced by turbidity (Baskerville-Bridges & Lindberg, 2004). Thus, Delta Smelt diets are largely comprised of small invertebrates (i.e., zooplankton) that inhabit the estuary's turbid, low-salinity, open-water habitats. Larval Delta

¹⁶ Distributions are based on monitoring data through March 16.

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

Smelt have particularly restricted diets (Nobriga, 2002). They do not feed on the full array of zooplankton with which they co-occur; they mainly consume three copepods: *Eurytemora affinis*, *Pseudodiaptomus forbesi*, and freshwater species of the family Cyclopidae. Further, the diets of first-feeding Delta Smelt larvae are largely restricted to the larval stages of these copepods. As Delta Smelt grow larger, mouth gape and swimming ability increase, enabling them to target larger copepods.

In the laboratory, a turbid environment (>25 Nephelometric Turbidity Units (NTU)) was necessary to elicit a first-feeding response (Baskerville-Bridges & Lindberg, 2004). Successful feeding seems to depend on a high density of food organisms and turbidity, and increases with stronger light conditions (Baskerville-Bridges & Lindberg, 2004; Mager *et al.*, 2003). The most common first prey of wild Delta Smelt larvae are larval stages of several copepod species which occur in the North Delta region. The variability of shallow and deep water habitat, and the resuspension of sediment due to wind and tidal action in the North Delta, may buffer effects of the proposed modifications because much, if not most, of the habitat in this region would remain suitable. Expectations for the North Delta contrast with the lower San Joaquin River where the upstream relocation of X2 may result in a greater proportion of the available habitat encompassing areas of high surface aquatic vegetation (SAV) and associated low turbidities. This could lower prey capture efficiency for Delta Smelt and increase predation rate on juveniles. There is moderate level of uncertainty in this conclusion.

In addition to turbidity effects, changes in flow may affect residence time, which in turn may influence planktonic production. Lower flows are expected to increase hydraulic residence times, potentially resulting in improved planktonic production (Lucas *et al.*, 2009). However, the specific effect is difficult to predict because benthic grazing can offset these benefits, hence the response of the food web to the changes in flow is unclear. There is a moderate level of uncertainty about this conclusion.

Summary of Effects on Delta Smelt

Adults

Small numbers of Delta Smelt adults and larvae observed in 2015 field surveys indicates the WY 2014 drought had a significant impact on the population. Like many other species in the Delta, the Delta Smelt population is showing low recruitment again this year due to effects of continued drought. Model results indicate the Proposed Action may increase entrainment risk for Delta Smelt moving around in the San Joaquin River above baseline conditions. As indicated by forecasted daily EC results, salinity is expected to shift the centroid of the distribution associated with X2 inland. If recent SKT and USFWS Jersey Point survey results reasonably reflect the current distribution of Delta Smelt, there is a diminishing presence of adult Delta Smelt in the vicinity of Jersey Point. Entrainment of these adults is unlikely to be a management issue this year. Published analyses of a 13-year dataset of salvage records at the CVP/SWP fish collection facilities indicate that increased salvage of adult Delta Smelt at the CVP/SWP occurs when turbidities increase in the South Delta and OMR flows are highly negative (Grimaldo *et al.*, 2009). Given the present low turbidity in the South Delta, migration of remaining adults into areas of elevated entrainment risk is not expected. The salvage of adult Delta Smelt typically ends by May (Reclamation 2014c). After the onset of spawning, salvage of adult Delta Smelt

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

diminishes, with regulatory focus shifting from protection of adults to protection of larvae/juveniles by the end of March (as determined by water temperatures or biological triggers; BO).

Larvae and Juveniles

Delta Smelt have a strong positive association with the position of X2, with more downstream positions providing higher quality habitat (Feyrer *et al.*, 2011). Under the proposed action, it is likely summer Delta Smelt distributions will not be in areas optimal for growth and survival (Nobriga *et al.*, 2008). In previous low-flow years, when water quality conditions became less tolerable for Delta Smelt in the Cache Slough Complex, the North Delta population appeared to have the capability to move quickly downstream towards the low salinity zone. It is likely, given the strongly tidal nature of the Cache Slough Complex, Delta Smelt are able to ride these tidal flows to escape unfavorable habitat conditions in the North Delta. Under the current proposal, X2 would move further upstream, reducing the potential for downstream movement beyond the limitations already anticipated from the unmodified severe drought conditions. The proportion of the total population of Delta Smelt in the North Delta in summer appears to be highly variable (Feyrer, 2015), but can be relatively substantial (Sommer & Mejia, 2013). There is a moderate level of uncertainty about the expected effects in the North Delta.

Ongoing IEP monitoring, Early Warning Monitoring, and fish salvage operations, will continue to inform management and advisory groups who will be providing input to Reclamation on a near real-time basis.

Status of Longfin Smelt

In Bay Study trawls conducted during the beginning of February, 2015, the majority of adult Longfin Smelt were detected in Suisun Bay, the Confluence area, and the lower Sacramento River (Figures 54-55; note the different scales between the figures). As of March 16, 2015, no adult or age-1 Longfin Smelt have been detected at either the CVP or SWP fish facilities. Earlier in the season (January), adult Longfin Smelt was detected in the Early Warning sampling in the lower San Joaquin River at Jersey Point, though recent surveys have not detected any in this area. This presence indicates that larval Longfin may be present in the central and south Delta, which is corroborated by the detection of larval Longfin in larval fish sampling at the salvage facilities (see below).

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

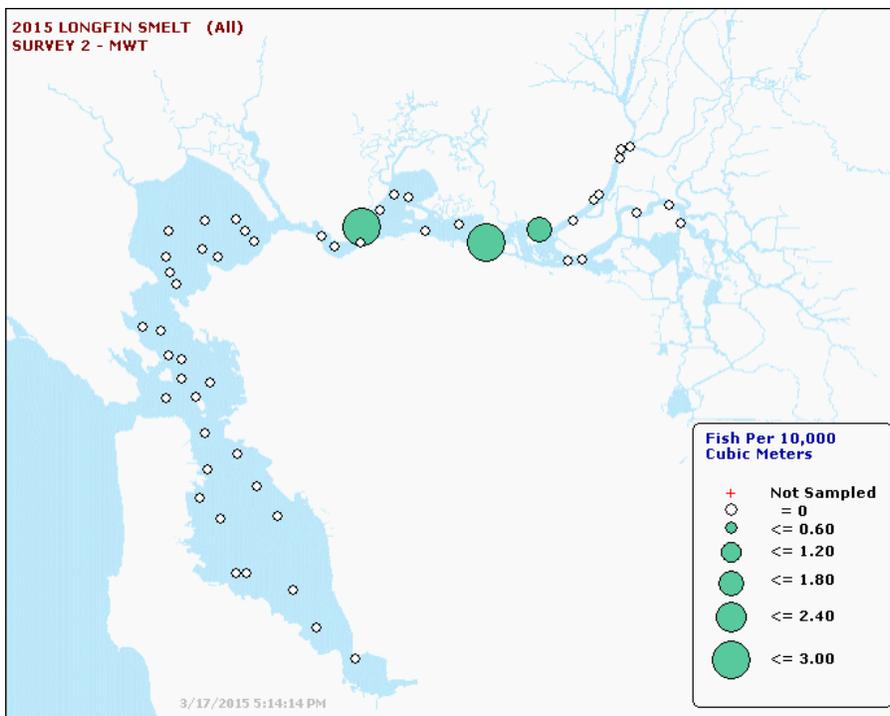

Figure 54. Distribution of adult Longfin Smelt in the Bay Study Midwater Trawl during February 2015

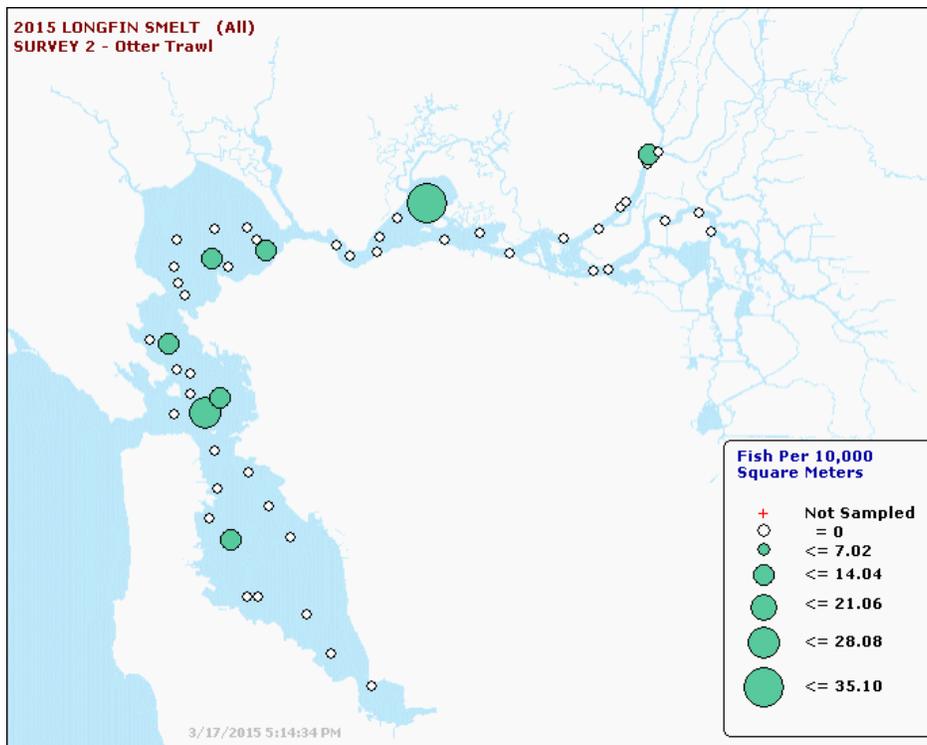

Figure 55. Distribution of adult Longfin Smelt in the Bay Study Otter Trawl during February 2015

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

The fifth Smelt Larva Survey (SLS), conducted during the week of March 2, 2015, found larval Longfin Smelt larvae were primarily distributed in the lower Sacramento River, at the confluence, and east of the confluence in Suisun Bay (Figure 56). Several larvae were also collected in the lower San Joaquin River at Jersey Point (n=1) and Oulton Point (n=3), and one larvae was collected in the south Delta at station 914 near Mildred Island. While larvae in these southern areas will be at a low to medium risk of entrainment during operations, larvae in the south Delta represent only 1% of the total larval catch in SLS #5 east of Carquinez Straights (n=101). As of March 16, 2015, one larvae each have been collected at the CVP and SWP salvage facilities, (February 27 and March 3, respectively). Compared to previous years, it appears Longfin Smelt spawning in 2015 is substantially reduced and larval abundances are low.

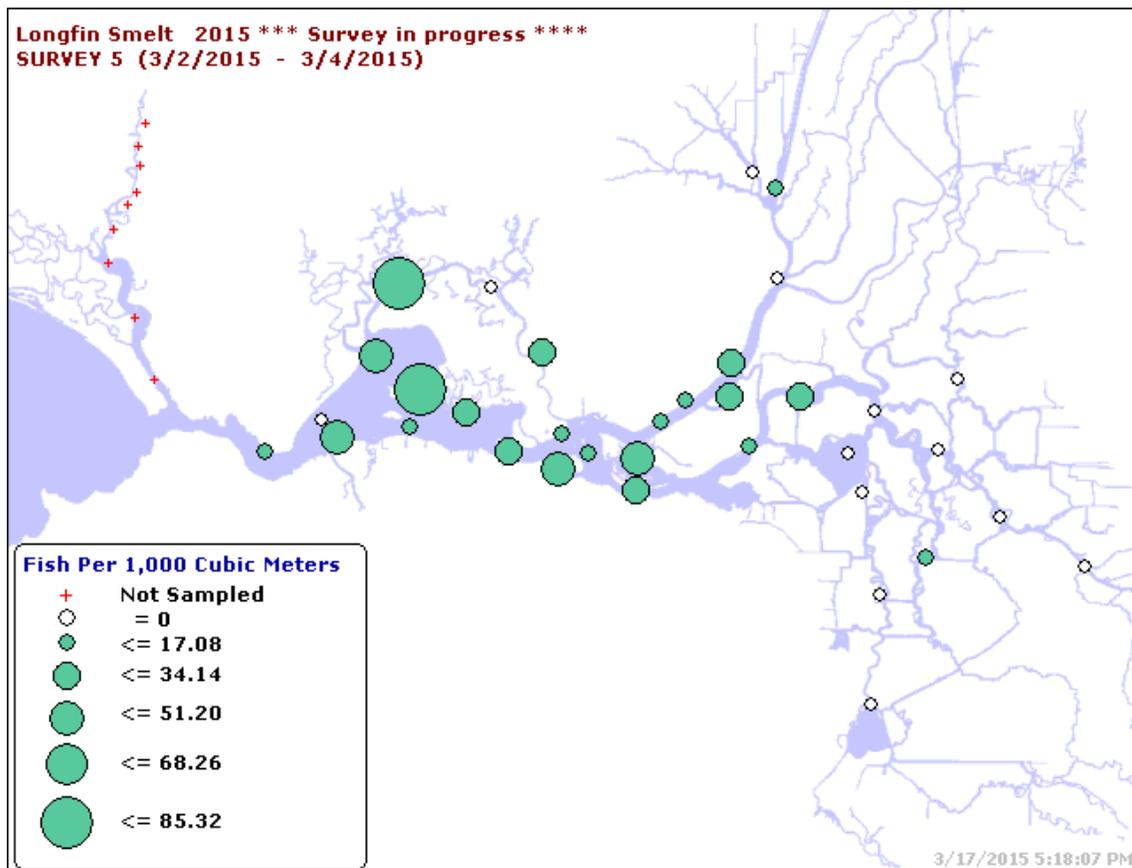

Figure 56. Distribution of larval Longfin Smelt from the Smelt Larva Survey #5 conducted in early March, 2015

It is likely that Longfin Smelt spawning is close to ending. However, the historical presence of recently-hatched larvae in sampling during March and April, indicates that spawning can continue into March (CDFG, 2009). It is possible Longfin Smelt distributed near the confluence may yet make spawning forays into the central and south Delta, which would put them at increased risk of entrainment, although these risks are inherently unquantifiable at this time due to the unprecedented circumstances of continued drought conditions (Table 24).

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

Table 24. Presence of Longfin Smelt During the Project Description Period and Potential Effects, based on the most recently available survey data¹⁷

Longfin Smelt	Life stage Affected	Change in Risk of Lowered Recruitment	Change in Risk of Entrainment at Facilities	Certainty
Eggs	Attached to substrate with very low risk of entrainment			
Larvae	Distribution based on Smelt Larva Survey #5			
~1% South Delta	Yes	Increased	Increased	High

0% San Joaquin River	Not Applicable	Not Applicable	Not Applicable	Moderate
<5% Sacramento River	No	Not Affected	Not Affected	Moderate
95% Confluence, Suisun & SF Bay	No	Not Affected	Not Affected	High

Effect of Proposed Action on Longfin Smelt

To estimate the effect of the proposed decrease in outflow on Longfin Smelt, particle tracking models were run using hydrology from the proposed action and baseline conditions, assuming an equally distributed population between injection points (Figure 29). The modeled conditions of the proposed reduced outflow to 4,000 cfs resulted in small changes in the fate of the majority of particles (at the end of the modeling period) compared to baseline conditions. Under all modeled conditions, particles originating from within the south Delta (injection node Railroad Cut) had the majority of particles arriving at the state and federal pumping facilities by May 31 (Figure 29). Of these particles, 78% were entrained at the pumping facilities as of May 31 under the proposed decrease in flows, compared to 73% under baseline. For particles originating at Prisoner's Point, 11% were entrained at the export facilities versus 5% under baseline conditions. Flux past Chippis for these particles was 17% compared to 40% for baseline conditions. Of the

¹⁷ Distributions are based on monitoring data through March 16.

Attachment 2. Biological Review for Endangered Species Act Compliance with the WY 2015 Drought Contingency Plan April through September Project Description

particles injected at Jersey Point under the proposed action, the percentage that moved past Chipps Island by May 31 was 40% (vs. 68% for baseline conditions) and entrainment at the facilities was 2% (vs. 0% for baseline conditions). For particles seeded in the Sacramento River (station 707) at Three-mile Slough above Decker Island, only 1% were entrained to the export facilities versus 0% under baseline conditions. Flux past Chipps Island for these particles was 45% versus 66% under baseline conditions. As larval Longfin Smelt are distributed in the lower San Joaquin and Sacramento Rivers, the general reduction in flux past Chipps Island negatively affect downstream larval transport. However, the majority of larval Longfin detected in SLS #5 were downstream of Chipps Island, so the population level impacts of this reduced flux may not be substantial. However, it is impossible to quantify whether the differences between baseline conditions and the proposed action are truly biologically significant to the Longfin Smelt populations without knowledge of the size of the population and more detailed knowledge of their distribution. However, a qualitative prediction is possible based on the PTM results and a historical relationship between outflow and Longfin Smelt recruitment.

The proposed action will reduce outflow, and increased outflow is one of the best predictors of Longfin Smelt year class strength (CDFG 2009). Therefore, it is likely the proposed action will exacerbate poor Longfin Smelt recruitment and survival already expected in 2015 due to the severity of the drought. Given the results of the PTM model, it is likely that Longfin Smelt larvae in the San Joaquin River (Prisoner's Point and upstream) and in the south Delta will have a somewhat increased risk of entrainment into the south Delta as part of the Proposed Action, where they are not expected to survive warming water temperatures (Table 24). Longfin Smelt already located in the south Delta, near Frank's Tract and within Old and Middle Rivers will be at high risk of entrainment at the export facilities under both baseline conditions and the proposed action. Larvae in other parts of the San Joaquin River and elsewhere in the Delta will also see an increase, though slight, in export entrainment risk.

Summary of Effects on Longfin Smelt

Like other species, Longfin Smelt are likely to experience poor recruitment this year due to effects of the continuing drought. Low spawning and larval detection rates this year seem to verify these low survival rates. The reduction in outflow due to the proposed action will likely have some negative impact on Longfin spawning and recruitment, though this effect is hard to quantify given the already poor environmental conditions due to the drought. The Proposed Action is unlikely to increase entrainment of Longfin Smelt to the export facilities in any substantive manner, as recent surveys indicate that the majorities of both adult and larval Longfin Smelt are distributed outside the zone of influence of the pumps. However, larval Longfin Smelt that are in the San Joaquin River (near Prisoner's Point), and especially those in the south Delta, will be at elevated risk of entrainment into the facilities.

DWR and Reclamation Request for Modifications of Revised Order that Approved a Temporary Urgency Change in License and Permit Terms and Conditions Requiring Compliance with Delta Water Quality Objectives in Response to Drought Conditions (dated March 5, 2015)

DWR and Reclamation Request for Modifications of Revised Order that Approved a Temporary Urgency Change in License and Permit Terms and Conditions Requiring Compliance with Delta Water Quality Objectives in Response to Drought Conditions (dated March 5, 2015)

Compliance with D-1641 Salinity Standards at Emmaton compared to Threemile Slough

The proposed change of the salinity compliance location from Emmaton to Threemile Slough would have very similar effects in 2015 as compared to 2014. This is because the DSM2 modeling that occurred in 2014 used the same Net Delta Outflow Index (NDOI) assumptions through the compliance season as Reclamation and DWR are requesting this year. Therefore, conclusions drawn from the 2014 request can be applied to 2015 and projected water quality results and flows will be very similar to the 2014 projections. Page 31 of the April 29, 2014 TUCP request describes the modeling assumptions used in the Delta modeling forecasts. In the DSM2 modeling simulations, a dry (90%) forecasted hydrology is used as the starting point for determining the necessary NDOI that will result in compliance with the following D-1641 water quality objectives:

- Emmaton – 2.78 mmhos/cm
Or Three Mile
- San Joaquin at Jersey Point – 2.20 mmhos/cm\
- South Fork at Terminous - 0.54 mmhos/cm
- San Joaquin at San Andreas Landing - 0.87 mmhos/cm
- West Canal at Mouth of CCFB – 1.0 mmhos/cm
- DMC at Tracy Pumping Plant – 1.0 mmhos/cm
- Rock Slough - 1.0 mmhos/cm

The forecasted hydrology is modified by adjusting the Sacramento inflow into the model. Using the minimum cost compliance tool, DSM2 is run, varying Sacramento inflow, until it just meets the salinity objectives while keeping the other inflows, exports, diversions, consumptive use and cross channel operations the same. Once the needed Sacramento flow to achieve the water quality objectives is determined, the NDOI is calculated.

Projected salinity and flow impacts for 2015 will be very similar to the 2014 impacts. The needed Net Delta Outflow for current objectives and for a movement of the Emmaton objective to Three Mile Slough will be the similar given the modeling assumptions for both forecasts. However, the needed 2015 Sacramento flow to meet the Emmaton and Three Mile objectives will be less due to lower projected exports in the summer months. A conservative comparison of salinity at Emmaton and Rio Vista is contained the 2015 Biological Review on pages 71-73, figure 51 and 52.

There may be some minor differences in salinity closer to the exports as there is not as much of a movement of Sacramento River flow upstream into Old and Middle River due to projected lower exports in 2015 (see table below). The upstream flow into Old and Middle Rivers for both 2014 and 2015 forecast will be impacted more by consumptive use in the central and south Delta.

The table below shows differences between 2014 and 2015 forecasted flows.

	2014 Forecast	2015 Forecast
Sacramento River	Adjusted to meet D-1641 Water Quality Objectives	Adjusted to meet D-1641 Water Quality Objectives
San Joaquin River	The 2014 forecast shows a flow of approximately 2000 cfs in April between 500 to 1000 cfs during the summer (p.49 of April 2014 petition)	A 2015 February forecast indicates that San Joaquin forecasted flows are approximately 1000 cfs in April falling to between 500 and 1000 cfs during the summer.
Exports (CVP and SWP)	Exports in the 2014 forecast were forecasted to be around 4000 in April falling to approximately 1500 in the summer months	Exports in the 2015 February forecast are estimated to be closer to 1000 cfs in the summer months.
Delta Cross Channel	D-1641 operation	D-1641 operation
Consumptive Use	Delta Coordinated Operations Model	Delta Coordinated Operations Model

Status of Species

Winter-run Chinook salmon

A small number of winter-run Chinook salmon (*Oncorhynchus tshawytscha*) (n=3,015; 90% CI= 2,741-3,290) returned to spawn in the upper Sacramento River in 2014. Of these 3,105 winter-run Chinook, 388 were collected for broodstock at the Keswick trap. Assuming that 3-year old fish make up the majority of each spawning cohort, returning adults in 2014 were produced by a much smaller spawning escapement in 2011 (i.e., 827 adult spawners). The effects of limited cold water storage and loss of temperature control out of Keswick Dam from early September through the fall of 2014 led to substantial egg and fry mortality (Figure 1). Typically, the peak of fry outmigration from the upper Sacramento River has occurred in early-to-mid October, with fish rearing in the middle reaches of the Sacramento River downstream of Red Bluff Diversion Dam (RBDD). However, in 2014, the winter-run Chinook salmon fry population appeared to start moving downstream past RBDD in September and no noticeable peaks in passage have been observed through the current period (Figures 2 and 3). A one-day emigration pulse event occurred in late October, which was associated with a spike in turbidity; but observation of migrating fry passed RBDD have so far remained extremely low even with large precipitation events in early and mid-December and their associated increases in turbidity and river flows.

Because of staffing issues and concerns about debris during the high flows in December, the rotary screw traps at RBDD were operated for just 8 of 31 days during December 2014¹. While this adds some uncertainty to the 2014 brood year passage estimates, historical patterns suggest that most winter-run Chinook salmon juveniles would have passed RBDD before December. Also, the seasonal passage estimates RBDD do include estimates of passage on non-sampled days based on interpolation. So, while it is possible that some of the higher passage days might not have been sampled and the estimated seasonal passage may be somewhat underestimating actual passage, the current RBDD passage estimate is less than half of the estimated passage for brood year 2011 juveniles, despite an adult escapement nearly four times the escapement observed in 2011.

Few winter-run Chinook salmon juveniles are currently being observed in the upper Sacramento River and the annual population estimates remain lower than expected. As of January 14, 2015, an estimated 402,000 winter-run Chinook salmon juveniles have migrated past RBDD (Gruber 2015). Flows from Keswick Dam were reduced during November for cold water pool conservation (Figure 4), and of 89 potential stranding sites along the Sacramento River from Tehama (Los Molinos) to Keswick Dam (about 70 river miles), only nine completely isolated sites were identified to have winter-run salmon trapped in them (Doug Killam, California

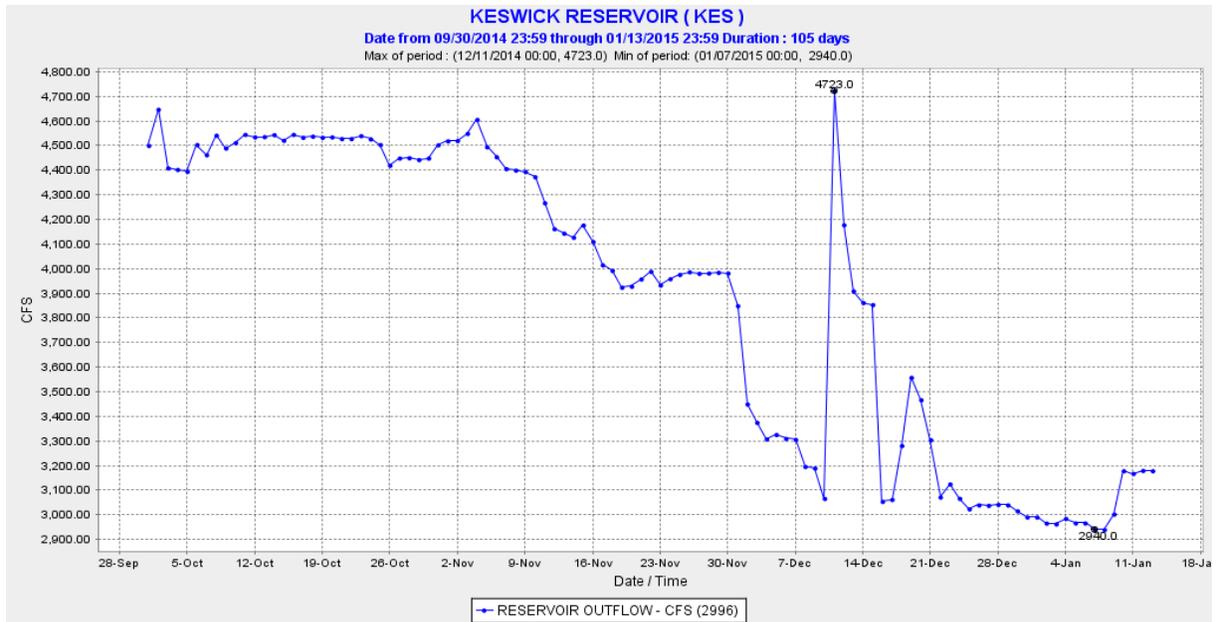

Figure 4. Keswick Reservoir outflow measured at Keswick Reservoir (KES) for water year (WY) 2015.⁵

These observations suggest that brood year (BY) 2014 winter-run Chinook salmon experienced substantial negative effects associated with drought-related environmental conditions. These effects are predicted to include significantly greater temperature mortality during the incubation of eggs and juvenile rearing stages than has previously been observed, truncation of the migration period from natal habitats due to the loss of a substantial proportion of the later portion of the incubating eggs and rearing juveniles, and significant reductions in the expression of a diversity of juvenile life history traits (parr and smolt migrants).

Del Rosario et al. (2013) described multiple pulses of distinctly different-sized juvenile winter-run Chinook salmon typically moving through the Lower Sacramento River past Knights Landing from November to January. These pulses of fish are associated with flow pulses greater than $400\text{m}^3/\text{s}$ (approximately 14,000 cfs) as measured at Wilkins Slough. For juvenile winter-run Chinook salmon BY2014 (through January 20, 2015), observations at Knights Landing and Tisdale Weir rotary screw traps (RST) indicate two migration pulses of juveniles have moved downstream into the Delta. The initial pulse emigrated during a storm event in late October that did not increase river flows on the Sacramento River substantially, but did increase turbidity in the mainstem Sacramento River. The second pulse emigrated during a large storm event in mid-December (Figure 3, Table 1). As a result, it appears that winter-run Chinook salmon juveniles

⁵ Downloaded from CDEC on January 14, 2015.

Salmonid and Green Sturgeon Supporting Information for Endangered Species Act Compliance for Temporary Urgency Change Petition Regarding Delta Water Quality January 27, 2015

emigrated from the upper Sacramento River between mid-October and mid-December, and the majority of the population (>95%) has moved out of the riverine system and entered the Delta.

Based on the 2014 adult winter-run Chinook salmon escapement (3,015 spawners, including 388 collected as hatchery broodstock), NMFS recently estimated a juvenile production estimate (JPE)⁶ for both natural-origin (124,251) and hatchery-produced (188,500) winter-run Chinook salmon entering the Delta during WY 2015. This year's JPE reflects a number of significant changes as a result of recommendations by the (1) Long Term Biological Opinion Independent Review Panel, (2) Interagency Ecological Program Winter-Run Project Work Team, and (3) internal discussions by NMFS with the NMFS-Southwest Fisheries Science Center. While NMFS presented three methods of calculating the JPE—historical NMFS JPE method, Cramer Fish Science (CFS) Model, and the Juvenile Production Index (JPI) from USFWS—NMFS decided that the JPI method was a better fit because both the NMFS JPE and CFS models inaccurately represented the extreme drought conditions and associated early life stage losses due to high temperatures that occurred in 2014 as described previously (Figure 1). On the basis of the JPE, the authorized level of incidental take under the 2009 biological opinion for the Long Term Operations for the combined CVP/SWP Delta pumping facilities from October 1, 2014 through June 30 2015 was set at 2,490 natural (non-clipped, i.e., wild) winter-run Chinook salmon juveniles. The incidental take for hatchery-produced winter-run Chinook salmon juveniles was set at 1,885.

Due to the very low estimated abundances of juvenile winter-run Chinook salmon entering the Delta, observational data from sampling programs could be negatively biased due to rarity of observing winter-run Chinook salmon in the monitoring efforts. Nonetheless, observations from the Delta Juvenile Fish Monitoring Program's beach seining and trawling surveys, and special drought monitoring surveys (i.e., trawling efforts at Jersey and Prisoners Point) to date support the conclusion that winter-run Chinook salmon have migrated downstream and are currently rearing extensively in the Lower Sacramento and Delta survey regions (Table 2). Natural origin winter-run Chinook salmon have been observed weekly in very low densities at the CVP and SWP facilities since December 14, 2014 (combined loss =110, as of January 26, 2015); this also suggests that some juveniles are also present in the south Delta waterways. Finally, few winter-run Chinook salmon juveniles have been observed at Chipps Island suggesting that the majority of the population has not yet migrated to the ocean and is currently rearing in the Delta (Table 2). This broad distribution of juvenile winter-run Chinook salmon across the Delta during the winter

The observations described herein (i.e., RBDD, Tisdale, and Knights Landing RSTs; Delta Juvenile Fish Monitoring Program's beach seining and trawling surveys, and special drought monitoring [i.e., trawling surveys at Jersey and Prisoner's Point]), have been reviewed by the Delta Operation for Salmon and Sturgeon (DOSS) work team to evaluate the distribution of winter-run Chinook salmon juveniles in the Central Valley. Based on the currently available data, DOSS estimates that the majority (>95%) of winter-run Chinook salmon are in the Delta, while <5% either remain upstream of Knights Landing or have already exited the Delta past Chipps Island. This estimate is based on the best professional judgment of the biologists participating on the DOSS work team.

At this time, adult winter-run Chinook salmon are starting to enter the Sacramento River system and have begun to migrate to the upper reaches of the river. These adult winter-run Chinook salmon must hold in the upper Sacramento River between the RBDD and the impassable Keswick Dam until they are ready to spawn during the summer. These fish require cold water holding habitat for several months prior to spawning to allow for maturation of their gonads, and then subsequently require cold water to ensure the proper development of their fertilized eggs, which are highly sensitive to thermal conditions during this embryo development period (i.e., embryogenesis). Adults returning to the river in 2015 are predominantly members of the cohort

⁸ Data updated through January 13, 2015.

Salmonid and Green Sturgeon Supporting Information for Endangered Species Act Compliance for Temporary Urgency Change Petition Regarding Delta Water Quality January 27, 2015

from BY2012 (assuming a 3-year cohort cycle). Based on cohort replacement rate (CRR) estimates, BY2012 had the fifth lowest CRR since 1992.

Spring-run Chinook Salmon

The 2014 spawning run of spring-run Chinook returning to the upper Sacramento River was lower in four of seven locations compared to the 2013 escapement, with considerably lower escapement observed in Butte Creek and Feather River Hatchery (Table 3).

Table 3. Spring run Chinook escapement in 2013 and 2014.

Location	2013	2014	Source
Battle Creek	608	429	Laurie Earley, USFWS
Clear Creek	659	95	
Antelope Creek	0	7	Matt Johnson, DFW
Mill Creek	644	679	
Deer Creek	708	830	
Butte Creek	16783	4815	Clint Garman, DFW
Feather River Hatchery	4294	2825	Penny Crenshaw, DWR

Spring-run Chinook salmon eggs in the Sacramento River underwent significant, and potentially complete, mortality due to high water temperature downstream of Keswick Dam starting in early September when water temperatures downstream of Keswick Dam exceeded 56°Fahrenheit (F) (see water temperatures during September and October in Figure 1). Spawning of spring-run Chinook salmon in the Sacramento River Basin occurs approximately from mid-August through mid-October, peaking in September. This peak in spawning activity corresponded with the high Sacramento River temperatures downstream of Keswick Dam throughout the fall of 2014, and illustrates the potential for high egg and alevin mortality. Spring-run Chinook salmon eggs spawned in the tributaries to the Sacramento River may also have experienced warmer temperatures this year due to low flows through late October, as well as scouring or sedimentation during rain events from late October through December. Extremely few juvenile spring-run Chinook salmon have been observed this year migrating downstream past RBDD (Figure 5) during high winter flows, when spring-run Chinook salmon originating from the upper Sacramento River, Clear Creek, and other northern tributaries are typically observed to outmigrate. While, as noted for winter-run Chinook, the rotary screw traps at RBDD were operated for just 8 of 31 days during December 2014⁹, the low RBDD passage estimates are a concern. A second pulse of juvenile spring-run Chinook salmon typically migrate past RBDD in the springtime (Poytress et al. 2014). However, this second pulse appears to positively bias

⁹ Biweekly reports from RBDD are available at: http://www.fws.gov/redbluff/RBDD%20JSM%20Biweekly/2014/rbdd_jsmp_2014.html

Salmonid and Green Sturgeon Supporting Information for Endangered Species Act Compliance for Temporary Urgency Change Petition Regarding Delta Water Quality January 27, 2015

estimates of spring Chinook passage due to the millions of unmarked fall-run Chinook salmon hatchery production fish falling into the spring-run Chinook salmon category based on the length-at-date run assignments (Poytress et al. 2014).

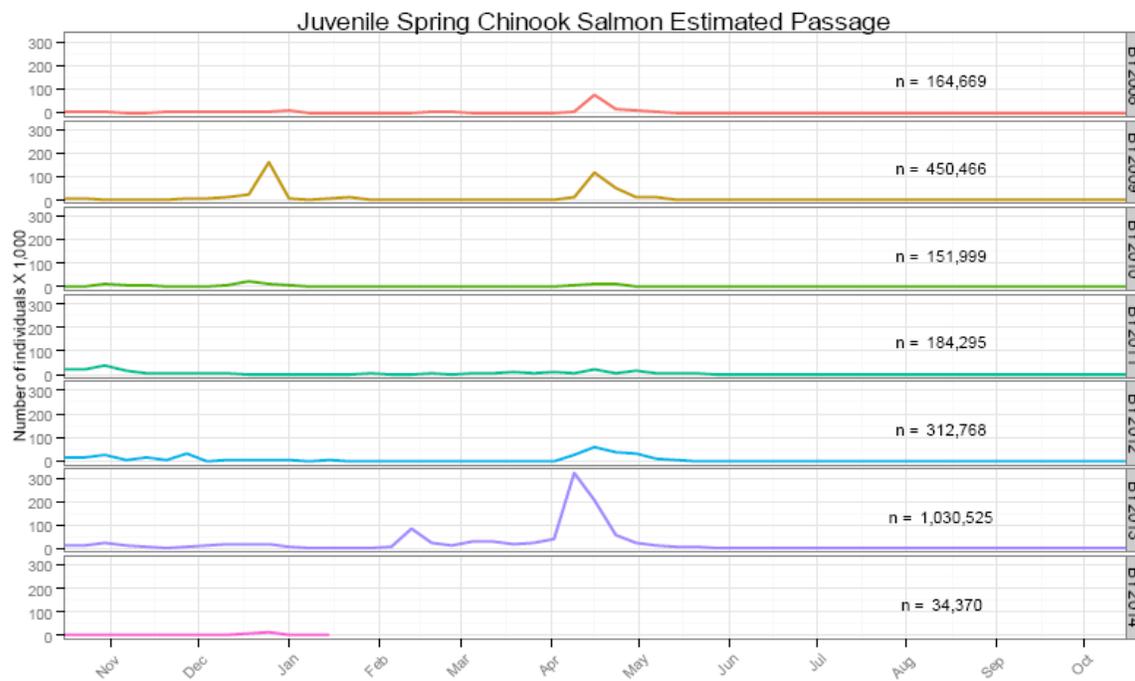

Figure 5. Weekly estimated passage of Juvenile Spring-Run Chinook Salmon at Red Bluff Diversion Dam (RK 391) by brood year (BY).¹⁰

In fall 2014, yearling spring-run Chinook salmon from Mill and Deer creeks experienced flow and temperature conditions typically associated with the outmigration of this life history expression from these tributaries. Although not currently monitored with RSTs, these tributaries have experienced flows (Figure 6-7) exceeding “First Alert” thresholds identified in the NMFS BiOp Action IV.1.2. Recent analyses of multiple years of RST data have determined that 99% of outmigrating yearlings are captured at flows greater than 95 cfs (Kevin Reece, DWR, pers. comm.). Based on the currently available data, DOSS estimates that the majority (80-90%) of yearling spring-run Chinook salmon are in the Delta, while <5% remain upstream of Knights Landing and <15% have already exited the Delta past Chipps Island. This estimate is based on the best professional judgment of the biologists participating on the DOSS work team.

Spring-run young-of-the-year (YOY) sized Chinook salmon juveniles have been observed at the Tisdale Weir and Knights Landing RSTs since early December, 2014 (Table 1). Likewise,

¹⁰ Fish were sampled using rotary-screw traps for the period July 1, 2008 to present. Figure supplied by USFWS on January 15, 2015.

Salmonid and Green Sturgeon Supporting Information for Endangered Species Act Compliance for Temporary Urgency Change Petition Regarding Delta Water Quality January 27, 2015

juvenile YOY spring-run Chinook have been observed in the catch from multiple Delta beach seine regions, and in the standard trawling and special drought monitoring trawling surveys, including those in the Central Delta. However, as of January 18, 2015, neither yearling nor YOY spring-run Chinook salmon have been observed at the state and federal fish collection facilities in the South Delta. Based on the currently available data, DOSS estimates up to half (25-50%) of YOY spring-run Chinook salmon are in the Delta, while 50-75% remain upstream of Knights Landing and <5% have already exited the Delta past Chipps Island. This estimate is based on the best professional judgment of the biologists participating on the DOSS work team.

Steelhead

California Central Valley steelhead (*Oncorhynchus mykiss*) smolts are seldom recovered in Sacramento River and Delta fish monitoring efforts due to sampling biases related to their larger size and enhanced swimming ability. False negatives (*i.e.*, zero catches when the target species is present) are more likely with steelhead smolts than smaller older juvenile Chinook salmon, but historic data can be assessed to consider their typical periodicity in Delta monitoring efforts. Between 1998 and 2011, temporal observations of wild steelhead juveniles (n=2,137) collected in Delta monitoring efforts occurred less than 10% of the time in January, >30% of the time during February, and >20% of the time during March.

Observed patterns of outmigrating *O. mykiss* from BY2014 at RBDD appear most similar to that of BY2011 (Figure 8); however, there was no peak migration observed in the typical August/September period. For WY2015 (as of January 12, 2015), five unmarked (two on 10/15/2014; and three between 1/7/2015 and 1/11/2015) and 828 marked steelhead (1/7/2015 to 1/12/2015) were captured at the GCID RST. The latter marked fish likely originated from a Coleman release of 688,000 brood year 2014 steelhead (100% marked with adipose clip only) in the Sacramento River at Bend Bridge (fish released in two groups: 144,700 on January 2, 2015, and 543,300 on January 5-9, 2015). For WY2015 (as of January 23, 2015), three unmarked (two captured between 1/5/2015 and 1/8/2015, and one on 12/22/2014) and 11 marked steelhead (first on 11/8/2014, 10 since 1/12/2015) were observed at the Tisdale Weir RST; and 12 clipped steelhead were captured at Knights Landing RST as of 1/22/2015.

¹² Downloaded from CDEC on January 14, 2015.

Salmonid and Green Sturgeon Supporting Information for Endangered Species Act Compliance for Temporary Urgency Change Petition Regarding Delta Water Quality January 27, 2015

For WY2015 (as of January 23, 2015), one steelhead (acoustic tagged) was observed in the Sacramento beach seine monitoring at Miller Park (300mm fish on 12/8/2014); one clipped steelhead was observed at Sherwood Harbor on 1/23/2015, but not at any of the other trawl locations (i.e, Chipps Island Trawl, Mossdale Trawl, or Jersey Point/Prisoner's Point Trawl); and three steelhead were observed at the SWP (one unmarked on 11/16/2014 for a total salvage of 4, two clipped: one each on 1/23/15 and 1/25/15 for a total salvage of 8) and none at the CVP fish collection facilities at the South Delta CVP/SWP export pumps.

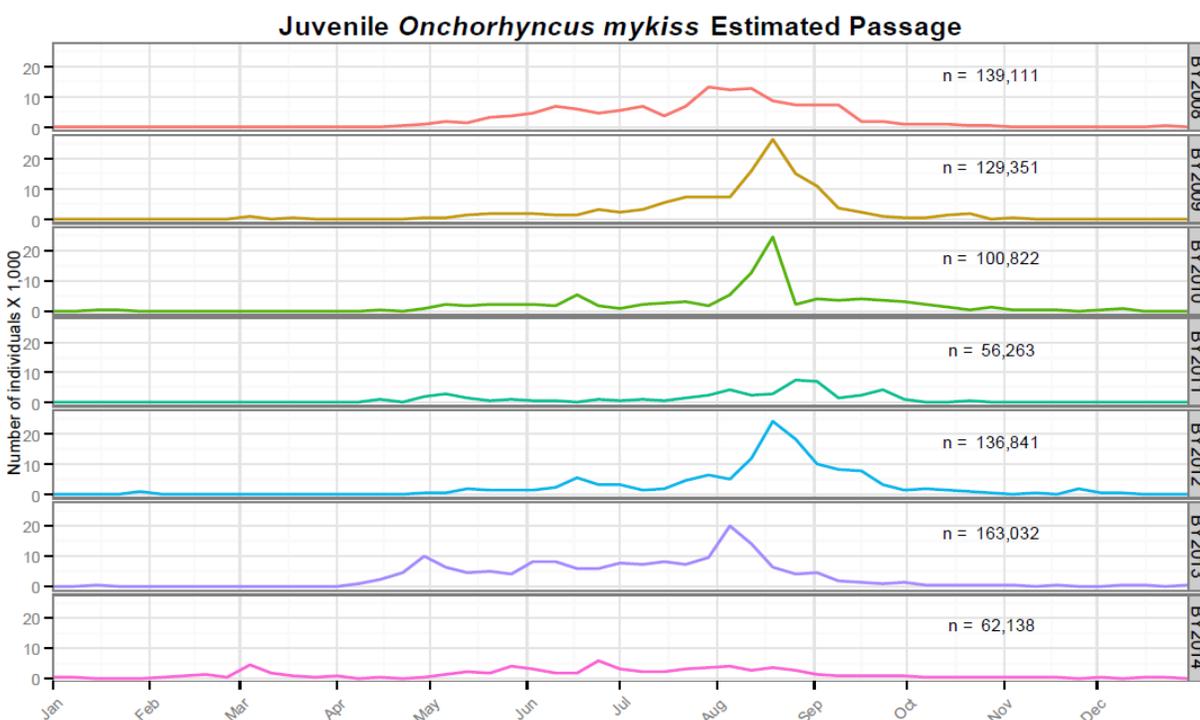

Figure 8. Weekly estimated passage of *O. mykiss* at Red Bluff Diversion Dam (RK 391) by brood year (BY).¹³

Green Sturgeon

Information on green sturgeon is extremely limited. Adult green sturgeon will migrate into the upper Sacramento River through the Delta between March and June. Spawning in the upper Sacramento River was documented during 2014. A review of telemetric data found 26 tagged green sturgeon entered the San Francisco Bay with only half migrating upstream of RBDD (M. Thomas, UC Davis, pers. comm.). Adult green sturgeon have been observed to overwinter in the Sacramento River, and a number of the tagged 2014 adults still appear to be present in the upper Sacramento River as of January 14, 2015 (R. Chase, Reclamation, pers. comm.). Larval green

¹³ Fish were sampled using rotary-screw traps for the period July 1, 2008 to present. Figure supplied by USFWS on January 15, 2015.

Salmonid and Green Sturgeon Supporting Information for Endangered Species Act Compliance for Temporary Urgency Change Petition Regarding Delta Water Quality January 27, 2015

sturgeon were observed at RBDD (n=319). This was greater than the long-term average of 186 fishes (Figure 9). At RBDD, two juvenile green sturgeon were also observed in the fall of 2014.

At GCID, ten juvenile green sturgeon (TL= 110-285) were observed from September 2014 to January 19, 2015. Green sturgeon observations are extremely rare in the Delta primarily related to the use of monitoring gear types that are not designed to sample the benthic habitats where green sturgeon are most likely to be found if they are present. Although the lower Sacramento and Delta fish monitoring surveys do not target benthic environments they have captured juvenile green sturgeon in the past, but no sturgeon have been observed in those surveys in recent years. Likewise, green sturgeon have not been observed at the state and federal fish collection facilities in the South Delta in recent years. In 2011 more than 3,000 juvenile green sturgeons were captured in the RSTs at RBDD, however no green sturgeon were observed in any of this years' river, Delta, or Bay fish monitoring surveys.

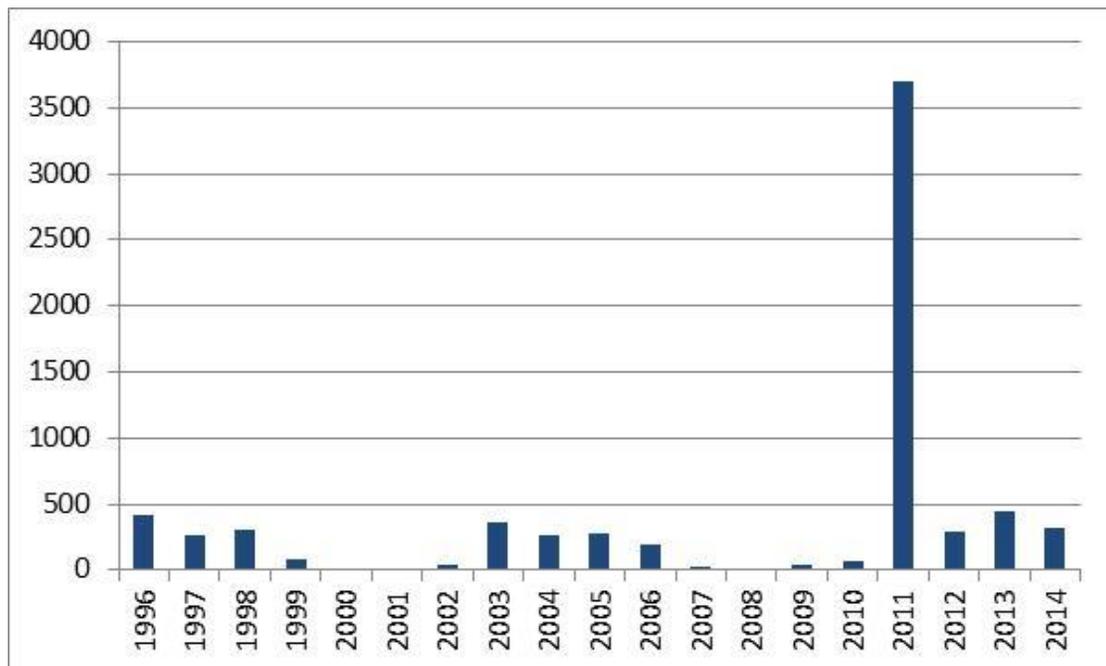

Figure 9. Larval Green sturgeon counted at Red Bluff Diversion Dam rotary screw traps.¹⁴

¹⁴ The annual average catch is 426 fish. In 2011, an egg was observed directly upstream of the rotary traps; thus, the large number of fish in 2011 represents a unique sampling of a spawning event (Josh Gruber, USFWS, pers comm.). If 2011 data is removed, the annual average of juvenile green sturgeon counted is 183 fishes.

Proposed Action

See Project Description for February – March 2015 Drought Response Actions provided to support Endangered Species Act consultation (Reclamation 2015).

Analytical Framework

Methods and Metrics

A conceptual model for impacts from drought management actions was developed as part of an interagency assessment of the WY2014 drought on winter-run Chinook salmon. The conceptual model describes freshwater behavioral responses to indicators of environmental conditions (e.g., outflow, inflow, Delta Cross Channel [DCC] gates, and exports) that are expected to be affected by the Petition’s Project Description. The NMFS BiOp (2009) was reviewed regarding biological linkage to these various actions.

This conceptual model was modified to provide a qualitative assessment of effects predicted to be linked to the four elements of this WY 2015 February and March Project Description: (1) modification to D-1641 Net Delta Outflow Index (NDOI), (2) modification to D-1641 export limits, (3) modification to the D-1641 DCC gate operation, and (4) modification of D-1641 San Joaquin River flow standard. This model highlights the biological linkages between drought management actions in the project description with predictions that can be assessed from the literature and modeling completed (Figure 10). Although OMR modifications are not proposed in the Project Description, they may be incorporated into a Temporary Urgency Change Petition (TUCP) request at a later date.

Figure 10. Conceptual model of drought contingency plan elements and their biological linkage to salmonids and assessment information available for evaluation.

Salmonid and Green Sturgeon Supporting Information for Endangered Species Act Compliance for Temporary Urgency Change Petition Regarding Delta Water Quality January 27, 2015

To evaluate February and March impacts to listed species due to Delta hydrodynamics caused by the proposed action's changes in outflow and exports, Delta Simulation Model II (DSM2) simulations were performed and evaluated for three different regulatory and operational management decision scenarios (Table 4). It is likely that actual conditions will differ somewhat from the modeled scenarios. Recent meteorological patterns appear to show a decoupled Sacramento and San Joaquin Valley storm pattern (with more rain falling in the Sacramento River basin), and if this continues, it is possible that actual Sacramento River outflow at Freeport could reach the modeled quantities, while actual San Joaquin outflow would not. In particular, if San Joaquin River flows at Vernalis remain low (<850 cfs) and pumping is increased as outflow is greater than 7,100 cfs, there may be a greater impact to San Joaquin fish than indicated in the results of the modeled scenarios. This increases the uncertainty of assessments of impacts to San Joaquin River steelhead.

Table 4. DSM2 regulatory and operational scenarios for February and March 2015 developed for biological review.

Scenario Name	Outflow (cfs)	Freeport flow (cfs)	Vernalis flow (cfs)	Combined Exports (cfs)	OMR (cfs)
4,000 Outflow	4,000	5,600	500	1,500	-1,400
5,500 Outflow	5,500	9,100	500	3,500	-3,200
99% Mod	7,100	11,700	850	6,000	-5,000
90% Least	11,400	15,300	1,400	6,400	-5,000

DSM2 modeling outputs for each scenario were used to evaluate the distribution of 15-minute flow and velocity values for multiple channels including:

- Upstream of Head of Old River (Channel 6)
- Downstream of Head of Old River (Channel 9)
- Upstream of Stockton Deepwater Shipping Channel (Channel 12)
- Downstream of Stockton Deepwater Shipping Channel (Channel 21)
- Turner Cut (Channel 173)
- Columbia Cut (Channel 160)
- Downstream of Head of Old River (Channel 54)
- Grant Line Canal (Channel 81)
- Old River at San Joaquin River (Channel 124)
- Jersey Point on San Joaquin River (Channel 49)
- Sherman Island on Sacramento River (Channel 434)
- Three Mile Slough near San Joaquin River (Channel 310)
- Sherman Island on San Joaquin River (Channel 50)

Salmonid and Green Sturgeon Supporting Information for Endangered Species Act Compliance for Temporary Urgency Change Petition Regarding Delta Water Quality January 27, 2015

- Sacramento River upstream of Delta Cross Channel (Channel 421)
- Sacramento River upstream of Georgiana Slough (Channel 422)
- Sacramento river downstream of Georgiana Slough (Channel 423)
- Sacramento River near Cache Slough (Channel 429)

Hydrodynamic metrics, such as daily proportion positive velocity and daily mean velocity, were used to assess changes in the Delta at these locations. Daily proportion positive velocity is the percentage of the day that river flows have a positive velocity value (flows in downstream direction). Daily mean velocity is the average of all velocities values summed over the 24 hour period which takes into account the effects of tidal stage on velocity magnitudes. Distributions of these hydrodynamic metrics under the different outflow and export ranges for each scenario were also examined to qualitatively describe comparisons between different operational conditions likely to occur under the Project Description.

We discuss effects within the Delta during February and March using currently available species distribution and abundance data along with expected upcoming life stage periodicity information. To evaluate impacts to listed species due to Delta outflow changes, DCC gate configuration, and Delta hydrodynamics caused by the proposed February – March 2015 drought response actions, relevant peer-reviewed literature on these factors and fish biology, behavior, and survival are reported. Results from these sources were used to describe modified operation of the DCC gates on reach-specific and through Delta survival.

Effects Analysis

January Forecasts

Current storage in Shasta and Folsom reservoirs is greater than in January 2014, yet remains low compared to long term historical conditions. Storage in Trinity, Oroville, and New Melones reservoirs remains lower than January 2014 storage levels in these reservoirs. CVP/SWP operators and fishery agencies have been attempting since fall 2014 to conserve cold water pools system-wide in these reservoirs for listed species' summer temperature and habitat requirements. The January 50%, 90%, and 99% exceedance forecasts for WY 2015 projects reservoir volumes throughout spring and summer operations that are below their historic averages for those months (Tables 5 -7). Actual January 2014 Delta conditions are between the 90% and 99% exceedance forecasts (Table 8).

End-of-April (EOA) storages, representing the end of the reservoir storage conservation period, are projected to be between approximately 3,030 TAF (90% forecast) and 4,140 TAF (50% forecast) in Shasta Reservoir. Although there remains a significant range of possible temperature management outcomes for the Sacramento River, neither forecast allows for targeting the furthest downstream temperature compliance point target of 56°F between April and September

Salmonid and Green Sturgeon Supporting Information for Endangered Species Act Compliance for Temporary Urgency Change Petition Regarding Delta Water Quality January 27, 2015

at Bend Bridge. Additionally, if the 90% forecast is realized, maximum Shasta Reservoir elevation would limit the flexibility of the Shasta Temperature Compliance Device to only the Middle, Lower, and Side gates, which is similar to temperature control condition in WY2014. Furthermore, the considerable precipitation that would be necessary to attain a 50% forecasted EOA Shasta Reservoir storage appears highly unlikely since recent meteorology has reflected less precipitation than was anticipated under even the 90% forecast.

These factors are reasonably likely to result in extremely high egg mortality or even complete failure of natural brood year 2015 spring-run Chinook and winter-run Chinook below Keswick due to water temperature exceedances above critical thresholds. Relaxation of Delta outflow standards and Vernalis flow standards, while still continuing to meet required tributary releases from Oroville, Folsom, and New Melones (Reclamation 2015), will enhance the opportunities for summertime cold water management across CVP/SWP operated reservoirs in WY2015.

Salmonid and Green Sturgeon Supporting Information for Endangered Species Act Compliance for Temporary Urgency Change Petition Regarding Delta Water Quality January 27, 2015

During February and March a continuation of Keswick minimal releases at the levels identified in the TUC Petition is hypothesized to increase the time needed for Chinook and steelhead smolts to emigrate down the Sacramento River, which will result in reduced outmigration survival (Singer et al 2013) and a reduced smoltification window (McCormick et al 1998). In contrast, any predicted increases in reservoir storage that may be realized by operating to the TUC Petition's outflow range will be critical to any measures to maintain water temperatures necessary for the biological needs of winter-run Chinook, spring-run Chinook, steelhead, and green sturgeon downstream of these reservoirs over the summer and fall of 2015. It should be noted that these January forecasts include later upstream impacts to BY 2015 fishes, including redd dewatering. Thus, this reduced outflow range in February and March is a proactive approach by Reclamation and DWR to immediately implement appropriate contingency measures that may benefit BY 2015 cold water listed species, as required in NMFS BiOp Action I.2.3.C.

Net Delta Outflow Index Modification

Although the NMFS BiOp (2009) does not contain NDOI standards, it did assume NDOI standards would be met. Based on the conceptual model, the reduction in outflow, as identified in the Petition's Project Description, may impact juvenile salmonids migrating through the North Delta between Sacramento and Rio Vista, where Sacramento River flows meet the tidally dominated western Delta. Currently, the greatest presence of salmonids in the Delta has been detected in the Lower Sacramento River and North Delta regions (DOSS 2015). The proposed reduction in minimum Delta outflow from a monthly average of 7,100 cfs to 4,000 cfs is lower than those under minimum standards to meet the D-1641 NDOI standards in February and March. This proposed reduction may reduce survival of juvenile salmonids migrating through the Lower Sacramento River and North Delta by increasing rates of predation mediated by hydrodynamic mechanisms (i.e. transit times, turbidity). However, once migrating fish reach the tidally-dominated regions in the western Delta (i.e. Rio Vista towards Chipps Island), South Delta, or Central Delta under the Petition's NDOI outflow threshold (4,000 cfs), they are likely to encounter a daily proportion of positive velocities and a mean velocity that are not substantially different from outflow conditions observed when a 7,100 cfs NDOI standard is being achieved (Table 9, Figures 11-12). This is due to the greater influence tides have in these

regions under low Delta inflows. There is high certainty in our understanding of how hydrodynamics are affected in these regions by the Petition's Project Description.

In the North Delta, DSM2 modeling between 7,100 and 4,000 NDOI levels demonstrate a decrease in outflow, which will impact the Delta hydrodynamics in two ways that will influence Salmonid migration speed and patterns. These hydrodynamic processes influence survival by changing juvenile salmonids exposure to predators in the Lower Sacramento River and other relevant reaches (i.e. Georgiana Slough, Delta Cross Channel, Sutter and Steamboat sloughs). First, reduced outflow may increase tidal excursion in the upstream direction over a greater spatial range (reduced daily proportion of positive velocities) into the Lower Sacramento River region. These increased upstream tidal excursions appear to increase the duration of reverse flows into Georgiana Slough and/or an open DCC gates (Table 9), which likely increases entrainment into these waterways. Survival rate in the main stem Sacramento River or in one of the multiple distributary channels is decreased due to the longer duration of the downstream emigration phase resulting from reduced flows as compared to periods of greater downstream flows (greater NDOI). Also, the increased tidal excursion may increase entrainment into Sutter and Steamboat sloughs by creating greater probability of flow convergence at these junctions. However, due to the lower flows the time needed to migrate downstream through these two migratory corridors is also expected to increase, resulting in diminished survival compared to higher flows. There is high certainty in our understanding of the biological processes affected by reduced outflow along the Sacramento River salmonid migration corridor.

Second, DSM2 results show reduced NDOI will cause the daily mean channel velocity along the Sacramento River and North Delta to be less positive even at channels along the Sacramento River at Sherman Island and near Cache Slough (Figure 12). When the DCC gates are open, the daily mean channel velocity becomes even less positive in these reaches. Reducing outflow likely causes a decrease in the daily proportion of positive velocities through the Sacramento River downstream of Sutter and Steamboat sloughs confluences with the Sacramento River. A review of a similar NDOI modification (Reclamation 2014a) indicated that the impacts of reduced NDOI on the proportion of daily positive flows and mean daily velocities propagate up to Sutter and Steamboat Sloughs, although this effect was not modeled for this Petition. Additionally, Georgiana Slough flows become less positive as tidal excursion causes flow reversals in this channel when outflow is reduced. When the DCC gates are open, the daily proportion of positive velocities further decreases in the Sacramento River upstream of the DCC gates and more noticeably between the DCC gate and Georgiana slough. When the DCC is open, there is a reduction in the daily proportion of positive flows through Georgiana Slough. There is high certainty in our understanding of how hydrodynamics is affected in these regions by the Petition's Project Description.

Decreased daily proportion of positive velocities and daily mean channel velocities, due to the Petition's reduced outflow range, will increase migrating salmonids' residence time in the North

Salmonid and Green Sturgeon Supporting Information for Endangered Species Act Compliance for Temporary Urgency Change Petition Regarding Delta Water Quality January 27, 2015

Delta, which likely exposes them to increased predation and mortality rates. There are no models to quantify the increase in mortality rates due to reduced flows in this reach, however comparisons may be made. The DCC's capacity is 3500cfs, which is in range of the Petition's change to the outflow standard. Two telemetry studies reported on changes in reach-specific survival when the DCC was open and closed, which provide a comparison for survival through the North Delta reach and downstream when this quantity of daily flow is removed from the channel. The average difference in survival rates for salmonids through the North Delta from Sutter and Steamboat sloughs to Rio Vista when the DCC was open (n=7, survival ranged from 0.012-0.306) versus closed (n=3, survival ranged from 0.099-0.233) was 3.4% (Table 2 in Romine et al. 2013). Perry et al. (2010) had a single measurement of survival in this reach when the DCC gates were open vs. closed and the difference was 12.1%. Reach-specific survival showed large variations within and between studies, and factors other than travel time and flow are suggested to have contributed to variations in survival estimates including environmental conditions and temporal shifts in predators (Perry et al. 2010) and tag failure (Romine et al. 2013). A previous study of steelhead (Singer et al. 2013) did not demonstrate interior routes to have the lowest survival. In that study, steelhead smolt survival was estimated to be higher through the eastern Delta route (i.e. Georgiana Slough, Mokelumne River, and San Joaquin River routes) than the western Delta route (Sutter and Steamboat sloughs) in one of two years studied, although survival was highest along the Sacramento River mainstem route in both years. There is moderate certainty in our understanding of the survival processes affected by flow associated with the DCC and Georgiana Slough migration routes.

BY2015 adult winter-run Chinook salmon may be affected by the Petition's proposed reduction in outflow, which would reduce detectable flow signal for upriver migration and may lead to longer transit times and increased predation mortality. Juveniles and sub-adult green sturgeon rearing and utilizing the Delta are not expected to be affected by the change in inflows to the Delta during February and March. Adult green sturgeon will be present in the Delta during the month of February, and are expected to migrate through the North Delta starting in March. Over the course of juvenile rearing in the Delta (1 to 3 years) the fish are exposed to a wide variety of flows, depending on where they happen to be at a particular moment. In most of the Delta where green sturgeon are expected to be rearing, flows are tidally dominated. There is low certainty in our understanding of the adult salmonid and green sturgeon biological processes affected by flow in the Delta.

Modification of Export Limits

Action IV.2.3 in the 2009 NMFS BiOp specifies fish loss density, daily older juvenile Chinook salmon and wild steelhead loss, and loss of surrogate hatchery releases of winter-run and late-fall run Chinook salmon as triggers to reduce the vulnerability of emigrating ESA-listed salmon and steelhead to entrainment into South Delta channels and at the pumps between January 1 and June 15. A calendar-based requirement, starting on January 1, is for the 14-day OMR average flow to be no more negative than -5,000cfs. Under the Petition's Project Description, these triggers will

Salmonid and Green Sturgeon Supporting Information for Endangered Species Act Compliance for Temporary Urgency Change Petition Regarding Delta Water Quality January 27, 2015

continue to be used to manage such that the 5-day net average OMR flow is not more negative than a calculated -3,500 or -2,500cfs OMR flow until fish densities return below levels of concern.

During February and March, juvenile and adult salmonids may experience South Delta hydrodynamic conditions under the Petition's Project Description that could result in greater export rates than were observed with modified NDOI targets during similar periods in WY2014. These modified export limits (subject to a 35% Export/Inflow standard per D-1641¹⁷) may occur when NDOI is less than 7,100 cfs but greater than 5,500 cfs. These export limits allow for combined pumping of 1,500 cfs when NDOI is less than 5,500 cfs. Old and Middle River conditions under these inflow and export management scenarios are predicted to be approximately -3,200 to -1,400 cfs. If precipitation events occur that enable Reclamation to comply with D-1641 standards and DCC gate closure requirements, then export levels may increase at the CVP/SWP. OMR management per NMFS BiOp Action IV.2.3 will continue to use fish loss density, daily loss, and loss of specific hatchery releases of late-fall and Winter-run Chinook salmon as triggers to reduce the vulnerability of emigrating ESA-listed salmon, steelhead, and green sturgeon to entrainment into South Delta channels and at the pumps between February 1 and March 30. Daily flows in Old and Middle River averaged approximately -4,885 cfs in December, 2014 and approximately -4140 cfs in January 2015 (through January 22) (Figure 13).

When comparing the Petition's Project Description's modeled conditions when NDOI is 4,000 cfs and OMR is -1,400 cfs to conditions when NDOI is 7,100 and OMR is -5,000 cfs, the majority of modeled channels in the South and Central Delta regions show no change in the mean daily proportion positive velocities under the lower NDOI. The only observed change in the metrics evaluated between these runs occurred at Columbia Cut, where with the NDOI of 4,000 cfs and OMR at -1,400 cfs, the daily average velocity becomes positive (0.01), instead of remaining negative (-0.01) similar to observed when NDOI is modeled at 7,100 cfs (0.02). The intermediate modeling with NDOI of 5,500 cfs and exports of 3,500 predicted similar conditions in the South and Central Delta regions compared to the model run with NDOI of 7,100 cfs and an OMR value of -5,000 cfs. These modeling results suggest that daily proportion of positive velocities may be quite balanced (i.e. similar frequencies of positive and negative velocities) rather than more riverine (i.e. predominantly positive velocities) at the intermediate or low NDOI condition in these regions and achieve similar tidal hydrodynamics throughout the San Joaquin River and South Delta.

¹⁷ As in WY 2014, the E/I standard will be implemented using the inflow averaging period (3-day or 14-day) that allows the greatest exports.

Salmonid and Green Sturgeon Supporting Information for Endangered Species Act Compliance for Temporary Urgency Change Petition Regarding Delta Water Quality January 27, 2015

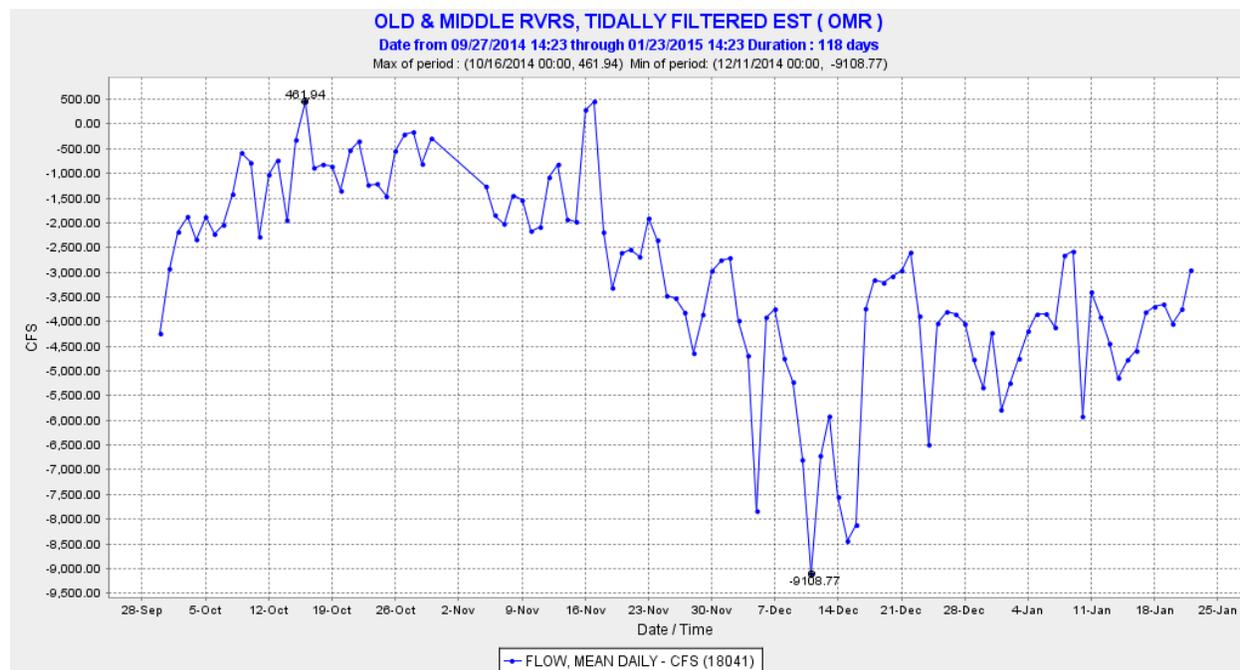

Figure 13. Old and Middle Rivers tidally-filtered daily flows (cubic feet per second) measured at Old & Middle Rivers (OMR) for WY 2015.¹⁸

The conditions may increase transit rates for salmonids, reduce dispersion of tributary turbidity input, and provide stable conditions for non-native vegetation supporting predaceous fish species, which cumulatively reduces survival rates of juvenile salmonids along the San Joaquin River migration corridor and in the South Delta region. There is low certainty in our understanding of the biological and environmental processes affected by NDOI and exports along the San Joaquin River salmonid migration corridor.

The mean daily proportion positive velocities become less frequently positive in the NDOI 5,500 cfs model than in the NDOI 4,000 cfs model run in Grant Line Canal due to higher pumping and increased San Joaquin flow reaching the facilities without increased San Joaquin River flow at Vernalis. Reduced Vernalis flows in the NDOI 4,000 cfs and NDOI 5,100 cfs models shows the same reduction in mean daily proportion positive velocities upstream of Head of Old River due to similarly modeled San Joaquin River flows at Vernalis. Under greater exports when the NDOI is 7,100 cfs and OMRs are -5,000 cfs, South Delta locations proximal to the facilities (Grant Line Canal) show greater proportions of mean daily proportion positive velocities than when NDOI was modeled at 4,000 cfs and OMRs are 1,400 cfs. This would indicate that the effect of greater exports increases the mean daily proportion of positive velocities towards the facilities in these channels. Greater positive velocities may support outmigration through the Delta; however it may increase salvage and loss of salmonids in the South Delta region if these flows are towards the facilities it may increase facility salvage and loss of salmonids. This is particularly

¹⁸ Downloaded from CDEC on January 23, 2015.

Salmonid and Green Sturgeon Supporting Information for Endangered Species Act Compliance for Temporary Urgency Change Petition Regarding Delta Water Quality January 27, 2015

the case for San Joaquin River steelhead entering the South Delta through Old River. There is moderate certainty in our understanding of the biological processes affected by exports in South Delta salmonid migration corridors and fish collection facilities at the CVP/SWP pumps.

Impacts to juvenile and subadult life stages of green sturgeon are anticipated to remain minimal. Age 1 to 3 green sturgeon are expected to be rearing in the Delta, and are typically exposed to a broad spectrum of flows over the course of the year during this life history phase and freely move throughout the Delta to find suitable conditions for their needs. There is low certainty in our understanding of the biological processes in green sturgeon affected by exports in the South Delta region and fish collection facilities at the CVP/SWP pumps.

Delta Cross Channel Gate Modification

The 2009 BiOp (NMFS 2009) and D-1641 include a calendar-based closure of the DCC Gates between February 1 and May 20 to protect winter-run, spring-run, and fall-run Chinook salmon and steelhead from entrainment into the Interior Delta. Studies have shown that the mortality rate of the fish entrained into the DCC and subsequently into the Mokelumne River system is higher than for fish that remain in the mainstem corridor (Perry and Skalski 2008; Vogel 2004, 2008). Closure of the DCC gates during periods of salmon emigration eliminates the potential for entrainment into the DCC and the Mokelumne River system with its high mortality rates. In addition, closure of the gates appears to redirect the migratory paths of emigrating fish into channels with relatively less mortality (*e.g.*, Sutter and Steamboat sloughs), due to a redistribution of river flows among the channels. The overall effect is an increase in the apparent survival rate of these salmon populations as they move through the Delta. There is high certainty in our understanding of the biological processes in salmonids affected by DCC gate operations.

A series of studies conducted by Reclamation and U.S. Geological Survey (USGS, Horn and Blake 2004) used acoustic tracking of released juvenile Chinook salmon to follow their movements in the vicinity of the DCC under different flows and tidal conditions. The study results indicate that the behavior of the Chinook salmon juveniles increased their exposure to entrainment through both the DCC and Georgiana Slough. Horizontal positioning along the east bank of the Sacramento River during both the flood and ebb tidal conditions enhanced the probability of entrainment into the two channels. Upstream movement of fish with the flood tide demonstrated that fish could pass the channel mouths on an ebb tide and still be entrained on the subsequent flood tide cycle. In addition, diel movement of fish vertically in the water column exposed more fish at night (~70%) to entrainment into the DCC than during the day (~30%; Jon Burau, pers. comm.). Perry et al. (2010) included two releases of acoustically-tagged late fall-run Chinook salmon to evaluate the impact of DCC gate opening of reach specific and total Delta survival. Mainstem survival downstream of the DCC gate was lower when they were open (0.443) than when the closed (0.564). During 2008-2009, ten releases of juvenile late fall run Chinook salmon were made by USGS (Romine et al. 2013, Table 10) and through Delta survival was greater when the DCC gates were closed (0.170) than when they were open (0.123). These

Salmonid and Green Sturgeon Supporting Information for Endangered Species Act Compliance for Temporary Urgency Change Petition Regarding Delta Water Quality January 27, 2015

values are negatively biased due to tag failure (Romine et al. 2013). Perry et al. (2010) observed through-Delta survival to be greater with the DCC closed (0.543) than open (0.351), principally due to increased survival through the Sutter and Steamboat sloughs route from 0.263 to 0.561. In addition to the Petition's effects on emigrating juvenile salmonids, the Petition's opening of the DCC may increase straying of returning winter-run Chinook adult salmon on the Sacramento River mainstem by diverting a portion of the Sacramento River flows through the forks of the Mokelumne River and Central Delta. This will lead to false attraction and hence straying into these waterways.

Table 10. Average Values for Releases Described in Romine et al. (2013). Seven releases occurred with DCC open and three releases occurred with it closed.¹⁹

DCC Position	S_A	S_B	S_C	S_D	Ψ_A	Ψ_B	Ψ_C	Ψ_D	S_{TOTAL}
Open	0.143	0.1	0.098	0.159	0.486	0.267	0.064	0.182	0.123
Closed	0.177	0.205	-	0.102	0.521	0.276	-	0.202	0.17

During the fall and early winter when juvenile listed salmonids are not typically present in the Lower Sacramento River and Delta, action triggers in the Chinook salmon Decision Tree use fish monitoring catch indices from Knights Landing and Sacramento River to detect substantial winter-run Chinook migration into the lower Sacramento River. Catch index exceedance values were based on analyses of historic screw trap, beach seine, and trawl data (Chappell 2004). Historic analyses (Chappell 2004) modified the "critical trigger" and duration of DCC gate closure in the Chinook Salmon Decision Tree. Multiple exceedance levels were identified to modify DCC operations in a manner that reduces risks due to the elevated presence of spring-run and winter-run Chinook salmon upstream of the Delta. The Knights Landing Catch Index Catch Index of 23.2 on October 31, 2014 triggered closure of the DCC gates on November 2, 2014.

Currently, the greatest presence of winter-run Chinook salmon in Delta monitoring efforts appears to be in the Lower Sacramento River and the North Delta regions, and a majority of spring-run Chinook are also in these areas (DOSS 2015), which are proximal to the DCC. When emigrating salmonids are in proximity of the DCC gates they are vulnerable to entrainment through the DCC when the gates are open. Based on the conceptual model, greater percentages of ESA-listed salmonids, including hatchery winter-run Chinook, continue to enter the Delta through February and March, there is an increasing risk of exposure as greater proportions of these populations enter the Delta through the winter and spring.

Salmonid and Green Sturgeon Supporting Information for Endangered Species Act Compliance for Temporary Urgency Change Petition Regarding Delta Water Quality January 27, 2015

Vernalis Flows Modification

Under D-1641, the minimum monthly average flow objective in the lower San Joaquin River (measured at Airport Way Bridge, Vernalis) during February and March is 710 cfs or 1,140 cfs²⁰ during critically dry years such as WY 2015. The Project Description reduces the Vernalis monthly average base flows to 500 cfs for February and March.

Based on the conceptual model, the Petition's Project Description to reduce flows at Vernalis to less than the Critical WY D-1641 flow objective may reduce survival of juvenile salmonids migrating through the lower San Joaquin River. This change will increase their migration travel time, which increases their exposure to degraded habitats and predators. Reduced Vernalis flows, in combination with reduced NDOI, results in a reduction in the daily proportion of positive flows along the lower San Joaquin River downstream of the Head of Old River (Table 9). Although only a limited number of Lower San Joaquin River channels were assessed there did not appear to be an increase in the daily proportion of negative flows in these channels downstream of the Stockton Deepwater Ship Channel. Along Grant Line Canal, the DSM2 run with the more negative OMR flows (NDOI 7,100, OMR -5,000) had greater positive flows towards the facilities than compared to the run with very low NDOI and OMR flows of 4,000 cfs and -1,400 cfs, respectively. This suggests that a more positive OMR leads to greater tidal conditions (i.e. more balanced daily proportion of positive velocities and daily mean channel velocities) in local waterways such as Grant Line Canal, which will likely increase migrating salmonids' residence time in these waterways, and increase their exposure to predation and mortality. Effects of increasing exports and creating more negative OMR conditions in South Delta waterways north of the CVP/SWP export facilities would likely show an increase in the magnitude of negative velocities and a reduction in the daily average magnitude of flow velocities, indicating that less water was moving downstream to the ocean (positive direction) and more water was moving towards the export facilities. This would also lead to increasing the residence time of salmonids in these waterways, with a corresponding reduction in survival. The modeling conducted for the Project Description did not include these additional waterways.

There are no models to quantify the increase in mortality due to reduced flows in this reach; however, comparisons may be made using results from recent acoustic tagging studies of juvenile San Joaquin steelhead migration and survival through the South Delta (Buchanan et al. 2014). Although there are only two years of data and these studies were conducted during the spring (late March through June) under higher flow conditions (>3,000 cfs) and variable Head of Old River Barrier (HORB) status (in or out), they provide an indication of possible relative survival and travel time differences. Average survival rates of tagged steelhead released at Durham Ferry from the lower San Joaquin River through the Delta ranged from 0.38 to 0.69

²⁰ The higher flow objective applies when the 2-ppt isohaline (measured as 2.64 mmhos/cm surface salinity) is required to be at or west of Chipps Island.

Salmonid and Green Sturgeon Supporting Information for Endangered Species Act Compliance for Temporary Urgency Change Petition Regarding Delta Water Quality January 27, 2015

($SE \leq 0.05$) in 2011 when San Joaquin River flows were high ($>15,000$ cfs at Vernalis) and no HORB was installed. Average survival rates through the Delta ranged from 0.24 to 0.32 ($SE \leq 0.03$) in 2012 when river flows were considerably lower (about 3,000 cfs) and the HORB was installed. The median travel time of tagged steelhead from Durham Ferry to the Head of Old River was 5–6 days in both years, and ranged up to 28 days in 2011 and 35 days in 2012. These results, albeit not directly comparable due to timeframes and HORB conditions, provide limited evidence that steelhead survival may be reduced by proposed Vernalis flow requirements. Additionally, it appears that median travel times of surviving migrants are generally independent of flow level; however, travel times took up to an additional seven days for some migrants under lower flow conditions. This hints at the possibility that lower survival in 2012 may be associated with increased travel times of those fish not surviving. There is low certainty in our understanding of the hydrodynamic and biological processes in steelhead affected by exports along the San Joaquin River and in the South Delta.

Although travel times may increase and survival be reduced under lower flows, only about 5% of the total number of steelhead captured in the lower San Joaquin River during Mossdale trawling surveys (1997-2003) have been collected in February and March, and most were greater than 200 mm (one 115 mm). These surveys indicate that few, if any, juvenile steelhead can be expected to migrate in the lower San Joaquin River during February and March and, those that do migrate during this period will be less susceptible to predation due to their larger size. Given the low likelihood that steelhead will be migrating during this period, but the moderate to high potential for lower flows to effect migration travel times and survival for any juvenile steelhead migrating during February and March, changes in hydrodynamic conditions under the Project Description may have a moderate effect on juvenile steelhead in the lower San Joaquin River. There is moderate uncertainty in this prediction based on the unknown number and size of juvenile steelhead attempting to migrate through the lower San Joaquin River during February and March this year, and their behavioral response to flows as low as 500 cfs in the lower San Joaquin River.

Cumulative Effects of Action

The Petition's action to: 1) Reduce the D-1641 Delta outflow standard for February and March from at least 7,100 cfs to 4,000 cfs, 2) Allow exports of up to 3,500 cfs when NDOI is between 7,100 cfs and 5,500 cfs, exports of 1,500 cfs when NDOI is below 5,500 cfs, and exports up to those achieving OMR flows no more negative than -5,000 cfs when NDOI is greater than 7,100 cfs, 3) Modify the D-1641 and NMFS BiOp DCC gate operations using the triggers matrix in Attachment G of Reclamation 2014b, and 4) Reduce the D-1641 Vernalis flow to 500 cfs, will affect the abundance and spatial distribution of juvenile winter-run and spring-run Chinook salmon, steelhead, and green sturgeon. The modifications to outflow and DCC gate operations as part of the proposed action may affect the spatial distribution and abundance of adult winter-run Chinook salmon and green sturgeon. Life history diversity of steelhead may be affected due to

Salmonid and Green Sturgeon Supporting Information for Endangered Species Act Compliance for Temporary Urgency Change Petition Regarding Delta Water Quality January 27, 2015

reduced survival through the San Joaquin River migration corridor. There is moderate certainty in these analyses due to the limited variability in the modeling and potential for actual hydrodynamic conditions to vary from modeled conditions, especially on the San Joaquin River.

The proposed Project Description's modification of outflow, exports, and Vernalis flows may reduce survival of juvenile listed salmonids, steelhead and green sturgeon, and may modify their designated critical habitat. The modification of juvenile winter-run and spring-run Chinook salmon and steelhead survival due to changes in outflow would occur primarily in migratory corridors in the North Delta due to increased entrainment into the Interior Delta. Steelhead survival may also be reduced along the mainstem San Joaquin River downstream of the Stanislaus River until tidal hydrodynamics dominate this channel upstream of the Stockton Deepwater Ship Channel. The location where tides influence outflow will move upstream of the Head of Old River, thus leading to increased entrainment of steelhead toward the CVP/SWP facilities. The Petition's action to reduce Delta outflow keeps the CVP/SWP operation proactively compliant with implementation of NMFS RPA I.2.2C and I.2.3C. The Petition's outflow action will enhance the potential to operate summer reservoir releases by potentially increasing the ability to control in-river water temperatures. This may decrease the endangerment to brood year 2015 by reducing mortality to incubating winter-run and spring-run Chinook eggs and holding adults during the summer of 2015.

Modeling of the Petition's intermediate export limits when NDOI is between 5500 and 7,100 cfs suggests that exports at intermediate values (3500 cfs) lead to greater mean daily proportion of positive velocities in the South Delta proximal to the facilities from the San Joaquin River (i.e Grant Line Canal) but not along the San Joaquin River migration route's channels. This modeling suggests hydrodynamics in this South Delta region proximal to the facilities may reduce local salmonid travel times towards the facility, while San Joaquin River hydrodynamics do not change and travel times remain similar. Although not modeled, the South Delta waterways north of the CVP/SWP export facilities are likely to have decreased daily proportion of positive velocities when exports are increased, which may increase residence time of rearing salmonids. These effects may increase unmeasured mortality in the South Delta region by increasing entrainment towards the facilities where pre-screen mortality is likely very high due to unprecedented nonnative vegetation problems and also maintain long transit times on the San Joaquin River where exposure to degraded habitat and predaceous species is constant.

Under the driest conditions, if NDOI reaches 5,500 cfs, the CVP/SWP will reduce exports to 1,500 cfs, which increases positive flows in the South and Central Delta relative to the baseline condition of NDOI 7,100 cfs and OMR no more negative than -5,000 cfs. Under these driest conditions, there will be reduced entrainment and salvage of listed species at the CVP/SWP fish collection facilities adjacent to the South Delta export facilities.

Salmonid and Green Sturgeon Supporting Information for Endangered Species Act Compliance for Temporary Urgency Change Petition Regarding Delta Water Quality January 27, 2015

The Petition's DCC gate operation will minimize the additional mortality risk to juvenile outmigrating and rearing winter-run and spring-run Chinook and juvenile steelhead, since the DCC gate operations matrix limits DCC flexibilities when migrating ESA-listed salmonids are present in the Lower Sacramento River region. During the period the gates are open, exports will be limited to 1,500 cfs. This export limit along with the implementation of the DCC gate operations matrix will minimize entrainment of existing rearing fish in the Interior and South Delta. The Petition's DCC gate operations may also cause straying of adult winter-run Chinook and green sturgeon.

DEPARTMENT OF THE INTERIOR**Fish and Wildlife Service****50 CFR Part 17****[Docket No. FWS-R8-ES-2008-0045]****[4500030113]****Endangered and Threatened Wildlife and Plants; 12-month Finding on a Petition to List the San Francisco Bay-Delta Population of the Longfin Smelt as Endangered or Threatened****AGENCY:** Fish and Wildlife Service, Interior.**ACTION:** Notice of 12-month petition finding.

SUMMARY: We, the U.S. Fish and Wildlife Service (Service), announce a 12-month finding on a petition to list the San Francisco Bay-Delta distinct population segment (Bay Delta DPS) of longfin smelt as endangered or threatened and to designate critical habitat under the Endangered Species Act of 1973, as amended (Act). After review of the best available scientific and commercial information, we find that listing the longfin smelt rangewide is not warranted at this time, but that listing the Bay-Delta DPS of longfin smelt is warranted. Currently, however,

listing the Bay-Delta DPS of longfin smelt is precluded by higher priority actions to amend the Lists of Endangered and Threatened Wildlife and Plants. Upon publication of this 12-month finding, we will add the Bay-Delta DPS of longfin smelt to our candidate species list. We will develop a proposed rule to list the Bay-Delta DPS of longfin smelt as our priorities allow. We will make any determinations on critical habitat during the development of the proposed listing rule. During any interim period, we will address the status of the candidate taxon through our annual Candidate Notice of Review (CNOR).

DATES: The finding announced in this document was made on [INSERT DATE OF FEDERAL REGISTER PUBLICATION].

ADDRESSES: This finding is available on the Internet at <http://www.regulations.gov> at Docket Number [FWS-R8-ES-2008-0045]. Supporting documentation we used in preparing this finding is available for public inspection, by appointment, during normal business hours at the U.S. Fish and Wildlife Service, San Francisco Bay-Delta Fish and Wildlife Office, 650 Capitol Mall, Sacramento, CA 95814. Please submit any new information, materials, comments, or questions concerning this finding to the above street address.

FOR FURTHER INFORMATION CONTACT: Mike Chotkowski, Field Supervisor, San Francisco Bay-Delta Fish and Wildlife Office (see **ADDRESSES**); by telephone at 916-930-5603; or by facsimile at 916-930-5654. If you use a telecommunications device for the deaf (TDD), please call the Federal Information Relay Service (FIRS) at 800-877-8339.

SUPPLEMENTARY INFORMATION:

Background

Section 4(b)(3)(B) of the Endangered Species Act of 1973, as amended (Act) (16 U.S.C. 1531 *et seq.*), requires that, for any petition to revise the Federal Lists of Endangered and Threatened Wildlife and Plants that contains substantial scientific or commercial information that listing the species may be warranted, we make a finding within 12 months of the date of receipt of the petition. In this finding, we will determine that the petitioned action is: (1) Not warranted, (2) warranted, or (3) warranted, but the immediate proposal of a regulation implementing the petitioned action is precluded by other pending proposals to determine whether species are endangered or threatened, and expeditious progress is being made to add or remove qualified species from the Federal Lists of Endangered and Threatened Wildlife and Plants. Section 4(b)(3)(C) of the Act requires that we treat a petition for which the requested action is found to be warranted but precluded as though resubmitted on the date of such finding, that is, requiring a subsequent finding to be made within 12 months. We must publish these 12-month findings in the **Federal Register**.

Previous Federal Actions

On November 5, 1992, we received a petition from Mr. Gregory A. Thomas of the Natural Heritage Institute and eight co-petitioners to add the longfin smelt (*Spirinchus thaleichthys*) to the List of Endangered and Threatened Wildlife and designate critical habitat in

the Sacramento and San Joaquin Rivers and estuary. On July 6, 1993, we published a 90-day finding (58 FR 36184) in the **Federal Register** that the petition contained substantial information indicating the requested action may be warranted, and that we would proceed with a status review of the longfin smelt. On January 6, 1994, we published a notice of a 12-month finding (59 FR 869) on the petition to list the longfin smelt. We determined that the petitioned action was not warranted, based on the lack of population trend data for estuaries in Oregon and Washington, although the southernmost populations were found to be declining. Furthermore, we found the Sacramento-San Joaquin River estuary population of longfin smelt was not a distinct population segment (DPS) because we determined that the population was not biologically significant to the species as a whole, and did not appear to be sufficiently reproductively isolated.

On August 8, 2007, we received a petition from the Bay Institute, the Center for Biological Diversity, and the Natural Resources Defense Council to list the San Francisco Bay-Delta (hereafter referred to as the Bay-Delta) population of the longfin smelt as a DPS and designate critical habitat for the DPS concurrent with the listing. On May 6, 2008, we published a 90-day finding (73 FR 24911) in which we concluded that the petition provided substantial information indicating that listing the Bay-Delta population of the longfin smelt as a DPS may be warranted, and we initiated a status review. On April 9, 2009, we published a notice of a 12-month finding (74 FR 16169) on the August 8, 2007, petition. We determined that the Bay-Delta population of the longfin smelt did not meet the discreteness element of our DPS policy and, therefore, was not a valid DPS. We therefore determined that the Bay-Delta population of the longfin smelt was not a listable entity under the Act.

On November 13, 2009, the Center for Biological Diversity filed a complaint in U.S. District Court for the Northern District of California, challenging the Service on the merits of the 2009 determination. On February 2, 2011, the Service entered into a settlement agreement with the Center for Biological Diversity and agreed to conduct a rangewide status review and prepare a 12-month finding to be published by September 30, 2011. In the event that the Service determined in the course of the status review that the longfin smelt does not warrant listing as endangered or threatened over its entire range, the Service agreed to consider whether any population of longfin smelt qualifies as a DPS. In considering whether any population of longfin smelt qualifies as a DPS, the Service agreed to reconsider whether the Bay-Delta population of the longfin smelt constitutes a DPS. At the request of the Service, Department of Justice requested an extension from the Court to allow for a more comprehensive review of new information pertaining to the longfin smelt and to seek the assistance of two expert panels to assist us with that review. The plaintiffs filed a motion of non-opposition, and on October 3, 2011, the court granted an extension to March 23, 2012 for the publication of a new 12-month finding.

Species Information

Species Description and Taxonomy

Longfin smelt measure 9–11 centimeters (cm) (3.5–4.3 inches (in)) standard length, although third-year females may grow up to 15 cm (5.9 in). The sides and lining of the gut

cavity appear translucent silver, the back has an olive to iridescent pinkish hue, and mature males are usually darker in color than females. Longfin smelt can be distinguished from other smelts by their long pectoral fins, weak or absent striations on their opercular (covering the gills) bones, incomplete lateral line, low numbers of scales in the lateral series (54 to 65), long maxillary bones (in adults, these bones extend past mid-eye, just short of the posterior margin of the eye), and lower jaw extending anterior of the upper jaw (McAllister 1963, p. 10; Miller and Lea 1972, pp. 158–160; Moyle 2002, pp. 234–236).

The longfin smelt belongs to the true smelt family Osmeridae and is one of three species in the *Spirinchus* genus; the night smelt (*Spirinchus starksi*) also occurs in California, and the shishamo (*Spirinchus lanceolatus*) occurs in northern Japan (McAllister 1963, pp. 10, 15). Because of its distinctive physical characteristics, the Bay-Delta population of longfin smelt was once described as a species separate from more northern populations (Moyle 2002, p. 235). McAllister (1963, p. 12) merged the two species *S. thaleichthys* and *S. dilatatus* because the difference in morphological characters represented a gradual change along the north-south distribution rather than a discrete set. Stanley *et al.* (1995, p. 395) found that individuals from the Bay-Delta population and Lake Washington population differed significantly in allele (proteins used as genetic markers) frequencies at several loci (gene locations), although the authors also stated that the overall genetic dissimilarity was within the range of other conspecific fish species. They concluded that longfin smelt from Lake Washington and the Bay-Delta are conspecific (of the same species) despite the large geographic separation.

Delta smelt and longfin smelt hybrids have been observed in the Bay-Delta estuary,

although these offspring are not thought to be fertile because delta smelt and longfin smelt are not closely related taxonomically or genetically (California Department of Fish and Game (CDFG) 2001, p. 473).

Biology

Nearly all information available on longfin smelt biology comes from either the Bay-Delta population or the Lake Washington population. Longfin smelt generally spawn in freshwater and then move downstream to brackish water to rear. The life cycle of most longfin smelt generally requires estuarine conditions (CDFG 2009, p. 1).

Bay-Delta Population

Longfin smelt are considered pelagic and anadromous (Moyle 2002, p. 236), although anadromy in longfin smelt is poorly understood, and certain populations are not anadromous and complete their entire life cycle in freshwater lakes and streams (see *Lake Washington Population* section below). Within the Bay-Delta, the term pelagic refers to organisms that occur in open water away from the bottom of the water column and away from the shore. Juvenile and adult longfin smelt have been found throughout the year in salinities ranging from pure freshwater to pure seawater, although once past the juvenile stage, they are typically collected in waters with salinities ranging from 14 to 28 parts per thousand (ppt) (Baxter 1999, pp. 189–192). Longfin smelt are thought to be restricted by high water temperatures, generally greater than 22 degrees Celsius (°C) (71 degrees Fahrenheit (°F)) (Baxter *et. al.* 2010, p. 68), and will move down the

estuary (seaward) and into deeper water during the summer months, when water temperatures in the Bay-Delta are higher. Within the Bay-Delta, adult longfin smelt occupy water at temperatures from 16 to 20 °C (61 to 68 °F), with spawning occurring in water with temperatures from 5.6 to 14.5 °C (41 to 58 °F) (Wang 1986, pp. 6–9).

Longfin smelt usually live for 2 years, spawn, and then die, although some individuals may spawn as 1- or 3-year-old fish before dying (Moyle 2002, p. 36). In the Bay-Delta, longfin smelt are believed to spawn primarily in freshwater in the lower reaches of the Sacramento River and San Joaquin River. Longfin smelt congregate in deep waters in the vicinity of the low salinity zone (LSZ) near X2 (see definition below) during the spawning period, and it is thought that they make short runs upstream, possibly at night, to spawn from these locations (CDFG 2009, p. 12; Rosenfield 2010, p. 8). The LSZ is the area where salinities range from 0.5 to 6 practical salinity units (psu) within the Bay-Delta (Kimmerer 1998, p. 1). Salinity in psu is determined by electrical conductivity of a solution, whereas salinity in parts per thousand (ppt) is determined as the weight of salts in a solution. For use in this document, the two measurements are essentially equivalent. X2 is defined as the distance in kilometers up the axis of the estuary (to the east) from the Golden Gate Bridge to the location where the daily average near-bottom salinity is 2 psu (Jassby *et al.* 1995, p. 274; Dege and Brown 2004, p. 51)).

Longfin smelt in the Bay-Delta may spawn as early as November and as late as June, although spawning typically occurs from January to April (CDFG 2009, p. 10; Moyle 2002, p. 36). Longfin smelt have been observed in their winter and spring spawning period as far upstream as Isleton in the Sacramento River, Santa Clara shoal in the San Joaquin system, Hog

Slough off the South-Fork Mokelumne River, and in Old River south of Indian Slough (CDFG 2009a, p. 7; Radtke 1966, pp. 115–119).

Exact spawning locations in the Delta are unknown and may vary from year to year in location, depending on environmental conditions. However, it seems likely that spawning locations consist of the overlap of appropriate conditions of flow, temperature, and salinity with appropriate substrate (Rosenfield 2010, p. 8). Longfin smelt are known to spawn over sandy substrates in Lake Washington and likely prefer similar substrates for spawning in the Delta (Baxter *et. al.* 2010, p. 62; Sibley and Brocksmith 1995, pp. 32–74). Baxter found that female longfin smelt produced between 1,900 and 18,000 eggs, with fecundity greater in fish with greater lengths (CDFG 2009, p. 11). At 7°C (44.6°F), embryos hatch in 40 days (Dryfoos 1965, p. 42); however, incubation time decreases with increased water temperature. At 8–9.5°C (46.4–49.1 °F), embryos hatch at 29 days (Sibley and Brocksmith 1995, pp. 32–74).

Larval longfin smelt less than 12 millimeters (mm) (0.5 in) in length are buoyant because they have not yet developed an air bladder; as a result, they occupy the upper one-third of the water column. After hatching, they quickly make their way to the LSZ via river currents (CDFG 2009, p. 8; Baxter 2011a, pers comm.). Longfin smelt develop an air bladder at approximately 12–15 mm (0.5–0.6 in.) in length and are able to migrate vertically in the water column. At this time, they shift habitat and begin living in the bottom two-thirds of the water column (CDFG 2009, p. 8; Baxter 2008, p. 1).

Longfin smelt larvae can tolerate salinities of 2–6 psu within days of hatching, and can

tolerate salinities up to 8 psu within weeks of hatching (Baxter 2011a, pers. comm.). However, very few larvae (individuals less than 20 mm in length) are found in salinities greater than 8 psu, and it takes almost 3 months for longfin smelt to reach juvenile stage. A fraction of juvenile longfin smelt individuals are believed to tolerate full marine salinities (greater than 8 psu) (Baxter 2011a, pers. comm.).

Longfin smelt are dispersed broadly in the Bay-Delta by high flows and currents, which facilitate transport of larvae and juveniles long distances. Longfin smelt larvae are dispersed farther downstream during high freshwater flows (Dege and Brown 2004, p. 59). They spend approximately 21 months of their 24-month life cycle in brackish or marine waters (Baxter 1999, pp. 2–14; Dege and Brown 2004, pp. 58–60).

In the Bay-Delta, most longfin smelt spend their first year in Suisun Bay and Marsh, although surveys conducted by the City of San Francisco collected some first-year longfin in coastal waters (Baxter 2011c, pers. comm.; City of San Francisco 1995, no pagination). The remainder of their life is spent in the San Francisco Bay or the Gulf of Farallones (Moyle 2008, p. 366; City of San Francisco 1995, no pagination). Rosenfield and Baxter (2007, pp. 1587, 1590) inferred based on monthly survey results that the majority of longfin smelt from the Bay-Delta were migrating out of the estuary after the first winter of their life cycle and returning during late fall to winter of their second year. They noted that migration out of the estuary into nearby coastal waters is consistent with captures of longfin smelt in the coastal waters of the Gulf of Farallones. It is possible that some longfin smelt may stay in the ocean and not re-enter freshwater to spawn until the end of their third year of life (Baxter 2011d, pers. comm.). Moyle

(2010, p. 8) states that longfin smelt that migrate out of and back into the Bay-Delta estuary may primarily be feeding on the rich planktonic food supply in the Gulf of Farallones. Rosenfield and Baxter (2007, p. 1290) hypothesize that the movement of longfin smelt into the ocean or deeper water habitat in summer months is at least partly a behavioral response to warm water temperatures found during summer and early fall in the shallows of south San Francisco Bay and San Pablo Bay (Rosenfield and Baxter 2007, p. 1590).

In the Bay-Delta, calanoid copepods such as *Pseudodiaptomus forbesi* and *Eurytemora sp.*, as well as the cyclopoid copepod *Acanthocyclops vernalis* (no common names), are the primary prey of longfin smelt during the first few months of their lives (approximately January through May) (Slater 2009b, slide 45). Copepods are a type of zooplankton (organisms drifting in the water column of oceans, seas, and bodies of fresh water). The longfin smelt's diet shifts to include mysids such as opossum shrimp (*Neomysis mercedis*) and other small crustaceans (*Acanthomysis sp.*) as soon as they are large enough (20–30 mm (0.78–1.18 in)) to consume these larger prey items, sometime during the summer months of the first year of their lives (CDFG 2009, p. 12). Upstream of San Pablo Bay, mysids and amphipods form 80–95 percent or more of the juvenile longfin smelt diet by weight from July through September (Slater 2009, unpublished data). Longfin smelt occurrence is likely associated with the occurrence of their prey, and both of these invertebrate groups occur near the bottom of the water column during the day under clear water marine conditions.

Lake Washington Population

The Lake Washington population near Seattle, Washington is considered a landlocked population of longfin smelt, as are the populations of longfin smelt in Harrison and Pitt Lakes in British Columbia east of Vancouver (Chigbu and Sibley 1994, p. 1). These populations are not anadromous and complete their entire life cycle in freshwater. Young longfin smelt feed primarily on the copepods *Diaptomus*, *Diaphanosoma*, and *Epischura*, with older fish switching over to mysids (Wydoski and Whitney 2003, p. 105). Chigbu and Sibley (1994, pp. 11–14) found that mysids dominate the diets of longfin smelt in their second year of life (age-1), while amphipods, copepods, and daphnia also contributed substantially to the longfin smelt's diet. A strong spawning run of longfin smelt occurs on even years in Lake Washington, with weak runs on odd years. They spawn at night in the lower reaches of at least five streams that flow into Lake Washington. Water temperatures during spawning were 4.4° C (40° F) to 7.2° C (45° F) (Wydoski and Whitney 2003, p. 105). Chigbu and Sibley (1994, p. 9) found that female longfin smelt produced between 6,000 and 24,000 eggs, while Wydoski and Whitney (2003, p. 105) found that longfin smelt produced between 1,455 and 1,655 eggs. The reason for the large difference between the observations of these two studies is not known.

Habitat

Longfin smelt have been collected in estuaries from the Bay-Delta (33° N latitude) to Prince William Sound (62° N latitude), a distance of approximately 1,745 nautical miles (Figure 1). Mean annual water temperatures range from 2.4°C (36.3° F) in Anchorage to 14.1° C (57.3° F) in San Francisco (NOAA 2011a). The different estuary types that the longfin smelt is found in and the range of variability of environments where the species has been observed will be

discussed below.

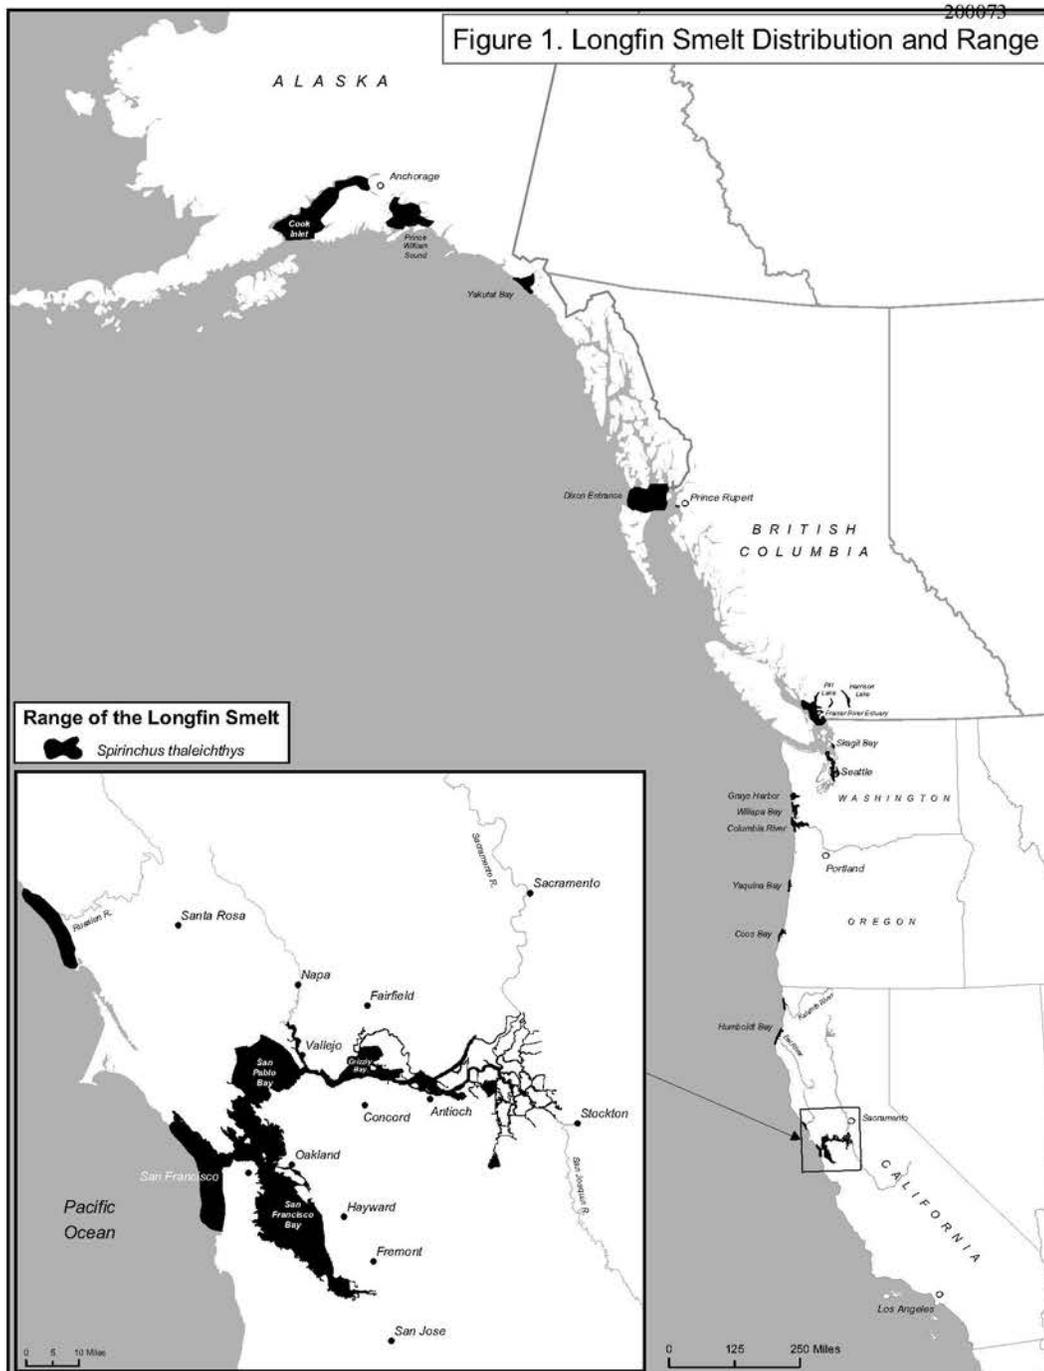

FIGURE 1. Map of coastal sites where longfin smelt are known to occur.

The origin and geomorphology of West Coast estuaries result from geologic forces driven by plate tectonics and have been modified by glaciations and sea level rise (Emmett *et al.* 2000, pp. 766–767). Major classifications of estuaries include fjord, drowned-river valley, lagoon, and bar-built. Fjords typically are long, narrow, steep-sided valleys created by glaciation, with moderately high freshwater inflow but little mixing with seawater due to the formation of a sill at the mouth (NOAA 2011b). Fjords generally have one large tributary river and numerous small streams (Emmett *et al.* 2000, p. 768). Drowned-river valleys, also termed coastal plain estuaries, are found primarily in British Columbia, Washington, and Oregon, and are the dominant type along the west coast, occurring as a result of rising sea levels following the last ice age. Lagoons, primarily found in California, occur where coastal river systems that are closed to the sea by sand spits for much of the year are breached during the winter (Emmett *et al.* 2000, p. 768). The rarest type of estuary is the bar-built, which is formed by a bar and semi-enclosed body of water (Emmett *et al.* 2000, p. 768). Estuaries have also been classified by physical or environmental variables into Northern Riverine, Southern California, Northern Estuarine, Central Marine, Fjord, and Coastal Northwest Groups (Monaco *et al.* 1992, p. 253). Longfin smelt have been collected from estuaries of all types and classifications.

The Bay-Delta is the largest estuary on the West Coast of the United States (Sommer *et al.* 2007, p. 271). The modern Bay-Delta bears only a superficial resemblance to the historical Bay-Delta. The Bay-Delta supports an estuary covering approximately 1,235 square kilometers (km²) (477 square miles (mi²)) (Rosenfield and Baxter 2007, p. 1577), which receives almost half of California's runoff (Lehman 2004, p. 313). The historical island marshes surrounded by low natural levees are now intensively farmed and protected by large, manmade structures

(Moyle 2002, p. 32). The watershed, which drains approximately 40 percent of the land area of California, has been heavily altered by dams and diversions, and nonnative species now dominate, both in terms of numbers of species and numbers of individuals (Kimmerer 2004, pp. 7–9). The Bay Institute has estimated that intertidal wetlands in the Delta have been diked and leveed so extensively that approximately 95 percent of the 141,640 hectares (ha) (350,000 acres (ac)) of tidal wetlands that existed in 1850 are gone (The Bay Institute 1998, p. 17).

The physical and biological characteristics of the estuary define longfin smelt habitat. The Bay-Delta is unique in that it contains significant amounts of tidal freshwater (34 km² (13 mi²)) and mixing zone (194 km² (75 mi²)) habitat (Monaco *et al.* 1992, pp. 254–255, 258). San Francisco Bay is relatively shallow and consists of a northern bay that receives freshwater inflow from the Sacramento-San Joaquin system and a southern bay that receives little freshwater input (Largier 1996, p. 69). Dominant fish species are highly salt-tolerant and include the commercially important Pacific sardine (*Sardinops sagax*) and rockfish (*Sebastes* spp.). Major habitat types include riverine and tidal wetlands, mud flat, and salt marsh, with substantial areas of diked wetland managed for hunting. The sandy substrates that longfin smelt are presumed to use for spawning are abundant in the Delta.

The Russian River collects water from a drainage area of approximately 3,846 km² (1,485 mi²), has an average annual discharge of 1.6 million acre-feet, and is approximately 129 km (80 mi) in length (Langridge *et al.* 2006, p. 4). Little information is available on potential spawning and rearing habitat for longfin smelt, but it is likely to be both small and ephemeral because spawning and rearing habitat is highly dependent upon freshwater inflow, and there may

be insufficient freshwater flows for spawning and rearing in some years (Moyle 2010, p. 5). A berm encloses the mouth of the Russian River during certain times of the year, essentially cutting it off from the coastal ocean. This results in a lack of connectivity with the ocean that could be important during dry years. However, in most years the berm is breached by freshwater flows, which allows longfin smelt to enter the Russian River and spawn.

The Eel River drains an area of 3,684 mi² (9,542 km²) and is the third largest river in California. Wetlands and tidal areas have been reduced 60 to 90 percent since the 1800s (Cannata and Hassler 1995, p. 1), resulting in changes in tidal influence and a reduction in channel connectivity (Downie 2010, p. 15). The estuary is characterized by a small area where freshwater and saltwater mix (Monaco *et al.* 1992, p. 258) and thus provides only limited potential longfin rearing habitat.

Humboldt Bay is located only 26 km (16 mi) north of the Eel River and is approximately 260 mi (418 km) north of the Bay-Delta. Humboldt Bay is the second largest coastal estuary in California after the Bay-Delta. However, true estuarine conditions rarely occur in Humboldt Bay because it receives limited freshwater input and experiences little mixing of freshwater and saltwater (Pequegnat and Butler 1982, p. 39).

The Klamath Basin has been extensively modified by levees, dikes, dams, and the draining of natural water bodies since the U.S. Bureau of Reclamation's Klamath Project, designed to improve the region's ability to support agriculture, began in 1905. These changes to the system have altered the biota of the basin (NRC 2008, p. 16). Over the years, loss of

thousands of acres of connected wetlands and open water in the Klamath River Basin has greatly reduced habitat value, likely depleting the ability of this area to cycle nutrients and affecting water quality (USFWS 2008, p. 55). The river drains a vast area of 10 million ac (4 million ha). Although a large river, the Klamath River estuary is characterized by small tidal freshwater and mixing zones (Monaco *et al.* 1992, p. 258) and thus provides limited potential longfin smelt rearing habitat.

Yaquina Bay is located on the mid-coastal region of Oregon, 201 km (125 mi) south of the Columbia River and 348 km (216 mi) north of the California border. Wetlands encompass 548 ha (1,353 ac), including 216 ha (534 ac) of mud flats and 331 ha (819 ac) of tidal marshes (Yaquina Bay Geographic Response Plan 2005, p. 2.1). Forty-eight percent of the estuary is intertidal (Brown *et al.* 2007, p. 6). The estuary has been modified greatly, being alternately dredged and filled at different locations as a result of development. Dredging, industrial, and residential uses have reduced fish habitat and water quality in the bay. Dredging disturbs sediment, resulting in increased turbidity and reduced sunlight penetration, which can impact native eelgrasses and the benthic species dependent eelgrass beds for breeding, spawning, and shelter (Oberrecht 2011, pp. 1–8).

On the Columbia River, dams, dikes, maintenance dredging, and urbanization have all contributed to habitat loss and alterations that have negatively affected fish and wildlife populations (Lower Columbia River Estuary Partnership 2011, p. 1). It is estimated that as much as 43 percent of estuarine tidal marshes and 77 percent of tidal swamps in the river estuary available for fish species have been lost since 1870 (Columbia River Estuary Study

Taskforce2006, pp. 1–30). Sixty square miles of peripheral tidal habitat have been lost to diking, filling, and conversion to upland habitat for industrial and agricultural use since 1870 (Columbia River Estuary Study Taskforce 2006, p. 1). Prior to construction of dams, estuary islands and much of the floodplain were inundated throughout the year, beginning in December and again in May or June. Dam operations on the Columbia River’s main stem and major tributaries have substantially reduced peak river flows. Dikes and levees have all but eliminated flooding in many low-lying areas. Dredging of shipping channels has caused loss of wetlands and altered shoreline configuration. Dredging has resulted in large sediment reductions upstream, and the dredged sediments have created islands downstream. This has likely reduced spawning habitat and sheltering sites for fish (OWJP 1991, pp. 1–24; Lower Columbia Fish Recovery Board 2004a, pp. 1–192).

Puget Sound is a large saltwater estuary of interconnected flooded glacial valleys located at the northwest corner of the State of Washington. Puget Sound is about 161 km (100 mi) long, covers about 264,179 ha (652,800 ac), and has over 2,092 km (1,300 mi) of shoreline. Fed by streams and rivers from the Olympic and Cascade Mountains, waters flow out to the Pacific Ocean through the Strait of Juan de Fuca (Lincoln 2000, p. 1). The basin consists of eight major habitat types, the largest of which is kelp and eelgrass, but also includes wetlands, mudflats, and sandflats. Puget Sound consists of five regions, each with its own physical and biological characteristics. Urban and industrial development borders the main basin, which is bounded by Port Townsend on the north and the Narrows (Tacoma) on the south. Approximately 30 percent of freshwater inflow to the main basin is from the Skagit River, which drains an area of approximately 8,011 km² (3,093 mi²). Sills at Admiralty Inlet and the Narrows influence

circulation. Puget Sound is highly productive. The fish community includes many commercially important species, such as Pacific herring, Pacific salmon, and several species of rockfish (NOAA 2011c, p. 11). There are 10 major dams and thousands of small water diversions in the Puget Sound system (Puget Sound Partnership 2008b, p. 21). Human activities in the region have resulted in the loss of 75 percent of the saltwater marsh habitat and 90 percent of the estuarine and riverine wetlands (Puget Sound Partnership 2008b, p. 21).

The coastline of British Columbia has been shaped by plate tectonics and extensive glaciations. Particularly in summer, prevailing winds drive coastal upwelling, which results in a highly productive food chain. The tidal amplitude is 3–5 meters (m) (9.8–16.4 ft) in most areas, and numerous large and small rivers provide freshwater inflow. Biological communities are diverse and highly variable, including coastal wetlands, kelp beds, and seaweed beds that support a diverse marine fauna (Dale 1997, pp. 13–15). Nearshore areas of British Columbia are characterized by steep to moderately sloping fjords, 20–50 m (65–164 ft) in depth, with salinities ranging from 18 to 28 ppt (AXYS Environmental Consulting 2001, pp. 5, 11, 20). Bar-built estuaries that are semi-enclosed by an ocean-built bar occur on the west coast of Vancouver Island and the Queen Charlotte Islands (Emmett *et al.* 2000, pp. 769–770). Oxygen depletion is common in fjords (Emmett *et al.* 2000, p. 776), but because they are anadromous, longfin smelt would presumably be able to avoid those conditions. However, if depletion were to occur during spawning or rearing, recruitment could be affected.

The Fraser River, at approximately 1,375 miles (2,213 km), is the longest river in British Columbia and the tenth longest river in Canada. The Fraser River drains an area of 220,000 km²

and flows to the Strait of Georgia at the City of Vancouver before it drains into the Pacific Ocean. Diking and drainage in the lower basin area have reduced the extent of estuarine wetlands that are important to the longfin smelt and other fishes that utilize these areas (Blomquist 2005, p. 8).

Habitat types common in Alaskan estuaries include eel grass beds, understory kelp, sand and gravel beds, and bedrock outcrops (NOAA 2011d). Shallow nearshore areas provide a mosaic of habitat types that support a variety of fishes (NOAA 2005, p. 59). In southwestern Alaska, the related osmerid species capelin (*Mallotus villosus*) was found to occur in sand-and-gravel habitats, and the surf smelt (*Hypomesus pretiosus*) was found to occur in bedrock habitats (NOAA 2005, pp. 27, 29). As in British Columbia, if oxygen depletion occurs in fjord habitats during spawning or rearing, longfin smelt recruitment could be affected.

Cook Inlet is a large mainland Alaskan estuary located in the northern Gulf of Alaska. Cook Inlet is approximately 290 km (180 miles) long. The watershed covers about 100,000 km² of southern Alaska (USACE 2011, p. 1).

Distribution

Longfin smelt are widely distributed along 3,541 km (2,200 mi) of Pacific coastline from the Bay-Delta to Cook Inlet, Alaska (Table 1). We found no evidence of range contraction; the current distribution of longfin smelt appears to be similar to its historical distribution.

California

The southernmost known population of longfin smelt is the Bay-Delta estuary, and longfin smelt occupy different habitats of the estuary at various stages in their life cycle (See Habitat section above). Eschmeyer (1983, p. 82) reported the southern extent of the range as Monterey Bay, and Wang (1986, pp. 6–10) reported that an individual longfin smelt had been captured at Moss Landing in Monterey Bay in 1980. Most sources, however, identify the Bay-Delta as the southern extent of the species' range (Moyle 2002, p. 235).

Small numbers of longfin were collected within the Russian River estuary each year between 1997 and 2000 (SCWA 2001, p. 18). No surveys were conducted in 2001 or 2002 (Cook 2011, pers. comm.). Recent surveys (since 2003) in the Russian River estuary conducted by Sonoma County Water Agency have not collected longfin smelt; however, in 2003, trawling surveys were replaced by beach seining, a type of survey less likely to capture a pelagic fish species such as the longfin smelt. Longfin smelt breeding has not been documented at the Russian River (Baxter 2011b, pers. comm.), and because of its limited size, the Russian River estuary is not believed to be capable of supporting a self-sustaining longfin smelt population

(The Bay Institute *et al.* 2007, p. ii; Moyle 2010, p. 5).

Longfin smelt were observed spawning in the Eel River estuary in 1974 (Puckett 1977, p. 19). Although longfin were observed in the Eel River in 2008 and 2009 (Cannata and Downie 2009), it is unknown whether or not they currently spawn there. Humboldt Bay is located 420 km (260 mi) north of the Bay-Delta. Longfin smelt were collected in Humboldt Bay or its tributaries every year from 2003 to 2009, with the exception of 2004 (CDFG 2010, unpublished data). Longfin smelt also have been observed in coastal waters adjacent to Humboldt Bay (Quirollo 1994, pers. comm.). The Humboldt Bay population is thought to be the nearest known breeding population to the Bay-Delta (Baxter 2011b, pers. comm.). Longfin smelt were collected consistently in the Klamath River estuary between 1979 and 1989 (Kisanuki *et al.* 1991, p. 72), and one longfin smelt was collected in the Klamath River in 2001 (CDFG 2009, p. 5).

Oregon

In Oregon, there are historical records of longfin smelt in Tillamook Bay, Columbia River, Coos Bay, and Yaquina Bay (ANHP 2006, p. 3). One individual was detected in Tillamook Bay in 2000 (Ellis 2002, p. 17). Williams *et al.* (2004, p. 30) collected 308 longfin in the Columbia River estuary in 2004. Longfin smelt were reported in the Columbia River estuary, the coastal waters adjacent to the Columbia River, and in Yaquina Bay in 2009 (Nesbit 2011, pers. comm.). In Coos Bay, longfin smelt were detected in low numbers in the early 1980s. However, longfin smelt do not appear to be common in Coos Bay and were not detected

during sampling that occurred in the 1970s and the late 1980s (Veroujean 1994, no pagination).

Washington

In Washington, within the Puget Sound Basin, longfin smelt are known to occur in the Nooksack River, Bellingham Bay, Snohomish River, Duwamish River, Skagit Bay, Strait of San Juan de Fuca, Twin River, and Pysht River (Table 1). Longfin smelt are known to occur in nearby Bellingham Bay (Penttila 2007, p. 4). Longfin smelt were collected in the Snohomish River estuary during extensive beach seine and fyke trapping in 2009 (Rice 2010, pers. comm.). Longfin smelt were captured (reported as non-target) in high-rise otter trawls in the lower Duwamish River (Anchor and King County 2007, p. 11). Longfin smelt are common in the Strait of San Juan de Fuca (Penttila 2007, p. 4). Miller *et al.* (1980, p. 28) found longfin smelt to be the second most common species in tow-net surveys conducted in the Strait of San Juan de Fuca. Most fish caught in these surveys were young of the year and were found near the Twin and Pysht Rivers, both of which may have suitable spawning grounds (Miller *et al.* 1980, p. 28). Occurrences of longfin smelt within northern Puget Sound and the Strait of Georgia may reflect the abundance and distribution of the anadromous populations from the Fraser River in British Columbia (Washington Department of Fish and Wildlife 2011, pp. 1–3). Currently, the National Park Service states that longfin smelt are probably present within Olympic National Park (NPS 2011, p. 1). Longfin smelt appear to be common in Grays Harbor (U.S. Army Corps of Engineers 2000, p. 2). Longfin smelt have been infrequently documented in the upper Chehalis estuary at Cosmopolis; however, when they do occur, they have been reported as abundant (Anderson 2011). Ocean trawls off Willapa Bay have collected longfin smelt, although no

spawning population has been identified in the basin (Anderson 2011).

A resident, freshwater population of longfin smelt occurs in Lake Washington (Chigbu and Sibley 1994, p. 1). First caught in 1959, it is believed that the longfin smelt either were introduced to the lake or became trapped during canal construction (Chigbu *et. al.* 1998, p. 180). In the 1960s, the abundance of longfin smelt in Lake Washington was low but increased to higher levels in the 1980s (Chigbu and Sibley 1994, p. 4).

British Columbia

Longfin smelt populations occur in Pitt Lake and Harrison Lake in British Columbia (Page and Burr 1991, p. 57; Taylor 2011, pers. comm.); these populations are believed to be resident fish that are not anadromous (that is, they are thought to complete their entire life cycle in freshwater). Pitt Lake is located approximately 64 river km (40 mi) up the Fraser and Pitt Rivers, and Harrison Lake is located approximately 121 river km (75 mi) up the Fraser and Harrison Rivers. Longfin smelt are known to occur within the Fraser River near Vancouver (Hart 1973, p. 147; Fishbase 2011a, p. 1; Fishbase 2011b, p. 1). Longfin smelt are also known to occur in the Skeena River estuary near Prince Rupert (Hart 1973, p. 147; Kelson 2011, pers. comm.; Gottesfeld 2002, p. 54)

Alaska

In Alaska, longfin smelt are known from Hinchinbrook Island, Prince William Sound,

Dixon Entrance, Yakutat Bay, and Cook Inlet (Alaska Natural Heritage Program 2006, p. 3). In nearly 1,000 recent beach seine surveys in Alaska, longfin smelt have only been caught off Fire Island in upper Cook Inlet in 2009 and 2010 (NOAA 2010b, p. 4; Johnson 2010, pers. comm.; Wing 2010, pers. comm.). However, as stated earlier, longfin smelt are unlikely to be caught in beach seine surveys because they are a pelagic species and do not typically occur near shore where beach seine surveys take place. Surveys in Prince William Sound did not collect longfin smelt in 2006 or 2007 (NOAA 2011, p. 1). Longfin smelt were collected in Wrangell-St. Elias National Park and Glacier Bay in 2001 and 2002 (Arimitsu 2003, pp. 35, 41). Longfin were collected in Kachemak Bay in 1996–1998 seine and trawling surveys (Abookire *et al.* 2000). The NPS was not able to confirm presence or absence in Lake Clark National Park and Preserve. The NPS concludes that presence is probable in Glacier Bay National Park and Preserve, Klondike Gold Rush National Historical Park, Sitka National Historical Park, and Wrangell-St. Elias National Park and Preserve (NPS 2011, p. 1).

Abundance

In most locations throughout their range, longfin smelt populations have not been monitored. Within the Bay-Delta, longfin smelt are consistently collected in the monitoring surveys that have been conducted by CDFG as far back as the late 1960s. We know of no similar monitoring data for other longfin smelt populations. CDFG did report catches of longfin smelt in Humboldt Bay from surveys conducted between 2003 and 2009; small numbers of longfin were collected each of the years except 2004 (CDFG 2010, unpublished data). Moyle (2002, p. 237; 2010, p. 4) noted that the longfin smelt population in Humboldt Bay appeared to

have declined between the 1970s and 2002, but survey data are not available from that time.

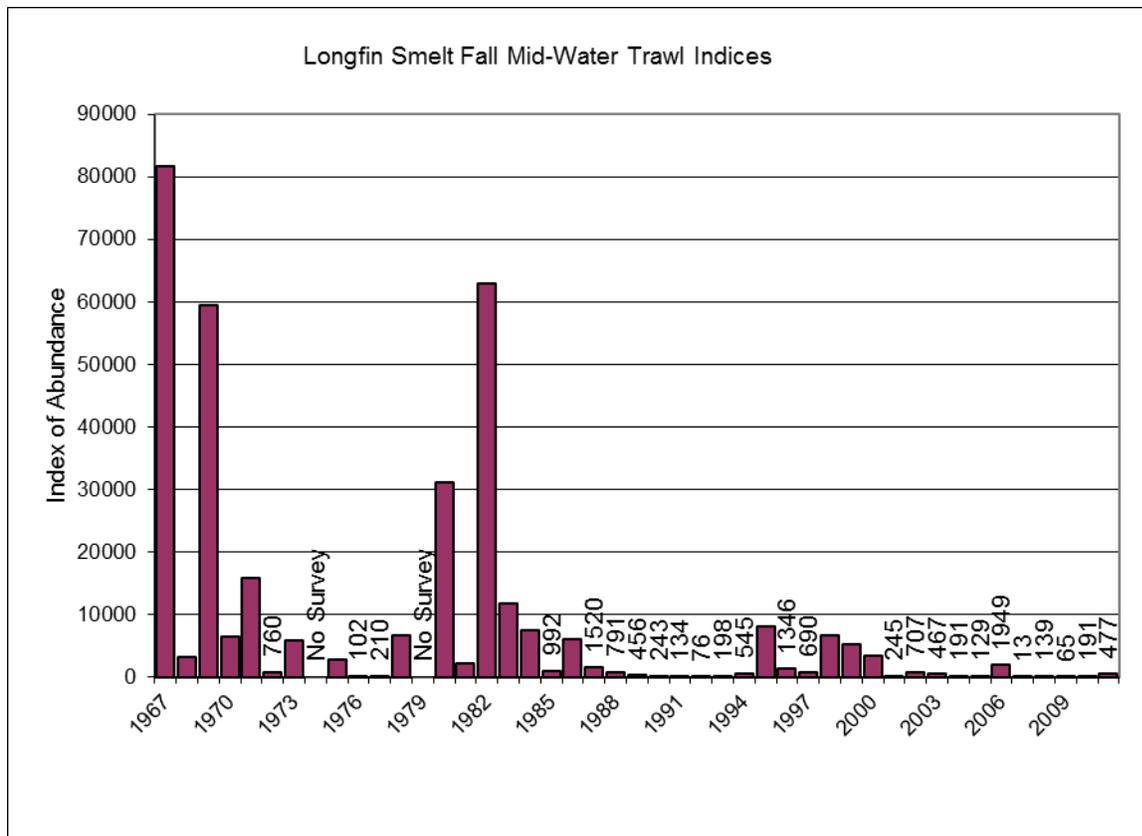

Longfin smelt numbers in the Bay-Delta have declined significantly since the 1980s (Moyle 2002, p. 237; Rosenfield and Baxter 2007, p. 1590; Baxter *et al.* 2010, pp. 61–64). Rosenfield and Baxter (2007, pp. 1577–1592) examined abundance trends in longfin smelt using three long-term data sets (1980–2004) and detected a significant decline in the Bay-Delta longfin smelt population. They confirmed the positive correlation between longfin smelt abundance and freshwater flow that had been previously documented by others (Stevens and Miller 1983, p. 432; Baxter *et al.* 1999, p. 185; Kimmerer 2002b, p. 47), noting that abundances of both adults and juveniles were significantly lower during the 1987–1994 drought than during either the pre- or post-drought periods (Rosenfield and Baxter 2007, pp. 1583–1584).

Despite the correlation between drought and low population in the 1980s and 90s, the declines in the first decade of this century appear to be caused in part by additional factors. Abundance of longfin smelt has remained very low since 2000, even though freshwater flows increased during several of these years (Baxter *et al.* 2010, p. 62). Abundance indices derived from the Fall Midwater Trawl (FMWT), Bay Study Midwater Trawl (BSMT), and Bay Study Otter Trawl (BSOT) all show marked declines in Bay-Delta longfin smelt populations from 2002 to 2009 (Messineo *et al.* 2010, p. 57). Longfin smelt abundance over the last decade is the lowest recorded in the 40-year history of CDFG's FMWT monitoring surveys. Scientists became concerned over the simultaneous population declines since the early 2000s of longfin smelt and three other Bay-Delta pelagic fish species—delta smelt (*Hypomesus transpacificus*), striped bass (*Morone saxatilis*), and threadfin shad (*Dorosoma petenense*) (Sommer *et al.* 2007,

p. 273). The declines of longfin smelt and these other pelagic fish species in the Bay-Delta since the early 2000s has come to be known as the Pelagic Organism Decline, and considerable research efforts have been initiated since 2005, to better understand causal mechanisms underlying the declines (Sommer *et al.* 2007, pp. 270–277; MacNally *et al.* 2010, pp. 1417–1430; Thomson *et al.* 2010, pp. 1431–1448). The population did increase in the 2011 FMWT index to 477 (Contreras 2011, p. 2), probably a response to an exceptionally wet year.

The FMWT index of abundance in the Bay-Delta shows great annual variation in abundance but a severe decline over the past 40 years (Figure 2). The establishment of the overbite clam (*Corbula amurensis*) in the Bay-Delta in 1987 is believed to have contributed to the population decline of longfin smelt (See Factor E: Introduced Species, below), as well as to the declining abundance of other pelagic fish species in the Bay-Delta (Sommer *et al.* 2007, p. 274). Figure 2 shows low values of the abundance index for longfin smelt during drought years (1976–1977 and 1986–1992) and low values overall since the time that the overbite clam became established in the estuary.

FIGURE 2. Longfin smelt abundance (total across year-classes) as indexed by the Fall Mid-Water Trawl of the Bay-Delta, 1967–2011.

* The survey was not conducted in 1974 or 1979.

** Index values for years of very low abundance were added.

Using data from 1975–2004 from the FMWT survey, Rosenfield and Baxter 2007 (p. 1589) found that longfin smelt exhibit a significant stock-recruitment relationship—abundance of juvenile (age-0) fish is directly related to the abundance of adult (age-1) fish from the previous year. They found that the abundance of juvenile fish declined by 90 percent during the time period analyzed. Rosenfield and Baxter (2007, p. 1589) also found a decline in age-1 individuals that was significant even after accounting for the decline in the age-0 population. If unfavorable environmental conditions persist for one or more years, recruitment into the population could be suppressed, affecting the species' ability to recover to their previous abundance. The current low abundance of adult longfin smelt within the Bay-Delta could reduce the ability of the species to

persist in the presence of various threats.

Conservation Actions

Bay-Delta

The CALFED program existed as a multi-purpose (water supply, flood protection, and conservation) program with significant ecosystem restoration and enhancement elements. Implemented by the California Bay-Delta Authority, the program brought together more than 20 State and Federal agencies to develop a long-term comprehensive plan to restore ecological health and improve water management for all beneficial uses in the Bay-Delta system. The program specifically addressed ecosystem quality, water quality, water supply, and levee system integrity. The California Bay-Delta Authority was replaced in 2009 by the Delta Stewardship Council, but many of its programs continue to be implemented and are now housed within the CALFED program's former member agencies.

The CALFED Ecosystem Restoration Program (ERP) developed a strategic plan for implementing an ecosystem-based approach for achieving conservation targets (CALFED 2000a, pp. 1–3). The CDFG is the primary implementing agency for the ERP. The goal of ERP in improving conditions for longfin smelt will carry forward, irrespective of the species Federal listing status. CALFED had an explicit goal to balance the water supply program elements with the restoration of the Bay-Delta and tributary ecosystems and recovery of the longfin smelt and other species. Because achieving the diverse goals of the program is iterative and subject to

annual funding by diverse agencies, the CALFED agencies have committed to maintaining balanced implementation of the program within an adaptive management framework. The intention of this framework is that the storage, conveyance, and levee program elements would be implemented in such a way that the longfin smelt's status would be maintained and eventually improved.

CALFED identified 54 species enhancement conservation measures for longfin smelt, more than half of which have been completed (CALFED Ecosystem Restoration Project 2011, entire). One such restoration action at Liberty Island at the southern end of the Yolo Bypass (a flood control project) has likely benefitted longfin smelt. After years of active agricultural production on Liberty Island, the levees were breached in 1997, and the island was allowed to return to a more natural state (Wilder 2010, slide 4). Wildlands Corporation has recently completed a restoration project removing several levees surrounding Liberty Island and creating 186 acres of various habitats for fish (Wildlands 2011, p. 1). Longfin smelt are utilizing the flooded island, and were collected in a number of surveys between 2003 and 2005 (Liberty Island Monitoring Program 2005, pp. 42–44; Marshall *et al.* 2006, p. 1).

The Bay-Delta Conservation Plan (BDCP), an effort to help provide restoration of the Bay-Delta ecosystem and reliable water supplies, is currently in preparation by a collaborative of water agencies, resource agencies, and environmental groups. The BDCP is intended to provide a basis for permitting take of listed species under sections 7 and 10 of the Act and the California Natural Communities Conservation Planning Act, and would provide a comprehensive habitat conservation and restoration plan for the Bay-Delta, as well as a new funding source. The BDCP

shares many of the same goals outlined in the 2000 CALFED Record of Decision (CALFED 2000) but would not specifically address all listed-species issues. The BDCP would, however, target many of the threats to current and future listed species and could contribute to species recovery. However, the BDCP, if completed, would not be initiated until at least 2013 or later. The plan's implementation is anticipated to extend through 2060.

Humboldt Bay

The Humboldt Bay Watershed Advisory Committee has completed the Humboldt Bay Salmon and Steelhead Conservation Plan with funding from CDFG, National Oceanographic Atmospheric Administration (NOAA), and the California State Coastal Conservancy with the purpose of protecting and restoring salmon habitat in Humboldt Bay through cooperative planning (Humboldt Bay Watershed Advisory Committee 2005, pp. 1–2). Many of the habitat restoration activities proposed may benefit longfin smelt, including restoration in freshwater streams and brackish sloughs. The Natural Resource Services has designed an enhancement program that is based on the Humboldt Bay Salmon and Steelhead Conservation Plan. Natural Resource Services has completed a tidal marsh enhancement project on Freshwater Creek and has other projects in the design stage (Don Allen 2011, pers. comm.). The Natural Resource Services is a division of the Redwood Community Action Agency dedicated to improving the health of northern California communities and the watersheds that they depend on (NRS 2011, p. 1). These types of restoration efforts are current and ongoing and may benefit longfin smelt by increasing access to intertidal areas within Humboldt Bay.

Puget Sound

The Puget Sound Partnership is a Washington State Agency created in 2007, to oversee the restoration and protection of Puget Sound. The Puget Sound Partnership created an Action Agenda that identifies and prioritizes work needed to protect and restore Puget Sound (Puget Sound Partnership 2008b, p. 2). Protection actions including local watershed planning, shoreline management planning, and citizen involvement through groups such as beach watchers and shore stewards are among the current restoration efforts in Puget Sound watershed (Puget Sound Partnership 2008a, pp. 1–2). These measures are expected to benefit longfin smelt by protecting and restoring habitat through legislative approval and funding for land acquisition for protection and restoration of ecologically important lands and habitats and by adding lands to State Aquatic Reserves program (Puget Sound Partnership 2008a, pp. 1–2).

Alaska

State and Federal land ownership affords protection for vast distances of shoreline within Glacier Bay and Wrangell-St. Elias National Parks, Tongass National Forest, and State landholdings. Kachemak Bay, located near the mouth of lower Cook Inlet, is a National Estuarine Research Reserve regarded as extremely important for marine biodiversity conservation (ADFG 2006, pp. 133–134). Alaska's only State wilderness park, Kachemak Bay State Park, is also located in Kachemak Bay (ADNR 2011, p. 1). Yakutat Bay lies between peninsular and mainland Alaska and is bordered by Wrangell-St. Elias National Park to the northwest and Tongass National Forest. The Federal lands surrounding Yakutat Bay protect it from the effects of development. The Tongass National Forest management plan requires that

logging activities be distanced from estuarine and riparian edges (ADFG 2006, p. 107). As a species group, the osmerids are identified in Alaska's Comprehensive Wildlife Conservation Strategy as Species of Greatest Conservation Need (ADFG 2006, pp. 140–143). The Conservation Action Plan for anadromous smelts identifies objectives, issues, and conservation actions to address information gaps. Determining life history, trophic ecology, instream flow and habitat needs, and monitoring protocols are included as measures that need to be undertaken as part of Alaska's Conservation Strategy to identify conservation status and needs of anadromous smelt including longfin.

Summary of Information Pertaining to the Five Factors

Section 4 of the Act (16 U.S.C. 1533) and implementing regulations (50 CFR part 424) set forth procedures for adding species to, removing species from, or reclassifying species on the Federal Lists of Endangered and Threatened Wildlife and Plants. Under section 4(a)(1) of the Act, a species may be determined to be endangered or threatened based on any of the following five factors:

- (A) The present or threatened destruction, modification, or curtailment of its habitat or range;
- (B) Overutilization for commercial, recreational, scientific, or educational purposes;
- (C) Disease or predation;
- (D) The inadequacy of existing regulatory mechanisms; or
- (E) Other natural or manmade factors affecting its continued existence.

In making these findings, information pertaining to each species in relation to the five factors provided in section 4(a)(1) of the Act is discussed below. In considering what factors might constitute threats to a species, we must look beyond the exposure of the species to a particular factor to evaluate whether the species may respond to the factor in a way that causes actual impacts to the species. If there is exposure to a factor and the species responds negatively, the factor may be a threat, and during the status review, we attempt to determine how significant a threat it is. The threat is significant if it drives or contributes to the risk of extinction of the species such that the species warrants listing as endangered or threatened as those terms are defined by the Act. However, the identification of factors that could impact a species negatively may not be sufficient to compel a finding that the species warrants listing. The information must include evidence sufficient to suggest that the potential threat has the capacity (i.e., it should be of sufficient magnitude and extent) to affect the species' status such that it meets the definition of endangered or threatened under the Act.

In making our 12-month finding on the petition, we considered and evaluated the best available scientific and commercial information. Much of the scientific and commercial information available on potential threats to longfin smelt comes from information on the Bay-Delta, and therefore the threats analysis is largely focused on the Bay-Delta longfin smelt population.

Factor A. The Present or Threatened Destruction, Modification, or Curtailment of Its Habitat or Range

Potential threats to longfin smelt habitat include the effects of reduced freshwater flow, climate change, and channel disturbance. Nearly all information available on Factor A threats to longfin smelt come from the Bay-Delta estuary. Therefore, our analysis below focuses on habitat impacts to the Bay-Delta population.

Reduced Freshwater Flow

Most longfin smelt populations, other than those in a few freshwater lakes in Washington and British Columbia, are known from estuaries. Estuaries are complex ecosystems with boundaries between freshwater, brackish water, and saltwater that vary in time and space. Drought and water diversions affect these boundaries by altering the amounts and timing of freshwater flow into and within the estuary. These altered freshwater flows affect the physical and biological characteristics of the estuary, and the physical and biological characteristics of the estuary define longfin smelt habitat.

Many environmental attributes respond to variance in freshwater flow into the estuary, including patterns of flooding and drought, nutrient loading, sediment loading (turbidity), concentration of organic matter and planktonic biota, physical changes in the movement and compression of the salt field, and changes in the hydrodynamic environment (Kimmerer 2002a, p. 40). The San Francisco Estuary exhibits one of the strongest and most consistent responses of biota to flow among large estuaries (Kimmerer 2004, p. 14).

Reduced freshwater flows into estuaries may affect fish and other estuarine biota in

multiple ways. Effects may include: (1) Decreased nutrient loading, resulting in decreased primary productivity; (2) decreased stratification of the salinity field, resulting in decreased primary productivity; (3) decreased organic matter loading and deposition into the estuary; (4) reduced migration cues; (5) decreased sediment loading and turbidity, which may affect both feeding efficiency and predation rates; (6) reduced dilution of contaminants; (7) impaired transport to rearing areas (e.g., low-salinity zones); and (8) reduction in physical area of, or access to, suitable spawning or rearing habitat Kimmerer (2002b, p. 1280).

Bay-Delta Population

Freshwater flow is strongly related to the natural hydrologic cycles of drought and flood. In the Bay-Delta estuary, increased Delta outflow during the winter and spring is the largest factor positively affecting longfin smelt abundance (Stevens and Miller 1983, pp. 431–432; Jassby *et al.* 1995; Sommer *et al.* 2007, p. 274; Thomson *et al.* 2010, pp. 1439–1440). During high outflow periods, larvae presumably benefit from increased transport and dispersal downstream, increased food production, reduced predation through increased turbidity, and reduced loss to entrainment due to a westward shift in the boundary of spawning habitat and strong downstream transport of larvae (CFDG 1992; Hieb and Baxter 1993; CDFG 2009a). Conversely, during low outflow periods, negative effects of reduced transport and dispersal, reduced turbidity, and potentially increased loss of larvae to predation and increased loss at the export facilities result in lower young-of-the-year recruitment. Despite numerous studies of longfin smelt abundance and flow in the Bay-Delta, the underlying causal mechanisms are still not fully understood (Baxter *et al.* 2010, p. 69; Rosenfield 2010, p. 9).

As California's population has grown, demands for reliable water supplies and flood protection have grown. In response, State and Federal agencies built dams and canals, and captured water in reservoirs, to increase capacity for water storage and conveyance resulting in one of the largest manmade water systems in the world (Nichols *et al.* 1986, p. 569). Operation of this system has altered the seasonal pattern of freshwater flows in the watershed. Storage in the upper watershed of peak runoff and release of the captured water for irrigation and urban needs during subsequent low flow periods result in a broader, flatter hydrograph with less seasonal variability in freshwater flows into the estuary (Kimmerer 2004, p. 15).

In addition to the system of dams and canals built throughout the Sacramento River-San Joaquin River basin, the Bay-Delta is unique in having a large water diversion system located within the estuary (Kimmerer 2002b, p. 1279). The State Water Project (SWP) and Central Valley Project (CVP) operate two water export facilities in the Delta (Sommer *et al.* 2007, p. 272). Project operation and management is dependent upon upstream water supply and export area demands. Despite the size of the water storage and diversion projects, much of the interannual variability in Delta hydrology is due to variability in precipitation from year to year. Annual inflow from the watershed to the Delta is strongly correlated to unimpaired flow (runoff that would hypothetically occur if upstream dams and diversions were not in existence), mainly due to the effects of high-flow events (Kimmerer 2004, p. 15). Water operations are regulated in part by the California State Water Resources Control Board (SWRCB) according to the Water Quality Control Plan (WQCP) (SWRCB 2000, entire). The WQCP limits Delta water exports in relation to Delta inflow (the Export/Inflow, or E/I ratio).

It is important to note that in the case of the Bay-Delta, freshwater flow is expressed as both Delta inflow (from the rivers into the Delta) and as Delta outflow (from the Delta into the lower estuary), which are closely correlated, but not equivalent. Freshwater flow into the Delta affects the location of the low salinity zone and X2 within the estuary. Because longfin smelt spawn in freshwater, they must migrate farther upstream to spawn as flow reductions alter the position of X2 and the low-salinity zone moves upstream (CDFG 2009, p. 17). Longer migration distances into the Bay-Delta make longfin smelt more susceptible to entrainment in the State and Federal water pumps (see Factor E: Entrainment Losses). In periods with greater freshwater flow into the Delta, X2 is pushed farther downstream (seaward); in periods with low flows, X2 is positioned farther landward (upstream) in the estuary and into the Delta. Not only is longfin smelt abundance in the Bay-Delta strongly correlated with Delta inflow and X2, but the spatial distribution of longfin smelt larvae is also strongly associated with X2 (Dege and Brown 2004, pp. 58–60; Baxter *et al.* 2010, p. 61). As longfin hatch into larvae, they move from the areas where they are spawned and orient themselves just downstream of X2 (Dege and Brown 2004, pp. 58-60). Larval (winter-spring) habitat varies with outflow and with the location of X2 (CDFG 2009, p. 12), and has been reduced since the 1990s due to a general upstream shift in the location of X2 (Hilts 2012, unpublished data). The amount of rearing habitat (salinity between 0.1 and 18 ppt) is also presumed to vary with the location of X2 (Baxter *et al.* 2010, p. 64). However, as previously stated, the location of X2 is of particular importance to the distribution of newly-hatched larvae and spawning adults. The influence of water project operations from November through April, when spawning adults and newly-hatched larvae are oriented to X2, is greater in drier years than in wetter years (Knowles 2002, p. 7).

Research on declines of longfin smelt and other pelagic fish species in the Bay-Delta since 2002 (referred to as Pelagic Organism Decline—see Abundance section, above) have most recently been summarized in the Interagency Ecological Program’s 2010 Pelagic Organism Decline Work Plan and Synthesis of Results (Baxter *et al.* 2010, pp. 61–69). While Baxter *et al.* (2010, pp. 17–19) acknowledge significant uncertainties about the causal mechanisms underlying the Pelagic Organism Decline, they have identified reduced Delta freshwater flows as one of several key factors that they believe contribute to recent declines in the abundance of longfin smelt (Baxter *et al.* 2010, pp. 61–69, Figure 5).

Other Populations

Information on effects of reduced freshwater flows on longfin smelt populations other than the Bay-Delta population are lacking. Dams and reservoirs are located in the inland water basins of most of the estuaries where longfin smelt occur. Some of these systems are large and consist of multiple dams and diversions (e.g., Klamath River basin, Columbia River basin). Water diversion systems with dams, canals, and water pipelines located upstream of the estuary may affect longfin smelt aquatic habitat by reducing freshwater flows into the estuary—especially if water is diverted out of the drainage basin—and altering the timing of freshwater flows into the estuary.

Climate Change

“Climate” refers to an area's long-term average weather statistics (typically for at least 20- or 30- year periods), including the mean and variation of surface variables such as temperature, precipitation, and wind, whereas “climate change” refers to a change in the mean and/or variability of climate properties that persists for an extended period (typically decades or longer), whether due to natural processes or human activity (Intergovernmental Panel on Climate Change (IPCC) 2007a, p. 78). Although changes in climate occur continuously over geological time, changes are now occurring at an accelerated rate. For example, at continental, regional, and ocean basin scales, recent observed changes in long-term trends include: a substantial increase in precipitation in eastern parts of North American and South America, northern Europe, and northern and central Asia, and an increase in intense tropical cyclone activity in the North Atlantic since about 1970 (IPCC 2007a, p. 30); and an increase in annual average temperature of more than 2° F (1.1°C) across the United States since 1960 (Global Climate Change Impacts in the United States (GCCIOUS) 2009, p. 27). Examples of observed changes in the physical environment include: an increase in global average sea level, and declines in mountain glaciers and average snow cover in both the northern and southern hemispheres (IPCC 2007a, p. 30); substantial and accelerating reductions in arctic sea-ice (e.g., Comiso *et al.* 2008, p. 1); and a variety of changes in ecosystem processes, the distribution of species, and the timing of seasonal events (e.g., GCCIOUS 2009, pp. 79-88).

The IPCC used Atmosphere-Ocean General Circulation Models and various greenhouse gas emissions scenarios to make projections of climate change globally and for broad regions through the 21st century (Meehl *et al.* 2007, p. 753; Randall *et al.* 2007, pp. 596–599), and reported these projections using a framework for characterizing certainty (Solomon *et al.* 2007,

pp. 22-23). Examples include: (1) It is virtually certain there will be warmer and more frequent hot days and nights over most of the earth's land areas; (2) it is very likely there will be increased frequency of warm spells and heat waves over most land areas, and the frequency of heavy precipitation events will increase over most areas; and (3) it is likely that increases will occur in the incidence of extreme high sea level (excludes tsunamis), intense tropical cyclone activity, and the area affected by droughts (IPCC 2007b, p. 8, Table SPM.2). More recent analyses using a different global model and comparing other emissions scenarios resulted in similar projections of global temperature change across the different approaches (Prinn *et al.* 2011, pp. 527, 529).

All models (not just those involving climate change) have some uncertainty associated with projections due to assumptions used, data available, and features of the models; with regard to climate change this includes factors such as assumptions related to emissions scenarios, internal climate variability, and differences among models. Despite this, however, under all global models and emissions scenarios, the overall projected trajectory of surface air temperature is one of increased warming compared to current conditions (Meehl *et al.* 2007, p. 762; Prinn *et al.* 2011, p. 527). Climate models, emissions scenarios, and associated assumptions, data, and analytical techniques will continue to be refined, as will interpretations of projections, as more information becomes available. For instance, some changes in conditions are occurring more rapidly than initially projected, such as melting of arctic sea ice (Comiso *et al.* 2008, p. 1; Polyak *et al.* 2010, p. 1797), and since 2000 the observed emissions of greenhouse gases, which are a key influence on climate change, have been occurring at the mid- to higher levels of the various emissions scenarios developed in the late 1990s and used by the IPCC for making projections

(e.g., Raupach *et al.* 2007, Figure 1, p. 10289; Manning *et al.* 2010, Figure 1, p. 377; Pielke *et al.* 2008, entire). Also, the best scientific and commercial data available indicate that average global surface air temperature is increasing and that several climate-related changes are occurring and will continue for many decades even if emissions are stabilized soon (e.g. Meehl *et al.* 2007, pp. 822-829; Church *et al.* 2010, pp. 411-412; Gillett *et al.* 2011, entire).

Changes in climate can have a variety of direct and indirect impacts on species, and can exacerbate the effects of other threats. Rather than assessing “climate change” as a single threat in and of itself, we examine the potential consequences to species and their habitats that arise from changes in environmental conditions associated with various aspects of climate change. For example, climate-related changes to habitats, predator-prey relationships, disease and disease vectors, or conditions that exceed the physiological tolerances of a species, occurring individually or in combination, may affect the status of a species. Vulnerability to climate change impacts is a function of sensitivity to those changes, exposure to those changes, and adaptive capacity (IPCC 2007, p. 89; Glick *et al.* 2011, pp. 19-22). As described above, in evaluating the status of a species, the Service uses the best scientific and commercial data available, and this includes consideration of direct and indirect effects of climate change. As is the case with all potential threats, if a species is currently affected or is expected to be affected by one or more climate-related impacts, this does not necessarily mean the species is an endangered or threatened species as defined under the Act. If a species is listed as endangered or threatened, this knowledge regarding its vulnerability to, and impacts from, climate-associated changes in environmental conditions can be used to help devise appropriate strategies for its recovery.

The effects of climate change do not act in isolation, but act in combination with existing threats to species and systems. We considered the potential effects of climate change on the longfin smelt based on projections derived from various modeling scenarios. Temperature increases are likely to lead to a continued rise in sea level, further increasing salinity within longfin smelt estuarine rearing habitat and likely shifting spawning and early rearing upstream as the boundary of fresh and brackish water moves upstream (Baxter 2011, pers. comm.). Reduced snowpack, earlier melting of the snowpack, and increased water temperatures will likely alter freshwater flows, possibly shifting and condensing the timing of longfin smelt spawning (Baxter 2011, pers. comm.).

Effects of climate change could be particularly profound for aquatic ecosystems and include increased water temperatures and altered hydrology, along with changes in the extent, frequency, and magnitude of extreme events such as droughts, floods, and wildfires (Reiman and Isaak 2010, p. 1). Numerous climate models predict changes in precipitation frequency and pattern in the western United States (IPCC 2007b, p. 8). Projections indicate that temperature and precipitation changes will diminish snowpack, changing the availability of natural water supplies (USBR 2011, p. 143). Warming may result in more precipitation falling as rain and less storage as snow. This would result in increased rain-on-snow events and increase winter runoff as spring runoff decreases (USBR 2011, p. 147). Earlier seasonal warming increases the likelihood of rain-on-snow events, which are associated with mid-winter floods. Smaller snowpacks that melt earlier in the year result in increased drought frequency and severity (Reiman and Isaak 2010, p. 6). These changes may lead to increased flood and drought risk

during the 21st century (USBR 2011, p. 149).

It is uncertain how a change in the timing and duration of freshwater flows will affect longfin smelt. The melting of the snowpack earlier in the year could result in higher flows in January and February, which are peak spawning and hatching months for longfin smelt. This would reduce adult migration distance and increase areas of freshwater spawning habitat during these months, potentially creating better spawning and larval rearing conditions. Associated higher turbidity may reduce predation on longfin smelt adults and larvae (Baxter 2011, pers. comm.). However, if high flows last only a short period, benefits may be negated by poorer conditions before and after the high flows. As the freshwater boundary moves farther inland into the Delta with increasing sea level (see below) and reduced flows, adults will need to migrate farther into the Delta to spawn, increasing the risk of predation and the potential for entrainment into water export facilities and diversions for both themselves and their progeny.

Global sea level rose at an average rate of 1.8 mm (0.07 in) per year from 1961 to 2003, and at an average rate of 3.1 mm (0.12 in) per year from 1993 to 2003 (IPCC 2007a, p. 49). The IPCC (2007b, p. 13) report estimates that sea levels could rise by 0.18 to 0.58 m (0.6 to 1.9 ft) by 2100; however, Rahmstorf (2007, p. 369) indicated that global sea level rise could increase by over 1.2 m (4 ft) in that time period (CEC 2009, p. 49). Even if emissions could be halted today, the oceans would continue to rise and expand for centuries due to their capacity to store heat (CEC 2009, pp. 49–50). In the Bay-Delta, higher tides combined with more severe drought and flooding events are likely to increase the likelihood of levee failure, possibly resulting in major alterations of the environmental conditions (Moyle 2008, pp. 362–363). It is reasonable to

conclude that more severe drought and flooding events will also occur in other estuaries where the longfin smelt occurs. Sea level rise is likely to increase the frequency and range of saltwater intrusion. Salinity within the northern San Francisco Bay is projected to rise 4.5 psu by the end of the century (Cloern *et al.* 2011, p. 7). Elevated salinity levels could push the position of X2 farther up the estuary and could result in increased distances that longfin smelt must migrate to reach spawning habitats. Elevated sea levels could result in greater sedimentation, erosion, coastal flooding, and permanent inundation of low-lying natural ecosystems (CDFG 2009, p. 30).

Typically, longfin smelt spawning in the Bay-Delta occurs at water temperatures between 7.0 and 14.5 °C (44.6–58.2 °F), although spawning has been observed at lower temperatures in other areas, such as Lake Washington (Moyle 2002, p. 236). Mean annual water temperatures within the upper Sacramento River portion of the Bay-Delta estuary are expected to approach or exceed 14 °C during the second half of this century (Cloern *et al.* 2011, p. 7). Increased water temperatures could compress the late-fall to early-spring spawning period and could result in shorter egg incubation time. Longfin smelt are adapted to hatching in cold, relatively unproductive waters where they grow slowly until ample food resources are available in spring. Warmer water during winter would likely result in increased metabolism of larvae, which may result in increased food needs for maintenance and growth and create a mismatch between food needs and availability (Baxter 2011, pers. comm.). If increased water temperatures compress the spawning period and lead to more synchronized hatching during winter, then prevailing low sunlight and low food resources could result in greater intra-specific (within species) competition (Baxter 2011, pers. comm.). Moreover, increasing water temperatures might also lead to earlier spawning and hatching of other fishes, and to greater inter-specific (between species)

competition.

Although climate change and sea level rise are projected to result in continued increases in water temperature and salinity, longfin smelt is considered euryhaline (tolerant of a wide range of salinities) (Moyle 2002, p. 236; Rosenfield and Baxter 2007 p. 1578) and is known to move between different parts of the estuary that vary greatly in temperature and salinity. Being able to move between aquatic habitats that vary greatly in water temperature and salinity may reduce the potential impacts of climate change and sea level rise to some degree.

Channel Disturbances

Dredging and other channel disturbances potentially degrade spawning habitat and cause entrainment loss of individual fish and eggs; disposal of dredge spoils also can create large sediment plumes that expose fish to gill-clogging sediments and possibly to decreased oxygen availability (Levine-Fricke 2004, p. 56). Longfin smelt is a pelagic species (living away from the bottom of the water column and shoreline), and thus less likely to be directly affected by dredging, sand and gravel mining, and other disturbances to the channel bed compared to bottom-dwelling fish species. Longfin smelt are likely most vulnerable to entrainment by dredging during spawning and egg incubation because eggs are deposited and develop on channel bottom substrates (CDFG 2009, p. 27). Egg development takes approximately 40 days (Moyle 2002, p. 236).

We have found no information documenting population impacts of dredging or sand and

gravel mining on longfin smelt. Channel maintenance dredging occurs regularly within the Bay-Delta and other estuaries that serve as shipping channels (e.g., Humboldt Bay, Coos Bay, Yaquina Bay, Columbia River). In their 2009 status review on longfin smelt, CDFG concluded that effects of regular maintenance dredging and sand mining within the Bay-Delta estuary on longfin smelt were expected to be small and localized (CDFG 2009, p. 26). They reviewed two studies on entrainment effects of channel dredging, and each study found that no longfin smelt were entrained during dredging (fish that were entrained were primarily bottom-dwelling species).

There is currently a proposal to deepen and selectively widen the Sacramento Deep Water Ship Channel and the lower portion of the Sacramento River in the Bay-Delta. This dredging project would remove between 6.1–7.6 million cubic meters (8 and 10 million cubic yards) of material from the channel and Sacramento River and extend for 74 km (45.8 mi) (USACE 2011a, entire). Potential effects of this new project to longfin smelt include mortality through loss of spawning substrate, habitat modification, and a shift in spawning and rearing habitat. The project also has potential to alter breeding and foraging behavior of the Bay-Delta longfin smelt population. However, this project is only a proposal at this time and is not certain to occur. Potential effects of the proposed project are currently under evaluation.

Summary of Factor A

Although we find that reduced freshwater flows are currently a threat to the Bay-Delta longfin smelt population, it is difficult to make inferences on the effects of reduced freshwater

flows to longfin smelt populations throughout the species range. Because the Bay-Delta system includes one of the largest man made water system in the world, it would be impractical to compare diversions and alterations in other estuaries to diversions and alterations in the Bay-Delta. The effects of water development in the Bay-Delta are unique to the physical, geologic, and hydrologic environment of the estuary. Reduced flow from diversions and dams in other estuaries is not expected to be as significant as the reduced flows that have been shown in the Bay-Delta because less water is exported from other estuaries. We have no information to show that reduced freshwater flow is a threat to longfin smelt in other estuaries. Therefore, we conclude that while reduced flow is a threat to the Bay-Delta population of longfin smelt, the best available science does not indicate that the lack of freshwater flow is a threat to the species in other parts of its range.

Climate change will likely affect longfin smelt in multiple ways, but longfin smelt are able to move between a wide range of aquatic environments that vary greatly in water temperature and salinity. These behavioral and physiological characteristics of the species may help it adapt to effects of climate change. We conclude at this time that the best available information does not indicate that climate change threatens the continued existence of longfin smelt across its range.

Channel disturbances may have localized impacts to longfin smelt habitat suitability, but the best available information does not indicate that they pose significant threats to the species throughout its range.

Based on the best available scientific information, we conclude that reduced freshwater flows, climate change, and channel disturbances are not significant current or future threats to longfin smelt across its range except in the Bay-Delta, where reduced freshwater flow is a threat.

Factor B. Overutilization for Commercial, Recreational, Scientific, or Educational Purposes

Recreational and Commercial Fishing

In California, longfin smelt was listed as a threatened species under the State's Endangered Species Act in 2009. This status makes take of longfin smelt illegal, unless authorized by an incidental take permit or other take authorization. However, longfin smelt are caught as bycatch in small bay shrimp trawl fishery and bait fishing (anchovies and sardines) operations in South San Francisco Bay, San Pablo Bay, and Carquinez Strait (CDFG 2009a, p. 1). CDFG (2009d, pp. 6, 9) estimated the total longfin smelt bycatch from shrimping in 1989 and 1990 at 15,539 fish, and in 2004 at 18,815–30,574 fish. CDFG noted in 2009 that the bay shrimp trawl fishery industry had declined since 2004 (CDFG 2009d, p. 3). No shrimp fishery currently takes place in Humboldt Bay (Mello 2011, pers. comm.).

In Oregon, smelt species may not be targeted in commercial fisheries, and if taken incidentally, smelt catch cannot exceed 1 percent of the total weight landed (ODFW 2011, p. 17). Rules limit in which estuaries bait fishing for herring, sardines, anchovies, and shad may occur. In Oregon, there is currently no known shrimping taking place within the estuaries where the longfin smelt might be found. Although a limited entry roe herring fishery is allowed in Yaquina

Bay, no landings have occurred there since 2003, because biomass estimates have generally been too low to make the fishery economically viable (Krutzikowsky 2011, pers. comm.). Anchovy fishing is allowed in Tillamook Bay, Yaquina Bay, and Coos Bay, but because there is currently no anchovy fishing occurring in these areas (Krutzikowsky 2011, pers. comm.), longfin smelt are not taken as bycatch. Records for commercial landings in Oregon show a total of 9.1 kilograms (kg) (20 pounds (lb)) landed from 2005 to 2010 for smelt species other than eulachon. Recreational fishing for smelt species is allowed only in marine waters (Oregon Sport Fishing Regulations, p. 11).

The State of Washington includes longfin smelt in a class of fish referred to as forage fish (small schooling fish that are major food items for many species of fish, birds, and marine mammals) (Bargmann 1998, p. 1). Both recreational and commercial fisheries exist for forage fish in Washington, but the recreational fishery is much smaller than the commercial fishery. A sport fishing license is not needed to catch smelt. Smelt can be harvested recreationally using a dip net or jig. Dip net fishing for longfin smelt is allowed in the Nooksack River and there are approximately two hundred trips a year made to fish for longfin smelt in this area (O'Toole 2011, pers. comm.). It is unlawful to use a herring or smelt rake. Sport and tribal commercial fisheries have been reported to occur on the Nooksack River longfin smelt stock (Bargmann 1998, p. 37). Longfin smelt may be caught incidentally in a medium-sized shore or pier-based recreational fishery for surf smelt in Puget Sound.

There is currently no commercial fishing regulation specific to longfin smelt in Washington (Paulson 2011, pers. comm.). The daily limit for smelt is 4.5 kg (10 lb) and, like

Oregon, is counted as an aggregate, which can include herring, sardines, sandlance, and anchovies (WDFW 2011, p. 27). There is a robust commercial herring fishery in Washington that takes approximately 450 metric tons (500 tons) of fish per year (for sport bait) and a commercial surf smelt fishery that takes approximately 450,000 kg (100,000 lb) of fish per year (for human consumption). Longfin smelt bycatch in both of these fisheries is low. Anchovy fishing in Washington primarily takes place in Grays Harbor and the mouth of the Columbia River (O'Toole 2011, pers. comm.).

In British Columbia, take of smelt from recreational fishing is limited to 20 kilograms (kg) (44 lb) per day and 40 kg (88 lb) of total catch in possession. The fishing season takes place from April 1 to June 14 (Department of Fisheries and Oceans Canada 2011a, p. 47). A commercial fishing industry targeting surf smelt may incidentally take longfin smelt (Department of Fisheries and Oceans Canada 2011b, p. 1). British Columbia supports a year-round shrimp fishery in Prince Rupert and Chatham Sound. Sardine and shrimp fishing occurs near Vancouver.

In Alaska, a commercial fishery for smelt, which includes eulachon, was reopened in 2005. This fishery is restricted to the brackish waters of Cook Inlet, from May 1 to June 30. The total annual harvest of eulachon and longfin smelt may not exceed 90 metric tons (100 tons) of smelt. However, longfin smelt are unlikely to be specifically targeted in this fishery due to their small numbers in relation to eulachon in the region (Shields 2005, p. 4). Sport fishing is limited to salt water, where herring and smelt may be taken (Alaska Department of Fish and Game (ADFG) 2010, p. 1). In Prince William Sound, the herring fishery has closed due to low

abundance of herring.

Monitoring Surveys

Fisheries monitoring surveys are conducted by NOAA's National Marine Fisheries Service, the Service and by State and local agencies in water bodies inhabited by longfin smelt throughout their range. Most of these surveys target other species, primarily salmonids, and rarely collect longfin smelt outside of the Bay-Delta area.

Within the Bay-Delta, longfin smelt are regularly captured in monitoring surveys. The Interagency Ecological Program (IEP) implements scientific research in the Bay-Delta. Although the focus of its studies and the level of effort have changed over time, in general, their surveys have been directed at researching the Pelagic Organism Decline in the Bay-Delta. Between the years of 1987 to 2011, combined take of longfin smelt less than 20 mm (0.8 in) in length ranged from 2,405 to 158,588 annually. All of these fish were preserved for research or assumed to die in processing. During the same time period, combined take for juveniles and adults (fish greater than or equal to 20 mm (0.8 in)) ranged from 461 to 68,974 annually (IEP 2011, no pagination). Although mortality is unknown, the majority of these fish likely do not survive. The Chipps Island survey, which is conducted by the Service, has captured an average of 2,697 longfin smelt per year during the past 10 years. Biologists attempt to release these fish unharmed, but at least 5,154 longfin smelt were known to have died during the Chipps Island survey between 2001 and 2008 (Service 2010, entire).

Survey methods have been modified recently to minimize potential impacts to delta smelt, a related species that also occurs in the Bay-Delta (75 FR 17669; April 7, 2010). These modifications are likely to result in reduced impacts to longfin smelt also. The Service conducts other surveys in the Bay-Delta to monitor salmon populations (Mosssdale trawl, Sacramento trawl, beach seine surveys), but few longfin smelt are captured during these surveys. Mortality due to monitoring surveys was not identified by the Interagency Ecological Program in its most recent synthesis of results as a factor in the decline of longfin smelt and other pelagic fish species in the Bay-Delta since the early 2000s (Baxter *et al.* 2010, pp. 19–53, 61–69).

Summary of Factor B

The species is incidentally caught in commercial shrimp and bait fishing operations throughout much of its range, but the bycatch numbers are usually low. In California, take of longfin smelt is illegal without authorization because the species is listed as threatened under the California Endangered Species Act. Because of its small size, it is not targeted by recreational angling, although it is certainly caught and used as bait for other larger recreational fish species. Monitoring surveys have resulted in high numbers of longfin smelt mortality in the Bay-Delta in the past, but efforts being made to reduce survey mortality for delta smelt, such as reductions in tow times, likely have also benefitted longfin smelt. The scientific collection surveys being conducted in the Bay-Delta are limited to research designed to benefit the species, and mortality from monitoring surveys has not been identified as a factor in the longfin smelt's recent population decline. We have no information indicating that mortality from monitoring surveys threatens any populations within the species' range. We conclude that overutilization due to

commercial, recreational, or scientific take is not a significant current or future threat to the longfin smelt throughout its range.

Factor C. Disease or Predation

Disease

All the information we found on disease in longfin populations originated from studies in the Bay-Delta. Two investigations published in 2006 and 2008 by the California-Nevada Fish Health Center detected no significant health problems in juvenile longfin smelt in the Bay-Delta (Foott and Stone 2008, pp. 15–16). The low observed rate of parasitic infection did not appear to affect the health of the fish, as indicated by the lack of associated tissue damage or inflammation (Foott and Stone 2008, p. 15). The only additional documentation of relevant wild fish disease in the Bay-Delta was a severe intestinal infection by a new species of myxozoan observed in nonnative juvenile yellowfin goby (*Acanthogobius flavimanus*) from Suisun Marsh (Baxa *et al.* in prep cited in Baxter *et al.* 2008, p. 16). The nonnative gobies could act as potential vectors of the parasite to other susceptible species in the Bay-Delta. It is unknown whether this or similar infections are affecting the health of longfin smelt.

The south Delta is fed by water from the San Joaquin River, where pesticides (e.g., chlorpyrifos, carbofuran, and diazinon), salts (e.g., sodium sulfates), trace elements (boron and selenium), and high levels of total dissolved solids are prevalent due to agricultural runoff (64 FR 5963; February 8, 1999). Pesticides and other toxic chemicals may adversely affect the

immune system of longfin smelt and other fish in the Bay-Delta and other estuaries, but we found no information documenting such effects (see Factor E: Contaminants, below).

Predation

As a forage species, longfin smelt are preyed upon by a variety of fishes, birds, and mammals (Barnhart *et al.* 1992, p. 44). However, we found little information on predation of longfin smelt other than information for the Bay-Delta population and Lake Washington population. The striped bass (*Morone saxatilis*) is a potential predator of longfin smelt in the Bay-Delta. Striped bass were introduced into the Bay-Delta in 1879 and quickly became abundant throughout the estuary. However, their numbers have declined substantially over the last 40 years (Thomson *et al.* 2010, p. 1440), and they are one of the four species studied under Pelagic Organism Decline investigations (Baxter *et al.* 2010, p. 16). Numbers of largemouth bass (*Micropterus dolomieu*), another introduced species in the Bay-Delta, have increased in the Delta over the past few decades (Brown and Michniuk 2007, p. 196). Largemouth bass, however, occur in shallow freshwater habitats, closer to shore than the pelagic longfin smelt, and do not typically co-occur with longfin smelt. Baxter *et al.* (2010, p. 40) reported that no longfin smelt have been found in largemouth bass stomachs sampled in a recent study of largemouth bass diet. Moyle (2002, p. 238) believed that inland silverside (*Menidia beryllina*), another nonnative predatory fish, may be an important predator on longfin smelt eggs, larvae, juveniles, and adults. Rosenfield (2010, p. 18) acknowledged that they are likely major predators of longfin smelt eggs and larvae but thought it unlikely that they were an important predator on juveniles and subadults because inland silversides prefer shallow water habitats whereas juvenile

and subadult longfin smelt do not.

In the Bay-Delta, predation of longfin smelt may be high in the Clifton Court Forebay, where the SWP water export pumping plant is located (Moyle 2002, p. 238; Baxter *et al.* 2010, p. 42). However, once they are entrained in the Clifton Court Forebay, longfin smelt mortality would be high anyway due to high water temperatures in the forebay (CDFG 2009b, p. 4) and entrainment into the SWP water export pumping plant. In addition to elevated predation levels in the Clifton Court Forebay, predation also is concentrated at sites where fish salvaged from the SWP and CVP export facilities are released (Moyle 2002, p. 238). However, few longfin smelt survive the salvage and transport process (see Factor E: Entrainment Losses, below) and therefore predation is not expected to be an important factor at drop-off sites. Reduced freshwater flows may result in lower turbidity and increased water clarity (see Factor A, above), which may contribute to increased risk of predation (Baxter *et al.* 2010, p. 64).

In Lake Washington, longfin are preyed upon by prickly sculpin (*Cottus asper*) (Tabor *et al.* 2007, p. 1085) and cutthroat trout (*Oncorhynchus clarki*) (Norwak *et al.* 2004, p. 632; Beauchamp *et al.* 1992, p. 156). Cutthroat trout have displaced the northern pikeminnow as the most important predator in Lake Washington and may be having an effect on other components of the ecosystem, including longfin smelt populations (Norwak *et al.* 2004, pp. 633–634).

Summary of Factor C

Similar to other threats, very little information is available about disease or predation

threats to longfin smelt populations outside of the Bay-Delta. We found no information that disease is a threat to the longfin smelt throughout its range. Longfin smelt is a small fish that is preyed upon by a wide variety of fish, birds, and mammals, but we found no information documenting predation as a threat to the species rangewide. Predation, along with mortality from entrainment (see Factor E: Entrainment Losses, below), has been identified as a top-down effect that may be contributing to recent declines of longfin smelt and other pelagic fish species in the Bay-Delta estuary (Pelagic Organism Decline) (Sommer *et al.* 2007, p. 275). However, factors contributing to the Pelagic Organism Decline are numerous and complex, and the combination of underlying causal mechanisms remains uncertain (Baxter *et al.* 2010, pp. 61–69). Therefore, based on our review of the best available scientific and commercial information, we conclude that disease or predation are not significant current or future threats to the longfin smelt throughout its range.

Factor D. The Inadequacy of Existing Regulatory Mechanisms

Federal Laws

A number of federal environmental laws and regulations exist that may provide some protection for longfin smelt: the National Environmental Policy Act, the Central Valley Project Improvement Act, and the Clean Water Act.

National Environmental Policy Act

The National Environmental Policy Act (NEPA) (42 U.S.C. 4321 *et seq.*) requires all Federal agencies to formally document, consider, and publicly disclose the environmental impacts of major Federal actions and management decisions significantly affecting the human environment. NEPA documentation is provided in an environmental impact statement, an environmental assessment, or a categorical exclusion, and may be subject to administrative or judicial appeal. However, the Federal agency is not required to select an alternative having the least significant environmental impacts, and may select an action that will adversely affect sensitive species provided that these effects are known and identified in a NEPA document. Therefore, we do not consider the NEPA process in itself is to be a regulatory mechanism that is certain to provide significant protection for the longfin smelt.

Central Valley Project Improvement Act

The Central Valley Project Improvement Act (Pub. L. 102-575) (CVPIA) amends the previous Central Valley Project authorizations to include fish and wildlife protection, restoration, and mitigation as project purposes having equal priority with irrigation and domestic uses, and fish and wildlife enhancement as having an equal priority with power generation (Pub. L. 102-575, October 30, 1992; Bureau of Reclamation 2009). Included in CVPIA section 3406 (b)(2) was a provision to dedicate 800,000 acre-feet of Central Valley Project yield annually (referred to as “(b)(2) water”) for fish, wildlife, and habitat restoration. Since 1993, (b)(2) water has been used and supplemented with acquired environmental water (Environmental Water Account and CVPIA section 3406 (b)(3) water) to increase stream flows and reduce Central Valley Project export pumping in the Delta. These management actions were taken to contribute to the CVPIA

salmonid population doubling goals and to protect Delta smelt and their habitat (Guinee 2011, pers. comm.). As discussed above, (see Biology and Factor A discussions), increased freshwater flows have been shown to be positively correlated with longfin smelt abundance; therefore, these management actions, although targeted towards other species, should also benefit longfin smelt.

Clean Water Act

Established in 1977, the Clean Water Act (33 U.S.C. 1251 *et seq.*) is the primary Federal law in the United States regulating water pollution. It employs a variety of regulatory and non-regulatory means to reduce direct water quality impacts and manage polluted runoff. The Clean Water Act provides the basis for the National Pollutant Discharge Elimination System (NPDES) and gives the Environmental Protection Agency (EPA) the authority to set effluent limits and require any entity discharging pollutants to obtain a NPDES permit. The EPA is authorized through the Clean Water Act to delegate the authority to issue NPDES permits to State governments and has done so in California. In States that have been authorized to implement Clean Water Act programs, EPA retains oversight responsibilities. Water bodies that do not meet applicable water quality standards are placed on the section 303(d) list of impaired water bodies, and the State is required to develop appropriate total maximum daily loads (TMDL) for the water body. A TMDL is a calculation of the maximum amount of a pollutant that a water body can receive and still meet water quality standards. At present, TMDLs are not in place in all impaired watersheds in which longfin smelt are known to occur. The Clean Water Act has not effectively limited ammonia input into the system, and ammonia has been shown to

negatively affect the longfin smelt's food supply.

State Laws

The State of California has a number of environmental laws and regulations which may provide some protection for longfin smelt: California Endangered Species Act, California Environmental Quality Act, California Marine Invasive Species Act, Porter-Cologne Water Quality Control Act, and regulatory prohibitions on streambed alterations.

California Endangered Species Act

Longfin smelt was listed as threatened under the California Endangered Species Act (CESA) (California Fish and Game Code 2050 et seq.) in 2009. The CESA prohibits unpermitted possession, purchase, sale, or take of listed species. However, the CESA definition of take does not include harm, which under the Act's implementing regulations includes significant modification or degradation of habitat that actually kills or injures wildlife by significantly impairing essential behavioral patterns (50 CFR 17.3). CESA allows take of species for otherwise lawful projects through use of an incidental take permit. An incidental take permit requires that impacts be minimized and fully mitigated (CESA sections 2081 (b) and (c)). Furthermore, CESA requires that the issuance of the permit will not jeopardize the continued existence of a State-listed species. The CESA does require consultation between CDFG and other State agencies to ensure that activities of State agencies will not jeopardize the continued existence of State-listed species (CERES 2009, p. 1). Longfin Smelt Incidental Take Permit No.

2081-2009-001-03 specifies that the Smelt Working Group, which was created under the Service's 2008 delta smelt biological opinion (Service 2008, p. 30), provide recommendations for export pumping reduction to CDFG if any of several criteria is reached. One of the criteria is that total salvage of adult longfin smelt (fish greater than or equal to 80 mm in length) at the State Water Project and Central Valley Project export pumps between December and February may not exceed five times the Fall Midwater Trawl longfin smelt annual abundance index. Also, if longfin abundance is low and surveys indicate that adults are distributed close to the export pumps, the Smelt Working Group may consider making recommendations for Old and Middle River Flows that would reduce pumping (CDFG 2009c, pp. 1–34; Smelt Working Group 2011, p. 4).

California Environmental Quality Act

The California Environmental Quality Act ((CEQA) (Public Resources Code section 21000 *et seq.*)) requires review of any project that is undertaken, funded, or permitted by the State of California or a local government agency. If significant effects are identified, the lead agency has the option of requiring mitigation through changes in the project or to decide that overriding considerations make mitigation infeasible (CEQA sec. 21002). In the latter case, projects may be approved that cause significant environmental damage, such as destruction of listed endangered species or their habitat. Protection of listed species through CEQA is, therefore, dependent on the discretion of the lead agency. The CEQA review process ensures that a full environmental review is undertaken prior to the permitting of any project within longfin smelt habitat.

California Marine Invasive Species Act

The California Marine Invasive Species Act (AB 433) was passed in 2003. This 2003 act requires ballast water management for all vessels that intend to discharge ballast water in California waters. All qualifying vessels coming from ports within the Pacific Coast region must conduct an exchange in waters at least 50 nautical mi offshore and 200 m (656 ft) deep or retain all ballast water and associated sediments. To determine the effectiveness of the management provisions of this 2003 act, the legislation also requires State agencies to conduct a series of biological surveys to monitor new introductions to coastal and estuarine waters. These measures should further minimize the introduction of new invasive species into California's coastal waters that could be a threat to the longfin smelt. The Coastal Ecosystems Protection Act of 2006 deleted a sunset provision of the Marine Invasive Species Act, making the program permanent.

Porter-Cologne Water Quality Control Act

The Porter-Cologne Water Quality Control Act (California Water Code 13000 *et seq.*) is a California State law that establishes the State Water Resources Control Board (SWRCB) and nine Regional Water Quality Control Boards that are responsible for the regulation of activities and factors that could degrade California water quality and for the allocation of surface water rights (California Water Code Division 7). In 1995, the SWRCB developed the Bay-Delta Water Quality Control Plan that established water quality objectives for the Delta. This plan is currently implemented by Water Rights Decision 1641, which imposes flow and water quality

standards on State and Federal water export facilities to assure protection of beneficial uses in the Delta (USFWS 2008, pp. 21–27). The various flow objectives and export restraints were designed, in part, to protect fisheries. These objectives include specific freshwater flow requirements throughout the year, specific water export restraints in the spring, and water export limits based on a percentage of estuary inflow throughout the year. The water quality objectives were designed to protect agricultural, municipal, industrial, and fishery uses; they vary throughout the year and by the wetness of the year.

In December 2010, the California Central Valley Regional Water Quality Control Board (Regional Board) adopted a new National Pollutant Discharge and Elimination System (NPDES) permit for the Sacramento Regional Wastewater Treatment Plant to address ammonia loading to the Sacramento River and the Delta. In January 2011, the Sacramento Regional County Sanitation District petitioned the Regional Board for a review of the permit, which may require a year or more. There is currently no TMDL in place for ammonia discharge into the Sacramento watershed. The EPA is currently updating freshwater ammonia criteria that will include new discharge limits on ammonia (EPA 2009, pp. 1–46). Ammonia has been shown to have negative effects on prey items that longfin smelt rely upon (see Factor E: Contaminants, below). This regulation does not adequately mitigate potential negative effects to longfin smelt from ammonia in the Bay-Delta.

Streambed Alteration

In California, section 1600 *et seq.* of the California Fish and Game Code authorizes

CDFG to regulate streambed alteration. The CDFG must be notified of and approve any work that substantially diverts, alters, or obstructs the natural flow or that substantially changes the bed, channel, or banks of any river, stream, or lake. If an existing fish or wildlife resource, including longfin smelt, may be substantially adversely affected by a project, the project proponent must submit proposals to protect the species to the CDFG at least 90 days before the start of the project. However, these proposals are subject to agreement by the project proponent. If CDFG deems proposed measures to be inadequate, a third party arbitration may be initiated. However, projects that cause significant environmental damage such as destruction of species and their habitat including longfin smelt may be approved because the CDFG has no authority to deny requests for streambed alteration.

Oregon Environmental Regulations

Oregon classifies longfin smelt as a native migratory fish under Oregon Administrative Rule (Division 412, 635-412-0005). Operators of artificial obstructions located in waters in which any native migratory fish are currently or were historically present must provide for fish passage requirements during installation, replacement, or abandonment of artificial obstructions (ODFW 2011, p. 1). This State law helps ensure passage of migratory longfin smelt between rearing and spawning habitat.

Washington Environmental Regulations

Washington's State Environmental Policy Act (RCW 43.21C) provides a process similar to CEQA and is applicable to every State and local agency in Washington State. This law requires State and local governments to consider impacts to the environment and include public participation in project planning and decision making (Washington Division of Wildlife 2011, p. 1). Project proponents must submit a proposal for their project to the appropriate city, county, or State lead agency where the project is taking place. The lead agency then makes a determination of whether or not the project will have significantly adverse environmental impacts. The lead agency then may require the applicant to change the proposal to minimize environmental impacts or in rare cases may deny the application (Washington State Department of Ecology (WSDE) 2002, pp. 1–2).

Alaska Environmental Regulations

The Anadromous Fish Act (AS 16.05.871- .901) requires that anyone desiring to alter a streambed or waterbody first obtain a permit from the Alaska Department of Fish and Game (ADFG). Regulated activities include construction, road crossings, gravel mining, water withdrawal, stream realignment, and bank stabilization. Although there are no minimization or mitigation components to this law, the ADFG commissioner has the ability to deny a permit if he or she finds the plans and specifications are insufficient for the proper protection of anadromous fish. The Fishway or Fish Passage Act (AS 15.05.841) requires that activities within or crossing a stream obtain permission from ADFG if they will impede the passage of resident or anadromous fish. This provides some degree of protection for longfin smelt, which is categorized as an anadromous fish in the State of Alaska.

Canadian Environmental Regulations

The Canadian Environmental Assessment Act (S.C. 1992, c. 37) was passed by the Canadian Parliament in 1992. The Act requires Federal departments to conduct environmental assessments for proposals where the government is the proposer or the project involves Federal funding or permitting. The Canadian Environmental Protection Act of 1999 is intended to prevent pollution, protect the environment and human health, and contribute to promoting sustainable development. Canada has the Canadian Environmental Protection Act (CEPA), which is equivalent to the United States' NEPA. It was enacted to protect Canada's natural resources through pollution prevention and sustainable development. This provides some level of protection for longfin smelt from pollution and habitat degradation. The longfin smelt is not currently a protected species under the Species at Risk Act (SARA) of 2002 (S.C. 2002 c. 29; SARA). SARA is similar to the United States' Endangered Species Act. If the longfin smelt were determined by the Canadian government to need protection in the future, it could be listed under SARA.

Summary of Factor D

We evaluate existing regulatory mechanisms that have an effect on threats that we have identified elsewhere in the threats analysis. We do not evaluate the lack of a regulatory mechanism that may address a particular threat if that regulatory mechanism does not exist. We find that the threats to the longfin smelt and its habitat on Federal, State, and private lands on a

range-wide basis are minimal (Factors A, B, C and E). Existing federal regulatory mechanisms provide a degree of protection for longfin smelt from these threats. Therefore, we find that regulatory mechanisms provide adequate protections to longfin smelt and its habitat throughout its range.

Factor E. Other Natural or Manmade Factors Affecting Its Continued Existence

Other natural or manmade factors potentially affecting the continued existence of longfin smelt include entrainment losses from water diversions, introduced species, and contaminants.

Entrainment Losses

The only information we found on entrainment losses of longfin smelt comes from the Bay-Delta population. Entrainment occurs when fish are drawn toward water diversions, where they are typically trapped or killed. In the Bay-Delta, water is diverted and fish potentially entrained at four major water export facilities within the Delta, two power plants, and numerous small water diversions throughout the Delta for agriculture and in Suisun Marsh for waterfowl habitat. In their 2009 status review of longfin smelt, CDFG (2009, pp. 19–26) summarized entrainment losses at these water diversions.

Water Export Facilities

The four State and Federal water export facilities (pumping stations) in the Delta are the State Water Project (SWP) facility in the south Delta, the Central Valley Project (CVP) in the south Delta, the Contra Costa facility in the south Delta, and the North Bay Aqueduct facility in the north Delta. The SWP and CVP facilities pump the majority of the water exported from the Delta. Average annual volumes of water exported from these facilities between 1995 and 2005 were 3.60 km³ at the SWP facility, 3.10 km³ at the CVP facility, 0.15 km³ at the Contra Costa facility, and 0.05 km³ at the North Bay Aqueduct facility (Sommer *et al.* 2007, p. 272).

Depending on upstream flow through the Delta, operation of the SWP and CVP facilities often causes reverse flows in the river channels leading to them; longfin smelt that occupy these channels during certain times of the year may be entrained by these reverse flows. The SWP and CVP water export facilities are equipped with their own fish collection facilities that divert entrained fish into holding pens using louver-bypass systems to protect them from being killed in the pumps. The fish collected at the facilities are referred to as “salvaged,” and are loaded onto tanker trucks and returned to the western Delta downstream (Aasen 2009, p. 36). The movement of fish can result in mortality due to overcrowding in the tanks, stress, moving procedures, or predation at locations where the fish are released. Salvage is an *index* of entrainment, not an estimate, and is much smaller than total entrainment (Castillo *et al.* in review). Of spawning age fish (age-1 and age-2), which contribute most to longfin smelt population dynamics in the Bay-Delta, the total number of longfin smelt salvaged at both pumps between 1993 and 2007 was 1,133 (CDFG 2009, Attachment 3, p. 2).

Fish entering the intake channel of the CVP or the radial gates of the 31,000-acre Clifton Court Forebay reservoir (SWP) are considered entrained (Fujimura 2009, p. 5; CDFG 2009b, p.

2). Most longfin smelt that become entrained in Clifton Court Forebay are unable to escape (CDFG 2009b, p. 4). The number of fish entrained at the SWP and CVP facilities has never been determined directly, but entrainment losses have been estimated indirectly using data from research and monitoring efforts. The magnitude of entrainment of larval longfin smelt is unknown because only fish greater than 20 mm in length are salvaged at the two facilities (Baxter *et al.* 2008, p. 21). In years with low freshwater flows, approximately half of the longfin smelt larvae and early juveniles may remain for weeks within the Sacramento-San Joaquin Delta (Dege and Brown 2004), where model simulations indicate they are vulnerable to entrainment into State Water Project, Central Valley Project, and other diversions (Kimmerer and Nobriga 2008, CDFG 2009a, p. 8).

Entrainment is no longer considered a major threat to longfin smelt in the Bay-Delta because of current regulations. Efforts to reduce delta smelt entrainment loss through the implementation of the 2008 delta smelt biological opinion and the listing of longfin smelt under the CESA have likely reduced longfin smelt entrainment losses. The high rate of entrainment that occurred in 2002 that threatened the Bay Delta longfin smelt population is unlikely to recur, and would no longer be allowed under today's regulations because limits on longfin smelt take due to CESA regulations (see Factor D discussion, below) would trigger reductions in the magnitude of reverse flows.

Power Plants

Two power plants located near the confluence of the Sacramento and San Joaquin Rivers, the Contra Costa Generating Station and the Pittsburg Generating Station, pose an entrainment risk to longfin smelt. Past entrainment losses of delta smelt at these two facilities were significant and considered a threat to delta smelt (75 FR 17671; April 7, 2010). Power plant operations have been substantially reduced since the late 1970s, when high entrainment and impingement were documented (CDFG 2009, p. 24); the power plants are now either kept offline or operating at very low levels, except as necessary to meet peak power needs. From 2007–2010, capacity utilization of these units averaged only 2.3 percent of maximum capacity. No longfin smelt were detected during impingement sampling conducted between May of 2010 and April of 2011 to monitor entrainment losses at the two power plants (Tenera Environmental 2011, entire). The company that owns the two power plants has committed to retiring one of the two power stations in 2013 (Contra Costa Generating Station) and has made this commitment enforceable through amendments to its Clean Air Act Title V permit (Raifsnider 2011, pers. comm.).

Agricultural Diversions

Water is diverted at numerous sites throughout the Bay-Delta for agricultural irrigation. Herren and Kawasaki (2001) reported over 2,200 such water diversions within the Delta, but CDFG (2009, p. 25) notes that number may be high because Herren and Kawasaki (2001) did not accurately distinguish intake siphons and pumps from discharge pipes. CALFED's Ecosystem Restoration Program (ERP) includes a program to screen remaining unscreened small agricultural diversions in the Delta and the Sacramento and San Joaquin Rivers. The purpose of

screening fish diversions is to prevent entrainment losses; however, very little information is available on the efficacy of screening these diversions (Moyle and Israel 2005, p. 20).

Agricultural operations begin to divert water in March and April, and many longfin smelt have begun leaving the Delta by this time. Water diversions are primarily located on the edge of channels and along river banks. Longfin smelt are a pelagic fish species and tend to occupy the middle of the channel and the middle of the water column, where they are unlikely to be vulnerable to entrainment into these diversions.

Suisun Marsh Diversions

There are 366 diversions in Suisun Marsh used to enhance waterfowl habitat (USFWS 2008, p. 172). Water is pumped at these diversions between October and May. Longfin larvae are abundant in the Marsh from February through April, while adults are abundant from October to February (Meng and Mattern 2001, p. 756; Rosenfield and Baxter 2007, p. 1588). During a 2-year study sampling 2.3 million m³ (81.2 million ft³) of water entering intakes, entrainment was found to be low, capturing only 124 adult longfin and 160 larvae (Enos *et al.* 2007, p. 16). Restrictions on pumping have been put in place to protect delta smelt and salmon. These restrictions likely also benefit longfin smelt.

Introduced Species

Nonnative introduced species (both plants and animals) are common in many of the estuaries within the range of the longfin smelt. Introduced species can significantly alter food

webs in aquatic ecosystems. Introduced animal species can adversely affect longfin smelt through predation (see Factor C discussion, above) or competition. Although introduced species are common within many of the estuaries occupied by longfin smelt, most of the information we found on effects of introduced species on longfin smelt was for the Bay-Delta population.

Bay-Delta Population

The Bay-Delta is considered one of the most highly invaded estuaries in the world (Sommer *et al.* 2007, p. 272). Longfin smelt abundance in the Bay-Delta has remained low since the mid-1980s (see Abundance section, above). This long-term decline has been at least partially attributed to effects of the introduced overbite clam (Kimmerer 2002a, p. 47; Sommer *et al.* 2007, p. 274; Rosenfield and Baxter 2007, p. 1589; Baxter *et al.* 2010, pp. 61–62). The overbite clam has impacted zooplankton abundance and species composition by grazing on the phytoplankton that comprise part of the zooplankton's food base (Orsi and Mecum 1996, pp. 384–386) and by grazing on larval stages of certain zooplankton like *Eurytemora affinis* (no common name) (Kimmerer 2002, p. 51; Sommer *et al.* 2007, pp. 274–276). Longfin smelt recruitment (replacement of individuals by the next generation) has steadily declined since 1987, even after adjusting for Delta freshwater flows (Nobriga 2010, slide 5). These data suggest that changes in the estuary's food web following introduction of the overbite clam may have had substantial and long-term impacts on longfin smelt population dynamics in the Bay-Delta.

Numerous other invasive plant and animal species have been introduced into the Bay-Delta, and ecosystem disruptions will undoubtedly continue as new species are introduced.

Sommer *et al.* (2007, p. 272) note that the quagga mussel (*Dreissna bugensis*) was discovered in southern California in late 2006, and that it could become established in the Bay-Delta and cause substantial ecosystem disruption.

Other Populations

The Eel River is undergoing a shift from native anadromous to resident introduced fish species. Of particular importance are the California roach (*Hesperoleucus symmetricus*) and the Sacramento pikeminnow (*Ptychocheilus grandis*) (Brown and Moyle 1997, p. 274). The Sacramento pikeminnow is known to cause shifts in spatial distribution of native species (Brown & Moyle 1991, p. 856). The Sacramento pikeminnow preys on native fishes, particularly emigrating juvenile salmonids (Moyle 2002, p. 156) and likely preys upon the longfin smelt when present.

In Humboldt Bay, one study recorded 73 nonnative species, with another 13 species of uncertain status (Boyd 2002, pp. 89–91). Many of the nonnative species, most of which are invertebrates, have been present in the Bay for over 100 years, although some introductions have also occurred more recently (Boyd 2002, pp. 89–91). It is possible that the presence of some of these introduced species have resulted in changes to the food web resulting in changes to longfin smelt food availability in Humboldt Bay, as has occurred in the Bay-Delta. However, there are no data with which to evaluate this hypothesis. Commercial oyster culturing in Humboldt Bay began in 1955 (Barrett 1963, p. 38). Oyster culture beds within the bay are located in areas that are favorable to eelgrass (*Zostera marina*), and the harvesting of oysters in these beds has

resulted in a reduction of and damage to native eelgrass in Humboldt Bay (Trianni 1996, p. 4; Rummrill and Poulton 2004, p. 2). Longfin smelt are known to feed on fauna found on native eelgrass, and therefore loss of eelgrass communities could result in lower levels of longfin smelt prey, possibly resulting in decreased longfin smelt survival.

Over 100 species of nonnative, invasive aquatic plants and animals have been documented in the Yaquina Bay estuary in Oregon (Oregon State University 2011, p. 1). One of the plants that has become established is *Zostera japonica*, a seagrass that was introduced to Yaquina Bay as live packing material for Japanese oysters. It poses a competitive threat to the native eelgrass (Brown *et al.* 2007, p. 9), and longfin smelt are known to feed on fauna found on native eelgrass (Phillips 1984, pp. 1–85). Invasive fish species in Yaquina Bay include American shad (*Alosa sapidissima*), common carp (*Cyprinus carpio*), bass (*Micropterus spp.*), and walleye (*Sander vitreum*).

Numerous nonnative, invasive plant and animal species have established populations within the Columbia River estuary. Nonnative, invasive plants and fish are the largest taxa to inhabit the estuary, followed by mollusks and crustaceans (Sanderson *et al.* 2009, pp. 245–256). American shad was introduced in the Columbia River soon after 1871 (Petersen *et al.* 2011, pp. 1–42). The spawning adult shad population in the Columbia River is more than 5,000,000 individuals, the largest anywhere (Petersen *et al.* 2011, pp. 1–42). Shad may have large, negative effects on Columbia River ecosystems, as adult and juvenile shad prey on zooplankton, thereby reducing the availability of prey for other fish species (Sanderson *et al.* 2009, pp. 245–256). Also present in the lower Columbia River are channel catfish (*Ictalurus punctatus*), striped

bass, smallmouth bass (*Microperterus dolomieu*), largemouth bass (*Micropterus salmoides*), and walleye (*Sander vitreus*). These nonnative fishes are aggressive predators and have likely substantially altered food webs in the Columbia River estuary (Sanderson *et al.* 2009, pp. 245–256). The Eurasian water milfoil (*Myriophyllum spicatum*) may have been introduced into the lower Columbia River by ballast water from European ships in the 1800s (Aiken *et al.* 1979, pp. 201–215). It forms dense mats of vegetation and results in reduced dissolved oxygen concentrations as the plants decompose, altering aquatic ecosystem chemistry and function (Cronin *et al.* 2006, pp. 37–43; Unmuth *et al.* 2000, pp. 497–503), which could potentially restrict longfin smelt distribution in the region.

Hundreds of invasive plants and animals have found their way into Puget Sound through importation of soils, plants, fruits, and seeds; through boat hulls and ship ballast water discharge; and through intentional human releases. Invasive tunicate species that reproduce quickly and cover docks and boat hulls are also present in the sound (Puget Sound Partnership 2008b, p. 26).

Contaminants

Bay-Delta

Similar to other potential threats to longfin smelt, most of the information available is for the Bay-Delta. In 2009, over 15 million pounds of pesticides were applied within the five-county Bay-Delta area (California Department of Pesticide Regulation 2011, p. 1). Toxicity to invertebrates has been noted in water and sediments from the Delta and associated watersheds

(e.g., Werner *et al.* 2000, pp. 218, 223). Fish exposed to agricultural drainage water from the San Joaquin River watershed can exhibit body burdens of selenium exceeding the level at which reproductive failure and increased juvenile mortality occur (Saiki *et al.* 2001, p. 629). Toxicity studies specific to longfin smelt are not available, but data do exist for other fish species such as the delta smelt, a related species. Longfin smelt could be similarly affected by contaminants as some life stages utilize similar habitat and prey resources, and longfin smelt have a physiology similar to delta smelt. Kuivila and Moon (2004, p. 239) found that peak densities of larval and juvenile delta smelt sometimes coincided in time and space with elevated concentrations of dissolved pesticides in the spring. These periods of co-occurrence lasted for up to 2 to 3 weeks. Concentrations of individual pesticides were low and much less than would be expected to cause acute mortality; however, the effects of exposure to the complex mixtures of pesticides are unknown.

Bay-Delta waters are listed as impaired for several legacy and currently used pesticides under the Clean Water Act section 303(d) (California Department of Pesticide Regulation 2011, p. 1). Concentrations of dissolved pesticides vary in the Delta both temporally and spatially (Kuivila 2000, p. 1). Several areas of the Delta, particularly the San Joaquin River and its tributaries, are impaired due to elevated levels of diazinon and chlorpyrifos, which are toxic at low concentrations to some aquatic organisms (MacCoy *et al.* 1995, pp. 21–30). Several studies have demonstrated the acute and chronic toxicity of two common dormant-spray insecticides, diazinon and esfenvalerate, in fish species (Barry *et al.* 1995, p. 273; Goodman *et al.* 1979, p. 479; Holdway *et al.*; 1994, p. 169; Scholz *et al.* 2000, p. 1911; Tanner and Knuth 1996, p. 244).

Pyrethroid pesticides are of particular concern because of their widespread use, and their tendency to be genotoxic (DNA damaging) to fishes at low doses (in the range of micrograms per liter) (Campana *et al.* 1999, p. 159). The pyrethroid esfenvalerate is associated with delayed spawning and reduced larval survival of bluegill sunfish (*Lepomis macrochirus*) (Tanner and Knuth 1996, pp. 246–250) and increased susceptibility of juvenile Chinook salmon (*Oncorhynchus tshawytscha*) to disease (Clifford *et al.* 2005, pp. 1770–1771). In addition, synthetic pyrethroids may interfere with nerve cell function, which could eventually result in paralysis (Bradbury and Coats 1989, pp. 377–378; Shafer and Meyer 2004, pp. 304–305).

Weston and Lydy (2010, p. 1835) found the largest source of pyrethroids flowing into the Delta to be coming from the Sacramento Regional Water Treatment Plant (SRWTP), where only secondary treatment occurs. Their data not only indicate the presence of these contaminants, but the concentrations found exceeded acute toxicity thresholds for the amphipod *Hyalella azteca*. This is of substantial concern because the use of insecticides in the urban environment had not before been considered the primary source of insecticides flowing into the Delta. Furthermore, this was not the case for the Stockton Waste Water Treatment facility, where tertiary treatment occurs, suggesting that the tertiary treatment that occurs at the Stockton facility could minimize or eliminate toxic effluent being dispersed from wastewater facilities (Baxter *et al.* 2010, p. 33).

Several studies were initiated in 2005 to address the possible role of contaminants and disease in the declines of Bay-Delta fish and other aquatic species. The primary study consists of twice-monthly monitoring of ambient water toxicity at 15 sites in the Bay-Delta and Suisun Bay (Baxter *et al.* 2010, pp. 16, 17, 30). Significant mortality of amphipods was observed in 5.6

percent of samples collected in 2006–2007 and 0.5 percent of samples collected in 2008–2009. Werner *et al.* (2010b, p. 3) found that larval delta smelt were between 1.8 and 11 times more sensitive than fathead minnows (*Pimephales promelas*) to copper, ammonia, and all insecticides except permethrin. Aquatic insects in which the longfin smelt relies upon for food have been shown to be sensitive to ammonia. *H. azteca* was the most sensitive to all pyrethroids tested, while *E. affinis* and *C. Dubia* were the most sensitive to ammonia (Werner *et al.* 2010b, pp. 18, 23). Pyrethroids are of particular interest because use of these insecticides has increased within the Bay-Delta watershed as use of organophosphate insecticides has declined. Longfin smelt are probably most vulnerable to the effects of toxic substances during the winter and spring, when their early life stages occur in the Delta and Suisun and San Pablo Bays, where they are closer to point and non-point inputs of contaminants from runoff.

The largest source of ammonia entering the Delta ecosystem is the Sacramento Regional Wastewater Treatment Plant (SRWTP), which accounts for 90 percent of the total ammonia load released into the Delta. Ammonia is un-ionized and has the chemical formula NH_3 . Ammonium is ionized and has the formula NH_4^+ . The major factors determining the proportion of ammonia or ammonium in water are water pH and temperature. This is important, as NH_3 ammonia is the form that can be directly toxic to aquatic organisms, and NH_4^+ ammonium is the form documented to interfere with uptake of nitrates by phytoplankton (Dugdale *et al.* 2007, p. 17; Jassby 2008, p. 3).

Effects of elevated ammonia levels on fish range from irritation of skin, gills, and eyes to reduced swimming ability and mortality (Wicks *et al.* 2002, p. 67). Delta smelt have been shown

to be directly sensitive to ammonia at the larval and juvenile stages (Werner *et al.* 2008, pp. 85–88). Longfin smelt could similarly be affected by ammonia as they utilize similar habitat and prey resources and have a physiology similar to delta smelt. Ammonia also can be toxic to several species of copepods important to larval and juvenile fishes (Werner *et al.* 2010, pp. 78–79; Teh *et al.* 2011, pp. 25–27).

In addition to direct effects on fish, ammonia in the form of ammonium has been shown to alter the food web by adversely impacting phytoplankton and zooplankton dynamics in the estuary ecosystem. Historical data show that decreases in Suisun Bay phytoplankton biomass coincide with increased ammonia discharge by the SRWTP (Parker *et al.* 2004, p. 7; Dugdale *et al.* 2011, p. 1). Phytoplankton preferentially take up ammonium over nitrate when it is present in the water. Ammonium is insufficient to provide for growth in phytoplankton, and uptake of ammonium to the exclusion of nitrate results in decreases in phytoplankton biomass (Dugdale *et al.* 2007, p. 23). Therefore, ammonium impairs primary productivity by reducing nitrate uptake in phytoplankton. Ammonium's negative effect on the food web has been documented in the longfin smelt rearing areas of San Francisco Bay and Suisun Bay (Dugdale *et al.* 2007, pp. 26–28). Decreased primary productivity results in less food available to longfin smelt and other fish in these bays.

Several streams that flow into the Bay-Delta are listed as impaired because of high concentrations of metals such as cadmium, copper, lead, and zinc. Metal concentrations have been found to be toxic to fish in the upper Sacramento River near and downstream from Redding (Alpers *et al.* 2000a, p. 4; 2000b, p. 5). Elevated levels of metals such as copper in streambed

sediment continue to occur in the upper Sacramento River Basin downstream from Redding (MacCoy and Domagalski 1999, p. 35). Copper and other metals may affect aquatic organisms in upper portions of contributing watersheds of the Delta. Mercury and its bioavailable form (methylmercury) are distributed throughout the estuary, although unevenly. Mercury has been known to bioaccumulate and cause neurological effects in some fish species, but it has not been associated with the Pelagic Organism Decline (Baxter *et al.* 2010, p. 28). No specific information is available on the effects of mercury exposures to longfin smelt. Selenium, introduced into the estuary primarily from agricultural irrigation runoff via the San Joaquin River drainage and oil refineries, has been implicated in toxic and reproductive effects in fish and wildlife (Baxter 2010 *et al.*, p. 28; Linville *et al.* 2002, p. 52). Selenium exposure has been shown to have effects on some benthic foraging species; however there is no evidence that selenium exposure is contributing to the decline of longfin smelt or other pelagic species in the Bay-Delta (Baxter *et al.* 2010, p. 28).

Large blooms of toxic *Microcystis aeruginosa* (blue-green algae) were first documented in the Bay-Delta during the summer of 1999 (Lehman *et al.* 2005, p. 87). *M. aeruginosa* forms large colonies throughout most of the Delta and increasingly down into eastern Suisun Bay (Lehman *et al.* 2005, p. 92). Blooms typically occur when water temperatures are above 20 °C (68 °F) (Lehman *et al.* 2005, p. 87). Preliminary evidence indicates that the toxins produced by local blooms are not directly toxic to fishes at current concentrations (Baxter *et al.* 2010, p. 10). However, the copepods that the related delta smelt eat are particularly susceptible to those toxins (Ger 2008, pp. 12, 13). *Microcystis* blooms may also decrease dissolved oxygen to lethal levels for fish (Lehman *et al.* 2005, p. 97). Blooms typically occur between late spring and early fall

when the majority of longfin smelt occur farther downstream, so effects are expected to be minimal.

Other Populations

As in the Bay-Delta, pesticide and metals contamination occurs in Yaquina Bay, the Columbia River, and the Fraser River (Johnson *et al.* 2007, p. 1; Lower Columbia River Estuary Partnership (LCREP) 2011, p. 1; Blomquist, 2005, p. 8). Ammonia contamination occurs in the Klamath River (Oregon Department of Environmental Quality (ODEQ) 2011, p. 1) and Cook Inlet (ADEC 2011a, p. 1), and toxic algal blooms occur in the Klamath River (California State Water Resources Control Board (CSWRCB) 2010, p. 1) and Yaquina Bay (ODEQ Water Quality Assessment Online Database 2011).

Industrial contaminants such as dioxins, polychlorinated biphenyls (PCBs), and polyaromatic hydrocarbons (PAHs) occur in Humboldt Bay (NCRWQCB 2010 pp. 3–4), Yaquina Bay (Johnson *et al.* 2007, p. 1), the Columbia River (LCREP 2011, p. 1), Puget Sound (Puget Sound Partnership 2008b, p. 21), and the Fraser River (British Columbia Ministry of Environment 2001, pp. 5–6; Blomquist, 2005, p. 8). Suspended sediment is a contaminant in the Eel River (Downie 2010, p. 10), Humboldt Bay (NCRWQCB 2010 pp. 3–4), Yaquina Bay (ODEQ Water Quality Assessment Online Database 2011), and Puget Sound (WA Department Ecology 2008, p. 1). Nutrient enrichment and low levels of dissolved oxygen occur in the Klamath River (CSWRCB 2010, p.1), Yaquina Bay (Bricker *et al.* 1999, pp. 1–71), and Fraser River (British Columbia Ministry of Environment 2001, pp. 5–6). Fecal coliform and other

forms of bacteria contaminate Yaquina Bay, Puget Sound, the Fraser River, and Cook Inlet (Brown et al 2007, pp. 16-17, WA Department Ecology 2008, p. 1, Blomquist, 2005, p. 8, ADEC 2011a, p. 1).

Oregon and Washington States have listed multiple reaches of the Lower Columbia River on their Federal Clean Water Act 303(d) lists, due to total dissolved gas levels exceeding State water quality standards. This occurs at several dams on these rivers where water flowing over the spillway of a dam creates air bubbles. When these are carried to depth in the dam's stilling basin, the higher hydrostatic pressure forces air from the bubbles into solution. The result is water supersaturated with dissolved nitrogen, oxygen, and the other constituents of air (ODEQ 2002, p. ix). High total dissolved gas levels can cause gas bubble trauma in fish, which can result in injury or mortality to fish species (ODEQ 2002, pp. 1–150).

Summary of Contaminants

Most fish including longfin smelt can be sensitive to adverse effects from contaminants in their larval or juvenile stages. Adverse effects to longfin smelt would be more likely to occur where sources of contaminants occur in close proximity to spawning and rearing habitats (brackish or fresh waters). Laboratory studies have shown certain contaminants to potentially have adverse effects on individual delta smelt, a related species. Field studies have shown that the contaminants of concern are elevated in some of the estuaries throughout the species' range, including the Bay-Delta.

Summary of Factor E

We evaluated whether entrainment losses, introduced species, and contaminants threaten the longfin smelt throughout its range. Longfin smelt is broadly distributed across a wide variety of estuaries from central California to Alaska, and there is no monitoring data documenting a population decline other than the population decline in the Bay-Delta.

Because the Bay-Delta system is one of the largest man made water systems in the world, it would be impractical to compare diversions and alterations in other estuaries to diversions and alterations in the Bay-Delta. The effects of entrainment in the Bay-Delta are unique to the estuary because of the large water diversions. Because diversions in other estuaries are much smaller, we expect that the effects from these diversions would be minimal in relation to the effects in the Bay-Delta. We have no information to show that entrainment is a threat to longfin smelt throughout its range.

Introduced species and contaminants are threats to the Bay-Delta long smelt population, but there is no information indicating that they are threats to the species in other parts of its range. Although invasive species are present in other estuaries, none have been documented to be having an effect on the longfin smelt food supply like the overbite clam has had. Similarly, although contaminants are present in other estuaries where the longfin smelt resides, none have been shown to have effects on the longfin smelt food supply like ammonia in the Bay-Delta has been shown to have.

Finding

As required by the Act, we considered the five factors in assessing whether the longfin smelt is endangered or threatened throughout all of its range. We have carefully examined the best scientific and commercial information available regarding the past, present, and future threats faced by the longfin smelt. We reviewed the petition, information available in our files, other available published and unpublished information, and we consulted with recognized longfin experts and other Federal and State agencies.

Little information is available on longfin smelt populations other than the Bay-Delta and Lake Washington populations. Smelt caught along the Pacific Coast are rarely identified to species. Therefore, information on longfin smelt distribution and abundance outside the Bay-Delta is limited. Although monitoring data indicate a significant decline in the abundance of longfin smelt in the Bay-Delta, population monitoring for other populations is not available. Estuaries are complex ecosystems, and different estuaries within the longfin smelt's range vary greatly in their environmental characteristics and in how they are managed. For example, in no estuary within the range of the longfin smelt, other than the Bay-Delta, are large volumes (up to 35 percent of freshwater inflow between February and June, and up to 65 percent of inflow between July and January) of freshwater pumped directly out of the estuary.

Under Factor A, channel disturbances may have localized impacts to longfin smelt habitat suitability. However, we conclude that these activities are not significant threats to longfin smelt throughout its range. Climate change will likely affect longfin smelt in multiple

ways, but longfin smelt are able to move between a wide range of aquatic environments that vary greatly in water temperature and salinity, and these behavioral and physiological characteristics of the species may help it adapt to the effects of climate change. We conclude that the best available information does not indicate that climate change threatens the continued existence of longfin smelt across its range. We conclude that reduced freshwater flows are a threat to the Bay-Delta longfin smelt population, but not to the species in the rest of its range. The Bay-Delta is unique among estuaries occupied by longfin smelt because large volumes of freshwater are exported away from the estuary on an annual basis. In addition, it is difficult to extrapolate from the Bay-Delta to other estuaries because the effects of water management in the Bay-Delta are likely unique to the physical, geologic, and hydrologic environment of that estuary. We conclude that the best scientific information available indicates that continued existence of the longfin smelt is not threatened in any part of its range outside of the Bay-Delta by the present or threatened destruction, modification, or curtailment of its habitat or range now or in the foreseeable future

Under Factor B, we evaluated potential threats from recreational and commercial fishing and from monitoring surveys on longfin smelt. Longfin smelt are protected from intentional take in California because the species is listed as threatened under CESA. Efforts have been made to reduce mortality of longfin smelt as bycatch in a bay shrimp trawl commercial fishery and in monitoring surveys in the Bay-Delta. Longfin smelt is caught as part of recreational or commercial fisheries in Oregon, Washington, British Columbia, and Alaska, but numbers of fish caught are considered low, and we found no evidence that fisheries harvest was causing population declines of longfin smelt. We conclude that overutilization is not a significant current

or future threat to longfin smelt across its range.

Under Factor C, we evaluated potential threats from disease and predation. We found no evidence of rangewide threats to the continued existence of the species due to disease or predation, now or in the foreseeable future.

Under Factor D, we conclude that several Federal and State laws and regulations provide varying levels of protection for the longfin smelt throughout its range. Several of these regulatory mechanisms promote protection of longfin smelt habitat and provide tools to implement these habitat protections. We conclude that longfin smelt is not threatened throughout its range by inadequate regulatory mechanisms, now or in the foreseeable future.

Under Factor E, we evaluated potential threats due to entrainment losses from water diversions, introduced species, and contaminants. Information indicates that introduced species are a threat to the Bay-Delta longfin smelt population and that ammonium may constitute a threat to the Bay-Delta longfin smelt population, but information does not indicate that entrainment losses, introduced species, or contaminants are threatening longfin smelt populations in other parts of its range, now or in the foreseeable future.

Based upon our review of the best available scientific and commercial information pertaining to the five factors, we find that the threats are not of sufficient imminence, intensity, or magnitude to indicate that the longfin smelt is in danger of extinction (endangered), or likely to become endangered within the foreseeable future (threatened), throughout all of its range.

Therefore, we find that listing the longfin smelt as an endangered or threatened species throughout all of its range is not warranted at this time.

Distinct Vertebrate Population Segment

Having found that the best available information does not indicate that the longfin smelt warrants listing rangewide, we now assess whether any distinct population segments of longfin smelt meet the definition of endangered or are likely to become endangered in the foreseeable future (threatened). Under the Services' (joint policy of the Fish and Wildlife Service and National Marine Fisheries Service) DPS policy (61 FR 4722; February 7, 1996), three elements are considered in the decision concerning the establishment and classification of a possible DPS. These are applied similarly for additions to or removal from the Federal List of Endangered and Threatened Wildlife. These elements include: (1) The discreteness of a population in relation to the remainder of the species to which it belongs; (2) the significance of the population segment to the species to which it belongs; and (3) the population segment's conservation status in relation to the Act's standards for listing, delisting, or reclassification (i.e., is the population segment endangered or threatened). We have identified one population that potentially meets all three elements of the 1996 DPS policy—the population that occurs in the Bay-Delta estuary. During the rangewide five-factor analysis, significant threats were identified only for the Bay-Delta population. Therefore, we determined that only the Bay-Delta population potentially meets the third element of the DPS.

Discreteness

Under the DPS policy, a population segment of a vertebrate taxon may be considered discrete if it satisfies either one of the following conditions:

(1) It is markedly separated from other populations of the same taxon as a consequence of physical, physiological, ecological, or behavioral factors. Quantitative measures of genetic or morphological discontinuity may provide evidence of this separation.

(2) It is delimited by international governmental boundaries within which differences in control of exploitation, management of habitat, conservation status, or regulatory mechanisms exist that are significant in light of section 4(a)(1)(D) of the Act.

Marked Separation from Other Populations as a Consequence of Physical, Physiological, Ecological, or Behavioral Factors

The limited swimming capabilities of the longfin smelt, existing ocean current patterns, and the great distances between the Bay-Delta and other known breeding populations make it unlikely that regular interchange occurs between the Bay-Delta and other longfin smelt breeding populations. Longfin smelt is a relatively short-lived species that completes its 2- to 3-year life cycle moving between freshwater spawning habitat in the Delta and brackish water rearing habitat downstream (seaward) in the estuary within Suisun Bay, San Pablo Bay, and central San Francisco Bay. At least a portion of the population also migrates into the near-coastal waters of the Gulf of Farallones (Rosenfield and Baxter 2007, p. 1590). Although its swimming

capabilities have not been studied, it is a small fish believed to have a limited swimming capacity (Moyle 2010, pp. 5–6). How longfin smelt return to the Bay-Delta from the Gulf of Farallones is not known (Rosenfield and Baxter 2007, p.1590).

The Bay-Delta population is the southernmost population of longfin smelt and is separated from other longfin smelt breeding populations by 56 km (35 mi). The nearest location to the Bay-Delta where longfin smelt have been caught is the Russian River, located north of the Bay-Delta; however, little information is available for this population (see Distribution section, above). Due to limited freshwater flow into the estuary and interannual variation in freshwater flow, it is unlikely that the estuary provides sufficient potential spawning and rearing habitat to support a regularly breeding longfin smelt population (Moyle 2010, p. 4).

The Eel River and Humboldt Bay are the next nearest locations where longfin smelt are known to occur, and they are located much farther to the north—Eel River is located 394 km (245 mi) north of the Bay-Delta, and Humboldt Bay is located 420 km (260 mi) north of the Bay-Delta. Moyle (2010, p. 4) considered Humboldt Bay to be the only other estuary in California potentially capable of supporting longfin smelt in most years.

In our April 9, 2009, longfin smelt 12-month finding (74 FR 16169), we concluded that the Bay-Delta population was not markedly separated from other populations and, therefore, did not meet the discreteness element of the 1996 DPS policy. This conclusion was based in part on the assumption that ocean currents likely facilitated dispersal of anadromous longfin smelt to and from the Bay-Delta to other estuaries in numbers that could readily sustain the Bay-Delta

population group if it was to be extirpated. Since 2009, we have obtained information relevant to assumptions that we made in the 2009 12-month finding. Additional clarifying information comes in part from a declaration submitted to the U.S. District Court for the Northern District of California on June 29, 2010, by Dr. Peter Moyle, Professor of Fisheries Biology at the University of California at Davis (Moyle 2010, pp. 1–8). Moyle (2010, pp. 5–6) notes that he believes that we overestimated the swimming capacity of longfin smelt in our 2009 12-month finding. Moyle (2010, p. 8) states that longfin smelt that migrate out of and back into the Bay-Delta estuary may primarily be feeding on the rich planktonic food supply in the Gulf of Farallones, and that this migration between the Bay-Delta and near coastal waters of the Gulf of Farallones does not indicate that longfin smelt are necessarily dispersing long distances to other estuaries to the north.

At the time of our last finding, we did not have information available assessing the ability of longfin smelt to disperse northward from the Bay-Delta or southward to the Bay-Delta using currents in the Pacific Ocean. Since the time of our previous finding (74 FR 16169; April 9, 2009), we have reviewed additional information on ocean currents in nearshore waters and over the continental shelf from approximately the Gulf of Farallones north to Coos Bay. We have evaluated the potential for longfin smelt to disperse northward from the Bay-Delta or southward to the Bay-Delta. On October 28, 2011, we convened a panel of experts to evaluate the potential of longfin smelt dispersal via ocean currents. Oceanographers on the panel were tasked with answering a series of questions on how ocean currents would affect longfin smelt potentially dispersing into or out of the Bay-Delta. Much of the following analysis was derived from that panel discussion. Our analysis relies upon ocean current information as it relates to what is

known of longfin smelt biology and life history from the Bay-Delta population.

Table 2 overlays longfin smelt life history with general ocean current patterns in central and northern California. However, the California Current System exhibits a high degree of seasonality as well as weekly variability. Currents are highly variable in fall and winter but tend to be predominately northward. Surface currents are northward during the storm season from December to March and transition to southward in March or April. Offshore of central California the surface currents remain generally southward during summer. However, despite the predominant southward surface current, northward currents are common at depths around 60 to 200 m along the continental slope at all times of the year. This deeper current is known as the California Undercurrent (Paduan 2011, pers. comm.)

TABLE 2. Summary of longfin smelt life history within the Bay-Delta, and generalized coastal ocean circulation.

Month	Dec	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov
First Year		Peak Hatching-freshwater, upstream Delta										
		Larval Rearing San Pablo and San Francisco Bays-salinities <8 psu										
	Juveniles Rearing				Juvenile Rearing – Primarily San Pablo, San Francisco Bays-							
Second Year		Juvenile Rearing										
						– Juvenile Rearing -Movement to the coastal ocean begins in the summer, mass movement to coastal ocean begins in July and August						
	Spawning Migration											
	Peak Spawning-freshwater, Delta											

Coastal Current	Storm Season (Northward Flow)	Upwelling Season (Predominate Southward and Offshore Flow)	Relaxation Season (Weak Northward Flow)
-----------------	----------------------------------	--	--

Eddies (clockwise water circulation areas) exist at various points between the Bay-Delta and Humboldt Bay at landmarks such as Point Arena and Cape Mendocino. These eddies vary in their distance from shore between 10 to 100 km (6 to 62 mi) (Padaun 2011, pers. comm.). During the summer upwelling season, northerly winds drive a southward offshore flow of near-surface waters (Dever *et al.* 2006, p. 2109) and also set up a strong current over the continental shelf that is deflected offshore at capes such as Cape Mendocino, Point Arena, and Point Reyes (Magnell *et al.* 1990, p. 7; Largier 2004, p. 107; Halle and Largier 2011, pp. 1–24). Several studies have used drifters (flotation devices tracked by satellites) and pseudo-drifters (computer-simulated satellite-tracked flotation devices) to evaluate currents in the California region of the Pacific Ocean. These studies indicate that the circulation patterns located off Point Arena and Cape Mendocino limit dispersal (particularly southward) of flotation devices in the region (Sotka *et al.* 2004, p. 2150; Drake *et al.* 2011, pp. 1–51; Halle and Largier 2011, posters). This limitation is important because Cape Mendocino and Point Arena are between the Bay-Delta and the nearest likely self-sustaining population of longfin smelt in Humboldt Bay.

Longfin smelt are an euryhaline species, of which an unknown fraction of the population exhibits anadromy (Moyle 2002, p. 236; Rosenfield and Baxter 2007 p. 1578). Based on their small size and limited swimming ability, we expect that longfin smelt would be largely dependent on ocean currents to travel the large distance between the Bay-Delta and the Humboldt Bay. During wet years, newly spawned longfin smelt larvae may be flushed out to the

ocean between December and March. It is unlikely that longfin smelt larvae can survive ocean transport because larvae are not known to tolerate salinities greater than 8 ppt (Baxter 2011b, pers. comm.), and surface salinities less than 8 ppt do not exist consistently in the ocean (Bograd and Paduan 2011, pers. comm.).

A portion of the longfin smelt that spawn in the Bay-Delta make their way to the ocean once they are able to tolerate full marine salinities, sometime during the late spring or summer of their first year of life (age-0) (City of San Francisco and CH2MHill 1984 and 1985, entire), and may remain there for 18 months or longer before returning to the Bay-Delta to spawn (Baxter 2011c, pers. comm.). A larger portion of longfin smelt enter the coastal ocean during their second year of life (age-1) (City of San Francisco and CH2MHill 1984 and 1985, entire) and remain there for 3 to 7 months until they re-enter the Bay-Delta to spawn in early winter (Rosenfield and Baxter 2007, p 1590; Baxter 2011c, pers. comm.). Most of these age-1 longfin smelt move to coastal waters in July and August, possibly to escape warm water temperatures or to obtain food (Moyle 2010, p. 8; Rosenfield and Baxter 2007, p. 1290). Some longfin smelt may live to 3 years of age and may remain in the coastal ocean until they are 3 years old. However, no 3-year old longfin smelt have been observed in the coastal ocean (Baxter 2011d, pers. comm.; Service 2011, unpublished data).

It is possible that some of these juvenile or adult longfin smelt could make their way into the Russian River, Eel River, or Humboldt Bay and supplement or sustain those populations by utilizing northward ocean currents (Padaun 2011, pers. comm.; Service 2011b, pp. 1-4), but there is no documentation of such long-distance coastal movements. The northward ocean currents are

strongest and most reliable in winter, when satellite-tracked particles move between the Bay-Delta and Humboldt Bay in as little as 2 months (Service 2011, p. 3).

Opportunities for longfin smelt dispersal utilizing ocean currents from northern estuaries to the Bay-Delta are more limited. Studies have revealed that currents near Cape Mendocino and Point Arena would carry small objects to the west away from the coast (Padaun 2011b, pers. comm.; Bograd 2011, pers. comm.). It is possible that longfin smelt in nearshore waters could travel south past these eddies if they stay close enough to shore. It is even possible that some longfin smelt may be moved closer to shore by the eddies (Bograd 2011, pers. comm.; Paduan 2011, pers. comm.). However, any longfin smelt that do travel south past the Cape Mendocino and Point Arena escarpments would be unlikely to re-enter the Bay-Delta. These offshore ocean currents could displace any longfin smelt potentially moving south more than 100 km (62 mi) offshore of the Bay-Delta (Paduan 2011a, pers. comm.). Pathways that transport objects close to shore would be expected to be rare, if they exist at all (Padaun 2011b, pers. comm.; Bograd 2011, pers. comm.). So while we considered whether ocean currents may transport or facilitate movement of longfin smelt from northern estuaries to the Bay-Delta estuary, there is no information showing that such dispersal movement occurs.

Using the best scientific data available, we compared longfin smelt biology and life history with the latest available ocean current data provided by oceanographers. We conclude that longfin smelt in the Bay-Delta population do not regularly breed or interact with longfin smelt in other breeding populations to the north and are therefore markedly separated from other longfin smelt populations.

Under the 1996 DPS policy, the discreteness standard does not require absolute separation of a DPS from other members of its species, nor does the standard require absolute reproductive isolation (61 FR 4722). Because of the great distances between the Bay-Delta and known breeding populations to the north, the small size of the longfin smelt, and the low likelihood that ocean currents could facilitate longfin smelt movements between widely separated populations, we conclude that the Bay-Delta population is markedly separated from other longfin smelt populations and therefore discreet.

Quantitative Measures of Genetic or Morphological Discontinuity

The 1996 DPS policy states that quantitative measures of genetic or morphological discontinuity may provide evidence of marked separation and discreteness. Stanley *et al.* (1995, p. 395) compared allozyme variation between longfin smelt from the Bay-Delta population and the Lake Washington population using electrophoresis. They found that individuals from the populations differed significantly in allele (portions of a chromosome that code for the same trait) frequencies at several loci (gene locations). However, the authors also stated that the overall genetic dissimilarity was within the range of other conspecific (of the same species) fish species, and concluded that longfin smelt from Lake Washington and the Bay-Delta are conspecific, despite the large geographic separation (Stanley *et al.* 1995, p. 395). This study provided evidence that the Bay-Delta population of longfin smelt differed in genetic characteristics from the Lake Washington population, but did not compare other populations rangewide to the Bay-Delta population. More recently, Israel *et al.* (2011, pp. 1–10) presented

preliminary results from an ongoing study, but these results were inconclusive in providing evidence of whether the Bay-Delta population is markedly separated from other longfin smelt populations (Cope 2011, pers. comm.; Service 2011a, pp. 1-3).

We conclude that the limited quantitative genetic and morphological information available does not provide additional evidence of marked separation of the Bay-Delta longfin smelt population beyond the evidence presented above under Marked Separation from Other Populations as a Consequence of Physical, Physiological, Ecological, or Behavioral Factors.

Delimited by International Governmental Boundaries Within Which Differences in Control of Exploitation, Management of Habitat, Conservation Status, or Regulatory Mechanisms Exist that are Significant in Light of Section 4(a)(1)(D) of the Act

The Bay-Delta population of longfin smelt is not delimited by an international boundary. Therefore, we conclude that it does not meet the international governmental boundaries criterion for discreteness.

Conclusion for Discreteness

Because of its limited swimming capabilities and because of the great distances between the Bay-Delta and known breeding populations to the north, we conclude that the Bay-Delta population is markedly separated from other longfin smelt populations, and thus meets the discreteness element of the 1996 DPS policy. The best available information indicates that

longfin smelt from the Bay-Delta population complete their life cycle moving between freshwater, brackish water, and saltwater portions of the estuary and nearby coastal ocean waters in the Gulf of Farallones. The nearest known breeding population of longfin smelt is Humboldt Bay, 420 km (260 mi) north of the Bay-Delta. As a result, potential interchange between the Bay-Delta population and other longfin smelt breeding populations is limited. Although the best scientific information suggests that potential movement of longfin smelt northward from the Bay-Delta would be facilitated by ocean currents, potential movement from more northern estuaries south to the Bay-Delta would be more difficult and unlikely because of ocean currents. Based on our review of the best available scientific and commercial information available, we conclude that the Bay-Delta population of longfin smelt is markedly separated from other longfin smelt populations as a consequence of physical, physiological, ecological, or behavioral factors.

Significance

Since we have found that the Bay-Delta longfin smelt population meets the discreteness element of the 1996 DPS policy, we now consider its biological and ecological significance in light of Congressional guidance that the authority to list DPSes be used “sparingly” while encouraging the conservation of genetic diversity. In making this determination, we consider available scientific evidence of the discrete population segment’s importance to the taxon to which it belongs. As precise circumstances are likely to vary considerably from case to case, the DPS policy does not describe all the classes of information that might be used in determining the biological and ecological importance of a discrete population. However, the DPS policy describes four possible classes of information that provide evidence of a population segment’s

biological and ecological importance to the taxon to which it belongs. As specified in the DPS policy, this consideration of the population segment's significance may include, but is not limited to, the following:

(1) Persistence of the discrete population segment in an ecological setting unusual or unique to the taxon;

(2) Evidence that loss of the discrete population segment would result in a significant gap in the range of a taxon;

(3) Evidence that the discrete population segment represents the only surviving natural occurrence of a taxon that may be more abundant elsewhere as an introduced population outside its historic range; or

(4) Evidence that the discrete population segment differs markedly from other populations of the species in its genetic characteristics.

A population segment needs to satisfy only one of these conditions to be considered significant. Furthermore, other information may be used as appropriate to provide evidence for significance.

(1) Persistence of the discrete population segment in an ecological setting unusual or unique to the taxon.

The Bay-Delta population is the southernmost breeding population in the range of the species. Populations at the edge of a species' range may be important in species conservation because environmental conditions at the periphery of a species' range can be different from environmental conditions nearer the center of a species' range. Thus, populations at the edge of the taxon's range may experience different natural selection pressures that promote divergent evolutionary adaptations (Scudder 1989, entire; Fraser 2000, entire). Lomolino and Channell (1998, p. 482) hypothesized that because peripheral populations should be adapted to a greater variety of environmental conditions, they may be better suited to deal with anthropogenic (human-caused) disturbances than populations in the central part of a species' range; however, this hypothesis remains unproven. This could be especially important because of changing natural selection pressures associated with climate change.

For example, increasing ocean temperatures is an environmental change to which the Bay-Delta population of longfin smelt may be uniquely adapted. Because it is the southern-most estuary within the species' range, the Bay-Delta has warmer average water temperatures than estuaries in central and northern parts of the species' range. As a result, the Bay-Delta longfin smelt population may have behavioral or physiological adaptations for coping with higher water temperatures that may come as a result of climate change (see discussion under Factor A: Climate Change). Baxter *et al.* (2010, p. 68) conclude that high water temperatures in the Bay-Delta influence spatial distribution of longfin smelt in the estuary. Rosenfield and Baxter (2007, p. 1290) hypothesize that the partial anadromy exhibited by the population (part of the population is believed to migrate out into the cooler, nearby coastal ocean waters in the Gulf of

Farallones) and concentrations of longfin smelt in deeper water habitat in summer months is at least partly a behavioral response to warm water temperatures found during summer and early fall in the shallows of south San Francisco Bay and San Pablo Bay (Rosenfield and Baxter 2007, p. 1590).

The Bay-Delta estuary, although greatly degraded, is the largest estuary on the Pacific Coast of the United States (Sommer *et al.* 2007, p. 271). Because of its large size and diverse habitat, it is capable of supporting a large longfin smelt population. Large populations are valuable in the conservation of species because of their lower extinction risks compared to small populations. Historically, longfin smelt is believed to have been one of the more abundant pelagic fishes in the Bay-Delta. The areal extent of tidal freshwater habitat in the Bay-Delta estuary exceeds that of other California estuaries by an order of magnitude (NOAA 2007, p. 1), providing not only more available spawning habitat but also important habitat diversity should conditions at any one location become unsuitable. The Bay-Delta contains significant amounts of tidal freshwater and mixing zone habitat (Monaco *et al.* 1992, p. 255), which is crucial for spawning and rearing of juvenile longfin smelt. Other Pacific Coast estuaries where longfin smelt occur are predominately river-dominated estuaries (e.g., Russian River, Eel River, Klamath River, Columbia River), which have much smaller areas of low-salinity brackish water for longfin smelt rearing habitat.

(2) Evidence that loss of the discrete population segment would result in a significant gap in the range of a taxon.

Loss of the Bay-Delta population of longfin smelt would result in a significant gap in the range of the taxon because the nearest persistent longfin smelt breeding population to the Bay-Delta population is in Humboldt Bay, which is located approximately 420 km (260 mi) away. Loss of the Bay-Delta population would truncate the range of the species by hundreds of miles.

(3) Evidence that the discrete population segment represents the only surviving natural occurrence of a taxon that may be more abundant elsewhere as an introduced population outside its historic range.

This factor does not apply to the Bay-Delta longfin smelt population because other naturally occurring populations are found within the species' range.

(4) Evidence that the discrete population segment differs markedly from other populations of the species in its genetic characteristics.

As discussed above under Quantitative Measures of Genetic or Morphological Discontinuity, two studies have evaluated genetic characteristics of the Bay-Delta longfin smelt population. One study concluded that genetic characteristics of the Bay-Delta population differed from the Lake Washington population but did not compare any other populations (Stanley *et al.* 1995, pp. 390–396). Israel *et al.* (2011, pp. 1–10) presented preliminary results from an ongoing study, but these results are inconclusive in determining whether the Bay-Delta population differs markedly from other longfin smelt populations in its genetic characteristics. Therefore, although information indicates that the genetic characteristics of the Bay-Delta

population differs from at least one other longfin smelt population (Lake Washington), there is no other information currently available indicating that the genetic characteristics of the Bay-Delta population differ markedly from other longfin smelt populations.

Conclusion for Significance

We conclude that the Bay-Delta population is biologically significant to the longfin smelt species because the population occurs in an ecological setting unusual or unique for the species and its loss would result in a significant truncation of the range of the species. The Bay-Delta longfin smelt population occurs at the southern edge of the species' range and has likely experienced different natural selection pressures than those experienced by populations in middle portions of the species' range. The population may therefore possess unique evolutionary adaptations important to the conservation of the species. The Bay-Delta also is unique because it is the largest estuary on the Pacific Coast of the United States. Because of its large size and diverse aquatic habitats, the Bay-Delta has the potential to support a large longfin smelt population and is thus potentially important in the conservation of the species. The Bay-Delta population also is significant to the taxon because the nearest known breeding population of longfin smelt is hundreds of miles away, so loss of the Bay-Delta population would significantly truncate the range of the species and result in a significant gap in the species' range. Based on our review of the best available scientific and commercial information, we conclude that the Bay-Delta population meets the significance element of the 1996 DPS policy.

Determination of Distinct Population Segment

Because we have determined that the Bay-Delta population meets both the discreteness and significance elements of the 1996 DPS policy, we find that the Bay-Delta longfin smelt population is a valid DPS and thus is a listable entity under the Act. Therefore, we next evaluate its conservation status in relation to the Act's standards for listing (i.e., is the population segment, when treated as if it were a species, endangered or threatened?).

Distinct Population Segment Five-Factor Analysis

Because the Bay-Delta population of longfin smelt meets the criteria for a DPS, we will now evaluate its status with regard to its potential for listing as endangered or threatened under the five factors enumerated in section 4(a) of the Act. Our evaluation of the Bay-Delta DPS of longfin smelt follows.

Under **Summary of Information Pertaining to the Five Factors**, we evaluated threats to longfin smelt throughout its range. Much of this rangewide analysis focused on threats to the Bay-Delta population because so little information exists for other parts of the species' range. Although the threats of lack of freshwater flow, contaminants, and invasive species do not rise to the level of being significant threats rangewide, the best available scientific and commercial data indicates that these threats are significant to the species within the Bay-Delta. We utilized the vast amounts of research that have been conducted within the Bay-Delta by the Interagency Ecological Program and University of California at Davis to make our determinations of threats

in the Bay-Delta.

Factor A. The Present or Threatened Destruction, Modification, or Curtailment of Its Habitat or Range

Reduced Freshwater Flow

As we discussed above in the rangewide analysis, a primary threat to the Bay-Delta longfin smelt is reduced freshwater flows. In the Bay-Delta, freshwater flow is strongly related to the natural hydrologic cycles of drought and flood. Studies of Bay-Delta longfin smelt have found that increased Delta outflow during the winter and spring is the largest factor positively affecting longfin smelt abundance (Stevens and Miller 1983, pp. 431–432; Jassby *et al.* 1995, p. 285; Sommer *et al.* 2007, p. 274; Thomson *et al.* 2010, pp. 1439–1440). During high outflow periods larvae are believed to benefit from increased transport and dispersal downstream, increased food production, reduced predation through increased turbidity, and reduced loss to entrainment due to a westward shift in the boundary of spawning habitat and strong downstream transport of larvae (CFDG 1992, pp. 45-61; Hieb and Baxter 1993, pp. 106-107; CDFG 2009a, p. 18). Conversely, during low outflow periods, the negative effects of reduced transport and dispersal, reduced turbidity, and potentially increased loss of larvae to predation and increased loss at the export facilities result in lower young-of-the-year recruitment. Despite numerous studies of longfin smelt abundance and flow in the Bay-Delta, the underlying causal mechanisms are still not fully understood (Baxter *et al.* 2010, p. 69; Rosenfield 2010, p. 9).

As California's population has grown, demands for reliable water supplies and flood protection have grown. In response, State and Federal agencies built dams and canals, and captured water in reservoirs, to increase capacity for water storage and conveyance resulting in one of the largest manmade water systems in the world (Nichols *et al.* 1986, p. 569). Operation of this system has altered the seasonal pattern of freshwater flows in the watershed. Storage in the upper watershed of peak runoff and release of the captured water for irrigation and urban needs during subsequent low flow periods result in a broader, flatter hydrograph with less seasonal variability in freshwater flows into the estuary (Kimmerer 2004, p. 15).

In addition to the system of dams and canals built throughout the Sacramento River-San Joaquin River basin, the Bay-Delta is unique in having a large water diversion system located within the estuary (Kimmerer 2002b, p. 1279). The State Water Project (SWP) and Central Valley Project (CVP) operate two water export facilities in the Delta (Sommer *et al.* 2007, p. 272). Project operation and management is dependent upon upstream water supply and export area demands. Despite the size of the water storage and diversion projects, much of the interannual variability in Delta hydrology is due to variability in precipitation from year to year. Annual inflow from the watershed to the Delta is strongly correlated to unimpaired flow (runoff that would hypothetically occur if upstream dams and diversions were not in existence), mainly due to the effects of high-flow events (Kimmerer 2004, p. 15). Water operations are regulated in part by the California State Water Resources Control Board (SWRCB) according to the Water Quality Control Plan (WQCP) (SWRCB 2000, entire). The WQCP limits Delta water exports in relation to Delta inflow (the Export/Inflow, or E/I ratio).

It is important to note that in the case of the Bay-Delta, freshwater flow is expressed as both Delta inflow (from the rivers into the Delta) and as Delta outflow (from the Delta into the lower estuary), which are closely correlated, but not equivalent. Freshwater flow into the Delta affects the location of the low salinity zone and X2 within the estuary. As longfin smelt spawn in freshwater, they must migrate farther upstream to spawn as flow reductions alter the position of X2 and the low-salinity zone moves upstream (CDFG 2009, p. 17). Longer migration distances into the Bay-Delta make longfin smelt more susceptible to entrainment in the State and Federal water pumps (see Factor E: Entrainment Losses, below). In periods with greater freshwater flow into the Delta, X2 is pushed farther downstream (seaward); in periods with low flows, X2 is positioned farther landward (upstream) in the estuary and into the Delta. Not only is longfin smelt abundance in the Bay-Delta strongly correlated with Delta inflow and X2, but the spatial distribution of longfin smelt larvae is also strongly associated with X2 (Dege and Brown 2004, pp. 58–60; Baxter *et al.* 2010, p. 61). As longfin hatch into larvae, they move from the areas where they are spawned and orient themselves just downstream of X2 (Dege and Brown 2004, pp. 58-60). Larval (winter-spring) habitat varies with outflow and with the location of X2 (CDFG 2009, p. 12), and has been reduced since the 1990s due to a general upstream shift in the location of X2 (Hilts 2012, unpublished data). The amount of rearing habitat (salinity between 0.1 and 18 ppt) is also presumed to vary with the location of X2 (Baxter *et al.* 2010, p. 64). However, as previously stated, the location of X2 is of particular importance to the distribution of newly-hatched larvae and spawning adults. The influence of water project operations from November through April, when spawning adults and newly-hatched larvae are oriented to X2, is greater in drier years than in wetter years (Knowles 2002, p. 7).

In addition to the effects of reduced freshwater flow on habitat suitability for longfin smelt and other organisms in the Bay-Delta, one of the principal concerns over the biological impacts of these water export facilities has been entrainment of fish and other aquatic organisms. For a detailed discussion, see Factor E: Entrainment Losses, below.

Given the observed negative association between the reduction of freshwater outflow and longfin smelt abundance, we consider the current reductions in freshwater outflow to pose a significant threat to the Bay-Delta DPS of longfin smelt. Based on the observed associations in the Bay-Delta between freshwater outflow and longfin abundance, the lack of effective control mechanisms, and projections of freshwater outflow fluctuations, we expect the degree of this threat to continue and likely increase within the foreseeable future. We conclude that lack of freshwater flow is a significant current and future threat to the Bay-Delta DPS of longfin smelt.

Climate Change

Climate change may affect the Bay-Delta DPS of longfin smelt habitat as a result of (1) Changes in the timing and availability of freshwater flow into the estuary due to reduced snowpack and earlier melting of the snowpack; (2) sea level rise and saltwater intrusion into the estuary; (3) effects associated with increased water temperatures; and (4) effects related to changes in frequency and intensity of storms, floods, and droughts. It is difficult to evaluate effects related to changes in the timing and availability of freshwater flow into the estuary due to reduced snowpack and earlier melting of the snowpack because these potential effects will likely be impacted to some extent through decisions on water management in the intensively managed

Sacramento River-San Joaquin River water basin. Continued sea level rise will result in saltwater intrusion and landward displacement of the low-salinity zone, which would likely negatively affect longfin smelt habitat suitability. Increasing water temperatures would likely affect distribution and movement patterns of longfin smelt in the estuary; longfin smelt may be displaced to locations with deeper and cooler water temperatures. This displacement may result in decreased survival and productivity. Increased frequency and severity of storms, floods, and droughts could result in reduced longfin smelt habitat suitability, but it is difficult to estimate these effects because of uncertainty about the frequency and severity of these events. However, warming may result in more precipitation falling as rain and less storage as snow, increasing winter runoff as spring runoff decreases (USBR 2011, p. 147).

It is uncertain how a change in the timing and duration of freshwater flows will affect longfin smelt. Higher flows in January and February (peak spawning and hatching months) resulting from snow packs that melt sooner and rain-on-snow events could potentially create better spawning and larval rearing conditions. This would reduce adult migration distance and increase areas of freshwater spawning habitat during these months. In addition, the higher turbidity associated with these flows may reduce predation on longfin smelt adults and larvae (Baxter 2011, pers. comm.). However, if high flows last only a short period, benefits may be negated by poorer conditions before and after the high flows. As the freshwater boundary moves farther inland into the Delta with increasing sea level (see below) and reduced flows, adults will need to migrate farther into the Delta to spawn, increasing the risk of predation and the potential for entrainment into water export facilities and diversions for both themselves and their progeny. Because of the uncertainties surrounding climate change and the potential for increased winter

runoff that could benefit longfin smelt, we determined that there is not sufficient information to conclude that climate change threatens the continued existence of the Bay-Delta DPS of longfin smelt.

Channel Disturbances

Channel dredging in the Bay-Delta is an ongoing periodic disturbance of longfin smelt habitat, but most activity occurs in areas where longfin smelt are not likely to be present. We conclude that the effects of ongoing channel maintenance dredging are small and localized and do not rise to a level that would significantly affect the population as a whole.

There is currently a proposal to deepen and selectively widen the Sacramento Deep Water Ship Channel and the lower portion of the Sacramento River in the Bay-Delta. This dredging project would remove between 6.1–7.6 million cubic meters (8 and 10 million cubic yards) of material from the channel and Sacramento River and extend for 74 km (45.8 mi) (USACE 2011a, entire). Potential effects of this new project to longfin smelt include mortality through loss of spawning substrate, habitat modification, and a shift in spawning and rearing habitat. The project also has potential to alter breeding and foraging behavior of the Bay-Delta longfin smelt population. However, this project is only a proposal at this time and is not certain to occur. Potential effects of the proposed project are currently under evaluation.

Summary of Factor A

In summary, we conclude that the best available scientific and commercial information available indicates that the effects of reduced freshwater flows constitute a current and future threat to the Bay-Delta DPS of longfin smelt. We find that the Bay-Delta DPS of longfin smelt is currently threatened in part due to the present or threatened destruction, modification, or curtailment of its habitat or range due to reduced freshwater flow.

Factor B. Overutilization for Commercial, Recreational, Scientific, or Educational Purposes

Commercial and Recreational Take

Because of its status as a threatened species under the California Endangered Species Act, take of longfin smelt in the Bay-Delta is illegal, unless authorized by an incidental take permit or other take authorization. However, longfin smelt are caught as bycatch in a small bay shrimp trawl commercial fishery that operates in South San Francisco Bay, San Pablo Bay, and Carquinez Strait (Hieb 2009, p. 1). CDFG (Hieb 2009, pp. 6, 9) estimated the total longfin smelt bycatch from this fishery from 1989–1990 at 15,539 fish, and in 2004 at 18,815–30,574 fish. CDFG noted in 2009 that they thought the bay shrimp trawl fishery had declined since 2004 (Hieb, p. 3) and just recently reported the number of active shrimp permits at less than 10 (Hieb 2011, pers. comm.).

Scientific Take

Within the Bay-Delta, longfin smelt are regularly captured in monitoring surveys. The Interagency Ecological Program (IEP) implements scientific research in the Bay-Delta. Although the focus of its studies and the level of effort have changed over time, in general, their surveys have been directed at researching the Pelagic Organism Decline in the Bay-Delta. Between the years of 1987 to 2011, combined take of longfin smelt less than 20 mm (0.8 in) in length ranged from 2,405 to 158,588 annually. All of these fish were preserved for research or assumed to die in processing. During the same time period, combined take for juveniles and adults (fish greater than or equal to 20 mm (0.8 in)) ranged from 461 to 68,974 annually (IEP 2011). Although mortality is unknown, the majority of these fish likely do not survive. The Chipps Island survey, which is conducted by the Service, has captured an average of 2,697 longfin smelt per year during the past 10 years. Biologists attempt to release these fish unharmed, but at least 5,154 longfin smelt were known to have died during the Chipps Island survey between 2001 and 2008 (Service 2010, entire).

Incidental take from bycatch and monitoring surveys has not been identified as a possible factor related to recent longfin smelt population declines in the Bay-Delta (Baxter *et al.* 2010, pp. 61–69). CDFG (2009, p. 32) recommended adaptively managing scientific collection of longfin smelt to avoid adverse population effects, and survey methods have been modified recently to minimize potential impacts to delta smelt (75 FR 17669; April 7, 2010). These modifications likely have resulted in reduced impacts to longfin smelt. Based on the best scientific and commercial information, we conclude that the Bay-Delta DPS of longfin smelt is not currently threatened by overutilization for commercial, recreational, scientific, or educational purposes, nor do we anticipate overutilization posing a significant threat in the future.

Factor C. Disease or Predation

Disease

Little information is available on incidence of disease in the Bay-Delta longfin smelt DPS. Larval and juvenile longfin smelt were collected from the Bay-Delta in 2006 and 2007 and analyzed for signs of disease and parasites (Foott and Stone 2006, entire; Foott and Stone 2007, entire). No significant health problem was detected in either year (Foott and Stone 2007, p. 15). The south Delta is fed by water from the San Joaquin River, where pesticides (e.g., chlorpyrifos, carbofuran, and diazinon), salts (e.g., sodium sulfates), trace elements (boron and selenium), and high levels of total dissolved solids are prevalent due to agricultural runoff (64 FR 5963; February 8, 1999). Pesticides and other toxic chemicals may adversely affect the immune system of longfin smelt and other fish in the Bay-Delta and other estuaries, but we found no information documenting such effects.

Predation

Striped bass were introduced into the Bay-Delta in 1879 and quickly became abundant throughout the estuary. However, their numbers have declined substantially over the last 40 years (Thomson *et al.* 2010, p. 1440), and they are themselves one of the four species studied under Pelagic Organism Decline investigations (Baxter *et al.* 2010, p. 16). Numbers of largemouth bass, another introduced species in the Bay-Delta, have increased in the Delta over

the past few decades (Brown and Michniuk 2007, p. 195). Largemouth bass, however, occur in shallow freshwater habitats, closer to shore than the pelagic longfin smelt, and so do not tend to co-occur with longfin for much of their life history. Baxter *et al.* (2010, p. 40) reported that no longfin smelt have been found in largemouth bass stomachs sampled in a recent study of largemouth bass diet. Moyle (2002, p. 238) believed that inland silverside, another nonnative predatory fish, may be an important predator on longfin eggs and larvae, but Rosenfield *et al.* (2010, p. 18) believed that to be unlikely because inland silversides prefer shallow water habitats where juvenile and subadult longfin smelt are rare.

In the Bay-Delta, predation of longfin smelt may be high in the Clifton Court Forebay, where the SWP water export pumping plant is located (Moyle 2002, p. 238; Baxter *et al.* 2010, p. 42). However, once they are entrained in the Clifton Court Forebay, longfin smelt mortality would be high anyway due to high water temperatures in the Forebay (CDFG 2009b, p. 4) and entrainment into the SWP water export pumping plant. In addition to elevated predation levels in the Clifton Court Forebay, predation also is concentrated at sites where fish salvaged from the SWP and CVP export facilities are released (Moyle 2002, p. 238). However, few longfin smelt survive the salvage and transport process (see Factor E: Entrainment Losses, below), and therefore predation is not expected to be an important factor at drop off sites. As discussed above, reduced freshwater flows may result in lower turbidity and increased water clarity (see discussion under DPS' Factor A), which may contribute to increased risk of predation (Baxter *et al.* 2010, p. 64).

Based on a review of the best available scientific and commercial information, we conclude that disease does not constitute a threat to the Bay-Delta longfin smelt DPS. Available information indicates that Bay-Delta longfin smelt experience elevated levels of predation near the water diversions at the SWP and CVP water export facilities in the south Delta and at the salvage release sites. Reduced freshwater flows resulting from water diversions result in increased water clarity, and increased water clarity may result in increased predation risks to longfin smelt.

In summary, striped bass predation is in decline and largemouth bass predation is unlikely a threat because of the minimal overlap in time and space of largemouth bass and longfin smelt. Therefore, the current rates of predation on longfin smelt are not expected to be having a substantial effect on the overall population level. Based on the best available scientific and commercial information, we conclude that neither disease nor predation are significant current or future threats to the Bay-Delta longfin smelt DPS.

Factor D. The Inadequacy of Existing Regulatory Mechanisms

Existing Federal and State regulatory mechanisms discussed under Factor D of the rangewide analysis that provide protections or reduce threats to the Bay-Delta DPS of longfin smelt include: California Endangered Species Act, Porter-Cologne Water Quality Control Act, California Marine Invasive Species Act, Central Valley Project Improvement Act, and Clean Water Act (including the National Pollutant Discharge Elimination System). Several of these regulatory mechanisms provide important protections for the Bay-Delta DPS of longfin smelt

and act to reduce threats, such as reduction of freshwater outflow, the invasion of the overbite clam and ammonia discharges (See Factors A, above, and E, below).

The longfin smelt was listed under the California Endangered Species Act as threatened throughout its range in California on March 5, 2009 (CDFG 2009, p. V). CESA does allow take of species for otherwise lawful projects through use of an incidental take permit. A take permit requires that impacts be minimized and fully mitigated (CESA sections 2081 (b) and (c)). Furthermore, the CESA ensures through the issuance of a permit for a project that may affect longfin smelt or its habitat, that the project will not jeopardize the continued existence of a State-listed species.

The Porter-Cologne Water Quality Control Act is the California State law that establishes the State Water Resources Control Board (SWRCB) and nine Regional Water Quality Control Boards that are responsible for the regulation of activities and factors that could degrade California water quality and for the allocation of surface water rights. The State Water Resources Control Board Water Rights Decision 1641 (D-1641) imposes flow and water quality standards on the State and Federal water export facilities to assure protection of beneficial uses in the Delta (FWS 2008, pp. 21-27). The various flow objectives and export restraints are designed, in part, to protect fisheries. These objectives include specific outflow requirements throughout the year, specific water export restraints in the spring, and water export limits based on a percentage of estuary inflow throughout the year. The water quality objectives are designed to protect agricultural, municipal, industrial, and fishery uses; they vary throughout the year and by the wetness of the year. These protections have had limited effectiveness in providing

adequate freshwater flows within the Delta. Lack of freshwater outflow continues to be the primary contributing factor to the decline of the longfin smelt in the Bay-Delta (see Factor A, above, for further discussion).

The California Marine Invasive Species Act requires ballast water management for all vessels that intend to discharge ballast water in California waters. All qualifying vessels coming from ports within the Pacific Coast region must conduct an exchange in waters at least 50 nautical mi offshore and 200 m (656 ft) deep or retain all ballast water and associated sediments. To determine the effectiveness of the management provisions of the this State act, the legislation also requires State agencies to conduct a series of biological surveys to monitor new introductions to coastal and estuarine waters. These measures should further minimize the introduction of new invasive species into California's coastal waters that could be a threat to the longfin smelt.

The Central Valley Project Improvement Act amends the previous Central Valley Project authorizations to include fish and wildlife protection, restoration, and mitigation as project purposes having equal priority with irrigation and domestic uses, and fish and wildlife enhancement as having an equal priority with power generation. Included in CVPIA section 3406 (b)(2) was a provision to dedicate 800,000 acre-feet of Central Valley Project yield annually (referred to as "(b)(2) water") for fish, wildlife, and habitat restoration. Since 1993, (b)(2) water has been used and supplemented with acquired environmental water (Environmental Water Account and CVPIA section 3406 (b)(3) water) to increase stream flows and reduce Central Valley Project export pumping in the Delta. These management actions were taken to

contribute to the CVPIA salmonid population doubling goals and to protect Delta smelt and their habitat (Guinee 2011, pers. comm.). As discussed above (under Biology and Factor A), increased freshwater flows have been shown to be positively correlated with longfin smelt abundance; therefore, these management actions, although targeted towards other species, should also benefit longfin smelt.

The Clean Water Act (CWA) provides the basis for the National Pollutant Discharge Elimination System (NPDES). The CWA gives the EPA the authority to set effluent limits and requires any entity discharging pollutants to obtain a NPDES permit. The EPA is authorized through the CWA to delegate the authority to issue NPDES Permits to State governments. In States that have been authorized to implement CWA programs, the EPA still retains oversight responsibilities (EPA 2011, p. 1). California is one of these States to which the EPA has delegated CWA authority. The Porter-Cologne Water Quality Control Act established the California State Water Resources Control Board (SWRCB) and nine Regional Water Quality Control Boards that are now responsible for issuing these NPDES permits, including permits for the discharge of effluents such as ammonia. The SWRCB is responsible for regulating activities and factors that could degrade California water quality (California Water Code Division 7, section 13370-13389).

The release of ammonia into the estuary is having detrimental effects on the Delta ecosystem and food chain (see Factor E, below). The release of ammonia is controlled primarily by the CWA (Federal law) and secondarily through the Porter-Cologne Water Quality Control Act (State law). EPA is currently updating freshwater discharge criteria that will include new

limits on ammonia (EPA 2009, pp. 1-46). An NPDES permit for the Sacramento Regional Wastewater Treatment Plant, a major discharger, was prepared by the California Central Valley Regional Water Quality Control Board in the fall of 2010, with new ammonia limitations intended to reduce loadings to the Delta. The permit is currently undergoing appeal, but it is likely that the new ammonia limits will take effect in 2020. Until that time, CWA protections for longfin smelt are limited, and do not reduce the current threat to longfin smelt.

Summary of Factor D

A number of Federal and State regulatory mechanisms exist that can provide some protections for the Bay-Delta DPS of longfin smelt. However, the continued decline in longfin smelt trend indicators suggests that existing regulatory mechanisms, as currently implemented, are not adequate to reduce threats to the species. Therefore, based on a review of the best scientific information available, we conclude that existing regulatory mechanisms are not sufficient to protect the species.

Factor E. Other Natural or Manmade Factors Affecting Its Continued Existence

Other factors affecting the continued existence of the Bay-Delta DPS of longfin smelt are entrainment losses due to water diversions, introduced species, and contaminants (see Factor E of the **Summary of Information Pertaining to the Five Factors** section, above).

Entrainment Losses Due to Water Diversions

Entrainment losses at the SWP and CVP water export facilities are a known source of mortality of longfin smelt and other pelagic fish species in the Bay Delta, although the full magnitude of entrainment losses and population-level implications of these losses is still not fully understood. High entrainment losses of longfin smelt and other Bay-Delta pelagic fish between 2000 and 2005 correspond with high volumes of water exports during winter (Baxter *et al.* 2010, p. 63). Baxter *et al.* (2010, p. 62) hypothesize that entrainment is having an important effect on the longfin smelt population during winter, particularly during years with low freshwater flows when a higher proportion of the population may spawn farther upstream in the Delta. However, Baxter *et al.* (2010, p. 63) conclude that these losses have yet to be placed in a population context, and no conclusions can be drawn regarding their effects on recent longfin smelt abundance. CDFG (2009, p. 22) believes that efforts to reduce past delta smelt entrainment loss through the implementation of the 2008 delta smelt biological opinion for SWP and CVP operations may have reduced longfin smelt entrainment losses, incidentally providing a benefit to the longfin smelt. These efforts to manage entrainment losses in drier years, when entrainment risk is greater, substantially reduce the threat of entrainment for longfin smelt.

Estimates of entrainment have shown that it may have been a threat to the Bay-Delta longfin smelt DPS in the past. Fujimura (2009) estimated cumulative longfin smelt entrainment at the SWP facility between 1993 and 2008 at 1,376,432 juveniles and 11,054 adults, and estimated that 97.6 percent of juveniles and 95 percent of adults entrained were lost. Fujimura (2009) estimated cumulative longfin entrainment at the CVP facility between 1993 and 2008 at 224,606 juveniles and 1,325 adults, and estimated that 85.2 percent of the juveniles and 82.1

percent of the adults entrained were lost. These estimated losses are 4 times higher than observed salvage at the CVP and 21 times higher than the actual salvage numbers at the SWP (Fujimura 2009, p. 2). The estimated entrainment numbers were much higher than the actual salvage numbers at the SWP, due in large part to the high pre-screen losses in the Clifton Court Forebay (CDFG 2009a, p. 21). It should be noted that these estimates were calculated using equations and parameters devised for other species and may not accurately estimate longfin smelt losses. Further, estimates may be misleading because the majority of estimated losses occurred during the dry year of 2002 (1.1 million juveniles estimated at the SWP) while during all other years estimated entrainment was below 70,000 individuals.

Entrainment is no longer considered a threat to longfin in the Bay-Delta because of current regulations. Efforts to reduce delta smelt entrainment loss through the implementation of the 2008 delta smelt biological opinion and the listing of longfin smelt under the CESA have likely reduced longfin smelt entrainment losses. The high rate of entrainment that occurred in 2002 that threatened the Bay Delta longfin smelt DPS is very unlikely to recur, and would no longer be allowed under today's regulations because limits on longfin smelt take due to CESA regulations (see DPS' Factor D discussion, above) would trigger reductions in the magnitude of reverse flows.

Although larval and adult longfin smelt are lost as a result of entrainment in the water export facilities in the Delta, we conclude that the risk of entrainment is generally greatest when X2 is upstream and export volumes from the CVP and SWP pumps are high. Therefore, we have

determined that longfin smelt are not currently threatened by entrainment, nor do we anticipate longfin smelt will be threatened by entrainment in the future.

Introduced Species

In Suisun Bay, a key longfin smelt rearing area, phytoplankton biomass is influenced by the overbite or Amur River clam. A sharp decline in phytoplankton biomass occurred following the invasion of the estuary by this species, even though nutrients were not found to be limiting (Alpine and Cloern 1992, pp. 950-951). Abundance of zooplankton decreased across several taxa, and peaks that formerly occurred in time and space were absent, reduced or relocated after 1987 (Kimmerer and Orsi 1996, p. 412). The general decline in phytoplankton and zooplankton is likely affecting longfin smelt by decreasing food supply for their prey species, such as *N. mercedis* (Kimmerer and Orsi 1996, pp. 418–419). Models indicate that the longfin smelt abundance index has been on a steady linear decline since about the time of the invasion of the non-native overbite (or Amur) clam in 1987 (Rosenfield and Swanson 2010, p. 14).

Given the observed negative association between the introduction of the overbite clam and longfin smelt abundance in the Bay-Delta and the documented decline of key longfin smelt prey items, we consider the current overbite clam population to pose a significant threat to the Bay-Delta DPS of longfin smelt. Based on the observed associations in the Bay-Delta between overbite clam invasion and longfin abundance and the lack of effective control mechanisms, we expect the degree of this threat will continue into the foreseeable future. The Bay-Delta has numerous other invasive species that have disrupted ecosystem dynamics; however, only the

overbite clam has been shown to have an impact on the longfin smelt population. We consider the overbite clam to be a significant ongoing threat to the Bay-Delta longfin smelt population.

Contaminants

Extensive research on the role of contaminants in the Pelagic Organism Decline is currently being conducted (Baxter *et al.* 2010, pp. 28–36). Of potential concern are effects of high levels of mercury and other metals; high ammonium concentrations from municipal wastewater; potentially harmful cyanobacteria algal blooms; and pesticides, especially pyrethroid pesticides, which are heavily used in San Joaquin Valley agriculture. Contaminants may have direct toxic effects to longfin smelt and other pelagic fish and indirect effects as a result of impacts to prey abundance and composition. Ammonium has been shown to impact longfin smelt habitat by affecting primary production and prey abundance within the Bay-Delta (Dugdale *et al.* 2007, p. 26). While contaminants are suspected of playing a role in declines of pelagic fish species in the Bay-Delta (Baxter *et al.* 2010, p. 28), contaminant effects remain unresolved.

The largest source of ammonia entering the Delta ecosystem is the Sacramento Regional Wastewater Treatment Plant (SRWTP), which accounts for 90 percent of the total ammonia load released into the Delta. Ammonia is un-ionized and has the chemical formula NH_3 . Ammonium is ionized and has the formula NH_4^+ . The major factors determining the proportion of ammonia or ammonium in water are water pH and temperature. This is important, as NH_3 ammonia is the form that can be directly toxic to aquatic organisms, and NH_4^+ ammonium is the form

documented to interfere with uptake of nitrates by phytoplankton (Dugdale *et al.* 2007, p. 17; Jassby 2008, p. 3).

In addition to potential direct effects on fish, ammonia in the form of ammonium has been shown to alter the food web by adversely impacting phytoplankton and zooplankton dynamics in the estuary ecosystem. Historical data suggest that decreases in Suisun Bay phytoplankton biomass coincide with increased ammonia discharge by the SRWTP (Parker *et al.* 2004, p. 7; Dugdale *et al.* 2011, p. 1). Phytoplankton preferentially take up ammonium over nitrate when it is present in the water. Ammonium is insufficient to provide for growth in phytoplankton, and uptake of ammonium to the exclusion of nitrate results in decreases in phytoplankton biomass (Dugdale *et al.* 2007, p. 23). Therefore, ammonium impairs primary productivity by reducing nitrate uptake in phytoplankton. Ammonium's negative effect on the food web has been documented in the longfin smelt rearing areas of San Francisco Bay and Suisun Bay (Dugdale *et al.* 2007, pp. 27–28). Decreased primary productivity results in less food available to longfin smelt and other fish in these bays.

In summary, although no direct link has been made between contaminants and longfin smelt (Baxter *et al.* 2010, p. 68), ammonium has been shown to have a direct effect on the food supply that the Bay-Delta longfin smelt DPS relies upon. Therefore, we conclude that high ammonium concentrations may be a significant current and future threat to the Bay-Delta DPS of longfin smelt.

Summary of Factor E

The best available information indicates that introduced species constitute a threat to the Bay-Delta DPS of longfin smelt and that and contaminants (high ammonium concentrations) may constitute a threat to the Bay-Delta DPS of longfin smelt. Entrainment is a potential threat to the DPS, but information currently available does not indicate that entrainment threatens the continued existence of the Bay-Delta longfin smelt population. Although entrainment results in mortality of longfin smelt, Baxter *et al.* (2010, p. 63) concluded that these losses have yet to be placed in a population context, and no conclusions can be drawn regarding their effects on recent longfin smelt abundance. Therefore, based on the best scientific evidence available, we conclude that the Bay-Delta longfin smelt DPS is threatened in part due to other natural or manmade factors including the nonnative overbite clam and high ammonium concentrations.

Finding

This status review identified threats to the Bay-Delta DPS of longfin smelt attributable to Factors A, D, and E, as well as interactions between these threats. The primary threat to the DPS is from reduced freshwater flows. Upstream dams and water storage exacerbated by water diversions, especially from the SWP and CVP water export facilities, result in reduced freshwater flows within the estuary, and these reductions in freshwater flows result in reduced habitat suitability for longfin smelt (Factor A). Freshwater flows, especially winter-spring flows, are significantly correlated with longfin smelt abundance—longfin smelt abundance is lower when winter-spring flows are lower. While freshwater flows have been shown to be significantly correlated with longfin smelt abundance, causal mechanisms underlying this

correlation are still not fully understood and are the subject of ongoing research on the Pelagic Organism Decline.

In addition to the threat caused by reduced freshwater flow into the Bay-Delta, and alteration of natural flow regimes resulting from water storage and diversion, there appear to be other factors contributing to the Pelagic Organism Decline (Baxter 2010 *et al.*, p. 69). Models indicate a steady linear decline in abundance of longfin smelt since about the time of the invasion of the nonnative overbite clam in 1987 (Rosenfield and Swanson 2010, pp. 13–14; see Factor E: Introduced Species) in the Bay-Delta. However, not all aspects of the longfin smelt decline can be attributed to the overbite clam invasion, as a decline in abundance of pre-spawning adults in Suisun Marsh occurred before the invasion of the clam, and a partial rebound in longfin smelt abundance occurred in the early 2000s (Rosenfield and Baxter 2007, p. 1589).

The long-term decline in abundance of longfin smelt in the Bay-Delta has been partially attributed to reductions in food availability and disruptions of the Bay-Delta food web caused by establishment of the nonnative overbite clam in 1987 (Factor E) and ammonium concentrations (Factor E). Impacts of the overbite clam and ammonium on the Bay-Delta food web have been long-lasting and are ongoing. We conclude that ongoing disruptions of the food web caused by the overbite clam are a threat to the continued existence of the Bay-Delta DPS of longfin smelt. We also conclude that high ammonium concentrations in the Bay-Delta may constitute a threat to the continued existence of the overbite clam.

Multiple existing Federal and State regulatory mechanisms provide important protections

for the Bay-Delta DPS of longfin smelt and act to reduce threats to the DPS. However, the continued decline in the abundance of the Bay-Delta longfin smelt DPS indicates that existing regulatory mechanisms, as currently implemented, are not adequate to sufficiently reduce threats identified in this finding. Therefore, we find that inadequate existing regulatory mechanisms contribute to threats faced by the Bay-Delta longfin smelt DPS.

The threats identified are likely acting together to contribute to the decline of the population (Baxter *et al.* 2010, p. 69). Reduced freshwater flows result in effects to longfin smelt habitat suitability, at the same time that the food web has been altered by introduced species and ammonium concentrations. It is possible that climate change could exacerbate these threats; however, due to uncertainties of how longfin smelt will respond to climate change effects, we cannot conclude that climate change will threaten the continued existence of the Bay-Delta longfin smelt DPS. The combined effects of reduced freshwater flows, the invasive overbite clam (reduced levels of phytoplankton and zooplankton that are important to the Bay-Delta food web), and high ammonium concentrations act to significantly reduce habitat suitability for longfin smelt.

The best scientific and commercial information available indicates that the threats facing the Bay-Delta DPS of longfin smelt are of sufficient imminence, intensity and magnitude to threaten the continued existence of the species now or in the foreseeable future. Therefore, we find that listing the Bay-Delta longfin smelt DPS is warranted. We will make a determination on the status of the DPS as endangered or threatened when we prepare a proposed listing determination. However, as explained in more detail below, an immediate proposal of a

regulation implementing this action is precluded by higher priority listing actions, and progress is being made to add or remove qualified species from the Lists of Endangered and Threatened Wildlife and Plants.

We reviewed the available information to determine if the existing and foreseeable threats render the species at risk of extinction now such that issuing an emergency regulation temporarily listing the species under section 4(b)(7) of the Act is warranted. We determined that issuing an emergency regulation temporarily listing the DPS is not warranted at this time because the threats are not of sufficient magnitude and imminence to pose an immediate threat to the continued existence of the DPS. However, if at any time we determine that issuing an emergency regulation temporarily listing the Bay-Delta DPS of longfin smelt is warranted, we will initiate this action at that time.

Significant Portion of Its Range

The Act defines “endangered species” as any species which is “in danger of extinction throughout all or a significant portion of its range,” and “threatened species” as any species which is “likely to become an endangered species within the foreseeable future throughout all or a significant portion of its range.” The definition of “species” is also relevant to this discussion. The Act defines “species” as “any subspecies of fish or wildlife or plants, and any distinct population segment [DPS] of any species of vertebrate fish or wildlife which interbreeds when mature” (16 U.S.C. 1532(16)). The phrase “significant portion of its range” (SPR) is not defined by the statute, and we have never addressed in our regulations: (1) The consequences of a

determination that a species is either endangered or likely to become so throughout a significant portion of its range, but not throughout all of its range; or (2) what qualifies a portion of a range as “significant.”

Two recent district court decisions have addressed whether the SPR language allows the Service to list or protect less than all members of a defined “species”: *Defenders of Wildlife v. Salazar*, 729 F. Supp. 2d 1207 (D. Mont. 2010), concerning the Service’s delisting of the Northern Rocky Mountain gray wolf (74 FR 15123, April 2, 2009); and *WildEarth Guardians v. Salazar*, 2010 U.S. Dist. LEXIS 105253 (D. Ariz. September 30, 2010), concerning the Service’s 2008 finding on a petition to list the Gunnison’s prairie dog (73 FR 6660, February 5, 2008). The Service had asserted in both of these determinations that it had authority, in effect, to protect only some members of a “species,” as defined by the Act (i.e., species, subspecies, or DPS), under the Act. Both courts ruled that the determinations were arbitrary and capricious on the grounds that this approach violated the plain and unambiguous language of the Act. The courts concluded that reading the SPR language to allow protecting only a portion of a species’ range is inconsistent with the Act’s definition of “species.” The courts concluded that once a determination is made that a species (i.e., species, subspecies, or DPS) meets the definition of “endangered species” or “threatened species,” it must be placed on the list in its entirety and the Act’s protections applied consistently to all members of that species (subject to modification of protections through special rules under sections 4(d) and 10(j) of the Act).

Consistent with that interpretation, and for the purposes of this finding, we interpret the phrase “significant portion of its range” in the Act’s definitions of “endangered species” and

“threatened species” to provide an independent basis for listing; thus there are two situations (or factual bases) under which a species would qualify for listing: a species may be endangered or threatened throughout all of its range; or a species may be endangered or threatened in only a significant portion of its range. If a species is in danger of extinction throughout an SPR, it, the species, is an “endangered species.” The same analysis applies to “threatened species.” Based on this interpretation and supported by existing case law, the consequence of finding that a species is endangered or threatened in only a significant portion of its range is that the entire species will be listed as endangered or threatened, respectively, and the Act’s protections will be applied across the species’ entire range.

We conclude, for the purposes of this finding, that interpreting the SPR phrase as providing an independent basis for listing is the best interpretation of the Act because it is consistent with the purposes and the plain meaning of the key definitions of the Act; it does not conflict with established past agency practice (i.e., prior to the 2007 Solicitor’s Opinion), as no consistent, long-term agency practice has been established; and it is consistent with the judicial opinions that have most closely examined this issue. Having concluded that the phrase “significant portion of its range” provides an independent basis for listing and protecting the entire species, we next turn to the meaning of “significant” to determine the threshold for when such an independent basis for listing exists.

Although there are potentially many ways to determine whether a portion of a species’ range is “significant,” we conclude, for the purposes of this finding, that the significance of the portion of the range should be determined based on its biological contribution to the conservation

of the species. For this reason, we describe the threshold for “significant” in terms of an increase in the risk of extinction for the species. We conclude that a biologically based definition of “significant” best conforms to the purposes of the Act, is consistent with judicial interpretations, and best ensures species’ conservation. Thus, for the purposes of this finding, and as explained further below, a portion of the range of a species is “significant” if its contribution to the viability of the species is so important that without that portion, the species would be in danger of extinction.

We evaluate biological significance based on the principles of conservation biology using the concepts of redundancy, resiliency, and representation. *Resiliency* describes the characteristics of a species and its habitat that allow it to recover from periodic disturbance. *Redundancy* (having multiple populations distributed across the landscape) may be needed to provide a margin of safety for the species to withstand catastrophic events. *Representation* (the range of variation found in a species) ensures that the species’ adaptive capabilities are conserved. Redundancy, resiliency, and representation are not independent of each other, and some characteristic of a species or area may contribute to all three. For example, distribution across a wide variety of habitat types is an indicator of representation, but it may also indicate a broad geographic distribution contributing to redundancy (decreasing the chance that any one event affects the entire species), and the likelihood that some habitat types are less susceptible to certain threats, contributing to resiliency (the ability of the species to recover from disturbance). None of these concepts is intended to be mutually exclusive, and a portion of a species’ range may be determined to be “significant” due to its contributions under any one or more of these concepts.

For the purposes of this finding, we determine if a portion's biological contribution is so important that the portion qualifies as "significant" by asking whether *without that portion*, the representation, redundancy, or resiliency of the species would be so impaired that the species would have an increased vulnerability to threats to the point that the overall species would be in danger of extinction (i.e., would be "endangered"). Conversely, we would not consider the portion of the range at issue to be "significant" if there is sufficient resiliency, redundancy, and representation elsewhere in the species' range that the species would not be in danger of extinction throughout its range if the population in that portion of the range in question became extirpated (extinct locally).

We recognize that this definition of "significant" (a portion of the range of a species is "significant" if its contribution to the viability of the species is so important that without that portion, the species would be in danger of extinction) establishes a threshold that is relatively high. On the one hand, given that the consequences of finding a species to be endangered or threatened in an SPR would be listing the species throughout its entire range, it is important to use a threshold for "significant" that is robust. It would not be meaningful or appropriate to establish a very low threshold whereby a portion of the range can be considered "significant" even if only a negligible increase in extinction risk would result from its loss. Because nearly any portion of a species' range can be said to contribute some increment to a species' viability, use of such a low threshold would require us to impose restrictions and expend conservation resources disproportionately to conservation benefit: listing would be rangewide, even if only a portion of the range of minor conservation importance to the species is imperiled. On the other

hand, it would be inappropriate to establish a threshold for “significant” that is too high. This would be the case if the standard were, for example, that a portion of the range can be considered “significant” only if threats in that portion result in the entire species’ being currently endangered or threatened. Such a high bar would not give the SPR phrase independent meaning, as the Ninth Circuit held in *Defenders of Wildlife v. Norton*, 258 F.3d 1136 (9th Cir. 2001).

The definition of “significant” used in this finding carefully balances these concerns. By setting a relatively high threshold, we minimize the degree to which restrictions will be imposed or resources expended that do not contribute substantially to species conservation. But we have not set the threshold so high that the phrase “in a significant portion of its range” loses independent meaning. Specifically, we have not set the threshold as high as it was under the interpretation presented by the Service in the *Defenders* litigation. Under that interpretation, the portion of the range would have to be so important that current imperilment there would mean that the species would be *currently* imperiled everywhere. Under the definition of “significant” used in this finding, the portion of the range need not rise to such an exceptionally high level of biological significance. (We recognize that if the species is imperiled in a portion that rises to that level of biological significance, then we should conclude that the species is in fact imperiled throughout all of its range, and that we would not need to rely on the SPR language for such a listing.) Rather, under this interpretation we ask whether the species would be endangered everywhere without that portion, *i.e.*, if that portion were completely extirpated. In other words, the portion of the range need not be so important that even the species being in danger of extinction in that portion would be sufficient to cause the species in the remainder of the range to be endangered; rather, the *complete extirpation* (in a hypothetical future) of the species in that

portion would be required to cause the species in the remainder of the range to be endangered.

The range of a species can theoretically be divided into portions in an infinite number of ways. However, there is no purpose to analyzing portions of the range that have no reasonable potential to be significant or to analyzing portions of the range in which there is no reasonable potential for the species to be endangered or threatened. To identify only those portions that warrant further consideration, we determine whether there is substantial information indicating that: (1) The portions may be “significant,” *and* (2) the species may be in danger of extinction there or likely to become so within the foreseeable future. Depending on the biology of the species, its range, and the threats it faces, it might be more efficient for us to address the significance question first or the status question first. Thus, if we determine that a portion of the range is not “significant,” we do not need to determine whether the species is endangered or threatened there; if we determine that the species is not endangered or threatened in a portion of its range, we do not need to determine if that portion is “significant.” In practice, a key part of the determination that a species is in danger of extinction in a significant portion of its range is whether the threats are geographically concentrated in some way. If the threats to the species are essentially uniform throughout its range, no portion is likely to warrant further consideration. Moreover, if any concentration of threats to the species occurs only in portions of the species’ range that clearly would not meet the biologically based definition of “significant,” such portions will not warrant further consideration.

We have determined that the longfin smelt does not face elevated threats in most portions of its range, and we have determined that the portion of the range that has concentrated threats

(the Bay-Delta portion of the range) is a DPS. The rangewide five factor analysis for longfin smelt does not identify any portions of the species' range outside of Bay-Delta where threats are concentrated. Potential threats to the species are by and large uniform throughout its range with the exception of the Bay-Delta. Therefore, we will not further consider the Bay-Delta DPS as an SPR.

Listing Priority Number

The Service adopted guidelines on September 21, 1983 (48 FR 43098) to establish a rational system for utilizing available resources for the highest priority species when adding species to the Lists of Endangered or Threatened Wildlife and Plants or reclassifying species listed as threatened to endangered status. The system places greatest importance on the immediacy and magnitude of threats, but also factors in the level of taxonomic distinctiveness by assigning priority in descending order to monotypic genera (genus with one species), full species, and subspecies (or equivalently, distinct population segments of vertebrates (DPS)). As a result of our analysis of the best available scientific and commercial information, we assign the Bay-Delta DPS of longfin smelt a listing priority number of 3, based on the high magnitude and immediacy of threats. A number three listing priority is the highest listing allowed for a DPS under the current listing priority guidance. One or more of the threats discussed above are occurring (or we anticipate they will occur in the near future) within the range of the Bay-Delta DPS of the longfin smelt. These threats are ongoing and, in some cases (such as nonnative species), are considered irreversible. While we conclude that listing the Bay-Delta DPS of longfin smelt is warranted, an immediate proposal to list this species is precluded by other higher

priority listings, which we address below.

Preclusion and Expeditious Progress

Preclusion is a function of the listing priority of a species in relation to the resources that are available and the cost and relative priority of competing demands for those resources. Thus, in any given fiscal year (FY), multiple factors dictate whether it will be possible to undertake work on a listing proposal regulation or whether promulgation of such a proposal is precluded by higher priority listing actions.

The resources available for listing actions are determined through the annual Congressional appropriations process. The appropriation for the Listing Program is available to support work involving the following listing actions: Proposed and final listing rules; 90-day and 12-month findings on petitions to add species to the Lists of Endangered and Threatened Wildlife and Plants (Lists) or to change the status of a species from threatened to endangered; annual “resubmitted” petition findings on prior warranted-but-precluded petition findings as required under section 4(b)(3)(C)(i) of the Act; critical habitat petition findings; proposed and final rules designating critical habitat; and litigation-related, administrative, and program-management functions (including preparing and allocating budgets, responding to Congressional and public inquiries, and conducting public outreach regarding listing and critical habitat). The work involved in preparing various listing documents can be extensive and may include, but is not limited to: Gathering and assessing the best scientific and commercial data available and conducting analyses used as the basis for our decisions; writing and publishing documents; and obtaining, reviewing, and evaluating public comments and peer review comments on proposed

rules and incorporating relevant information into final rules. The number of listing actions that we can undertake in a given year also is influenced by the complexity of those listing actions; that is, more complex actions generally are more costly. The median cost for preparing and publishing a 90-day finding is \$39,276; for a 12-month finding, \$100,690; for a proposed rule with critical habitat, \$345,000; and for a final listing rule with critical habitat, \$305,000.

We cannot spend more than is appropriated for the Listing Program without violating the Anti-Deficiency Act (see 31 U.S.C. 1341(a)(1)(A)). In addition, in FY 1998 and for each fiscal year since then, Congress has placed a statutory cap on funds that may be expended for the Listing Program, equal to the amount expressly appropriated for that purpose in that fiscal year. This cap was designed to prevent funds appropriated for other functions under the Act (for example, recovery funds for removing species from the Lists), or for other Service programs, from being used for Listing Program actions (see House Report 105-163, 105th Congress, 1st Session, July 1, 1997).

Since FY 2002, the Service's budget has included a critical habitat subcap to ensure that some funds are available for other work in the Listing Program ("The critical habitat designation subcap will ensure that some funding is available to address other listing activities" (House Report No. 107 - 103, 107th Congress, 1st Session, June 19, 2001)). In FY 2002 and each year until FY 2006, the Service has had to use virtually the entire critical habitat subcap to address court-mandated designations of critical habitat, and consequently none of the critical habitat subcap funds have been available for other listing activities. In some FYs since 2006, we have been able to use some of the critical habitat subcap funds to fund proposed listing determinations for high-priority candidate species. In other FYs, while we were unable to use any of the critical

habitat subcap funds to fund proposed listing determinations, we did use some of this money to fund the critical habitat portion of some proposed listing determinations so that the proposed listing determination and proposed critical habitat designation could be combined into one rule, thereby being more efficient in our work. At this time, for FY 2012, we plan to use some of the critical habitat subcap funds to fund proposed listing determinations.

We make our determinations of preclusion on a nationwide basis to ensure that the species most in need of listing will be addressed first and also because we allocate our listing budget on a nationwide basis. Through the listing cap, the critical habitat subcap, and the amount of funds needed to address court-mandated critical habitat designations, Congress and the courts have in effect determined the amount of money available for other listing activities nationwide. Therefore, the funds in the listing cap, other than those needed to address court-mandated critical habitat for already listed species, set the limits on our determinations of preclusion and expeditious progress.

Congress identified the availability of resources as the only basis for deferring the initiation of a rulemaking that is warranted. The Conference Report accompanying Pub. L. 97-304 (Endangered Species Act Amendments of 1982), which established the current statutory deadlines and the warranted-but-precluded finding, states that the amendments were “not intended to allow the Secretary to delay commencing the rulemaking process for any reason other than that the existence of pending or imminent proposals to list species subject to a greater degree of threat would make allocation of resources to such a petition [that is, for a lower-ranking species] unwise.” Although that statement appeared to refer specifically to the “to the maximum extent practicable” limitation on the 90-day deadline for making a “substantial

information” finding, that finding is made at the point when the Service is deciding whether or not to commence a status review that will determine the degree of threats facing the species, and therefore the analysis underlying the statement is more relevant to the use of the warranted-but-precluded finding, which is made when the Service has already determined the degree of threats facing the species and is deciding whether or not to commence a rulemaking.

In FY 2011, on April 15, 2011, Congress passed the Full-Year Continuing Appropriations Act (Pub. L. 112-10), which provided funding through September 30, 2011. The Service had \$20,902,000 for the listing program. Of that, \$9,472,000 was used for determinations of critical habitat for already listed species. Also \$500,000 was appropriated for foreign species listings under the Act. The Service thus had \$10,930,000 available to fund work in the following categories: Compliance with court orders and court-approved settlement agreements requiring that petition findings or listing determinations be completed by a specific date; section 4 (of the Act) listing actions with absolute statutory deadlines; essential litigation-related, administrative, and listing program-management functions; and high-priority listing actions for some of our candidate species. In FY 2010, the Service received many new petitions and a single petition to list 404 species. The receipt of petitions for a large number of species is consuming the Service’s listing funding that is not dedicated to meeting court-ordered commitments. Absent some ability to balance effort among listing duties under existing funding levels, the Service was only able to initiate a few new listing determinations for candidate species in FY 2011. For FY 2012, on December 17, 2011, Congress passed a continuing resolution which provides funding at the FY 2011 enacted level with a 1.5 percent rescission through December 23, 2011 (Pub. L. 112-68). Until Congress appropriates funds for FY 2012,

we will fund listing work based on the FY 2011 amount minus the 1.5 percent.

In 2009, the responsibility for listing foreign species under the Act was transferred from the Division of Scientific Authority, International Affairs Program, to the Endangered Species Program. Therefore, starting in FY 2010, we used a portion of our funding to work on the actions described above for listing actions related to foreign species. In FY 2011, we anticipated using \$1,500,000 for work on listing actions for foreign species, which reduces funding available for domestic listing actions; however, only \$500,000 was allocated for this function. Although there are no foreign species issues included in our high-priority listing actions at this time, many actions have statutory or court-approved settlement deadlines, thus increasing their priority. The budget allocations for each specific listing action are identified in the Service's FY 2011 and FY 2012 Allocation Tables (part of our record).

For the above reasons, funding a proposed listing determination for the Bay-Delta DPS of longfin smelt is precluded by court-ordered and court-approved settlement agreements, listing actions with absolute statutory deadlines, and work on proposed listing determinations for those candidate species with a higher listing priority (i.e., candidate species with LPNs of 1 or 2).

Based on our September 21, 1983, guidelines for assigning an LPN for each candidate species (48 FR 43098), we have a significant number of species with a LPN of 2. Using these guidelines, we assign each candidate an LPN of 1 to 12, depending on the magnitude of threats (high or moderate to low), immediacy of threats (imminent or nonimminent), and taxonomic status of the species (in order of priority: monotypic genus (a species that is the sole member of

a genus); species; or part of a species (subspecies, or distinct population segment)). The lower the listing priority number, the higher the listing priority (that is, a species with an LPN of 1 would have the highest listing priority).

Because of the large number of high-priority species, we have further ranked the candidate species with an LPN of 2 by using the following extinction-risk type criteria: International Union for the Conservation of Nature and Natural Resources (IUCN) Red list status/rank, Heritage rank (provided by NatureServe), Heritage threat rank (provided by NatureServe), and species currently with fewer than 50 individuals, or 4 or fewer populations. Those species with the highest IUCN rank (critically endangered), the highest Heritage rank (G1), the highest Heritage threat rank (substantial, imminent threats), and currently with fewer than 50 individuals, or fewer than 4 populations, originally comprised a group of approximately 40 candidate species (“Top 40”). These 40 candidate species have had the highest priority to receive funding to work on a proposed listing determination. As we work on proposed and final listing rules for those 40 candidates, we apply the ranking criteria to the next group of candidates with LPNs of 2 and 3 to determine the next set of highest priority candidate species. Finally, proposed rules for reclassification of threatened species to endangered species are lower priority, because as listed species, they are already afforded the protections of the Act and implementing regulations. However, for efficiency reasons, we may choose to work on a proposed rule to reclassify a species to endangered if we can combine this with work that is subject to a court-determined deadline.

With our workload so much bigger than the amount of funds we have to accomplish it, it is important that we be as efficient as possible in our listing process. Therefore, as we work on proposed rules for the highest priority species in the next several years, we are preparing multi-species proposals when appropriate, and these may include species with lower priority if they overlap geographically or have the same threats as a species with an LPN of 2. In addition, we take into consideration the availability of staff resources when we determine which high-priority species will receive funding to minimize the amount of time and resources required to complete each listing action.

As explained above, a determination that listing is warranted but precluded must also demonstrate that expeditious progress is being made to add and remove qualified species to and from the Lists of Endangered and Threatened Wildlife and Plants. As with our “precluded” finding, the evaluation of whether progress in adding qualified species to the Lists has been expeditious is a function of the resources available for listing and the competing demands for those funds. (Although we do not discuss it in detail here, we are also making expeditious progress in removing species from the list under the Recovery program in light of the resource available for delisting, which is funded by a separate line item in the budget of the Endangered Species Program. During FY 2011, we completed delisting rules for three species.) Given the limited resources available for listing, we find that we made expeditious progress in FY 2011 and are making expeditious progress in FY 2012 in the Listing Program. This progress included preparing and publishing the following determinations:

FY 2011 and FY 2012 Completed Listing Actions

Publication Date	Title	Actions	FR Pages
10/6/2010	Endangered Status for the Altamaha Spiny mussel and Designation of Critical Habitat	Proposed Listing Endangered	75 FR 61664-61690
10/7/2010	12-month Finding on a Petition to list the Sacramento Splittail as Endangered or Threatened	Notice of 12-month petition finding, Not warranted	75 FR 62070-62095
10/28/2010	Endangered Status and Designation of Critical Habitat for Spikedace and Loach Minnow	Proposed Listing Endangered (uplisting)	75 FR 66481-66552
11/2/2010	90-Day Finding on a Petition to List the Bay Springs Salamander as Endangered	Notice of 90-day Petition Finding, Not substantial	75 FR 67341-67343
11/2/2010	Determination of Endangered Status for the Georgia Pigtoe Mussel, Interrupted Rocksnail, and Rough Hornsnail and Designation of Critical Habitat	Final Listing Endangered	75 FR 67511-67550
11/2/2010	Listing the Rayed Bean and Snuffbox as Endangered	Proposed Listing Endangered	75 FR 67551-67583
11/4/2010	12-Month Finding on a Petition to List <i>Cirsium wrightii</i> (Wright's Marsh Thistle) as Endangered or Threatened	Notice of 12-month petition finding, Warranted but precluded	75 FR 67925-67944
12/14/2010	Endangered Status for Dunes Sagebrush Lizard	Proposed Listing Endangered	75 FR 77801-77817
12/14/2010	12-month Finding on a Petition to List the North American Wolverine as Endangered or Threatened	Notice of 12-month petition finding, Warranted but precluded	75 FR 78029-78061
12/14/2010	12-Month Finding on a Petition to List the Sonoran Population of the Desert Tortoise as Endangered or Threatened	Notice of 12-month petition finding, Warranted but precluded	75 FR 78093-78146
12/15/2010	12-Month Finding on a Petition to List <i>Astragalus microcymbus</i> and <i>Astragalus schmollii</i> as Endangered or Threatened	Notice of 12-month petition finding, Warranted but precluded	75 FR 78513-78556
12/28/2010	Listing Seven Brazilian Bird Species as Endangered Throughout Their Range	Final Listing Endangered	75 FR 81793-81815
1/4/2011	90-Day Finding on a Petition to List the Red Knot subspecies <i>Calidris canutus roselaari</i> as Endangered	Notice of 90-day Petition Finding, Not substantial	76 FR 304-311
1/19/2011	Endangered Status for the Sheepnose and Spectaclecase Mussels	Proposed Listing Endangered	76 FR 3392-3420

2/10/2011	12-Month Finding on a Petition to List the Pacific Walrus as Endangered or Threatened	Notice of 12-month petition finding, Warranted but precluded	76 FR 7634-7679
2/17/2011	90-Day Finding on a Petition To List the Sand Verbena Moth as Endangered or Threatened	Notice of 90-day Petition Finding, Substantial	76 FR 9309-9318
2/22 /2011	Determination of Threatened Status for the New Zealand-Australia Distinct Population Segment of the Southern Rockhopper Penguin	Final Listing Threatened	76 FR 9681-9692
2/22/2011	12-Month Finding on a Petition to List <i>Solanum conocarpum</i> (marron bacora) as Endangered	Notice of 12-month petition finding, Warranted but precluded	76 FR 9722-9733
2/23/2011	12-Month Finding on a Petition to List Thorne's Hairstreak Butterfly as Endangered	Notice of 12-month petition finding, Not warranted	76 FR 9991-10003
2/23/2011	12-Month Finding on a Petition to List <i>Astragalus hamiltonii</i> , <i>Penstemon flowersii</i> , <i>Eriogonum soledium</i> , <i>Lepidium ostleri</i> , and <i>Trifolium friscanum</i> as Endangered or Threatened	Notice of 12-month petition finding, Warranted but precluded & Not Warranted	76 FR 10166-10203
2/24/2011	90-Day Finding on a Petition to List the Wild Plains Bison or Each of Four Distinct Population Segments as Threatened	Notice of 90-day Petition Finding, Not substantial	76 FR 10299-10310
2/24/2011	90-Day Finding on a Petition to List the Unsilvered Fritillary Butterfly as Threatened or Endangered	Notice of 90-day Petition Finding, Not substantial	76 FR 10310-10319
3/8/2011	12-Month Finding on a Petition to List the Mt. Charleston Blue Butterfly as Endangered or Threatened	Notice of 12-month petition finding, Warranted but precluded	76 FR 12667-12683
3/8/2011	90-Day Finding on a Petition to List the Texas Kangaroo Rat as Endangered or Threatened	Notice of 90-day Petition Finding, Substantial	76 FR 12683-12690
3/10/2011	Initiation of Status Review for Longfin Smelt	Notice of Status Review	76 FR 13121-13122
3/15/2011	Withdrawal of Proposed Rule to List the Flat-tailed Horned Lizard as Threatened	Proposed rule withdrawal	76 FR 14210-14268
3/15/2011	Proposed Threatened Status for the Chiricahua Leopard Frog and Proposed Designation of Critical Habitat	Proposed Listing Threatened; Proposed Designation of Critical Habitat	76 FR 14126-14207
3/22/2011	12-Month Finding on a Petition to List the Berry Cave Salamander as Endangered	Notice of 12-month petition finding, Warranted but precluded	76 FR 15919-15932
4/1/2011	90-Day Finding on a Petition to List the Spring Pygmy Sunfish as Endangered	Notice of 90-day Petition Finding, Substantial	76 FR 18138-18143

4/5/2011	12-Month Finding on a Petition to List the Bearmouth Mountainsnail, Byrne Resort Mountainsnail, and Meltwater Lednian Stonefly as Endangered or Threatened	Notice of 12-month petition finding, Not Warranted and Warranted but precluded	76 FR 18684-18701
4/5/2011	90-Day Finding on a Petition To List the Peary Caribou and Dolphin and Union population of the Barren-ground Caribou as Endangered or Threatened	Notice of 90-day Petition Finding, Substantial	76 FR 18701-18706
4/12/2011	Proposed Endangered Status for the Three Forks Springsnail and San Bernardino Springsnail, and Proposed Designation of Critical Habitat	Proposed Listing Endangered; Proposed Designation of Critical Habitat	76 FR 20464-20488
4/13/2011	90-Day Finding on a Petition To List Spring Mountains Acastus Checkerspot Butterfly as Endangered	Notice of 90-day Petition Finding, Substantial	76 FR 20613-20622
4/14/2011	90-Day Finding on a Petition to List the Prairie Chub as Threatened or Endangered	Notice of 90-day Petition Finding, Substantial	76 FR 20911-20918
4/14/2011	12-Month Finding on a Petition to List Hermes Copper Butterfly as Endangered or Threatened	Notice of 12-month petition finding, Warranted but precluded	76 FR 20918-20939
4/26/2011	90-Day Finding on a Petition to List the Arapahoe Snowfly as Endangered or Threatened	Notice of 90-day Petition Finding, Substantial	76 FR 23256-23265
4/26/2011	90-Day Finding on a Petition to List the Smooth-Billed Ani as Threatened or Endangered	Notice of 90-day Petition Finding, Not substantial	76 FR 23265-23271
5/12/2011	Withdrawal of the Proposed Rule to List the Mountain Plover as Threatened	Proposed Rule, Withdrawal	76 FR 27756-27799
5/25/2011	90-Day Finding on a Petition To List the Spot-tailed Earless Lizard as Endangered or Threatened	Notice of 90-day Petition Finding, Substantial	76 FR 30082-30087
5/26/2011	Listing the Salmon-Crested Cockatoo as Threatened Throughout its Range with Special Rule	Final Listing Threatened	76 FR 30758-30780
5/31/2011	12-Month Finding on a Petition to List Puerto Rican Harlequin Butterfly as Endangered	Notice of 12-month petition finding, Warranted but precluded	76 FR 31282-31294
6/2/2011	90-Day Finding on a Petition to Reclassify the Straight-Horned Markhor (<i>Capra falconeri jerdoni</i>) of Torghar Hills as Threatened	Notice of 90-day Petition Finding, Substantial	76 FR 31903-31906
6/2/2011	90-Day Finding on a Petition to List the Golden-winged Warbler as Endangered or Threatened	Notice of 90-day Petition Finding, Substantial	76 FR 31920-31926
6/7/2011	12-Month Finding on a Petition to List the Striped Newt as Threatened	Notice of 12-month petition finding, Warranted but precluded	76 FR 32911-32929

6/9/2011	12-Month Finding on a Petition to List <i>Abronia ammophila</i> , <i>Agrostis rossiae</i> , <i>Astragalus proimanthus</i> , <i>Boechea (Arabis) pusilla</i> , and <i>Penstemon gibbensii</i> as Threatened or Endangered	Notice of 12-month petition finding, Not Warranted and Warranted but precluded	76 FR 33924-33965
6/21/2011	90-Day Finding on a Petition to List the Utah Population of the Gila Monster as an Endangered or a Threatened Distinct Population Segment	Notice of 90-day Petition Finding, Not substantial	76 FR 36049-36053
6/21/2011	Revised 90-Day Finding on a Petition To Reclassify the Utah Prairie Dog From Threatened to Endangered	Notice of 90-day Petition Finding, Not substantial	76 FR 36053-36068
6/28/2011	12-Month Finding on a Petition to List <i>Castanea pumila</i> var. <i>ozarkensis</i> as Threatened or Endangered	Notice of 12-month petition finding, Not warranted	76 FR 37706-37716
6/29/2011	90-Day Finding on a Petition to List the Eastern Small-Footed Bat and the Northern Long-Eared Bat as Threatened or Endangered	Notice of 90-day Petition Finding, Substantial	76 FR 38095-38106
6/30/2011	12-Month Finding on a Petition to List a Distinct Population Segment of the Fisher in Its United States Northern Rocky Mountain Range as Endangered or Threatened with Critical Habitat	Notice of 12-month petition finding, Not warranted	76 FR 38504-38532
7/12/2011	90-Day Finding on a Petition to List the Bay Skipper as Threatened or Endangered	Notice of 90-day Petition Finding, Substantial	76 FR 40868-40871
7/19/2011	12-Month Finding on a Petition to List <i>Pinus albicaulis</i> as Endangered or Threatened with Critical Habitat	Notice of 12-month petition finding, Warranted but precluded	76 FR 42631-42654
7/19/2011	Petition To List Grand Canyon Cave Pseudoscorpion	Notice of 12-month petition finding, Not warranted	76 FR 42654-42658
7/26/2011	12-Month Finding on a Petition to List the Giant Palouse Earthworm (<i>Drilolerius americanus</i>) as Threatened or Endangered	Notice of 12-month petition finding, Not warranted	76 FR 44547-44564
7/26/2011	12-month Finding on a Petition to List the Frigid Ambersnail as Endangered	Notice of 12-month petition finding, Not warranted	76 FR 44566-44569
7/27/2011	Determination of Endangered Status for <i>Ipomopsis polyantha</i> (Pagosa Skyrocket) and Threatened Status for <i>Penstemon debilis</i> (Parachute Beardtongue) and <i>Phacelia submutica</i> (DeBeque Phacelia)	Final Listing Endangered, Threatened	76 FR 45054-45075

7/27/2011	12-Month Finding on a Petition to List the Gopher Tortoise as Threatened in the Eastern Portion of its Range	Notice of 12-month petition finding, Warranted but precluded	76 FR 45130-45162
8/2/2011	Proposed Endangered Status for the Chupadera Springsnail (<i>Pyrgulopsis chupaderae</i>) and Proposed Designation of Critical Habitat	Proposed Listing Endangered	76 FR 46218-46234
8/2/2011	90-Day Finding on a Petition to List the Straight Snowfly and Idaho Snowfly as Endangered	Notice of 90-day Petition Finding, Not substantial	76 FR 46238-46251
8/2/2011	12-Month Finding on a Petition to List the Redrock Stonefly as Endangered or Threatened	Notice of 12-month petition finding, Not warranted	76 FR 46251-46266
8/2/2011	Listing 23 Species on Oahu as Endangered and Designating Critical Habitat for 124 Species	Proposed Listing Endangered	76 FR 46362-46594
8/4/2011	90-Day Finding on a Petition To List Six Sand Dune Beetles as Endangered or Threatened	Notice of 90-day Petition Finding, Not substantial and substantial	76 FR 47123-47133
8/9/2011	Endangered Status for the Cumberland Darter, Rush Darter, Yellowcheek Darter, Chucky Madtom, and Laurel Dace	Final Listing Endangered	76 FR 48722-48741
8/9/2011	12-Month Finding on a Petition to List the Nueces River and Plateau Shiners as Threatened or Endangered	Notice of 12-month petition finding, Not warranted	76 FR 48777-48788
8/9/2011	Four Foreign Parrot Species [crimson shining parrot, white cockatoo, Philippine cockatoo, yellow-crested cockatoo]	Proposed Listing Endangered and Threatened; Notice of 12-month petition finding, Not warranted	76 FR 49202-49236
8/10/2011	Proposed Listing of the Miami Blue Butterfly as Endangered, and Proposed Listing of the Cassius Blue, Ceraunus Blue, and Nickerbean Blue Butterflies as Threatened Due to Similarity of Appearance to the Miami Blue Butterfly	Proposed Listing Endangered Similarity of Appearance	76 FR 49408-49412
8/10/2011	90-Day Finding on a Petition To List the Saltmarsh Topminnow as Threatened or Endangered Under the Endangered Species Act	Notice of 90-day Petition Finding, Substantial	76 FR 49412-49417
8/10/2011	Emergency Listing of the Miami Blue Butterfly as Endangered, and Emergency Listing of the Cassius Blue, Ceraunus Blue, and Nickerbean Blue Butterflies as Threatened Due to Similarity of Appearance to the Miami Blue	Emergency Listing Endangered and Similarity of Appearance	76 FR 49542-49567

	Butterfly		
8/11/2011	Listing Six Foreign Birds as Endangered Throughout Their Range	Final Listing Endangered	76 FR 50052-50080
8/17/2011	90-Day Finding on a Petition to List the Leona's Little Blue Butterfly as Endangered or Threatened	Notice of 90-day Petition Finding, Substantial	76 FR 50971-50979
9/01/2011	90-Day Finding on a Petition to List All Chimpanzees (<i>Pan troglodytes</i>) as Endangered	Notice of 90-day Petition Finding, Substantial	76 FR 54423-54425
9/6/2011	12-Month Finding on Five Petitions to List Seven Species of Hawaiian Yellow-faced Bees as Endangered	Notice of 12-month petition finding, Warranted but precluded	76 FR 55170-55203
9/8 /2011	12-Month Petition Finding and Proposed Listing of <i>Arctostaphylos franciscana</i> as Endangered	Notice of 12-month petition finding, Warranted; Proposed Listing Endangered	76 FR 55623-55638
9/8/2011	90-Day Finding on a Petition To List the Snowy Plover and Reclassify the Wintering Population of Piping Plover	Notice of 90-day Petition Finding, Not substantial	76 FR 55638-55641
9/13/2011	90-Day Finding on a Petition To List the Franklin's Bumble Bee as Endangered	Notice of 90-day Petition Finding, Substantial	76 FR 56381-56391
9/13/2011	90-Day Finding on a Petition to List 42 Great Basin and Mojave Desert Springsnails as Threatened or Endangered with Critical Habitat	Notice of 90-day Petition Finding, Substantial and Not substantial	76 FR 56608-56630
9/21/2011	12-Month Finding on a Petition to List Van Rossem's Gull-billed Tern as Endangered or Threatened	Notice of 12-month petition finding, Not warranted	76 FR 58650-58680
9/22/2011	Determination of Endangered Status for Casey's June Beetle and Designation of Critical Habitat	Final Listing Endangered	76 FR 58954-58998
9/27/2011	12-Month Finding on a Petition to List the Tamaulipan Agapema, <i>Sphingicampa blanchardi</i> (no common name), and <i>Ursia furtiva</i> (no common name) as Endangered or Threatened	Notice of 12-month petition finding, Not warranted	76 FR 59623-59634
9/27/2011	Partial 90-Day Finding on a Petition to List 404 Species in the Southeastern United States as Endangered or Threatened With Critical Habitat	Notice of 90-day Petition Finding, Substantial	76 FR 59836-59862
9/29 /2011	90-Day Finding on a Petition to List the American Eel as Threatened	Notice of 90-day Petition Finding, Substantial	76 FR 60431-60444

10/4/2011	12-Month Finding on a Petition to List the Lake Sammamish Kokanee Population of <i>Oncorhynchus nerka</i> as an Endangered or Threatened Distinct Population Segment	Notice of 12-month petition finding, Not warranted	76 FR 61298-61307
10/4/2011	12-Month Finding on a Petition to List <i>Calopogon oklahomensis</i> as Threatened or Endangered	Notice of 12-month petition finding, Not warranted	76 FR 61307-61321
10/4/2011	12-Month Finding on a Petition To List the Amargosa River Population of the Mojave Fringe-toed Lizard as an Endangered or Threatened Distinct Population Segment	Notice of 12-month petition finding, Not warranted	76 FR 61321-61330
10/4/2011	Endangered Status for the Alabama Pearlshell, Round Ebonyshell, Southern Sandshell, Southern Kidneyshell, and Choctaw Bean, and Threatened Status for the Tapered Pigtoe, Narrow Pigtoe, and Fuzzy Pigtoe; with Critical Habitat	Proposed Listing Endangered	76 FR 61482-61529
10/4/2011	90-Day Finding on a Petition To List 10 Subspecies of Great Basin Butterflies as Threatened or Endangered with Critical Habitat	Notice of 90-day Petition Finding, Substantial and Not substantial	76 FR 61532-61554
10/5/2011	90-Day Finding on a Petition to List 29 Mollusk Species as Threatened or Endangered With Critical Habitat	Notice of 90-day Petition Finding, Substantial and Not substantial	76 FR 61826-61853
10/5/2011	12-Month Finding on a Petition to List the Cactus Ferruginous Pygmy-Owl as Threatened or Endangered with Critical Habitat	Notice of 12-month petition finding, Not warranted	76 FR 61856-61894
10/5/2011	12-Month Finding on a Petition to List the Northern Leopard Frog in the Western United States as Threatened	Notice of 12-month petition finding, Not warranted	76 FR 61896-61931
10/6/2011	Endangered Status for the Ozark Hellbender Salamander	Final Listing Endangered	76 FR 61956-61978
10/6/2011	Red-Crowned Parrot	Notice of 12-month petition finding, Warranted but precluded	76 FR 62016-62034
10/6/2011	12-Month Finding on a Petition to List Texas Fatmucket, Golden Orb, Smooth Pimpleback, Texas Pimpleback, and Texas Fawnsfoot as Threatened or Endangered	Notice of 12-month petition finding, Warranted but precluded	76FR 62166-62212
10/6/2011	12-Month Finding on a Petition to List the Mohave Ground Squirrel as Endangered or Threatened	Notice of 12-month petition finding, Not warranted	76 FR 62214-62258
10/6/2011	Partial 90-Day Finding on a	Notice of 90-day	76 FR 62260-62280

	Petition to List 404 Species in the Southeastern United States as Threatened or Endangered With Critical Habitat	Petition Finding, Not substantial	
10/7/2011	12-Month Finding on a Petition to List the Black-footed Albatross as Endangered or Threatened	Notice of 12-month petition finding, Not warranted	76 FR 62504-62565
10/11 /2011	12-Month Finding on a Petition to List <i>Amoreuxia gonzalezii</i> , <i>Astragalus hypoxylus</i> , and <i>Erigeron piscaticus</i> as Endangered or Threatened	Notice of 12-month petition finding, Not warranted	76 FR 62722-62740
10/11/2011	12-Month Finding on a Petition and Proposed Rule to List the Yellow-Billed Parrot	Notice of 12-month petition finding, Warranted Propose Listing, threatened	76 FR 62740-62754
10/11/2011	12-Month Finding on a Petition to List the Tehachapi Slender Salamander as Endangered or Threatened	Notice of 12-month petition finding, Not warranted	76 FR 62900-62926
10/11/2011	Endangered Status for the Altamaha Spiny mussel and Designation of Critical Habitat	Final Listing Endangered	76 FR 62928-62960
10/11/2011	12-Month Finding for a Petition to List the California Golden Trout as Endangered	Notice of 12-month petition finding, Not warranted	76 FR 63094-63115
10/12/2011	12-Month Petition Finding, Proposed Listing of Coquí Llanero as Endangered, and Designation of Critical Habitat for Coquí Llanero	Notice of 12-month petition finding, Warranted; Proposed Listing Endangered	76 FR 63420-63442
10/12/2011	12-Month Finding on a Petition to List Northern Leatherside Chub as Endangered or Threatened	Notice of 12-month petition finding, Not warranted	76 FR 63444-63478
10/12/2011	12-Month Finding on a Petition to List Two South American Parrot Species	Notice of 12-month petition finding, Not warranted	76 FR 63480-63508
10/13/2011	12-Month Finding on a Petition to List a Distinct Population Segment of the Red Tree Vole as Endangered or Threatened	Notice of 12-month petition finding, Warranted but precluded	76 FR 63720-63762

2/14/2012	Determination of Endangered Status for the Rayed Bean and Snuffbox Mussels Throughout Their Ranges	Final Listing Endangered	77 FR 8632-8665

Our expeditious progress also includes work on listing actions that we funded in previous fiscal years and in FY 2012 but have not yet been completed to date. These actions are listed below. Actions in the top section of the table are being conducted under a deadline set by a court. We are implementing a work plan that establishes a framework and schedule for resolving by September 30, 2016, the status of all of the species that the Service had determined to be qualified as of the 2010 Candidate Notice of Review. The Service submitted such a work plan to the U.S. District Court for the District of Columbia in *In re Endangered Species Act Section 4 Deadline Litigation*, No. 10-377 (EGS), MDL Docket No. 2165 (D. D.C. May 10, 2011), and obtained the court's approval. The Service had already begun to implement that work plan last FY and many of these initial actions in our work plan include work on proposed rules for candidate species with an LPN of 2 or 3. As discussed above, selection of these species is partially based on available staff resources, and when appropriate, include species with a lower priority if they overlap geographically or have the same threats as the species with the high priority. Including these species together in the same proposed rule results in considerable savings in time and funding, when compared to preparing separate proposed rules for each of them in the future. Actions in the lower section of the table are being conducted to meet

statutory timelines, that is, timelines required under the Act.

Actions funded in Previous FYs and in FY 2012 but not yet completed	
Species	Action
Actions Subject to Court Order/Settlement Agreement	
4 parrot species (military macaw, yellow-billed parrot, scarlet macaw) ⁵	12-month petition finding
Longfin smelt	12-month petition finding
20 Maui-Nui candidate species ² (17 plants, 3 tree snails) (14 with LPN = 2, 2 with LPN = 3, 3 with LPN = 8)	Proposed listing
Umtanum buckwheat (LPN = 2) and white bluffs bladderpod (LPN = 9) ⁴	Proposed listing
Grotto sculpin (LPN = 2) ⁴	Proposed listing
2 Arkansas mussels (Neosho mucket (LPN =2) & Rabbitsfoot (LPN = 9)) ⁴	Proposed listing
Diamond darter (LPN = 2) ⁴	Proposed listing
Gunnison sage-grouse (LPN =2) ⁴	Proposed listing
Coral Pink Sand Dunes Tiger Beetle (LPN = 2) ⁵	Proposed listing
Lesser prairie chicken (LPN = 2)	Proposed listing
4 Texas salamanders (Austin blind salamander (LPN = 2), Salado salamander (LPN = 2), Georgetown salamander (LPN = 8), Jollyville Plateau (LPN = 8)) ³	Proposed listing
West Texas aquatics (Gonzales Spring Snail (LPN = 2), Diamond Y springsnail (LPN =2), Phantom springsnail (LPN = 2), Phantom Cave snail (LPN = 2), Diminutive amphipod (LPN = 2)) ³	Proposed listing
2 Texas plants (Texas golden gladecress (<i>Leavenworthia texana</i>) (LPN = 2), Neches River rose-mallow (<i>Hibiscus dasycalyx</i>) (LPN = 2)) ³	Proposed listing
4 AZ plants (Acuna cactus (<i>Echinomastus erectocentrus</i> var. <i>acunensis</i>) (LPN = 3), Fickeisen plains cactus (<i>Pediocactus peeblesianus fickeiseniae</i>) (LPN = 3), Lemmon fleabane (<i>Erigeron lemmonii</i>) (LPN = 8), Gierisch mallow (<i>Sphaeralcea gierischii</i>) (LPN =2)) ⁵	Proposed listing
FL bonneted bat (LPN =2) ³	Proposed listing
3 Southern FL plants (Florida semaphore cactus (<i>Consolea corallicola</i>) (LPN = 2), shellmound applecactus (<i>Harrisia</i> (= <i>Cereus</i>) <i>aboriginum</i> (= <i>gracilis</i>)) (LPN = 2), Cape Sable thoroughwort (<i>Chromolaena frustrata</i>) (LPN = 2)) ⁵	Proposed listing
21 Big Island (HI) species ⁵ (includes 8 candidate species – 6 plants & 2 animals;	Proposed listing

4 with LPN = 2, 1 with LPN = 3, 1 with LPN = 4, 2 with LPN = 8)	
12 Puget Sound prairie species (9 subspecies of pocket gopher (<i>Thomomys mazama</i> ssp.) (LPN =3), streaked horned lark (LPN = 3), Taylor's checkerspot (LPN = 3), Mardon skipper (LPN = 8)) ³	Proposed listing
2 TN River mussels (fluted kidneyshell (LPN = 2), slabside pearlymussel (LPN = 2)) ⁵	Proposed listing
Jemez Mountain salamander (LPN = 2) ⁵	Proposed listing
Actions with Statutory Deadlines	
5 Bird species from Colombia and Ecuador	Final listing determination
Queen Charlotte goshawk	Final listing determination
6 Birds from Peru & Bolivia	Final listing determination
Loggerhead sea turtle (assist National Marine Fisheries Service) ⁵	Final listing determination
Platte River caddisfly (from 206 species petition) ⁵	12-month petition finding
Ashy storm-petrel ⁵	12-month petition finding
Honduran emerald	12-month petition finding
Eagle Lake trout ¹	90-day petition finding
Spring Mountains checkerspot butterfly	90-day petition finding
Aztec gilia ⁵	90-day petition finding
White-tailed ptarmigan ⁵	90-day petition finding
Bicknell's thrush ⁵	90-day petition finding
Sonoran talussnail ⁵	90-day petition finding
2 AZ Sky Island plants (<i>Graptopetalum bartrami</i> & <i>Pectis imberbis</i>) ⁵	90-day petition finding
Desert massasauga	90-day petition finding
Boreal toad (eastern or southern Rocky Mtn population) ⁵	90-day petition finding
Alexander Archipelago wolf ⁵	90-day petition finding
Eastern diamondback rattlesnake	90-day petition finding

¹ Funds for listing actions for these species were provided in previous FYs.

² Although funds for these high-priority listing actions were provided in FY 2008 or 2009, due to the complexity of these actions and competing priorities, these actions are still being developed.

³ Partially funded with FY 2010 funds and FY 2011 funds.

⁴ Funded with FY 2010 funds.

⁵ Funded with FY 2011 funds.

We have endeavored to make our listing actions as efficient and timely as possible, given the requirements of the relevant law and regulations, and constraints relating to workload and

personnel. We are continually considering ways to streamline processes or achieve economies of scale, such as by batching related actions together. Given our limited budget for implementing section 4 of the Act, these actions described above collectively constitute expeditious progress.

The Bay-Delta DPS of longfin smelt will be added to the list of candidate species upon publication of this 12-month finding. We will continue to evaluate this DPS as new information becomes available. Continuing review will determine if a change in status is warranted, including the need to make prompt use of emergency listing procedures.

We intend that any proposed listing determination for the Bay-Delta DPS of longfin smelt will be as accurate as possible. Therefore, we will continue to accept additional information and comments from all concerned governmental agencies, the scientific community, industry, or any other interested party concerning this finding.

Abstract.— Fall, late-fall, spring, and winter-run Chinook salmon (*Oncorhynchus tshawytscha*) and Steelhead/Rainbow trout (*Oncorhynchus mykiss*) spawn in the Sacramento River and tributaries in California's Central Valley upstream of Red Bluff Diversion Dam (RBDD) throughout the year. Sampling of juvenile anadromous fish at RBDD allows for year-round quantitative production and passage estimates of all runs of Chinook and *O. mykiss*. Incidental capture of Green Sturgeon (*Acipenser medirostris*) and various Lamprey species (*Lampetra spp. and Entosphenus tridentatus*) has occurred throughout juvenile Chinook monitoring activities since 1995. This compendium report addresses, in detail, juvenile anadromous fish monitoring activities at RBDD for the period April 4, 2002 through September 30, 2013.

Sampling was conducted along a transect using four 8-foot diameter rotary-screw traps attached via aircraft cables directly to RBDD. Trap efficiency (i.e., the proportion of the juvenile salmonid population passing RBDD captured by traps) was modeled with percent of river discharge sampled (%Q) to develop a simple least-squares regression equation. Chinook and *O. mykiss* passage were estimated by employing the trap efficiency model. The ratio of fry to pre-smolt/smolt passing RBDD was variable among years. Therefore, juvenile passage was standardized to determine juvenile production by estimating a fry-equivalent Juvenile Production Index (JPI) for among-year comparisons. Catch per unit volume (CPUV) was used as an index of relative abundance for Green Sturgeon and Lamprey species. Abiotic data collected or calculated throughout sample efforts included: water temperature, flow, turbidity, and moon illuminosity (fraction of moon illuminated). The abiotic variables were analyzed to determine if relationships existed throughout the migration periods of the anadromous species.

A trap efficiency model developed in 2000 to estimate fish passage demonstrated improved correlation between 2002 and 2013 with the addition of 85 mark-recapture trials. The model's *r*-squared value improved greatly with the addition of numerous mark-recapture trials that used wild fry size-class salmon over a variety of river discharge levels. Total passage estimates including annual effort values with 90% confidence intervals (CI) are presented, by brood year, for each run of Chinook. Fry and pre-smolt/smolt Chinook passage estimates with 90% CI's are summarized annually by run in Appendix 1. Comparisons of relative variation within and between runs of Chinook were performed by calculating Coefficients of Variation (CV). Fall Chinook annual total passage estimates ranged between 6,627,261 and 27,736,868 juveniles for brood years 2002-2012 ($\bar{y} = 14,774,923$, CV = 46.2%). On average, fall Chinook passage was composed of 74% fry and 26% pre-smolt/smolt size-class fish (SD = 10.3). Late-fall

Chinook annual total passage estimates ranged between 91,995 and 2,559,519 juveniles for brood years 2002-2012 (\bar{y} = 447,711, CV = 159.9%). On average, late-fall Chinook passage was composed of 38% fry and 62% pre-smolt/smolt size-class fish (SD = 22.5). Winter Chinook annual total passage estimates ranged between 848,976 and 8,363,106 juveniles for brood years 2002-2012 (\bar{y} = 3,763,362, CV = 73.2%). On average, winter Chinook passage was composed of 80% fry and 20% pre-smolt/smolt size-class fish (SD = 11.2). Spring Chinook annual total passage estimates for spring Chinook ranged between 158,966 and 626,925 juveniles for brood years 2002-2012 (\bar{y} = 364,508, CV = 45.0%). On average, spring Chinook passage was composed of 54% fry and 46% pre-smolt/smolt size-class fish (SD = 20.0). Annual total passage estimates for *O. mykiss* ranged between 56,798 and 151,694 juveniles for calendar years 2002-2012 (\bar{y} = 116,272, CV = 25.7).

A significant relationship between the estimated number of adult females and fry-equivalent fall Chinook production estimates was detected (r^2 = 0.53, df = 10, P = 0.01). Recruits per female were calculated and ranged from 89 to 1,515 (\bar{y} = 749). Egg-to-fry survival estimates averaged 13.9% for fall Chinook. A significant relationship between estimated number of females and fry-equivalent late-fall Chinook production estimates was detected (r^2 = 0.67, df = 10, P = 0.002). Recruits per female were calculated and ranged from 47 to 243 (\bar{y} = 131). Egg-to-fry survival estimates averaged 2.8% for late-fall Chinook. A significant relationship between estimated number of females and fry-equivalent winter Chinook production estimates was detected (r^2 = 0.90, df = 10, P < 0.001). Recruits per female were calculated and ranged from 846 to 2,351 (\bar{y} = 1,349). Egg-to-fry survival estimates averaged 26.4% for winter Chinook. No significant relationship between estimated number of females and fry-equivalent spring Chinook production estimates was detected (r^2 = 0.00, df = 10, P = 0.971). Recruits per female were calculated and ranged from 1,112 to 8,592 (\bar{y} = 3,122). Egg-to-fry survival estimates averaged 61.5% for spring Chinook. Spring Chinook juvenile to adult correlation values appear unreasonable and well outside those found for other runs and from other studies.

Catch of Green Sturgeon was highly variable, not normally distributed and ranged between 0 and 3,701 per year (median = 193). Catch was primarily composed of recently emerged, post-exogenous feeding larvae. The 10-year median capture total length averaged 27.3 mm (SD = 0.8). Green Sturgeon annual CPUV was typically very low and ranged from 0.0 to 20.1 fish/ac-ft (\bar{y} = 2.5 fish/ac-ft, SD = 5.9). Data were positively skewed and median annual CPUV was 0.8 fish/ac-ft.

Lamprey species sampled included adult and juvenile Pacific Lamprey (*Entosphenus tridentatus*) and to a much lesser extent River Lamprey (*Lampetra ayresi*) and Pacific Brook Lamprey (*Lampetra pacifica*). Unidentified lamprey ammocoetes and Pacific Lamprey composed 99.8% of all captures, 24% and 75%, respectively. River Lamprey and Pacific Brook Lamprey composed the remaining 0.2%, combined. Lamprey captures occurred throughout the year between October and September. Lamprey ammocoete annual relative abundance ranged from 3.6 to 11.7 fish/ac-ft (\bar{y} = 6.8 fish/ac-ft, SD = 2.6). Overall, these data were normally distributed as median annual CPUV was 6.5 fish/ac-ft, similar to the mean value. Pacific Lamprey macrophthalmia

annual relative abundance was generally higher than ammocoete relative abundance and ranged from 2.1 to 112.8 fish/ac-ft ($\bar{y} = 41.0$ fish/ac-ft, $SD = 34.7$). Overall, Pacific Lamprey data was slightly positively skewed and median CPUV was 34.1 fish/ac-ft.

Tabular summaries of the abiotic conditions encountered during each annual capture period were summarized for each run of salmon, *O. mykiss*, Green Sturgeon and Lamprey species. The range of temperatures experienced by Chinook fry and pre-smolt/smolt in the last 11 years of passage at RBDD have been within the optimal range of temperature tolerances for juvenile Chinook survival. Green Sturgeon have likely benefitted from temperature management efforts aimed at winter Chinook spawning and production, albeit less comprehensively. Lamprey species have also likely benefitted from temperature management as temperatures for early life stages of Lamprey in the mainstem Sacramento River appear to have been, on average, optimal in the last 11 years.

The relationship between river discharge, turbidity, and fish passage are complex in the Upper Sacramento River where ocean and stream-type Chinook of various size-classes (i.e., runs, life stages and ages) migrate daily throughout the year. Fish passage increases often coincided with an increase in turbidity which were sampled more effectively than increases in river discharge. A positive bias of fish passage estimates may result if the peak turbidity event was sampled following an un-sampled peak flow event. The importance of the first storm event of the fall or winter period cannot be overstated. Smolt passage and juvenile Lamprey passage increase exponentially and fry passage can be significant during fall storm events.

Rotary trap passage data indicated fry size-class winter Chinook exhibit decreased nocturnal passage levels during and around the full moon phase in the fall. Pre-smolt/smolt winter Chinook appeared less influenced by nighttime light levels and much more influenced by changes in discharge levels. Spring, fall and late-fall Chinook fry exhibited varying degrees of decreased passage during full moon periods, albeit storms and related hydrologic influx dominated peak migration periods.

Introduction

The United States Fish and Wildlife Service (USFWS) has conducted direct monitoring of juvenile Chinook salmon (*Oncorhynchus tshawytscha*) passage at Red Bluff Diversion Dam (RBDD; RM 243) on the Sacramento River, CA since 1994 (Johnson and Martin 1997). Martin et al. (2001) developed quantitative methodologies for indexing juvenile Chinook passage using rotary-screw traps to assess the impacts of the RBDD Research Pumping Plant. Absolute abundance (production and passage) estimates were needed to determine the level of impact from the entrainment of salmonids and other fish community populations through experimental 'fish friendly' Archimedes and internal helical pumps (Borthwick and Corwin 2001). The original project objectives were met by 2000 and funding of the project was discontinued.

In 2001, funding was secured through a CALFED Bay-Delta Program grant for three years of annual monitoring operations to determine the effects of restoration activities in the Upper Sacramento River aimed primarily at winter Chinook¹ salmon. Through various amendments, extensions, and grant approvals by the CALFED Ecosystem Restoration Program, the State of California based funding source lasted until 2008. At this point, the State of California defaulted on their funding agreement and internal USFWS funding sources through the Central Valley Project Improvement Act (CVPIA) bridged the gap for a period of time until State funding was restored. The US Bureau of Reclamation, the primary proponent of the Central Valley Project (CVP) of which this project provides monitoring and abundance trend information, has funded this project since 2010 due to regulatory requirements contained within the Biological Opinion for the Operations and Criteria Plan for the CVP (NMFS 2009).

Protection, restoration, and enhancement of anadromous fish populations in the Sacramento River and its tributaries is an important element of the CVPIA Section 3402. The CVPIA has a specific goal to double populations of anadromous fishes in the Central Valley of California. Juvenile salmonid production monitoring is an important component authorized under Section 3406 (b)(16) of CVPIA and has funded many anadromous fish restoration actions which were outlined in the CVPIA Anadromous Fisheries Restoration Program (AFRP) Working Paper (USFWS 1995), and Draft Restoration Plan (USFWS 1997; finalized in 2001).

¹ The National Marine Fisheries Service first listed Winter-run Chinook salmon as threatened under the emergency listing procedures for the ESA (16 U.S.C.R. 1531-1543) on August 4, 1989 (54 FR 32085). A proposed rule to add winter Chinook salmon to the list of threatened species beyond expiration of the emergency rule was published by the NMFS on March 20, 1990 (55 FR 10260). Winter Chinook salmon were formally added to the list of federally threatened species by final rule on November 5, 1990 (55 FR 46515), and they were listed as a federally endangered species on January 4, 1994 (59 FR 440). Critical habitat for winter Chinook salmon has been designated from Keswick Dam (RM 302) to the Golden Gate Bridge (58 FR 33212; June 16, 1993). Winter Chinook salmon have been listed as endangered under the CESA since September 22, 1989 (California Code of Regulations, Title XIV, Section 670.5). Their federal endangered status was reaffirmed in June 2005 (70 FR 37160).

Since 2002, the USFWS rotary trap winter Chinook juvenile production indices (JPI's) have primarily been used in support of production estimates generated from carcass survey derived adult escapement data using the National Oceanic and Atmospheric Administration's (NOAA) Juvenile Production Estimate Model. Martin et al. (2001) stated that RBDD was an ideal location to monitor juvenile winter Chinook production because (1) the spawning grounds occur almost exclusively above RBDD (Vogel and Marine 1991; Snider et al. 1997, USFWS 2011), (2) multiple traps could be attached to the dam and sample simultaneously across a transect, and (3) operation of the dam could control channel morphology and hydrological characteristics of the sampling area providing for consistent sampling conditions for purposes of measuring juvenile fish passage.

Fall, late-fall, spring, and winter-run Chinook salmon and Steelhead/Rainbow Trout (*Oncorhynchus mykiss*) spawn in the Sacramento River and tributaries upstream of RBDD throughout the year resulting in year-round juvenile salmonid passage (Moyle 2002). Sampling of juvenile anadromous fish at RBDD allows for year-round quantitative production and passage estimates of all runs of Chinook and Steelhead/Rainbow trout. Timing and abundance data have been provided in real-time for fishery and water operations management purposes of the CVP since 2004². Since 2009, confidence intervals, indicating uncertainty in weekly passage estimates, have been included in real-time bi-weekly reports to allow better management of available water resources and to reduce impact of CVP operations on both federal Endangered Species Act (ESA) listed and non-listed salmonid stocks. Currently, Sacramento River winter Chinook are ESA listed as endangered. Central Valley spring Chinook and Central Valley Steelhead (hereafter *O. mykiss*) are listed as threatened within the Central Valley Endangered Species Unit.

Incidental capture of Green Sturgeon (*Acipenser medirostris*) and various Lamprey species (*Lampetra spp. and Entosphenus sp.*) has occurred throughout juvenile Chinook monitoring activities at RBDD since 1995 (Gaines and Martin 2002). Although rotary traps were designed to capture outmigrating salmonid smolts, data from the incidental capture of sturgeon and lamprey species has become increasingly relied upon for basic life-history information and as a measure of relative abundance and species trend data. The Southern distinct population segment of the North American Green Sturgeon was proposed for listing as threatened under the Federal ESA on April 7, 2006 (FR 17757) which then took effect June 6, 2006. Pacific Lamprey (*Entosphenus tridentatus*) are thought to be extirpated from at least 55% of their historical habitat and have been recognized by the USFWS as a species needing a comprehensive plan to conserve and restore these fish (Goodman and Reid 2012).

The objectives of this compendium report are to: (1) summarize the estimated abundance of all four runs of Chinook salmon and *O. mykiss* passing RBDD for brood

² Real-time biweekly reports located for download at: http://www.fws.gov/redbluff/rbdd_biweekly_final.html

years (BY) 2002 through 2012, (2) estimate annual relative abundance of Green Sturgeon and Lamprey species production for eleven consecutive years, (3) define temporal patterns of abundance for all anadromous species passing RBDD, (4) correlate juvenile salmon production with adult salmon escapement estimates, (5) perform exploratory data analyses of potential environmental covariates driving juvenile fish migration trends, and (6) describe various life-history attributes of anadromous juvenile fish produced in the Upper Sacramento River as determined through long-term monitoring efforts at RBDD.

This compendium report addresses, in detail, our juvenile anadromous fish monitoring activities at RBDD for the period April 4, 2002 through September 30, 2013. This report includes JPI's and relative abundance estimates for the 2002-2012 brood year emigration periods and will be submitted to the California Department of Fish and Wildlife to comply with contractual reporting requirements for Ecosystem Restoration Program Grant Agreement Number P0685507 and to the US Bureau of Reclamation who funded in part or in full the surveys from years 2008 through 2013 (Interagency Agreement No. R10PG20172).

Study Area

The Sacramento River originates in Northern California near Mt. Shasta from the springs of Mt. Eddy (Hallock et al. 1961). It flows south through 370 miles of the state draining numerous slopes of the coast, Klamath, Cascade, and Sierra Nevada ranges and eventually reaches the Pacific Ocean via San Francisco Bay (Figure 1). Shasta Dam and its associated downstream flow regulating structure, Keswick Dam, have formed a complete barrier to upstream anadromous fish passage since 1943 (Moffett 1949). The 59-river mile (RM) reach between Keswick Dam (RM 302) and RBDD (RM 243) supports areas of intact riparian vegetation and largely remains unobstructed. Within this reach, several major tributaries to the Sacramento upstream of RBDD support various Chinook salmon spawning populations. These include Clear Creek and Cottonwood Creek (including Beegum Creek) on the west side of the Sacramento River and Cow, Bear, Battle and Payne's Creek on the east side (Figure 1). Below RBDD, the river encounters greater anthropogenic impacts as it flows south to the Sacramento-San Joaquin Delta. Impacts include, but are not limited to, channelization, water diversion, agricultural and municipal run-off, and loss of associated riparian vegetation.

RBDD is located approximately 1.8 miles southeast of the city of Red Bluff, California (Figure 1). The dam is 740-feet (ft) wide and composed of eleven, 60-ft wide fixed-wheel gates. Between gates are concrete piers 8-ft in width. The USBR's dam operators were able to raise the RBDD gates allowing for run-of-the-river conditions or lower them to impound and divert river flows into the Tehama-Colusa and Corning canals. USBR operators generally raised the RBDD gates from September 16 through May 14 and lowered them May 15 through September 15 during the years 2002-2008. As of the spring of 2009, the RBDD gates were no longer lowered prior to June 15 and

were raised by the end of August or earlier (NMFS 2009) in an effort to reduce the impact to spring Chinook salmon and Green Sturgeon. Since the fall of 2011, the RBDD gates have been left in the raised position allowing unobstructed upstream and downstream passage of adult and juvenile anadromous fish. The RBDD has been replaced by a permanent pumping plant upstream of the RBDD and the facilities have been relinquished to the Tehama Colusa Canal Authority as of spring 2012. Mothballing of the RBDD infrastructure was scheduled to occur in 2014.

Methods

Sampling Gear.—Sampling was conducted along a transect using four 8-ft diameter rotary-screw traps (E.G. Solutions® Corvallis, Oregon) attached via aircraft cables directly to RBDD. The horizontal placement of rotary traps across the transect varied throughout the study but generally sampled in the river-margin (east and west river-margins) and mid-channel habitats simultaneously (Figure 2). Rotary traps were positioned within these *spatial zones* unless sampling equipment failed, river depths were insufficient (< 4-ft), or river hydrology restricted our ability to sample with all traps (water velocity < 2.0 ft/s).

Sampling Regimes.—In general, rotary traps sampled continuously throughout 24-hour periods and samples were processed once daily. During periods of high fish abundance, elevated river flows, or heavy debris loads, traps were sampled multiple times per day, continuously, or at randomly pre-selected periods to reduce incidental mortality. When abundance of Chinook was very high, sub-sampling protocols were implemented to reduce listed species take and incidental mortality in accordance with National Marine Fisheries Service (NMFS) Section 10(a)(1)(A) research permit terms and conditions. The specific sub-sampling protocol implemented was contingent upon the number of Chinook captured or the probability of successfully sampling various river conditions. Initially, rotary trap cones were structurally modified to only sample one-half of the normal volume of water entering the cones (Gaines and Poytress 2004). If further reductions in capture were needed, the number of traps sampled was reduced from four to three. During storm events and associated elevated river discharge levels, each 24-hour sampling period was divided into four or six non-overlapping strata and one or two strata was randomly selected for sampling (Martin et al 2001). Estimates were extrapolated to un-sampled strata by dividing catch by the strata-selection probability (i.e., $P = 0.25$ or 0.17). If further reductions in effort were needed or river conditions were intolerable, sampling was discontinued or not conducted. When days or weeks were unable to be sampled, mean daily passage estimates were imputed for missed days based on weekly or monthly mean daily estimates (i.e., interpolated).

Data Collection.—All fish captured were anesthetized, identified to species, and enumerated with fork lengths (FL) measured to the nearest millimeter (mm). When capture of Chinook juveniles exceeded approximately 200 fish/trap, a random sub-sample of the catch to include approximately 100 individuals was measured, with all

additional fish being enumerated and recorded. Chinook salmon race was assigned using length-at-date criteria developed by Greene³ (1992). Juvenile salmon were assigned to a fry or pre-smolt/smolt life stage based on their fork length. Individuals ≤ 45 mm were classified as fry, and individuals ≥ 46 mm were classified as pre-smolt/smolts.

O. mykiss between 80 and 200-mm fork length were weighed to the nearest gram using a digital scale with a stated accuracy of ± 0.5 grams. This size range was selected to reduce the influence of measurement error for fish lengths <80 mm (Pope and Kruse 2007). Additionally, state and federal permit regulations restricted the use of anesthetizing agents for fish that may be consumed by the public (i.e., fish >200 mm). *O. mykiss* were visually assessed and assigned a life-stage rating based on morphological features following protocols developed by the Comprehensive Assessment and Monitoring Program (CAMP; USFWS 1997). Furthermore, *O. mykiss* annual weight-length regression coefficients were generated by transforming (Log_{10}) the weight and fork length data to create a linear regression equation:

$$\text{Log}_{10}(\text{Total Weight}) = b(\text{Log}_{10}\text{Fork Length}) + a$$

Confidence interval overlap between the annual slope coefficients was used to test if the annual *O. mykiss* growth rates between years were significantly different (Pope and Kruse 2007). If the 95% confidence intervals around any two slope coefficients did not overlap they were considered significantly different.

Green Sturgeon and Lamprey species were measured for total length (TL) to the nearest mm. Identification of Green Sturgeon larvae was possible based on meristics for individuals > 46 mm TL and assumed for all individuals <46 mm⁴. Lamprey species were identified to the genus level during the ammocoete stage and described as ammocoetes. Adult and macrophthalmia (eyed juveniles) were identified to the genus and species level using dentition patterns, specifically by the number of inner lateral horny plates on the sucking disk (Moyle 2002).

Trap Effort. Data quantifying effort by each rotary trap were collected at each trap sampling and included the length of time each trap sampled (expressed as sample weight with 1440 minutes equal to 1.0 for 24-hour samples), water velocity immediately in front of the cone at a depth of 2-ft, and depth of cone “opening” submerged. Water velocity was measured using a General Oceanic® Model 2030 flowmeter. These data collectively were used to calculate the estimated volume of water sampled by traps (X_i)

³ Generated by Sheila Greene, California Department of Water Resources, Environmental Services Office, Sacramento (May 8, 1992) from a table developed by Frank Fisher, California Department of Fish and Game, Inland Fisheries Branch, Red Bluff (revised February 2, 1992). Fork lengths with overlapping run assignments were placed with the latter spawning run.

⁴ To confirm the identification of larval sturgeon, samples were transferred to UC Davis to be grown-out between 1996 and 1997 (Gaines and Martin 2002) and annual subsamples of larvae were sent to UC Davis for genetic analyses between 2003 and 2012 (Israel et al 2004, Israel and May 2010). To date, all samples have been confirmed to be Green Sturgeon.

in acre-feet (ac-ft). Trap effort data were then standardized to a sample weight of 1.0 for within- and between-day comparisons. Individual (X_i) data were summed for the number of traps operating within a 24-hour sample period to estimate daily water volume sampled (X_d). The percent river volume sampled by traps ($\%Q_d$) was estimated as the ratio of river volume sampled (X_d) to total river volume passing RBDD in acre-feet. River volume (Q_d) was obtained from the United States Geological Survey gauging station at Bend Bridge at RM 258 (USGS site no. 11377100, http://waterdata.usgs.gov/usa/nwis/uv?site_no=11377100). Daily river volume at RBDD was adjusted from Bend Bridge river flows by subtracting daily RBDD diversions, when applicable.

Sampling Effort. Annual rotary trap sampling effort was quantified by assigning a value of 1.00 to a sample consisting of four, 8-ft diameter rotary-screw traps sampling 24 hours daily, three hundred and sixty-five days a year. Annual values <1.00 represent occasions where less than four traps were sampling, traps were structurally modified to sample only one-half the normal volume of water, or when less than the entire year were sampled. Annual passage estimate effort was calculated by summing the total number of days passage was estimated, based on 3 or 4 traps sampling (minimum required to generate passage estimate; Martin et al. 2001), and divided by the sum of the annual total number of days sampled plus the number of days unsampled.

Mark-Recapture Trials. Chinook collected as part of daily samples were marked with bismark brown staining solution (Mundie and Traber 1983) prepared at a concentration of 21.0 mg/L of water. Fish were stained for a period of 45-50 minutes, removed, and allowed to recover in fresh water. Marked fish were held for 6-24 hours before being released 2.5-miles upstream from RBDD after official sunset. Recapture of marked fish was recorded for up to five days after release. Trap efficiency was calculated based on the proportion of recaptures to total fish released (i.e., mark-recapture trials). Trials were conducted as fish numbers and staffing levels allowed under a variety of river discharge levels and trap effort combinations.

Trap Efficiency Modeling. To develop a trap efficiency model, mark-recapture trials were conducted as noted above. Estimated trap efficiency (i.e., the proportion of the juvenile population passing RBDD captured by traps; \hat{T}_d) was modeled with $\%Q$ to develop a simple least-squares regression equation (eq. 5). The equation (slope and intercept) was then used to calculate daily trap efficiencies based on daily estimated river volume sampled. Each successive year of mark-recapture trials were added annually to the original trap efficiency model developed by Martin et al. (2001) on July 1 of each year.

Daily Passage Estimates (\hat{P}_d).—The following procedures and formulae were used to derive daily and weekly estimates of total numbers of unmarked Chinook and *O. mykiss* passing RBDD. We defined C_{di} as catch at trap i ($i = 1, \dots, t$) on day d ($d = 1, \dots, n$),

and X_{di} as volume sampled at trap i ($i = 1, \dots, t$) on day d ($d = 1, \dots, n$). Daily salmonid catch and water volume sampled were expressed as:

$$1. \quad C_d = \sum_{i=1}^t C_{di}$$

and,

$$2. \quad X_d = \sum_{i=1}^t X_{di}$$

The %Q was estimated from the ratio of water volume sampled (X_d) to river discharge (Q_d) on day d .

$$3. \quad \% \hat{Q}_d = \frac{X_d}{Q_d}$$

Total salmonid passage was estimated on day d ($d = 1, \dots, n$) by

$$4. \quad \hat{P}_d = \frac{C_d}{\hat{T}_d}$$

where,

$$5. \quad \hat{T}_d = (a)(\% \hat{Q}_d) + b$$

and, $\hat{T}_d =$ estimated trap efficiency on day d .

Weekly Passage (\hat{P}).—Population totals for numbers of Chinook and *O. mykiss* passing RBDD each week were derived from \hat{P}_d where there are N days within the week:

$$6. \quad \hat{P} = \frac{N}{n} \sum_{d=1}^n \hat{P}_d$$

Estimated Variance.—

$$7. \quad \text{Var}(\hat{P}) = \left(1 - \frac{n}{N}\right) \frac{N^2}{n} s_{\hat{P}_d}^2 + \frac{N}{n} \left[\sum_{d=1}^n \text{Var}(\hat{P}_d) + 2 \sum_{i \neq j}^n \text{Cov}(\hat{P}_i, \hat{P}_j) \right]$$

The first term in eq. 7 is associated with sampling of days within the week.

8.
$$s_{\hat{P}_d}^2 = \frac{\sum_{d=1}^n (\hat{P}_d - \hat{P})^2}{n-1}$$

The second term in eq. 7 is associated with estimating \hat{P}_d within the day.

9.
$$Var(\hat{P}_d) = \frac{\hat{P}_d(1-\hat{T}_d)}{\hat{T}_d} + Var(\hat{T}_d) \frac{\hat{P}_d(1-\hat{T}_d) + \hat{P}_d^2 \hat{T}_d}{\hat{T}_d^3}$$

where,

10.
$$Var(\hat{T}_d) = \text{error variance of the trap efficiency model}$$

The third term in eq. 7 is associated with estimating both \hat{P}_i and \hat{P}_j with the same trap efficiency model.

11.
$$Cov(\hat{P}_i, \hat{P}_j) = \frac{Cov(\hat{T}_i, \hat{T}_j) \hat{P}_i \hat{P}_j}{\hat{T}_i \hat{T}_j}$$

where,

12.
$$Cov(\hat{T}_i, \hat{T}_j) = Var(\hat{\alpha}) + x_i Cov(\hat{\alpha}, \hat{\beta}) + x_j Cov(\hat{\alpha}, \hat{\beta}) + x_i x_j Var(\hat{\beta})$$

for some $\hat{T}_i = \hat{\alpha} + \hat{\beta} x_i$

Confidence intervals (CI) were constructed around \hat{P} using eq. 13.

13.
$$P \pm t_{\alpha/2, n-1} \sqrt{Var(\hat{P})}$$

Annual JPI's were estimated by summing \hat{P} across weeks.

14.
$$JPI = \sum_{week=1}^{52} \hat{P}$$

Fry-Equivalent Chinook Production Estimates.—The ratio of Chinook fry (<46 mm FL) to pre-smolt/smolt (>45 mm FL) passing RBDD was variable among years. Therefore, we standardized juvenile production by estimating a fry-equivalent JPI for among-year comparisons. Fry-equivalent JPI's were estimated by the summation of fry JPI and a weighted (1.7:1) pre-smolt/smolt JPI (inverse value of 59% fry-to-presmolt/smolt survival; Hallock undated). Rotary trap JPI's could then be directly compared to determine variability in production between years.

Relative Abundance.—Catch per unit volume (CPUV; Gaines and Martin 2002) was used as an index of relative abundance (RA) for Green Sturgeon and Lamprey species at RBDD.

$$15. \quad RA_{dt} = \frac{C_{dt}}{V_{dt}}$$

RA_{dt} = relative abundance on day d by trap t (catch/acre-foot),
 C_{dt} = number of fish captured on day d by trap t , and
 V_{dt} = volume of water sampled on day d by trap t .

The volume of water sampled (V_{dt}) was estimated for each trap as the product of one-half the cross sectional area (wetted portion) of the cone, water velocity (ft/s) directly in front of the cone at a depth of 2-feet, cone modified (multiplied by 0.5) or not (multiplied by 1.0), and duration of sampling.

Exploratory Data Analyses.—The sampling of four runs of Chinook, *O. mykiss*, Green Sturgeon, and Lamprey occurred over 11 years and a variety of environmental conditions. Abiotic data collected or calculated throughout sample efforts included water temperature, flow, turbidity, and moon illuminosity (fraction of moon illuminated). The abiotic factors were analyzed to determine if patterns or trends existed throughout the migration periods of the various species. Additional statistical analyses were performed, when applicable, and additional methods are noted within the results section for species-specific data trends analyzed.

Results

Sampling Effort.—Annual sampling effort varied throughout the 11-year period of reporting. The reasons for less than 100% effort varied by time of year and run sampled due to numerous factors. These factors can be categorized as either intentional or unintentional decreases in effort. Intentional decreases in effort were primarily due to ESA Section 10(a)1(A) take and incidental mortality limits, the desire to decrease potential impacts to ESA listed fish or hatchery released production groups, or when staffing levels were not appropriate for the conditions encountered. Unintentional decreases in effort were due primarily to storm activity and related debris flows or conditions considered too dangerous to sample. Additionally, during the years RBDD was in operation (2002-2011), many days were not sampled due to operational requirements imposed by USBR operators (e.g., lowering or raising of the dam gates).

Annual sample effort was assigned a value of 1.0 based on sampling four traps 365 days a year. Annual sample effort values by salmonid species and run are described in Table 1. Overall, annual sample effort for all salmonids combined ranged from 0.53 to

0.91 ($\bar{y} = 0.80$, $SD = 0.10$) following annual juvenile salmonid brood year cycles. The lowest values corresponded to the year 2002 when sampling did not begin until mid-April of the year. The highest value corresponded to the year 2007 when flow events were mild, staffing levels were optimal, and permit restrictions did not dictate major sampling effort reductions (Table 1).

Mark-Recapture Trials.—Trap efficiency estimates were calculated by conducting mark-recapture trials (Volkhardt et al. 2007) using unmarked salmon collected from daily trap samples. Trials were conducted when trap catch values allowed the release of 1,000 fish per trial, generally, as well as when staffing and river conditions would allow. Mark-recapture trials were also employed to validate daily trap efficiency estimates by comparing actual with predicted (modeled) estimates. This was especially important during peak salmon outmigration periods.

The number of trials conducted each calendar year ranged from 0 in 2010 to 21 in 2004 ($\bar{y} = 7.7$) and totaled 85 trials between 2002 and 2013 (Table 2). Trials were conducted with four rotary traps ($N = 74$) or three traps ($N = 11$). Some trials were conducted with cones modified to sample half the volume of water ($N = 25$) or mixed ($N = 1$), but primarily unmodified and sampling full effort ($N = 59$). Trap efficiencies were tested with the RBDD gates raised ($N = 72$) and lowered ($N = 13$) during the years when RBDD was in operation (Table 2).

Trials were conducted through a variety of flow and trap effort conditions representing actual sampling conditions detected throughout various fish migration periods (Table 2). Estimates of the percentage of river water volume sampled by traps (%Q) ranged from 0.72 to 6.87% ($\bar{y} = 3.10$, $SD = 1.32$). Efficiency estimates for the 85 trials ranged from 0.34 to 5.48% ($\bar{y} = 2.37\%$, $SD = 0.01$).

Released fish groups ranged from 340 to 5,143 individuals ($\bar{y} = 1,598$) and recaptured fish numbers ranged from 7 to 119 ($\bar{y} = 36$) per trial. Trials were conducted predominantly with fry size-class (<46 mm fork length), naturally produced fall Chinook (67%) and to a lesser extent winter Chinook (22%). Trials were conducted in some years using unmarked pre-smolt/smolt (11%) following annual Coleman National Fish Hatchery Fall Chinook production releases⁵ during spring, as conditions and staffing levels allowed (Table 2).

Average fork lengths of release groups in the fry size-class had fork lengths ranging from 35.5 to 57.1 mm ($\bar{y} = 37.2$ mm). Recaptured fork lengths ranged from 34.6 to 62.4 mm ($\bar{y} = 37.3$ mm). Average fork lengths of fish released in the pre-smolt/smolt size-class ranged from 68.7 to 81.2 mm ($\bar{y} = 75.3$ mm). Recaptured fork lengths ranged from 61.3 to 80.2 mm ($\bar{y} = 75.3$ mm; Table 2). A paired t-test was performed on the average

⁵ Coleman National Fish Hatchery is located upstream of RBDD on Battle Creek a tributary to the Sacramento. Fall Chinook production fish (~12 million per year) were adipose clipped (i.e., marked) in varying proportions over the years of study between 0 and 25%. Unmarked fish were included in some efficiency trials as they could not be distinguished from naturally produced fish.

release and recaptured fish lengths for all trials and indicated no significant difference between the released and recaptured fish sizes ($P = 0.759$, $df = 83$, $t = -0.308$).

Trap Efficiency Modeling.—Between 1998 and 2000, Martin et al. (2001) developed a trap efficiency model for the RBDD rotary trapping operation by conducting 58 mark-recapture trials (one trial excluded due to zero efficiency value). These data were used as the basis of the trap efficiency model to calculate daily passage estimates. The model was further developed between 2002 and 2013 with the addition of 85 mark-recapture trials. Trap efficiency was positively correlated to (% Q), with higher efficiencies occurring as the relative percentage of discharge volume sampled by rotary traps increased. Trap efficiency was inversely related to river discharge (Q), as river discharge increased, trap efficiency decreased.

As mark-recapture trials were conducted, the trap efficiency model was typically updated one time each year. The newest model was applied on July 1 of each year, the beginning of the annual winter Chinook juvenile brood year period. Between 2002 and 2013 nine different models were utilized. The specific dates and model parameters with P -values used throughout the reporting period are listed chronologically below the groups of mark-recapture trials incorporated into the models in Table 2. The net result over the 11-year period was stabilization and improvement of the trap efficiency model with the addition of 85 mark-recapture trials. Overall, the P -values indicated a high level of significance for the parameter % Q in all years ($P < 0.001$). The model's r -squared value dropped in the first few years and then improved greatly with the addition of numerous naturally produced fry size-class mark-recapture trials over a variety of river discharge levels (Table 2; Figure 3).

Over the 11 years' data was collected a wide range of % Q values were sampled (0.44 to 6.86%, $\bar{y} = 2.90$, $SD = 0.01$). On 10 occasions, extremely low % Q values (<0.72%) were sampled outside of the range of values tested through efficiency trials (Figure 3). The net result was that trap efficiency values were extrapolated outside the range of the model on a mere 10 of 3,315 days sampled (0.3%).

Chinook Capture Fork Length Analyses.—Chinook run assignment based on length-at-date (LAD) criteria was originally developed from growth data in the Upper Sacramento River at the Tehama Colusa Fish Facility using fall Chinook production records from 1972 through 1981 (Fisher 1992). An estimate of apparent growth rate was originally developed from fall Chinook < 90 mm FL as fish migrated or were depleted from the spawning channels by this size (Fisher 1992). Johnson et al. (1992) further developed (extrapolated) the data to predict run for fish ≥ 90 mm and ≤ 250 mm FL. The data was further refined by Frank Fisher of the California Department of Fish and Game, whereby estimated growth curves were produced for all runs based on adult timing, water temperatures, and juvenile emergence timing and growth (Brown and Greene 1992). The growth curves were fitted to a table of daily growth increments (i.e., fork length at age in days) by the California Department of Water Resources in the early

1990's (Brown and Greene 1992; Greene 1992). The following fork length data encompassed fish sampled by rotary traps using the LAD tables up to 180 mm FL, as fish were rarely captured above this length (i.e., extreme outliers).

Fall Chinook sampled from brood years 2002-2012 were heavily weighted to the fry size-class category (<46mm). On average, 75.7% of all fish sampled as fall could be described as fry (SD = 6.9) with 71.0% of the fry measuring less than 40 mm FL (Figure 4a). The remaining 24.3% (SD = 6.9) were attributed to the pre-smolt/smolt category (>45 mm) with fish between 70 and 89 mm composing 71.0% of that value. Overall, fall Chinook were sampled between 30 and 134 mm annually, with trivial numbers below or above this range (Figure 4b). Fall Chinook showed little growth, on average, between December and March, followed by a significant increase in length in April, followed by more moderate and variable growth through November (Figure 4c). The growth pattern exhibited by fall Chinook appears strongly influenced by the duration of the fall Chinook spawning period and the LAD criteria. Beginning on April 1, newly emerged fry were classified as late-fall Chinook instead of fall Chinook thereby significantly increasing the median fork length of fall Chinook during the first two weeks of April.

Late-fall Chinook sampled from brood years 2002-2012 were not heavily weighted to the fry size-class category (<46mm). On average, 24.9% of all fish sampled as late-fall could be described as fry (SD = 12.8) with 96.3% of the fry measuring less than 40 mm FL (Figure 5a). The remaining 75.1% (SD = 12.8) were attributed to the pre-smolt/smolt category (>45 mm) with fish between 70 and 89 mm composing 48.3% of that value. Overall, late-fall Chinook were sampled between 26 and 180 mm annually (Figure 5b). Late-fall Chinook showed little growth, on average, between April and May, followed by a significant increase in length in June and July, followed by more moderate and variable growth between late-September and February (Figure 5c). The growth pattern exhibited by late-fall Chinook appears modestly influenced by the LAD criteria. Beginning on July 1, newly emerged fry were classified as winter Chinook instead of late-fall Chinook slightly increasing the median fork length of late-fall Chinook during the first few weeks of July. In mid-September and to a lesser extent in late-December, the overall fork length distribution for late-fall Chinook increases from one week to the next and was likely a result of decreased sampling effort due to RBDD gate operations and initial winter storms.

Winter Chinook sampled from brood years 2002-2012 were heavily weighted to the fry size-class category (<46mm). On average, 77.9% of all fish sampled as winter could be described as fry (SD = 8.8) with 92.8% of the fry measuring less than 40 mm FL (Figure 6a). The remaining 22.1% (SD = 8.8) were attributed to the pre-smolt/smolt category (>45 mm) with fish between 46 and 69 mm composing 85.3% of that value. Overall, winter Chinook were sampled between 27 and 162 mm annually (Figure 6b). Winter Chinook showed little growth, on average, between July and October, followed by a significant increase in length in mid-October, followed by more moderate growth through December. The growth pattern was then highly variable between January and

April (Figure 6c). The growth pattern exhibited by winter Chinook appears moderately influenced by the LAD criteria. Beginning on October 16, newly emerged fry were classified as spring Chinook instead of winter Chinook thereby significantly increasing the median fork length of winter Chinook during the last two weeks of October.

Spring Chinook sampled from brood years 2002-2012 were slightly weighted to the fry size-class category (<46mm). On average, 58.6% of all fish sampled as spring could be described as fry (SD = 19.6) with 90.0% of the fry measuring less than 40 mm FL (Figure 7a). The remaining 41.4% (SD = 19.6) were attributed to the pre-smolt/smolt category (>45 mm) with fish between 70 and 89 mm composing 69.2% of that value. Overall, spring Chinook were sampled between 28 and 143 mm annually (Figure 7b). Spring Chinook showed moderate growth, on average, between October and mid-December, followed by more consistent increasing growth through May (Figure 7c). Spring Chinook disappear from the catch typically by June with sporadic capture of large smolts in July of some years. The growth pattern exhibited by spring Chinook appears moderately influenced by the LAD criteria. Beginning on December 1, newly emerged fry were classified as fall Chinook instead of spring Chinook likely resulting in positive size-class bias for spring Chinook.

O. mykiss Capture Size Analyses.—Following the conventions used by Gaines and Martin (2002) size categorization for *O. mykiss* followed a slightly different pattern than Chinook and was organized by fork length as fry (<41 mm), sub-yearling (41–138 mm), and yearling (>138 mm). Moyle (2002) described Sacramento River *O. mykiss* populations as highly variable, but typically reaching 140-150 mm FL in their first year. The focus of our data reporting is age-0 and the focus of our size-class analyses was primarily < 139mm and secondarily < 200 mm for length-weight analyses.

O. mykiss sampled from calendar years 2002-2012 were heavily weighted towards the 41-80 mm size-class (79.2%; Figure 8a) which fell into the sub-yearling category (Figure 8b). On average, a modest 8.2% could be categorized as fry (Table 3). Overall, *O. mykiss* yearling and estimated age-2 fish were annually sampled at rates of 2.4% and 0.6%, respectively (Table 3). There was little variation detected within any size-class between categories, yet variance in weekly captures was high throughout the year (Figure 8c). The variable life-history strategies of *O. mykiss* resident and anadromous forms was evident from our size-class capture data. In general, newly emerged fry occurred in early-April and increased in size to early July. Thereafter, a second cohort of either resident trout or summer steelhead⁶ was sampled which demonstrated a secondary growth pattern through December (Figure 8c).

O. mykiss CAMP Program Life-Stage Comparisons.— *O. mykiss* capture patterns appeared to be different than that of Chinook salmon as relatively few *O. mykiss* were captured as fry (\bar{y} = 8.3%) and the majority were sampled as sub-yearlings (\bar{y} = 88.7%;

⁶ Summer steelhead are believed to be extirpated since the construction of dams blocked access to headwater habitat (Moyle 2002).

Table 3; Figure 8b). Fry capture was highest in 2002 and 2006 (11.2% and 17.5%) although these years sampled the first and third fewest *O. mykiss* of the 11 years, respectively. Yearling and age-2 capture was generally low averaging only 3.0%.

Life stage classification of fry was uniform throughout all years (\bar{y} = 6.8%, SD = 2.6%) and did not vary greatly in 2002 and 2006 in contrast to age classification. Parr and silvery-parr accounted for 91.5% of the *O. mykiss* handled at RBDD although there was a large difference between the two categories, 74.0% and 17.5% respectively. Annual variability in parr and silvery-parr classifications (SD = 15.5 and 16.8) seemed to change after 2005 and was likely due to a protocol change or interpretation of morphological characteristics by field staff. Juveniles showing signs of anadromy (i.e., smolts) made up only 1.6% of individuals sampled.

O. mykiss Weight-Length Analysis.—Log₁₀ transformed *O. mykiss* weight-length data showed a strong overall relationship between the two variables (r^2 = 0.942, Table 4). The annual slope coefficients for the 11-year period varied slightly, ranging from 2.858 to 3.052. The variability in growth was not considered significant as the 95% CI annual slope coefficients encompassed the slope coefficient of the overall mean (Table 4). Typical of most weight-length models (Pope and Kruse 2007), the variability about the regression increased with the overall length of the fish (Figure 9).

Salmonid Passage.—Passage estimates for the four runs of Chinook were calculated weekly as fry and pre-smolt/smolt passage. The sum of the weekly fry and pre-smolt/smolt passage values equal the weekly *total* passage values. Confidence intervals (CI) were calculated at the 90% level for all runs for weekly passage estimates. Weekly CI values were summed to obtain the annual CI's around the annual passage estimate (i.e., summed weekly passage estimates). Negative CI values were set to zero and result in some years CI's being asymmetrical around the annual passage estimate. Annual passage estimates (i.e., total passage estimates), by brood year, with CI's and annual effort values are presented for Chinook within Tables 5a-5d and graphically in Figures 10, 12, 14, and 16. Fry and pre-smolt/smolt Chinook passage estimates with 90% CI's summarized annually by run can be found in Appendix 1 (Tables A1-A8). Comparisons of relative variation within and between runs of Chinook were performed by calculating Coefficients of Variation (Sokal and Rohlf 1995) of passage estimates.

Fall Chinook annual passage estimates ranged between 6,627,261 and 27,736,868 juveniles for brood years 2002-2012 (\bar{y} = 14,774,923, CV = 46.2%; Table 5a). On average, fall Chinook passage was composed of 74% fry and 26% pre-smolt/smolt size-class fish (SD = 10.3). Proportions as low as 56% and as high as 87% fry were detected (Table 5a). Annual effort values resulted in interpolations of between 9 and 60% of annual passage estimates (\bar{y} = 28%). In general, the effect of annual effort on CI width indicated greater spread of CI's with decreasing effort (Figure 10).

On average, weekly fall passage equated to 5% of total annual fall Chinook passage between mid-January and early March (Figure 11a). Weekly passage varied considerably during this period with some weeks' passage totals accounting for >25% of annual passage values. Between BY 2002 and 2012, 75% of average annual passage occurred by the end of March, signifying January through March as the greatest period of migration. A second, albeit much diminished, mode of passage occurred between late April and May of each year due to the release of unmarked fall Chinook production fish from Coleman National Fish Hatchery. These fish could not be distinguished from wild fish due to fractional marking processes that varied over the 11-year period from 0 to 25%. Overall, fall passage was complete by the end of July each year with sporadic small pulses of smolts through November (Figure 11b).

Late-fall Chinook annual passage estimates ranged between 91,995 and 2,559,519 juveniles for brood years 2002-2012 ($\bar{y} = 447,711$, CV = 159.9%; Table 5b). On average, late-fall Chinook passage was composed of 38% fry and 62% pre-smolt/smolt size-class fish (SD = 22.5). Proportions as low as 11% and as high as 72% fry were detected (Table 5b). Annual effort values resulted in interpolations of between 9 and 56% of annual passage estimates ($\bar{y} = 31\%$). The effect of annual effort on CI width indicated greater spread of CI's with decreasing effort due to hatchery fish releases, in general (Figure 12).

On average, weekly late-fall passage started abruptly and held at $\leq 5\%$ of total annual passage between April and May (Figure 13a). Weekly passage varied considerably during this period with some weeks' passage totals accounting for >35% of annual passage values. A second, similar magnitude mode of passage occurred between July and August in most years. A third, albeit diminished, mode occurred during October and November with passage accounting for up to 35% of the annual run in some years. Between BY 2002 and 2012, 75% of average annual passage occurred by mid-September, signifying April through September as the greatest period of migration. Overall, late-fall passage was complete by the end of December each year with sporadic small pulses of smolts through February (Figure 13b).

Winter Chinook annual passage estimates ranged between 848,976 and 8,363,106 juveniles for brood years 2002-2012 ($\bar{y} = 3,763,362$, CV = 73.2%; Table 5c). On average, winter Chinook passage was composed of 80% fry and 20% pre-smolt/smolt size-class fish (SD = 11.2). Proportions as low as 53% and as high as 90% fry were detected (Table 5c). Annual effort values resulted in interpolations of between 8 and 42% of annual passage estimates ($\bar{y} = 18\%$). The effect of annual effort on CI width indicated greater spread of CI's with decreasing effort due to subsampling measures during peak migration periods (i.e., take or impact reduction), in general (Figure 14).

On average, weekly winter passage increased consistently through September to a peak into early October. Weekly passage varied considerably during August through December with some weeks' passage totals accounting for >20% of annual passage values. Between BY 2002 and 2012, 75% of average annual passage occurred by mid-

October. Weekly passage between October and December indicated wide variability over the 11-year period, yet the trend showed steady decreases followed by a second increase or mode of winter passage in November and December (Figure 15a). Overall, winter passage was 99% complete by the end of December each year with sporadic pulses of smolts through March that contributed minimally to the annual total winter passage estimate (Figure 15b).

Spring Chinook annual passage estimates ranged between 158,966 and 626,925 juveniles for brood years 2002-2012 ($\bar{y} = 364,508$, $CV = 45.0\%$; Table 5d). On average, spring Chinook passage was composed of 54% fry and 46% pre-smolt/smolt size-class fish ($SD = 20.0$). Proportions as low as 24% and as high as 91% fry were detected (Table 5d). Annual effort values resulted in interpolations of between 1 and 49% of annual passage estimates ($\bar{y} = 29\%$). The effect of annual effort on CI width indicated a slightly greater spread of CI's with decreasing effort due to subsampling during winter storm events, in general (Figure 16).

On average, weekly spring passage started abruptly and held at roughly 5% of total annual passage between mid-October and mid-November (Figure 17a). Weekly passage varied somewhat during this period with some weeks' passage totals accounting for up to 20% of annual passage values. A second, increased magnitude mode of passage occurred during December in most years with a single week accounting for nearly 50% of the annual passage estimate. Between BY 2002 and 2012, 75% of average annual passage occurred by mid-April, signifying October through April as the greatest period of migration. A third mode of similar magnitude to the second mode occurred during April and May with passage accounting for up to 45% of the annual run in some years. This could be characterized as an erroneous increase in spring passage. Unmarked fall production fish exceeded the size-class for fall run and therefore fell within the spring run category using LAD criteria. Between 2007 and 2012, on average, 4.3% of the marked fall production fish fell within the spring-run size-class using LAD criteria. Assumedly, a similar proportion of the unmarked fish were added into the spring-run passage estimates as they could not be distinguished from naturally produced fish. Overall, spring Chinook passage was complete by the end of May each year (Figure 17b).

O. mykiss passage estimates were generated using trap efficiency estimates calculated using the Chinook-based trap efficiency model. Caution should be exercised when interpreting the following results as Chinook and *O. mykiss* trap efficiency values likely differ, perhaps greatly. Irrespective of the accuracy of the magnitude of passage estimates based on Chinook efficiency trials, the trends in abundance remain plausible due to the standardization of effort and catch. Unlike Chinook, *O. mykiss* were not attributed to a fry or pre-smolt/smolt category and passage estimates with 90% CI's were calculated that included all size-classes and life-stages combined.

Annual passage estimates for *O. mykiss* ranged between 56,798 and 151,694 juveniles for calendar years 2002-2012 ($\bar{y} = 116,272$, $CV = 25.7\%$; Table 5e). Annual

effort values resulted in interpolations of between 4 and 56% of annual passage estimates ($\bar{y} = 22\%$). The effect of annual effort on CI width indicated a slightly greater spread of CI's with decreasing effort, in general (Figure 18).

On average, weekly *O. mykiss* passage was low (<5% on average) from April through July of each year with some variability. In 11 years of sampling only once did passage exceed 10% of annual passage during these months. Weekly passage between July and August increased to peak values ranging from 5% to nearly 25% (Figure 19a). Between 2002 and 2012, 75% of average annual passage occurred by mid-August. Weekly passage generally declined between September and October. Overall, *O. mykiss* passage was negligible between December and the following February each year (Figure 19b).

Fry-Equivalent Chinook Production Estimates.—Juvenile Chinook passage values were standardized to *fry-equivalent* production estimates for within- and between-year comparisons. As noted above, the various runs were sampled with oftentimes considerable variability in fry to pre-smolt/smolt ratios over the 11-year sample period (Table 5a-5d). By multiplying 1.7 to all fish sampled in the pre-smolt/smolt category (>45mm) within each run, annual Chinook production above the RBDD transect could be estimated. These standardized production estimates could then be compared to adult escapement estimates calculated from the California Central Valley Chinook Population Report (Azat 2013) or carcass survey data in the case of winter Chinook (USFWS 2006-2011 and 2013). Moreover, by comparing production to the number of adult Chinook females each year (by run) and estimating fecundity data from CNFH and Livingston Stone National Fish Hatchery (LSNFH) hatchery production records, estimated recruits per female and egg-to-fry survival estimates were generated.

Fall Chinook fry-equivalent production estimates between 2002 and 2012 ranged from 7,554,574 to 30,624,209 ($\bar{y} = 17,262,473$, CV = 43.2%). Lower and upper 90% CI's were generated for each week, summed annually, and averaged between 6,670,475 and 30,707,529 (Table 6a).

Adult fall Chinook escapement estimates above RBDD (mainstem Sacramento River plus tributaries reported) estimated escapement between 12,908 and 458,772 ($\bar{y} = 93,661$) for the same years. Fall Chinook carcass survey data collected by California Department of Fish and Wildlife (CDFW) provided annual female:male sex ratio estimates averaging 0.46:0.54 (D. Killam, unpublished data). A significant relationship between estimated number of females and fry-equivalent fall Chinook production estimates was detected ($r^2 = 0.53$, $df = 10$, $P = 0.01$; Figure 20a). Recruits per female were calculated ranging from 89 to 1,515 ($\bar{y} = 749$). Assuming an average female fecundity value of 5,407, based on fall Chinook spawning records from CNFH between 2008 and 2012 (K. Brown, unpublished data), resulted in an egg-to-fry survival estimate averaging 13.9% for fall Chinook (Table 6a).

Late-fall Chinook fry-equivalent production estimates between 2002 and 2012 ranged from 116,188 to 4,041,505 ($\bar{y} = 669,939$, $CV = 169.8\%$). Lower and upper 90% CI's were generated for each week, summed annually, and averaged between 222,044 and 1,236,432 (Table 6b).

Adult late-fall Chinook escapement estimates above RBDD estimated escapement between 2,931 and 36,220 ($\bar{y} = 9,108$) for the same years. Late-fall Chinook annual female:male sex ratio estimates relied on an assumption of the average ratio found for fall Chinook (i.e., 0.46:0.54). A significant relationship between estimated number of females and fry-equivalent late-fall Chinook production estimates was detected ($r^2 = 0.67$, $df = 10$, $P = 0.002$; Figure 20b). Recruits per female were calculated ranging from 47 to 243 ($\bar{y} = 131$). Assuming an average female fecundity value of 4,662 based on late-fall Chinook spawning records from CNFH between 2008 and 2012 (K. Brown, unpublished data) resulted in an egg-to-fry survival estimate averaging 2.8% for late-fall Chinook (Table 6b).

Winter Chinook fry-equivalent production estimates between 2002 and 2012 ranged from 996,621 to 8,943,194 ($\bar{y} = 4,152,547$, $CV = 70.1\%$). Lower and upper 90% CI's were generated for each week, summed annually, and averaged between 2,265,220 and 6,124,494 (Table 6c).

Adult winter Chinook escapement estimates above RBDD (USFWS/CDFW carcass survey data; available at http://www.fws.gov/redbluff/he_reports.aspx) estimated escapement between 824 and 17,205 ($\bar{y} = 6,532$) for the same years. Winter Chinook annual female:male sex ratio estimates were estimated during the annual carcass surveys (Table 6c). A highly significant relationship between estimated number of females and fry-equivalent winter Chinook production estimates was detected ($r^2 = 0.90$, $df = 10$, $P < 0.001$; Figure 20c). Recruits per female were calculated ranging from 846 to 2,351 ($\bar{y} = 1,349$). Annual female fecundity values were estimated based on winter Chinook spawning records from LSNFH between 2008 and 2012 (USFWS Annual Propagation Reports; available at http://www.fws.gov/redbluff/he_reports.aspx) and resulted in an egg-to-fry survival estimate averaging 26.4% for winter Chinook (Table 6c).

Spring Chinook fry-equivalent production estimates between 2002 and 2012 ranged from 207,793 to 747,026 ($\bar{y} = 471,527$, $CV = 40.9\%$). Lower and upper 90% CI's were generated for each week, summed annually, and averaged between 199,365 and 792,668 (Table 6d).

Adult spring Chinook escapement estimates above RBDD (mainstem Sacramento River plus tributaries reported) estimated escapement between 77 and 399 ($\bar{y} = 195$) for the same years. Spring Chinook annual female:male sex ratio estimates relied on an assumption of the average ratio found for fall Chinook (i.e., 0.46:0.54). No significant relationship between estimated number of females and fry-equivalent spring Chinook production estimates was detected ($r^2 = 0.00$, $df = 10$, $P = 0.971$; Figure 20d). Recruits

per female were calculated ranging from 1,112 to 8,592 ($\bar{y} = 3,122$). Assuming an average female fecundity value of 5,078, based on averaging of 5 years of fall and late-fall Chinook spawning records from CNFH and 10 years of winter Chinook spawning records from LSNFH, resulted in an egg-to-fry survival estimate averaging 61.5% for spring Chinook (Table 6d).

Green Sturgeon Data.—Capture of young of the year sturgeon occurred annually between calendar years 2002 and 2012, except in 2008. Catch was highly variable, not normally distributed, and ranged between 0 and 3,701 per year (median = 193; Table 7). Sturgeon sampled by rotary traps could be positively identified as Green Sturgeon in the field *above* total length of 46 mm. At this size, lateral scutes were fully developed and could be counted to distinguish between White (*Acipenser transmontanus*) and Green Sturgeon (Moyle 2002). Of 2,912 sturgeon measured in the field, 99.14% were less than 46 mm. In all years, except 2007 and 2008, sub-samples of larval and/or juvenile sturgeon rotary trap catch (up to 50% in some years) were supplied to UC Davis for genetic research and all were determined to be Green Sturgeon (See Israel et al. 2004; Israel and May 2010). We therefore assumed all sturgeon captured in rotary traps were Green Sturgeon based on the results of genetic analyses. Moreover, Green Sturgeon were the only confirmed spawning Acipenserids sampled at or above the RBDD transect between 2008 and 2012 during sturgeon spawning surveys (Poytress et al. 2009-2013).

Green Sturgeon catch was primarily composed of recently emerged, post-exogenous feeding larvae with a 10-year median capture total length averaging 27.3 mm (SD = 0.8; Table 7). Sturgeon were sampled between 18 and 188 mm, but those sampled above 40 mm were considered outliers (N = 51; Table 7; Figure 21a).

The temporal pattern of Green Sturgeon captures occurred, on average, between May 1 and August 28 of each year. Green Sturgeon capture trends indicated annual variability, but on average 50% were sampled by the end of June each year and nearly 100% by the end of July (Figure 21b), with outliers (i.e., juveniles) captured in August, September and as late as November (e.g., 188 mm TL) in some years.

Relative abundance of Green Sturgeon was measured as catch per estimated water volume sampled (CPUV in ac-ft) through rotary trap cones and summed daily. Daily values were summed annually to produce each year's annual index of abundance. Absolute abundance estimates, via trap efficiency trials, could not be calculated due to low numbers of sturgeon sampled on a daily basis and the fragile nature of newly emerged exogenous feeding larvae.

Green Sturgeon annual CPUV was typically low and ranged from 0.0 to 20.1 fish/ac-ft ($\bar{y} = 2.5$ fish/ac-ft, SD = 5.9). Data were positively skewed and median annual CPUV was 0.8 fish/ac-ft. Relative abundance distribution data were highly influenced by samples collected in 2011 that equated to two orders of magnitude higher

than any other year's index (Figure 21c). Overall, variability in CPUV between years was relatively high as the CV was 236% for the eleven-year period (Table 7).

Lamprey Species Data.—Capture of multiple lamprey species occurred between water year (WY; October - September) 2003 and 2013. WY 2002 was excluded from analyses as less than 50% of the entire year was sampled. Lamprey species sampled included adult and juvenile Pacific Lamprey and to a much lesser extent River Lamprey (*Lampetra ayresi*), and Pacific Brook Lamprey (*Lampetra pacifica*). Unidentified lamprey ammocoetes and Pacific Lamprey (PL) composed 99.8% of all captures, 24% and 75%, respectively. River Lamprey and Pacific Brook Lamprey combined, composed the remaining 0.2% of all captures. Annual catch, length, and relative abundance information for River and Pacific Brook Lamprey can be found in Appendix 1 (Tables A9 and A10) and are not discussed further due to very low capture rates.

Annual catch of ammocoetes was relatively stable and ranged between 385 and 1,415 individuals per year ($\bar{y} = 757$, median = 657; Table 8a). The catch coefficient of variation for ammocoetes was 38.5%. Minimum TL of lamprey ammocoetes was 14 mm and maximum TL was 191. Over the eleven complete years sampled, the average minimum and maximum TL's were 32 and 164 mm, respectively ($\bar{y} = 105$, SD = 4.7; Figure 22a).

Annual catch of PL macrophthalmia and a small fraction of adults was variable and ranged between 204 and 5,252 individuals per year ($\bar{y} = 2,335$, median = 2,747; Table 8b). The catch coefficient of variation for PL was 75.3%. Minimum TL of PL was 72 mm and maximum TL was 834. Over the eleven years sampled, the average minimum and maximum TL's were 88 and 665 mm, respectively ($\bar{y} = 150$, SD = 37.3; Figure 23a).

Lamprey captures occurred throughout the year between October and September. Ammocoete capture trends indicated annual variability, but on average 25% were sampled by the end of January, 50% were sampled by the end of March, 75% were sampled by the end of May and 100% by the end of September (Figure 22b). Transformed PL (macrophthalmia and adult) capture trends indicated a different pattern of capture and annual variability compared to ammocoetes. On average, 5% were sampled through October, 50% were sampled through December, 75% were sampled through February, 90% by the beginning of April with a 100% by the end of September (Figure 23b).

Relative abundance of ammocoetes and PL were measured as CPUV through individual rotary trap cones and summed daily. Daily values were summed annually to produce each year's annual index of abundance. Absolute abundance estimates employing mark-recapture methods could not be calculated due to the sporadic capture of adequate numbers of juveniles (e.g., > 1,000 individuals) that would be needed for mark-recapture trials. Moreover, emphasis was placed on conducting Chinook mark-recapture trials at times of pronounced lamprey abundance.

Ammocoete annual relative abundance ranged from 3.6 to 11.7 fish/ac-ft (\bar{y} = 6.8 fish/ac-ft, SD = 2.6; Figure 22c). Overall, ammocoete data were normally distributed as median CPUV was 6.5 fish/ac-ft, similar to the mean value. Variability in CPUV between years was modest and the coefficient of variation was 39% for the eleven-year period (Table 8a).

PL annual relative abundance was generally higher than ammocoete relative abundance and ranged from 2.1 to 112.8 fish/ac-ft (\bar{y} = 41.0 fish/ac-ft, SD = 34.7; Figure 23c). Overall, PL data was slightly positively skewed and median CPUV was 34.1 fish/ac-ft. Variability in CPUV between years was moderate and the coefficient of variation was 85% for the eleven-year period (Table 8b).

Abiotic Conditions.—Tabular summaries of the abiotic conditions that were encountered during each annual capture period were summarized for each run of salmon, *O. mykiss*, Green Sturgeon and Lamprey species. Tabular summaries associated with each species annual captures are located in Tables 9a-9f and include: dates of capture, peak daily water temperature, peak daily river discharge levels and mean daily turbidity values. A series of exploratory plots comparing the above daily environmental data variables plus an index of moon illuminosity were generated for fry and pre-smolt Chinook daily passage estimates for visual analyses. Winter Chinook fry and pre-smolt/smolt plots are included in Appendix 2 (Figures A1-A23) for reference.

Annual environmental covariate data for fall Chinook salmon can be found in Table 9a. Results presented below describe data averaged over 11 brood years. Fall Chinook were sampled over a period of 250 to 273 days per year (\bar{y} = 264 days, SD = 7). Water temperatures ranged from 45 to 62 °F (\bar{y} = 55°F, SD = 0.8). Sacramento River discharge ranged from 5,605 to 72,027 CFS (\bar{y} = 14,844 CFS, SD = 5,442). Turbidity values ranged from 1.5 to 298.7 NTU (\bar{y} = 14.4 NTU, SD = 6.3).

Annual environmental covariate data for late-fall Chinook salmon can be found in Table 9b. Results presented below describe data averaged over 11 brood years. Late-fall Chinook were sampled over a period of 270 to 338 days per year (\bar{y} = 300 days, SD = 24). Water temperatures ranged from 46 to 62 °F (\bar{y} = 56°F, SD = 0.7). Sacramento River discharge ranged from 5,536 to 67,520 CFS (\bar{y} = 12,580 CFS, SD = 2,829). Turbidity values ranged from 1.4 to 272.0 NTU (\bar{y} = 11.3 NTU, SD = 6.2).

Annual environmental covariate data for winter Chinook salmon can be found in Table 9c. Results presented below describe data averaged over 11 brood years. Winter Chinook were sampled over a period of 207 to 278 days per year (\bar{y} = 250 days, SD = 20). Water temperatures ranged from 46 to 61 °F (\bar{y} = 55°F, SD = 0.8). Sacramento River discharge ranged from 5,349 to 66,800 CFS (\bar{y} = 11,952 CFS, SD = 3,767). Turbidity values ranged from 1.3 to 290.2 NTU (\bar{y} = 12.5 NTU, SD = 5.1).

Annual environmental covariate data for spring Chinook salmon can be found in Table 9d. Results presented below describe data averaged over 11 brood years. Spring Chinook were sampled over a period of 221 to 250 days per year ($\bar{y} = 232$ days, $SD = 9$). Water temperatures ranged from 46 to 62 °F ($\bar{y} = 53^\circ\text{F}$, $SD = 0.6$). Sacramento River discharge ranged from 5,349 to 68,720 CFS ($\bar{y} = 13,370$ CFS, $SD = 6,116$). Turbidity values ranged from 1.4 to 305.9 NTU ($\bar{y} = 16.0$ NTU, $SD = 7.0$).

Annual environmental covariate data for *O. mykiss* can be found in Table 9e. Results presented below describe data averaged over 10 calendar years. *O. mykiss* were sampled over a period of 331 to 363 days per year ($\bar{y} = 349$ days, $SD = 12$). Water temperatures ranged from 46 to 63 °F ($\bar{y} = 56^\circ\text{F}$, $SD = 0.8$). Sacramento River discharge ranged from 5,333 to 67,610 CFS ($\bar{y} = 12,519$ CFS, $SD = 3,551$). Turbidity values ranged from 1.4 to 263.7 NTU ($\bar{y} = 11.4$ NTU, $SD = 4.1$).

Annual environmental covariate data for Green Sturgeon can be found in Table 9f. Results presented below describe data averaged over 11 calendar years. Green Sturgeon were sampled over a period of 56 to 151 days per year ($\bar{y} = 88$ days, $SD = 27$). Water temperatures ranged from 55 to 61 °F ($\bar{y} = 58^\circ\text{F}$, $SD = 0.9$). Sacramento River discharge ranged from 9,639 to 23,538 CFS ($\bar{y} = 13,483$ CFS, $SD = 2,181$). Turbidity values ranged from 2.4 to 93.9 NTU ($\bar{y} = 8.5$ NTU, $SD = 6.9$).

Due to the large amount of variability and lack of a normal distribution, all environmental covariate CPUV data analyses for Green Sturgeon were performed using natural log transformed data (Sokal and Rohlf 1995). Environmental covariates were regressed against the natural log of daily CPUV estimates for Green Sturgeon in a linear regression setting (Figure 24). Maximum daily water temperature was the only variable found to be significantly related to Green Sturgeon relative abundance, albeit the relationship explained ~5% of the variability around daily relative abundance ($r^2 = 0.045$, $df = 315$, $P < 0.001$).

Annual environmental covariate data for Lamprey *spp.* can be found in Table 9g. Results presented below describe data averaged over 11 water years. Lamprey were sampled over a period of 358 to 364 days per year ($\bar{y} = 362$ days, $SD = 2$). Water temperatures ranged from 46 to 63 °F ($\bar{y} = 56^\circ\text{F}$, $SD = 0.7$). Sacramento River discharge ranged from 5,347 to 68,873 CFS ($\bar{y} = 12,595$ CFS, $SD = 4,177$). Turbidity values ranged from 1.2 to 306.8 NTU ($\bar{y} = 11.9$ NTU, $SD = 4.4$).

Due to the variability and lack of a normal distribution, all environmental covariate CPUV data analyses for Lamprey *spp.* were performed using natural log transformed data. Environmental covariates were regressed against the natural log of daily CPUV data for Lamprey *spp.* in a linear and multiple regression setting. All four independent variables appear to contribute to predicting Lamprey *spp.* relative abundance and were significantly related to abundance levels ($r^2 = 0.223$, $df = 1999$, $P < 0.001$). Individual variable linear regression analyses indicated turbidity, water temperature, discharge,

and full moon illuminosity were correlated in descending order of magnitude (Figure 25). None of the covariates tested explained more than ~16% of the variability associated with daily CPUV data.

Discussion

Trap Efficiency Modeling.—Over the past 11 years, annual mark-recapture trials added 85 data points to the RBDD rotary trap efficiency linear regression model (Figure 3). Explanation of the variability associated with trap efficiency and %Q, in terms of the associated r-squared value, was reduced for the first few years and then steadily increased in more recent years. The reduction was due, in part, to more precise %Q calculations over the initial model when diversions from RBDD were not subtracted from daily river discharge values. Diversions were able to be removed from the total discharge (Q) passing the transect as these data became available in real-time starting in 2002.

The addition of a multitude of fry size-class trials over a variety of discharge levels greatly increased the accuracy of trap efficiency estimates. Fry size-class fish are the predominant size-class sampled at RBDD (i.e., fall and winter Chinook) thereby making them the best representatives for use in mark-recapture trials. The original trap efficiency model developed by Martin et al. (2001) employed primarily hatchery-raised smolts, as these fish were all that were available in large quantities and permitted for use in experiments to develop the initial model. However, hatchery fish weakly represented the primary fish size-class sampled by RBDD rotary traps. Roper and Scarnecchia (1996) and Whitton et al. (2008) found significant differences in trap efficiency when conducting paired mark-recapture trials using hatchery and wild caught fish. The most recent years of RBDD data support this concept.

While a simple linear regression model has worked well over the years for our real-time data output needs, analysis of the data within the model, other possible covariates, and other more advanced modeling techniques has been warranted. Analysis incorporating additional potential explanatory variables was conducted using a generalized additive model technique (GAM; Hastie and Tibshirani 1990). From this analysis, variables including turbidity, fish size and run, water temperature, weather condition, lunar phase, and river depth were explored in addition to %Q. The result was that only %Q and weather were found to be significant model explanatory variables ($r^2 = 0.68$; $df = 141$, $P < 0.01$). The weather variable needs focused testing by conducting more mark-recapture trials under a variety of weather conditions to determine the applicability or mechanism of this variable. The GAM modeling technique may be employed in the future as an improved statistical format to interpolate missed sample days.

At minimum, an update to the 142 trial linear trap efficiency model (Figure 3) needs to be implemented for future passage estimate calculations. The update will

include the removal of hatchery fish trials ($N=23$) used as surrogates for natural stocks. Removal of all RBDD “gates in” mark-recapture trials ($N=31$) due to the cessation of RBDD dam operations since 2011 (NMFS 2009) is also warranted.

The loss of annual maintenance and RBDD gate lowering operations at the rotary trap sample site (Figure 1) will allow the river channel’s geometry to change more frequently due to natural flow driven substrate transport mechanisms. RBDD operations of the past virtually “reset” the sample site to facilitate pumping during the gates-out period and improve fish passage at the fish ladders during the gates-in period. As the sample site’s channel configuration is allowed to fluctuate in the absence of dam operations, the overall effect could be differing trap efficiency values in relation to flow compared to previous years’ data. Annual mark-recapture trials will be needed to evaluate this phenomenon, which has been observed in other uncontrolled channel sampling locations (e.g., Clear Creek; Greenwald et. al. 2003). The use of a GAM model may also be of benefit in this situation as it could be constructed and employed annually to account for wide variation in annual trap efficiency values; albeit at the expense of being able to produce real-time data summaries.

A linear model that also removed the remaining pre-2002 trials ($N=16$) which estimated %Q in a less precise manner, would result in the most representative trap efficiency model. A post-RBDD wild Chinook model of this type would incorporate 72 mark-recapture trials with a high degree of significance ($N=72$, $r^2 = 0.669$, $F = 141.5$, $P < 0.001$) and be most representative of current sampling conditions in terms of fish size-class and environmental conditions.

Chinook Capture Size Analyses.—Overall capture of Chinook salmon by RBDD rotary traps was heavily weighted towards fry size-class less than 40mm in fork length. All four runs’ greatest proportion of fish were found in this size-class, albeit in a range of proportions from 24% for late-fall (Figure 5b) to over 72% for winter run (Figure 6b). The capture size-class results fit well with the migratory strategies of ‘stream’ and ‘ocean type’ as noted in Moyle (2002) for late-fall/spring and fall/winter Chinook, respectively. The question of size selectivity or capture bias of rotary traps, a passive sampling gear (Hubert 1996), comes into question when dealing with two very different migration strategies.

A two sample t-test was performed to evaluate the potential for size-class bias by comparing fry (fall and winter Chinook) size-class trap efficiency values ($N=43$) to pre-smolt/smolt (fall) trap efficiency values ($N=10$) between similar river discharge conditions. The t-test results did not indicate any significant difference between the mean efficiency values ($t = -0.398$, $df = 51$, $P = 0.624$). Interestingly, the mean efficiency and standard deviation of the values were identical ($\bar{y} = 2.1\%$, $SD = 0.01$) between groups. We recommend further study of the relationship between pre-smolt/smolt size-class and trap efficiency to determine if differences or bias may exist between or among Chinook runs. Additional sampling effort would be needed to capture

substantially more pre-smolts in the numbers required for efficiency trials in the Sacramento River to further test this potential bias. Smolting salmonids also appear to succumb to stress induced mortality at a much greater rate than fry, particularly in warmer water conditions due to relatively high respiration levels, adding to the difficulty in testing this potential bias.

O. mykiss Life-Stage and Growth.— Catch of *O. mykiss* was scattered throughout the year with multiple modes in abundance of predominately sub-yearling parr and silvery-parr occurring in early May and August. *O. mykiss* fry (<41 mm) made up 17.5% of the total *O. mykiss* catch in 2006 and was 2.4 standard deviations from the 11-year mean. In contrast, yolk-sac fry, made up only 9.4% of the *O. mykiss* catch in 2006 and varied less than 1 standard deviation from the 11-year mean (Table 3). Elevated spring discharge resulted in poor sampling conditions which reduced sampling effort, possibly scoured redds, and ultimately resulted in low overall *O. mykiss* catch in 2006. Regardless of the cause of low catch rates, it is unlikely the migration patterns of *O. mykiss* changed in 2006 and the variability in age-class distribution was likely due to our sampling effort in that year.

The small percentage of *O. mykiss* smolts that showed signs of anadromy were generally migrating during March through June which was consistent with outmigrating smolts found in Battle, Mill, and Deer Creeks (Johnson and Merrick 2012; Colby and Brown 2013). Interpretation of *O. mykiss* data collected at the RBDD was complicated as a robust resident (non-anadromous) population exists throughout the Upper Sacramento River and its' tributaries. Populations of anadromous and resident *O. mykiss* life history forms are often sympatric and may inter-breed (Zimmerman and Reeves 2000; Docker and Heath 2003), thereby reducing our abilities to separate the anadromous and non-anadromous components of this species. Donahue and Null (2013) conducted research using otolith Strontium/Calcium ratios to determine whether *O. mykiss* returning to a hatchery were progeny of anadromous or resident females. A similar analysis could be conducted using juvenile *O. mykiss* collected at the RBDD. Data from juveniles might provide incite as to whether temporal separation in spawn timing exists between anadromous and resident forms of *O. mykiss* coexisting within the Upper Sacramento River basin.

Linear regression equations developed using weight-length data obtained from *O. mykiss* showed a strong correlation between the two variables ($r^2 = 0.942$). The annual slope coefficient varied slightly between 2.858 and 3.052. Carlander (1969) suggested that slopes less than 3.0 might indicate a crowded or stunted population. However, permit restrictions may have introduced bias into our results as we were unable to anesthetize and weigh fish >200 mm thereby reducing the slope of the regression compared to that of a complete analysis of the population.

Sample Effort Influence on Passage Estimates.—Sampling effort had profound effects on the precision of passage estimates and confidence intervals (Figures 10, 12,

14, 16, and 18). In general, as sampling effort decreased, variance within weekly passage estimates increased and the width of confidence intervals subsequently increased. This effect was most prominent when effort was reduced during peak periods of outmigration or for long periods of time (> 1 week) when sharp increases or decreases in fish abundance occurred. Unfortunately, sampling of outmigrant Chinook on a large river system such as the Sacramento River is invariably subject to discharge events that are insurmountable for variable periods of time.

Logistical factors including staffing and permitting restrictions can also have significant effects on the precision of estimates. For example, a comparison of BY 2002 and BY 2005 winter Chinook passage with equivalent effort values (0.64) shows less precision of BY 2002 passage estimates over BY 2005 (Table 5c). The basis of the relatively low effort in 2002 was capture restrictions prompted by ESA Section 10(a)(1)(A) NMFS permits for endangered winter Chinook. Moreover, staff levels were initially low as the program was reinstated after a nearly two-year hiatus and substantial sub-sampling measures (i.e., standardized sub-sampling of repeated weeks) had to be taken during record abundance levels. The net effect was that sampling of fry, the predominant size-class of ocean type Chinook (Moyle 2002; Figure 6a/b), was reduced in terms of the number of days each week and hours of each night sampled during the peak emigration period. The overall net effect was 20% wider CI's about the 2002 estimate (i.e., less precision) compared to BY 2005. This was due to interpolation of 45% of the fry data which comprised 90% of the 2002 annual estimate. In contrast, BY 2005 sampled 90% of the fry data which comprised 90% of the annual estimate. Effort was reduced 36% in 2005 as a result of winter storms whereby sampling ceased for 3 straight weeks due to high river discharge levels. The effect of that lost sampling time in January did little to reduce the precision of the BY 2005 estimate as it was during a period when a mere fraction of a percent of total passage for winter Chinook typically occurs (Figure 15). The impact to the BY 2005 *fall Chinook* passage estimate, on the other hand, was very wide CI's about the estimate due to the lowest effort of all 11 years during a critical time period for that run's outmigration (Table 5a, Figure 11).

In summary, the precision of passage estimates can vary widely for numerous reasons within runs and among years. Inter-annual variability in environmental conditions will always be a factor when attempting to sample a riverine environment. Making good sampling decisions with knowledge of the species of interest and riverine conditions coupled with tenacity to sample critical periods of outmigration (Volkhardt et al. 2007) are key to generating passage estimates with an acceptable level of precision. Applying effort throughout each period of interest needs to be balanced between the value of data collected, an acceptable level of precision required of the data, the cost to attain the required precision, the impact sampling may have to a particular species, and the feasibility to appropriately sample the species of interest.

Chinook Passage Variability.—Juvenile Chinook passage by one to four runs occurs every single day of the year in varying proportions at RBDD. The sources and degree of

variability of juvenile Chinook passage are as diverse as the life-history and migration strategies of the runs they encompass. The magnitude of run-specific adult spawners appears to have the greatest influence on the overall magnitude of juvenile Chinook passage and associated variability.

In recent decades, fall Chinook adults consistently dominated the Upper Sacramento River spawning salmon populations (Williams 2006, Azat 2013). Throughout the past decade, we witnessed a ‘collapse’ of the Sacramento River fall Chinook adult population and accordingly tracked declines in juvenile passage (Figure 10). Lindley et al. (2009) analyzed the freshwater and marine components of fall Chinook outmigrants from BY 2004 and 2005 through their return as adults in 2007 and 2008. They indicated BY 2004 and 2005 juveniles encountered poor marine conditions upon ocean entry in the spring of 2005 and 2006 which resulted in the marked decline in fall Chinook adult abundance starting in 2007.

Juvenile fall Chinook had the greatest mean annual passage value (14,774,923) of the four runs sampled at RBDD (Table 5a). Fall Chinook passage also exhibited the second smallest degree of variability with a CV of 46.2%. Notably, fall Chinook annual production by the CNFH averages 12 million juveniles, a similar value to the mean passage value of unmarked fall Chinook⁷. Fall Chinook production fish from CNFH contributed heavily to the relative stability of the annual returning fall Chinook adult population (Williams 2006) and, consequently, juvenile passage estimates over the past eleven years (i.e., basis of fall Chinook population).

Temporal abundance patterns of fall Chinook indicate the primary passage of juveniles occurs between late December and March (Figure 11a/b). Over half the run passed RBDD by mid-February, yet this varied over the 11-year period by +/- one month. Fall run passage on the American River (Williams 2006), Clear Creek (Earley et al. 2013a) and Stanislaus River (Pyper and Justice 2006) in California generally subsides to low values by the end of March. This would be consistent with the ocean type migration strategy as noted by Moyle (2002). The remaining fall run smolts and subsequent ‘jump’ in abundance in April to May was a result of the unmarked proportion of the CNFH production releases. Reduced variability in weekly passage was observed in the final 20% of annual fall Chinook passage (Figure 11b).

Spring Chinook had the lowest average passage value of 364,000 juveniles and the lowest CV of 45% (Table 5d). The low value of spring Chinook passage at RBDD can be attributed to a relatively small number of adults spawning primarily in Battle and Clear Creeks (Figure 1). Some extant populations appear to inhabit Beegum Creek, a tributary to Cottonwood Creek (CDFG 2001), and in the mainstem Sacramento River (Killam 2009, Azat 2013). Of particular interest with respect to the accuracy of spring Chinook

⁷ Fall Chinook passages estimates do not include the marked proportion (0-25%) of CNFH production fish. Unmarked fish of hatchery origin are included in annual passage estimates and their occurrence is evidenced by increased passage values primarily in May through June of each calendar year (Figure 11b).

juvenile passage at RBDD is the annual spawn timing of adult spring Chinook and expected juvenile emergence timing. USFWS rotary trapping operations on Battle and Clear Creeks between 2003 and 2012 have not predicted emergence (i.e., through temperature unit analyses; Beacham and Murray 1990) nor sampled juvenile spring Chinook prior to November of each year. On average, the first spring Chinook juvenile migrants from Battle and Clear Creeks were sampled during the week of November 26th each year (USFWS, unpublished data). As a result, LAD criteria used to identify juvenile spring Chinook at RBDD are noticeably inaccurate as fish sampled prior to late November were not sampled upstream in primary production areas at that time of year.

Simulating a removal of all LAD spring run between October 16 and November 25 of each year sampled would result in *decreased* spring run passage estimates by 19%, on average (range 2.6 to 44.2%). The effects of removing incorrectly assigned fry annually did not indicate a statistically significant difference between annual estimates (paired *t*-test, $N = 11$, $P < 0.001$). When incorrectly assigned fry are removed, the slightly more accurate simulated spring Chinook annual passage values remain within the 90% CI of standard estimates.

Furthering the simulation by adding the weekly October through November spring Chinook estimated passage to the winter Chinook passage estimates (i.e., late spawning or emerging winter run most likely candidate; see USFWS 2013), had minimal effect on the magnitude of winter Chinook passage. The average *increase* to winter Chinook passage was a mere 2.6% (range 0.6 to 8.8%) and simulated passage remained within the 90% CI of the annual winter Chinook estimates in all years.

Winter Chinook average annual juvenile passage was the second highest of the four runs estimated at 3,763,362 (Table 5c). The CV of the annual estimates was 73.2%; higher than fall or spring, but moderately dispersed. Overall, passage in years 2002, 2003, 2005, and 2006 surpassed the highest previous value of winter Chinook passage since juvenile monitoring began in 1995 (Gaines and Martin 2002). Similar to fall Chinook, winter Chinook adult escapement and subsequent juvenile passage began a marked decline in 2007 (Figure 16). Juvenile winter Chinook have been determined to enter the ocean during March and April of each spring (Pyper et al. 2013). Overall, it is believed that juvenile winter Chinook suffered the same fate as juvenile fall Chinook with poor marine conditions upon ocean entry in the spring of 2005 and 2006. Winter Chinook juvenile cohort replacement rates dropped below 1.0 starting with BY 2007, similar to adult fall run as noted in Lindley et al. (2009). The lowest passage estimate between 2002 and 2012 for winter Chinook occurred in 2011 at 848,976. Not until 2014 will we know if adult or juvenile cohort replacement rates will improve to a value of 1.0 or greater. Winter Chinook passage estimates between BY 1999 to BY 2002 (Gaines and Poytress 2003) indicate that replacement rates can vary substantially and replacement rates of 3.0 or greater have been estimated between juvenile cohorts.

Late-fall Chinook passage averaged 447,711 juveniles for the 11-year period and exhibited the greatest amount of variability with a CV of 159.9%. Late-fall Chinook juvenile passage estimates are likely affected by LAD criteria similar to spring Chinook in terms of potential for overestimation. The variability associated with weekly late-fall passage shows a decrease in median abundance by the beginning of June each year which may be more representative of actual late-fall emergence. Additionally, as demonstrated by Figures 13 a/b, the late-fall migration starts abruptly unlike for fall and winter Chinook which follow a more bell-shaped pattern in abundance (See Figures 11a/b and 15 a/b). It was highly likely that early emergent late-fall fry were, in fact, late emerging fall Chinook. Run specific genetic monitoring (Banks et al. 2000, Banks and Jacobsen 2004) could assist in determining the magnitude of the error in run assignment.

Sampling effort during mid-April to mid-May, the early late-fall run emergent period, was also typically low in an effort to reduce impacts to CNFH fall Chinook production fish caught in rotary traps. Within trap predation of fry by CNFH production smolts could also negatively bias late-fall juvenile production estimates. Sub-sampling of portions of the day and night ($\leq 25\%$ of each period) were only feasible with full staffing in some years which can reduce potential bias. During all other years, multiple sample days were typically sacrificed to allow peaks in CNFH production fish to recede ultimately reducing the accuracy of late-fall passage estimates.

Fry-Equivalent Chinook Production Estimates.—Estimation and analyses of the productivity of salmon runs in the Upper Sacramento River basin can provide valuable information to a variety of interests. Management of California's complex water resources for agriculture, municipal, commercial, and ecological uses is an increasingly controversial and complex endeavor. Knowledge of the effects of manipulating water storage and river processes on the productivity of the Sacramento River fish populations can only benefit fishery and water operations managers in an attempt to balance the competing demands on the system. Reducing uncertainty associated with threatened and/or endangered fish population dynamics by employing knowledge of the abundance, migration timing, and variability of those populations over time can then inform the decision making processes guiding management of water and fishery resources into the future.

Fall Chinook fry-equivalent juvenile production indices (FEJPI; Table 6a) indicate a significant and moderate correlation with fall Chinook escapement estimates (Figure 20a). Approximately 53% of the variation associated with fall FEJPI's was attributed to the estimated number of females in the system above RBDD each year (Figure 20a). The CV of estimated fall run females was greater than 132% indicating wide dispersion of contributors to the juvenile population over the eleven-year period. Conversely, the CV of FEJPI's was relatively low valued at 43%. Furthermore, recruits per female and similarly egg-to-fry survival demonstrated moderately low average values of 749 and

13.9%, respectively, when compared to the estimated values for winter Chinook (Table 6a).

As noted in Kocik and Taylor (1987), factors limiting production are typically a combination of biotic and abiotic factors. The sources of variability relating to fall FEJPIs are directly and indirectly related to adult abundance, but abundance alone does not explain the low CV in fall run juvenile production. A simple, albeit incorrect, conclusion might be that adult escapement of fall Chinook in some years exceeds the useable spawning area of the system (Bovee 1982, Connor et al. 2001) or optimal spawning efficiency (Wales and Coots 1955). Upon closer examination of the likely origin(s) of juvenile production, the data indicate substantial variability in the distribution of fall run adults between the mainstem Sacramento River and tributaries, including Clear Creek and Battle Creek, between years. Proportions of returning adults within the mainstem and Battle Creek have demonstrated high degrees of variability (Figure 26). The overwhelming return of fall run to Battle Creek in 2002 resulted in the lowest value of fall Chinook recruits per female ($N = 89$) which was outside two standard deviations of the average (Table 6a). The number of adults returning to the CNFH clearly overwhelmed the capacity of Battle Creek to produce juveniles. Sub-optimal wetted useable spawning area (Bovee 1982), red superimposition (McNeil 1968, Heard 1978), and female stress resulting in egg retention (Neave 1953, Foerster 1968) were likely just some of the factors that reduced the overall productivity of the 2002 fall Chinook adults returning to the Upper Sacramento River.

In years when estimates of fall Chinook production were at their highest in terms of recruits/females (Table 6a), the proportions spawning in the mainstem and combined tributaries were closest to 50:50. Further examination indicates that when contributions from the Battle and Clear Creeks accounted for equal proportions (i.e., 25% each), peak values of $\sim 1,500$ recruits/females were estimated to have been produced resulting in the highest net spawning efficiency (Wales and Coots 1955). Optimal natural juvenile fall Chinook production values in the Upper Sacramento River system could result under some conditions if integration of restoration projects on Battle and Clear Creeks integrate with mitigation projects (e.g., CNFH production) for the mainstem Sacramento River. The effect of consistent hatchery fall Chinook production on Battle Creek irrespective of natural fish production in the Sacramento and Chinook-bearing tributaries should be considered for further evaluation as was noted in Williams (2006). The effects of restoration of Clear Creek appear to be providing production benefits on stream and basin wide scales. Management prerogatives and actions related to the CVP affect both factors, to varying degrees, and decisions should be prioritized to attain optimal results for both fisheries and water operations.

Late-fall Chinook FEJPIs indicated high variability (CV = 170%; Table 6b), but a strong correlation with escapement estimates ($r^2 = 0.67$; Figure 20b). The magnitude of late-fall FEJPIs were consistently an order of magnitude less than FEJPIs of fall Chinook. One exception was 2002, which increased the CV for the eleven-year period by 100%

(Table 6b). The fall and late-fall adult Chinook escapement values of 2001 and 2002 were high compared to the other 10 years of data (Azat 2013). A large run of late spawning fall run may also have contributed to the large number of juvenile fish falling within the late-fall size-class according to LAD criteria, but the adult estimate could have suffered similar inaccuracies in run assignment. Variability in CV values of anadromous fish was described by Rothchild and Dinardo (1987) as being inversely related to the number of years included within the time series analyses. While 2002 appears to be an outlier in this data set, it is likely with more years of data collection and analyses the CV associated with late-fall production would be more commensurate with other runs of Chinook.

The stream-type migration strategy noted by Moyle (2002) and our size classification method categorized the majority of late-fall outmigrants as smolts ($\bar{y} = 62\%$) which inflated the late-fall FEJPIs greatly at times (Table 5b, Table 6b). Recruits per female and similarly egg-to-fry survival had low CVs and the lowest average values of 131 and 2.8%, respectively, in comparison to other runs (Table 6b). This was unexpected as this metric does not appear to apply well to a run that was sampled primarily as smolts ($\bar{y} = 62\%$) over eleven years. Moreover, fry-equivalent calculations based on a static fry-to-smolt survival estimate of 59% (Hallock undated) was unlikely to be an accurate constant for late-fall Chinook as it was calculated from hatchery-based fall Chinook survival data. The fact that correlations with adult escapement were determined to be significant and moderately strong was unexpected given the vagaries of sampling late-fall Chinook smolts and the use of the static 59% survival estimate inversely applied to the majority of the run sampled. Additionally, difficulties with performing carcass surveys for late-fall Chinook due to low visibility, winter flow events or logistical issues (Killam 2009 and 2012) typically result in sub-optimal sampling conditions and, assumedly, would reduce the accuracy of the adult estimate.

Overall, production of late-fall Chinook appears low and the run has been characterized by some as vulnerable to extinction (Moyle et al. 2008, Katz et al. 2012). Greater attention to the relatively low abundance levels and juvenile rearing habitat needs of this genetically distinct run (Banks et al. 2000, Garza et al. 2007, Smith et al. 2009) with its unique over-summering, relatively long freshwater residency (Randall et al. 1987) and large size-at-outmigration strategy (Zabel and Achord 2004) should be afforded. The life-history strategies of late-fall Chinook have likely allowed them to persist in the Upper Sacramento River system as they occupy a distinct ecological niche. Juvenile monitoring of this run could benefit greatly if confidence in the accuracy of run assignment of juveniles was examined using non-lethal genetic techniques (Harvey and Stroble 2013).

Comparisons between winter Chinook adults and juvenile production began early using data generated by this monitoring project. Martin et al. (2001) demonstrated a strong relationship with only 5 years of data. The annual analyses of the winter FEJPI and adult estimates continually indicated a strong relationship with the addition of each

year's data (See Gaines and Poytress 2003, Poytress and Carrillo 2008, Poytress and Carrillo 2012). The analysis of the most recent 11 years of data continues to indicate a strong relationship between the two variables even as adult escapement values have varied an order of magnitude.

Winter Chinook FEJPIs indicated mild variability (CV = 67%; Table 6c) and a very strong level of significance and correlation with female adult escapement estimates ($r^2 = 0.90$; Figure 20c). Intensive adult and juvenile monitoring for this ESA listed endangered species coupled with superlative sampling conditions, in most years, appears to have resulted in very high quality information regarding the status and trends in adult and juvenile population abundance.

Egg-to-fry survival estimates generated from annual winter Chinook data indicate a range of values between 15 and 49% (Table 6c). At first glance, this appeared counterintuitive based on the highly regulated Sacramento River system (e.g., flow and water temperatures) that typically exists during the winter Chinook spawning period. The average egg-to-fry survival estimate of 26% is considerably higher than that determined from other studies on Pacific salmonids ($\bar{y} = 15\%$; e.g., Wales and Coats 1955) but was consistent with highly regulated aquatic systems (Groot and Margolis 1991). A very low CV of 38% also appeared consistent with a regulated system. Recruits per female, similarly, indicated a low CV of 36% and the second highest average value of 1,349 (Table 6c).

Natural log transformed adult female estimates influenced juvenile production and a significant relationship was determined accounting for roughly half of the variability associated with egg-to-fry survival rates ($r^2 = 0.51$, $df = 10$, $P = 0.012$). Densities of winter Chinook spawners are much lower currently than in the years estimated following the completion of Shasta Dam (USFWS 2001). Completion of the re-engineered Anderson-Cottonwood Irrigation District fish ladders in 2001 resulted in greater access and subsequently a greater concentration of spawners in the uppermost reaches accessible to anadromous fish (USFWS 2006-2011). Competition for optimal spawning habitat can result in lower juvenile production if sub-optimal wetted useable spawning area (Bovee 1982), red superimposition (McNeil 1968, Heard 1978), and female stress resulting in egg retention (Neave 1953, Foerster 1968) occur to varying degrees. Low resolution carcass recovery data (e.g., reach specific) indicate an abundance of spawners utilizing the uppermost 6 river miles of the Sacramento River (USFWS 2006-2011) even as seemingly suitable habitat has been made available for approximately 20+ river miles downstream of the terminus at Keswick Dam (RM 302). Geist et al. (2002) studied physiochemical characteristics affecting redd site selection preferences by Chinook and different growth and development rates have been attributed to different segments within the same river (Wells and McNeil 1970). High resolution redd surveys or spawning area mapping employing a GIS spatial analytical framework (Earley et al. 2013b) may shed light on the variability associated with winter Chinook spawning habitat over a variety of adult abundance levels. Analyses of these

types of data could result in less uncertainty over the annual specific density dependent mechanisms affecting juvenile production and provide direction for future restoration activities for winter Chinook.

Spring run Chinook FEJPIs were the lowest of all four runs monitored and indicated the lowest variability (CV = 41%; Table 6d). No relationship with female adult escapement estimates was detected ($r^2 = 0.00$; Figure 20d) and may be attributed substantially to measurement error (Sokal and Rohlf 1995). Estimates of recruits per female averaged 3,122 and the egg-to-fry survival value averaged 61.5%. These values appear unreasonable outside of a hatchery environment and well above those found for other runs (this report) and other studies (e.g., Wales and Coots 1955, Groot and Margolis 1991). Individual annual estimates varied moderately (CV= 70.8%) and nearly half appeared highly unlikely, with some values exceeding the number of eggs deposited by spawners (Table 6d).

Spring Chinook juvenile fish production estimates at RBDD were the least accurate and currently constitute 2.1%, on average, of total annual Chinook production above RBDD. Mainstem Sacramento River spawner estimates ranged from a low of 0 to a high of 370 between 2002 and 2012. Annual indexes of spring Chinook adult abundance above RBDD during the same years constitute 2.7% of the total escapement estimated in the Sacramento River system (Azat 2013). Given the relatively sporadic and low adult abundance levels, vagaries of using LAD criteria and annual CNFH fall Chinook production releases with fractional mark rates, no relationship could be found between adult escapement and spring Chinook FEJPIs when attempting to use methods to correct for these inaccuracies. The effects of inaccurate spring run assignment did not appear to affect the FEJPIs of other runs (e.g., winter or fall run) and therefore were not considered biologically significant. Genetic monitoring of fry in the fall after emergence from tributaries where emergence and migration data is collected (e.g., Earley et al. 2013a) may allow for more accurate estimation of the contributions of this run to the Upper Sacramento River outmigrant population.

Green Sturgeon Capture Dynamics.—Rotary traps were originally constructed to sample outmigrating salmonid smolts, but have been effective in sampling a variety of downstream migrating fish (Volkhardt et al. 2007). Rotary traps sampling at RBDD have been effective at monitoring temporal and spatial trends in relative abundance of Green Sturgeon since 1995 (Gaines and Martin 2002).

Annual adult Green Sturgeon aggregations were observed behind the RBDD when gates were lowered each spring (Brown 2007). Green sturgeon larvae were captured in 2012 (Table 7), the first year the RBDD gates were not lowered as it was replaced by a permanent pumping plant (NMFS 2009). Spawning was determined to have occurred in multiple locations as far as 20 river miles upstream of RBDD (Poytress et al. 2009-2013). The location of the RBDD rotary traps has been confirmed to be within the Green

Sturgeon spawning grounds as eggs were sampled directly below the RBDD and upstream of the RBDD traps in multiple years (Poytress et al. 2009, 2010, 2012).

Total length distribution data from Green Sturgeon collections at RBDD indicate a narrow and consistent size-class of larvae (Figure 21a). These data are consistent with laboratory-based studies conducted by Kynard et al. (2005) on the behavior of early life intervals of Klamath River Green Sturgeon. Their study determined that larvae migrated during two distinct periods (i.e., two-step migration). The first migration of newly exogenous feeding larvae was determined to be an initial dispersion from production areas. The second migration (of juveniles) to overwintering areas occurred in the fall some 180 days after hatching, on average. Our rotary trap data suggest we are sampling exclusively the initial redistribution of larvae from egg incubation and hatching areas.

Benthic D-net sampling conducted by Poytress et al. (2010-2011) targeted the lowest portion of the water column (inverse of rotary traps) and consistently captured Green Sturgeon larvae of the same size-class and temporal distribution pattern as rotary traps. D-net samples were collected between May and early-August (See Figure 21b for corresponding RST data only) downstream of spawning areas in years 2008-2011; even as no larvae were collected by rotary traps in 2008. Larvae were sampled by both methods primarily in the thalweg and in river velocities ≥ 1.3 ft/sec⁸. Conversely, zero *juveniles* were collected with benthic D-nets in a pilot study (Poytress et al. 2013) targeting this life-stage and habitat type in the benthos during the fall period. Rotary traps have collected a few sporadic juveniles (e.g., outliers; Figure 21a) over the entire sample record of the project. These data indicate that Green Sturgeon juveniles are no longer utilizing our sampling region or more likely using a different habitat type (Hayes et al. 1996). Accordingly, rotary traps appear to be a relatively ineffective gear type for sampling the secondary juvenile sturgeon migration.

Protections afforded to ESA listed southern distinct population segment of Green Sturgeon (since 2006), limited quantities of larvae, and the small size at capture have not allowed their drift distances (Auer and Baker 2002), rates (Braaten et al. 2008), or rotary trap efficiencies to be calculated for the initial dispersion migration of Sacramento River Green Sturgeon at RBDD. Relative abundance indices for Green Sturgeon were highly variable, typically low valued at <1.0 fish/ac-ft sampled (Table 7), and contained one extraordinarily strong year-class (Figure 21c). As noted by Allen and Hightower (2010), variations in recruitment by orders of magnitude between years is common among fish stocks. Moreover, strong and weak year classes greatly influence adult fish populations. Green sturgeon relative abundance indices should not be interpreted as recruitment to the adult population, but should be viewed as a production metric influencing recruitment (e.g., age-0 year class strength). Alternately,

⁸ Rotary traps generally require a minimum water velocity of 1.2 ft/sec to operate properly. D-nets sampled velocities ranging from 1.3 – 6.6 ft/sec. RST' sampled velocities ranging from 1.3 – 6.3 ft/sec.

Green Sturgeon larvae relative abundance indices could be viewed as an indirect metric for adult spawning population densities *upstream* of RBDD if genetic monitoring were conducted consistently (Israel and May 2010).

Lamprey Capture Dynamics.— Similar to Green Sturgeon, rotary trap sampling for Chinook salmon has provided the additional benefit of capturing out-migrating lamprey ammocoetes and juveniles. Greater attention to this ancestor of the earliest vertebrates (Moyle 2002) has recently been paid by the USFWS since it was petitioned for listing under the ESA in 2003 (Nawa et al. 2003). Although not listed due to inadequate data on the species' range and threats, the USFWS has engaged in a strategy to collaboratively conserve and restore Pacific Lamprey throughout their native range. Through the formation and development of the Pacific Lamprey Conservation Initiative, an assessment of Lamprey populations in California has recently been completed (Goodman and Reid 2012). The assessment noted that Lamprey species had been extirpated from at least 55% of their historical habitat north of Point Conception, CA by 1985. Long-term monitoring data sets including the RBDD rotary trap data, utilizing temporal and spatial distribution patterns as well as size-class and relative abundance levels of lamprey, can aid in the assessment and conservation of this ecologically vital species (Close et al. 2002).

Variability in annual size-class total length distributions was typically minor for both lamprey life stages sampled (Figure 22a and Figure 23a). Ammocoetes were slightly smaller than macrophthalmia and slightly more variable in their annual average length distributions valued at 110 mm TL (CV= 4.6%; Table 8a). Pacific Lamprey macrophthalmia were the dominant life stage sampled and the median size at capture was consistently near 125 mm TL (CV= 1.6%; Table 8b). Adults, typically noted as outliers, were encountered in much lower frequencies and were considered upstream migrants inadvertently captured when the RBDD gates were lowered as they sought upstream passage around the partial migration barrier.

Temporal distribution patterns indicated that ammocoetes and macrophthalmia migrate past RBDD year-round. Ammocoetes, on average, were sampled regularly throughout the year (Figure 22b), whereas macrophthalmia moved, en masse, episodically between November and March (Figure 23b). These data are consistent with studies of macrophthalmia in the Columbia River system as noted by Close et al. (1995) and Kostow (2002).

Relative abundance indices of ammocoetes (Figure 22c) varied little between years and little overall when compared with macrophthalmia (Figure 23c). Macrophthalmia abundance indices varied considerably between years (Table 8b). On average, macrophthalmia relative abundance was six times that of ammocoetes indicating metamorphosis and redistribution to different habitats from those used for rearing by ammocoetes (Goodman and Reid 2012). Differences in the relative abundance CV's of the two life stages likely indicates differences in catchability (Hubert and Fabrizio 2007)

or habitat use (Hayes et al. 1996), variable migration trigger effects, or variability in sampling effort that often occurred during periods of macrophthalmia migration.

Water Temperature and Juvenile Fish Dynamics.—Slight variation within and among salmonid runs (including *O. mykiss*) and years was noted for water temperatures found at RBDD (Tables 9a-e). Nonetheless, Upper Sacramento River salmonids were subjected to a relatively wide 20 degree range of water temperatures. Temperatures were recorded between 44 and 64 degrees with the average being 55 degrees each year. As summarized in Vogel and Marine (1991), the range of temperatures experienced by Chinook fry and pre-smolt/smolt in the last 11 years of passage at RBDD have been within the optimal range of thermal tolerances for survival.

Sacramento River water temperatures below Shasta/Keswick dams can be managed at certain times of the year under some conditions through discharge management to provide selective withdrawal at submerged intakes (USBR 1991 & 1994, Vermeyen 1997). Ambient air temperatures typically regulate river water temperatures during winter and early spring periods while storage and flood control operations are preeminent. The water temperatures recorded during the last 11 years appear to have been favorable for extant spring run spawners, and more so for fall and late-fall run Chinook and *O. mykiss* spawner and outmigrant populations.

The most vulnerable Chinook run to temperature management operations conducted by the USBR is winter Chinook (NMFS 2009). Temperature management of the Sacramento River via Shasta/Keswick releases by the USBR for winter Chinook appeared to be effective during the last 11 years as evidenced by the relatively favorable and stable egg-to-fry survival estimates (Table 6c). Moreover, temperature management of the upper 50 river miles of the Sacramento River aimed at winter Chinook resulted in benefits to over-summering late-fall Chinook pre-smolts and a relatively small proportion of fall Chinook smolts.

Temperature management during the summertime aimed at winter Chinook may have indirectly favored the resident form of *O. mykiss*. As noted by Lieberman et al. (2001), altering the thermal regime and food web structure by way of temperature management likely affects the proportion of anadromous to resident forms in large rivers. Lamprey species have likely benefitted from temperature management as temperatures for early life stages of lamprey in the mainstem Sacramento River appear to have been, on average, optimal (Meeuwig et al. 2005) in the last 11 years (Table 9g).

Green Sturgeon have likely benefitted from temperature management efforts aimed at winter Chinook spawning and production, albeit less comprehensively. Van Ennennaam et al. (2005) determined Green Sturgeon egg development temperatures to be optimal between 57.0 and 63.5° F. Mayfield and Cech (2004) determined optimal temperatures for larval development to be between 59.0 and 66.2°F. Temperatures recorded at RBDD during larval capture periods averaged 58.3°F and were generally

within sub-optimal (lower end) to optimal ranges (Table 9f). A weak negative relationship between Green Sturgeon CPUV and water temperatures was detected in our analysis indicating greater capture rates at lower water temperatures (Figure 24d). The slightly sub-optimal temperatures might result in larvae migrating from incubation areas prematurely. Conversely, the optimal thermal environment of the lab-based migration data from Kynard et al. (2005) resulted in very similar migration timing between the lab and larval captures in rotary traps in terms of days post hatch (Poytress et al. 2013). Sacramento River Green Sturgeon larvae appear to be following their natural life-history migration patterns as opposed to being coerced from their incubation areas due to sub-optimal water temperatures at RBDD. This may not be true for larvae migrating some 20 miles upstream where the effects of temperature management may have a more pronounced negative effect on Green Sturgeon larvae (Poytress et al. 2013). Temperature management for Chinook may also have the indirect negative effect of redirecting the spawning habitat of Green Sturgeon adults by 20 river miles. A habitat comparison study on the relative value of the upper 20 river miles of the Sacramento River versus 20 lower river miles of habitat currently benefitting Green Sturgeon adult spawners and eggs from temperature management efforts should be conducted.

River Discharge, Turbidity, and Juvenile Fish Dynamics.—Volkhardt et al. (2007) stated that “flow” (i.e., discharge) was a dominant factor in juvenile trapping operations. Trapping efficiency and migration rates are affected by flow and the RBDD rotary trap passage data reflect these statements well. Exploratory plots demonstrating fry (Appendix 2, Figures A1-A11) and pre-smolt/smolt winter Chinook passage (Appendix 2, Figures A12-A23) were produced to illustrate the effects of environmental variables on fish migration. Turbidity was plotted, but not included in the final plots presented as the effects could not be deciphered from discharge at the daily scale of analyses.

The effects of river discharge on turbidity and resultant fish passage are complex in the Upper Sacramento River where ocean and stream-type Chinook of various size-classes (i.e., runs, life stages and ages) migrate daily throughout the year. Decreases in discharge in the Shasta/Keswick dam regulated Sacramento River, typical of late summer to early winter periods, appear to coincide with relatively clear water conditions and low turbidity (e.g., ~ 1.5 NTU) at RBDD. Fall or early winter freshets and winter rain-driven storm events result in highly variable increases in discharge levels and turbidity measures in terms of the magnitude and duration depending upon the source(s) of run-off.

A course scale analyses of fish passage and river discharge and turbidity measurements during storm events typically indicates a pattern that fish passage increases with simultaneous increases in both variables. Inspection of Chinook passage on a daily time step typically demonstrate a reduction in fish passage a day prior to a storm or rain-event during periods of stable river discharge. As storms produced increases in run-off or discharge from tributary inputs outside of the Shasta/Keswick

dam complex, mean daily turbidity typically increased and fish passage began to increase. When storm related increases in discharge diminished, turbidity diminished, but Chinook passage often increased greatly for 24-72 hours after the peak flow event.

One problem confounding the results of storm and fish passage observations and analyses was that sampling during large storm run-off/discharge events often ceased due to safety concerns, concerns for fish impacts or simply due to the inability to sample the river when woody debris stop rotary traps from operating properly. In some years, storm events resulted in discharge levels too great to sample effectively or damaged traps which resulted in numerous days or weeks un-sampled afterwards. The results are typically negative bias in passage estimates if days following the peak discharge or concurrent turbidity events are un-sampled. Alternately, the direction of bias can be positive depending on time of year, interpolation methods, sample effort during extended storm periods, or fish developmental stage.

A fine scale, hourly analysis of fish passage, river discharge and turbidity during storm events indicated a more intricate relationship between the variables. As a comparison, two separate storm events (December 2005 and November 2012) were analyzed (Figure 27a/b). In 2005, 24-hour samples were conducted prior to and after the peak flow period which was missed due to an inability to sample the river as it more than quintupled in discharge (i.e., 7,000 CFS to ~35,000 CFS). During this storm event, sampling was conducted following the peak of river discharge as river stage decreased, but while turbidity continued to peak (Figure 27a). The planned 24-hour sample had to be cut short due to the huge influx of fry and smolt passage that occurred during the turbidity increase (i.e., from 10's to 1,000's per hour) and the need to reduce the potential impact to listed winter Chinook.

During a November 2012 storm event, a different strategy was employed to collect data more effectively throughout the storm period. For this event, we randomly sampled portions of the day and night in an attempt to manage the huge influx of fish anticipated to occur during the year's first storm event. Between 11/17/12 and 11/23/12, the project was able to collect 7-randomly selected samples that occurred throughout the first major river stage increase (Figure 27b). Samples were collected during increases and decreases in river stage. Samples were also collected prior to, during, and following a substantial increase in turbidity that lagged behind the initial stage increase by nearly 12 hours (Figure 27b). Fry and pre-smolt/smolt Chinook and juvenile lamprey fish passage increased exponentially. The peak period of fish capture occurred following the peak in river stage and during the increase and peak periods of turbidity measurements taken at RBDD. Capture rates subsided in the following days, but then increased greatly during the night-time period at the beginning of the next stage increase (Figure 27b).

Overall, it appears that flow and turbidity are important drivers for fish passage. The RBDD rotary trap data indicate that increased turbidity often results in greater fish

passage than increases in river discharge or stage alone which often occur as part of water management operations at Shasta Dam. The two variables generally increase sequentially with discharge increases followed by turbidity increases (Figure 27a/b). Fish passage increases often coincide with the increase in turbidity which can often be sampled more effectively than increases in river discharge and may result in positive bias of juvenile fish passage estimates if the peak turbidity event is sampled compared to the peak flow event.

The importance of the first storm event of the fall or winter period cannot be overstated. Chinook smolt and juvenile lamprey passage increased exponentially and fry passage can be significant if first storms occur as fall Chinook begin to emerge. Fishery and water operations managers should be aware of the importance of the first Sacramento River stage increases following the summer and fall Sacramento River flow regulation period. The redistribution of winter and over-summering fall and late-fall Chinook smolts, or more generally, all anadromous juvenile fish⁹ migrating from the Upper Sacramento River to the lower river and Sacramento San-Joaquin Delta with the first storm events of each water year should be incorporated into management plans for Delta operations.

Moon Illuminosity and Juvenile Fish Dynamics.—As noted in Hubert and Fabrizio (2007), species and life stages within species exhibit differing behaviors and therefore catchability in response to light levels. Gaines and Martin (2002) determined that Chinook passage occurred primarily during nocturnal periods except when turbidity levels and discharge increased with storm events. Further analyses of the effects of moon phase and ambient light levels in a statistical framework may be warranted for Chinook salmon as trends were detected based on observations. Rotary trap passage data indicated winter Chinook fry exhibit decreased nocturnal passage levels during and around the full moon phase in the fall (Appendix 3, Figures A1-A11). Pre-smolt/smolt winter Chinook appeared less influenced by night-time light levels and much more influenced by changes in discharge levels (Appendix 3, Figures A12-A23). A similar phenomenon was noted by Reimers (1971) for juvenile fall Chinook in Edson Creek, Oregon. Alternately, more data concerning night time cloud cover may further clarify the behavior associated with moon illuminosity as pre-smolt/smolt were more likely to encounter unclear night time weather between late October and December each year.

Spring, fall and late-fall Chinook fry exhibited varying degrees of decreased passage during full moon periods, albeit storms and related hydrologic influx dominated peak migration periods. *O. mykiss* relative abundance was not analyzed with respect to moon illuminosity. Lamprey CPUV regression analyses indicated a significant, but nearly imperceptible relationship (Figure 25a) likely due to the fact that lamprey are captured throughout the year under nearly all conditions. Green Sturgeon regression analysis

⁹ Juvenile Green Sturgeon have been captured sporadically during the first flow events along with large numbers of Pacific Lamprey juveniles and ammocoetes.

indicated no significant linear relationship between moon illuminosity and relative abundance (Figure 24a). Migration of age-0 Green Sturgeon larvae has been determined to occur during nocturnal hours (Kynard et al. 2005) primarily between 21:00 and 02:00 using D-nets (Poytress et al. 2011) and was presumed to be similar for rotary traps as periodic diel sampling events have not collected sturgeon during daytime sample periods.

Acknowledgments

The CALFED program and later California Bay-Delta Authority Ecosystem Restoration Program through a Directed Action of the California Department of Fish and Game (Grant # P0685507) provided funding for this project between 2002 and 2009. The U.S Bureau of Reclamation provided additional financial support during periods of fiscal insecurity by the State of California and for years 2010 through 2013 (Interagency Agreement No. R10PG20172). Numerous individuals over the years helped with development and implementation of this project including, but not limited to, Mark Belter, Brian Bissell, Oliver "Towns" Burgess, Michelle Casto-Yerty, David Colby, Nick Demetris, Melissa Dragan, Charles Elliott, Jessica Fischer, Sierra Franks, Phillip Gaines, Jerrad Goodell, Mike Gorman, Andrew Gross, Eric Grosvenor, Aime Gucker, Jeremy Haley, James Hoang, Matt Holt, Jess Johnson, Doug Killam, Tammy Knecht, Edwin Martin, Ryan Mertz, Josh Olsen, Erich Parizek, Andy Popper, Chad Praetorius, Adam Reimer, Ben Reining, Peter Roginski, Marie Schrecengost, Geoffrey Schroeder, Zach Sigler, Jennessy Toribio, David Trachtenbarg, Greg True, Charmayne Walker and Kara Yetifshfksy. Elizabeth Cook, Billie Jo DeMaagd, Valerie and Robert Emge, Tom Kisanuki, Christine Olsen, Harry Ostapenko, Deon Pollett, Jim Smith, Angela Taylor, and Keenan True provided programmatic support. We sincerely appreciate the support provided by the U.S. Bureau of Reclamation and former Red Bluff Diversion Dam staff, especially Jerry Sears and Paul Freeman.

Table 2. Summary of mark-recapture experiments conducted by RBDD rotary trap project between 2002 and 2013. Summaries include trap effort data, fish release and recapture group sizes (N) and mean fork lengths (FL), percentage of river discharge sampled (%Q) and estimated trap efficiency for each trial (%TE). Model data below each trial period indicate dates model was employed, total trials incorporated into model and linear regression values of slope, intercept, p -value and coefficient of determination.

Figures

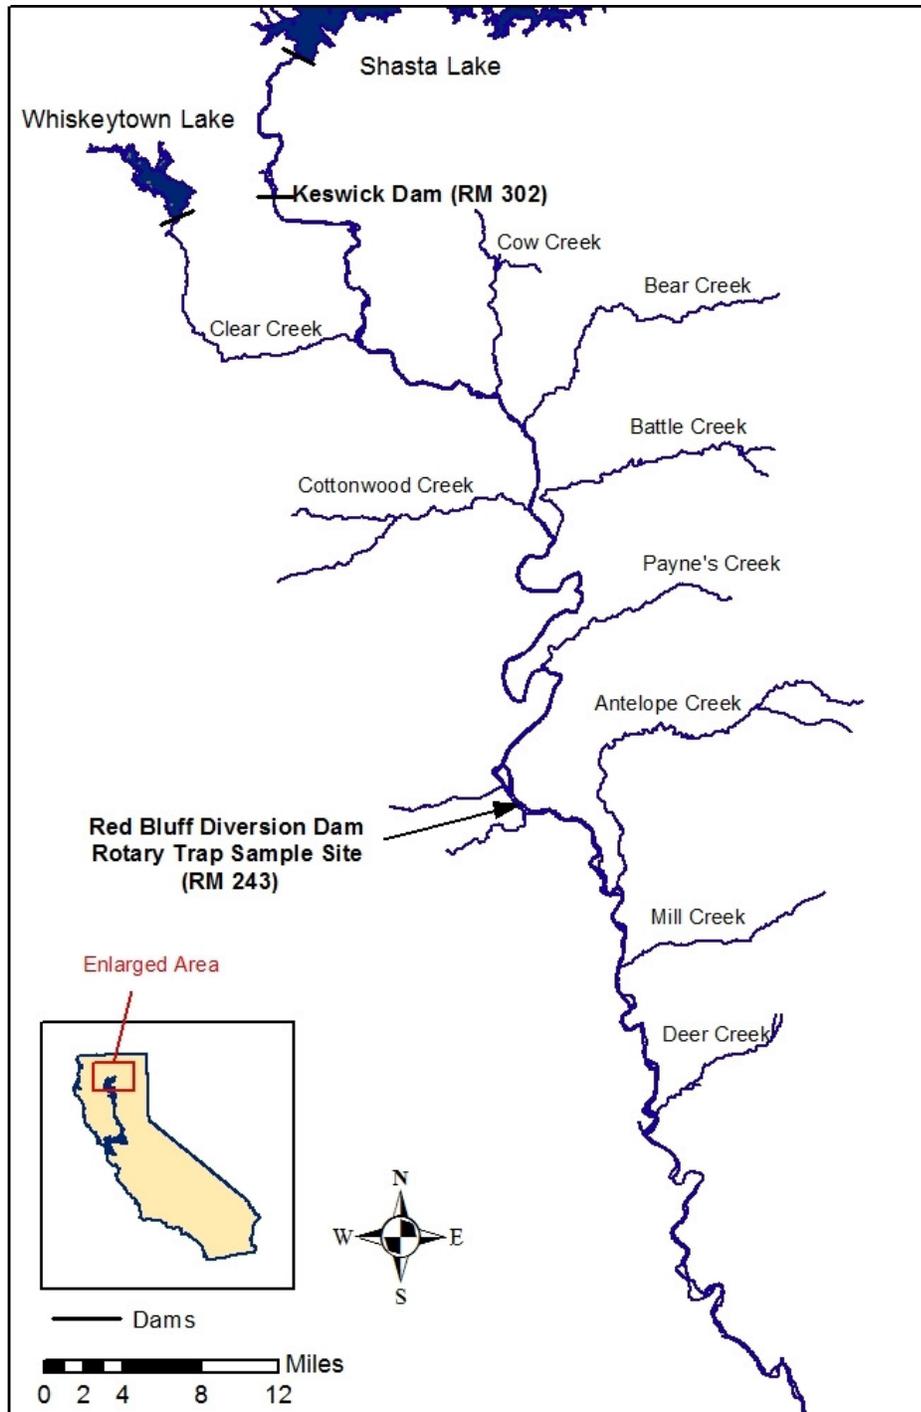

Figure 1. Location of Red Bluff Diversion Dam rotary trap sample site on the Sacramento River, California (RM 243).

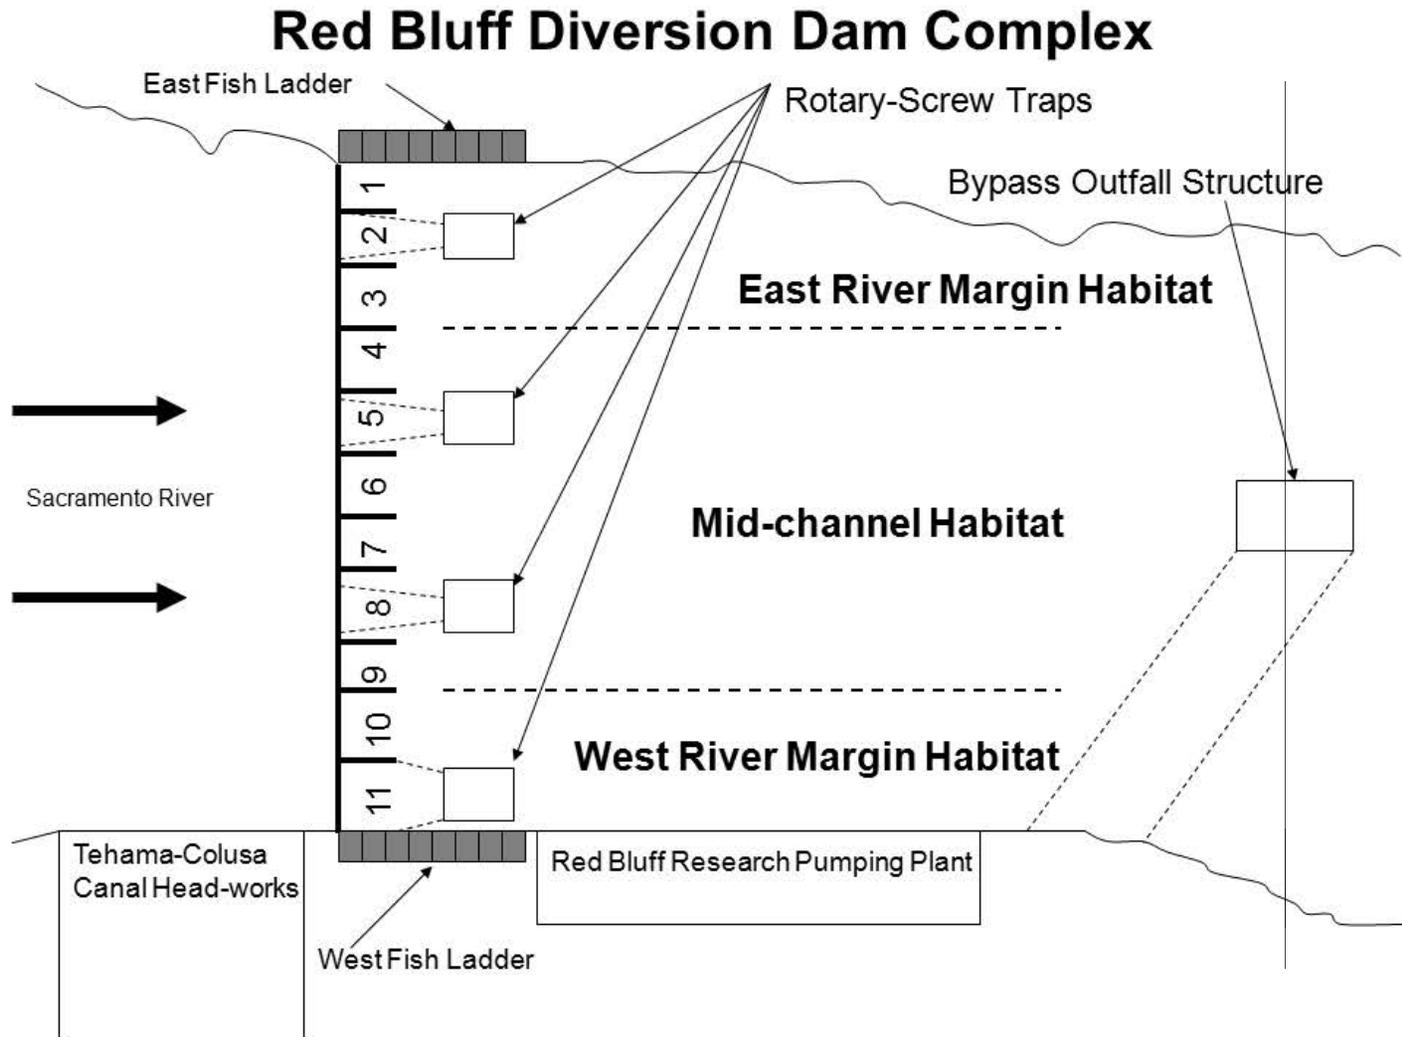

Figure 2. Rotary-screw trap sampling transect at Red Bluff Diversion Dam Site (RM 243) on the Sacramento River, California.

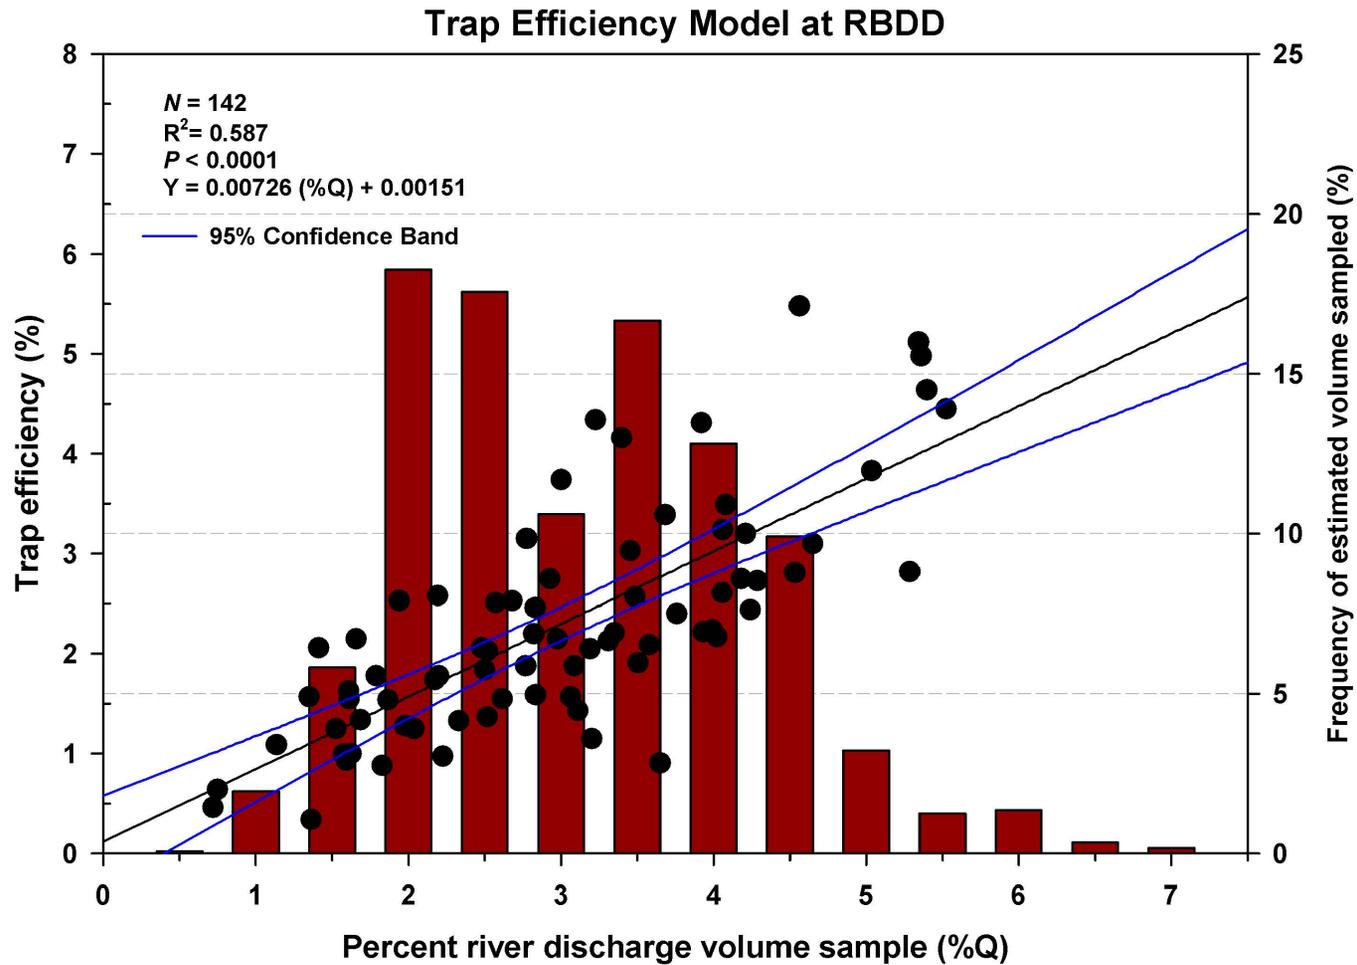

Figure 3. Trap efficiency model for combined 8-ft diameter rotary traps at Red Bluff Diversion Dam (RM 243), Sacramento River, CA. Mark-recapture trials ($N = 142$) were used to estimate trap efficiencies. Histogram indicates percentage of time traps sampled various levels (half percent bins) of river discharge between April 2002 and September 2013.

BY 2002-2012 Fall Chinook Capture Fork Length Summaries

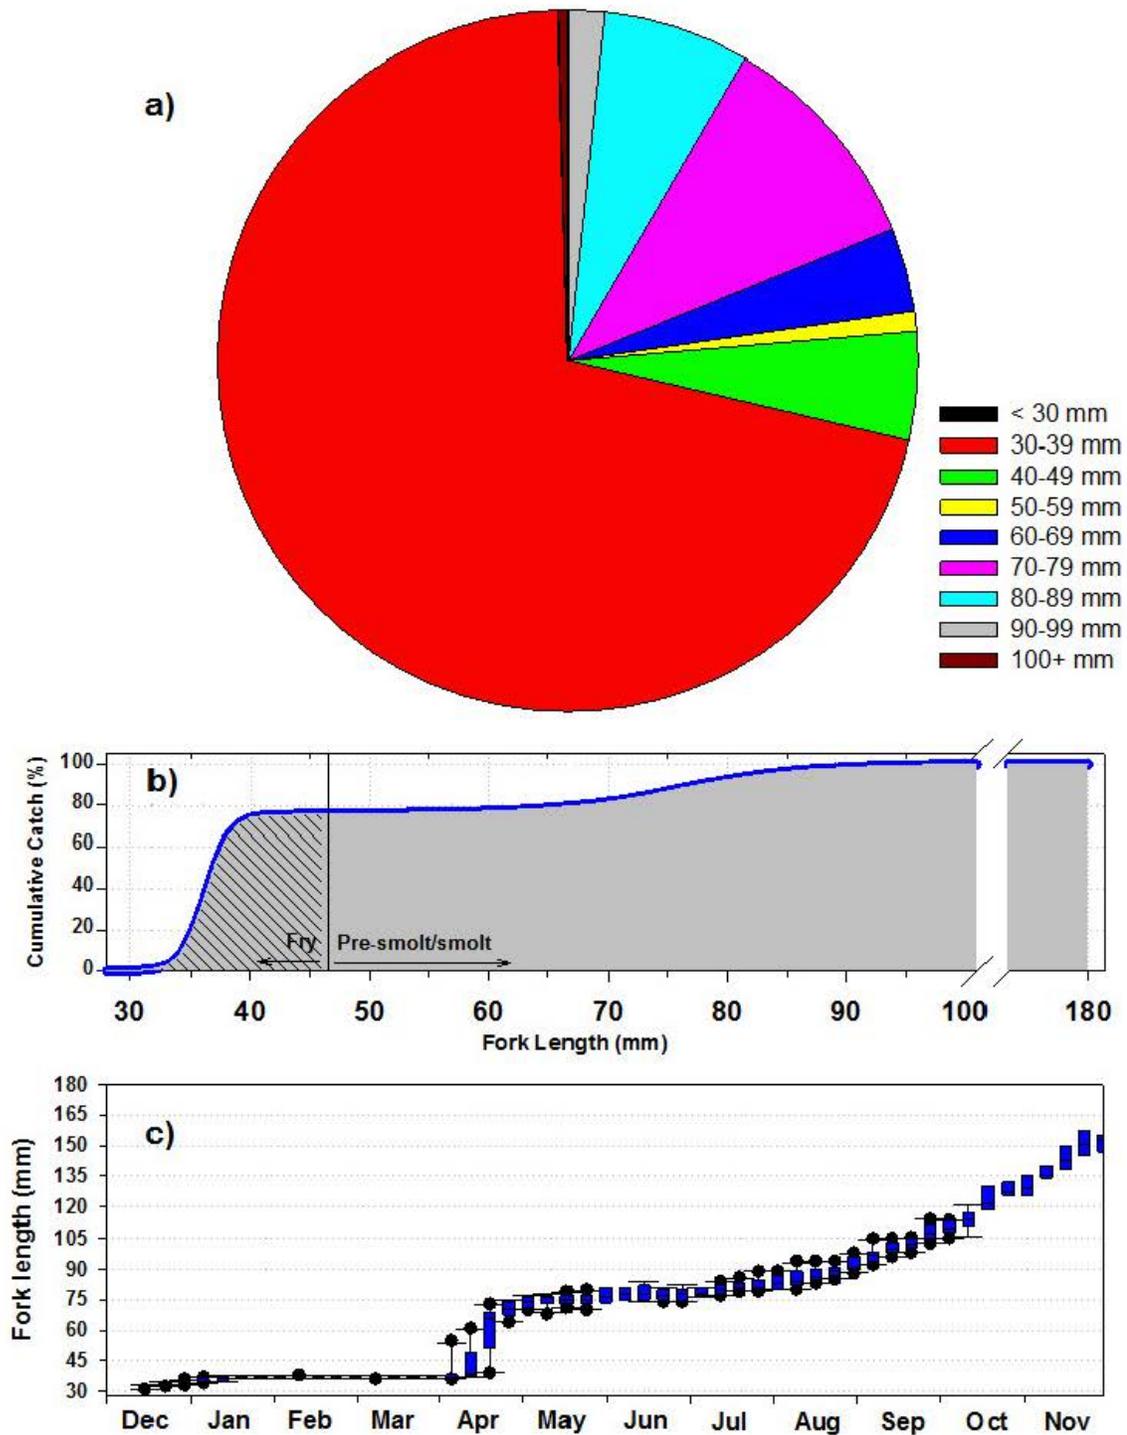

Figure 4. Fall Chinook fork length (a) capture proportions, (b) cumulative capture size curve, and (c) average weekly median boxplots for fall Chinook sampled by rotary traps at RBDD between December 2002 and September 2013.

BY 2002- 2012 Late-Fall Chinook Capture Fork Length Summaries

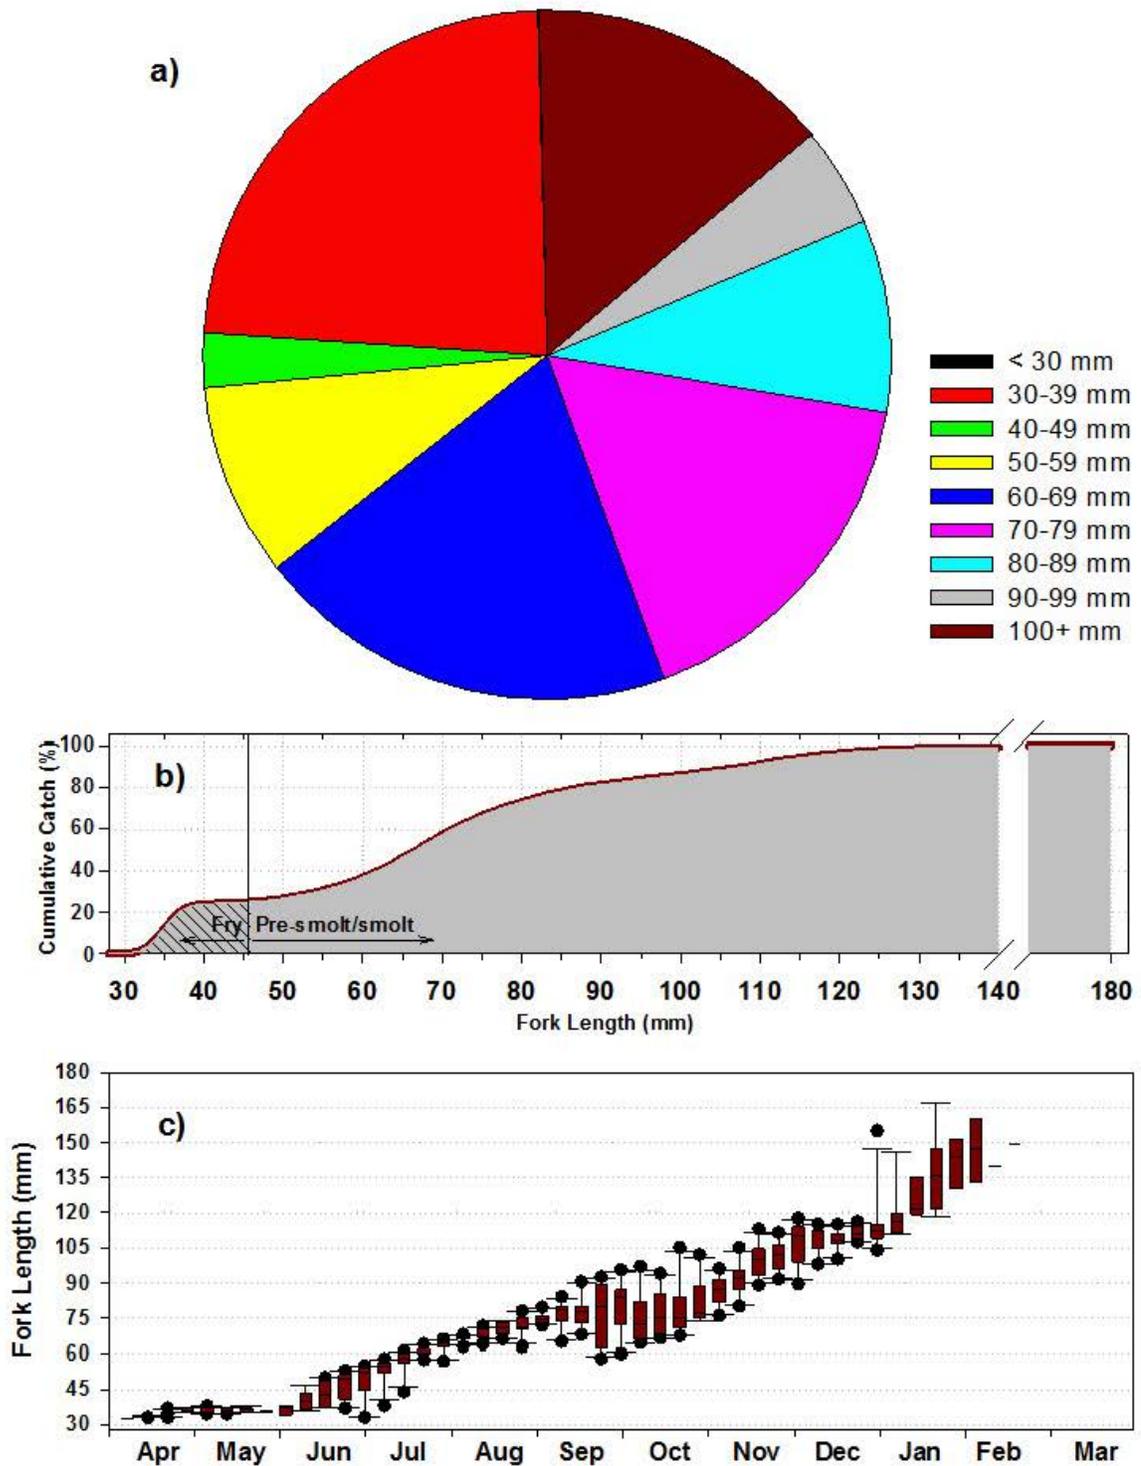

Figure 5. Late-fall Chinook fork length (a) capture proportions, (b) cumulative capture size curve, and (c) average weekly median boxplots for late-fall Chinook sampled by rotary traps at RBDD between April 2002 and March 2013.

BY 2002-2012 Winter Chinook Capture Fork Length Summaries

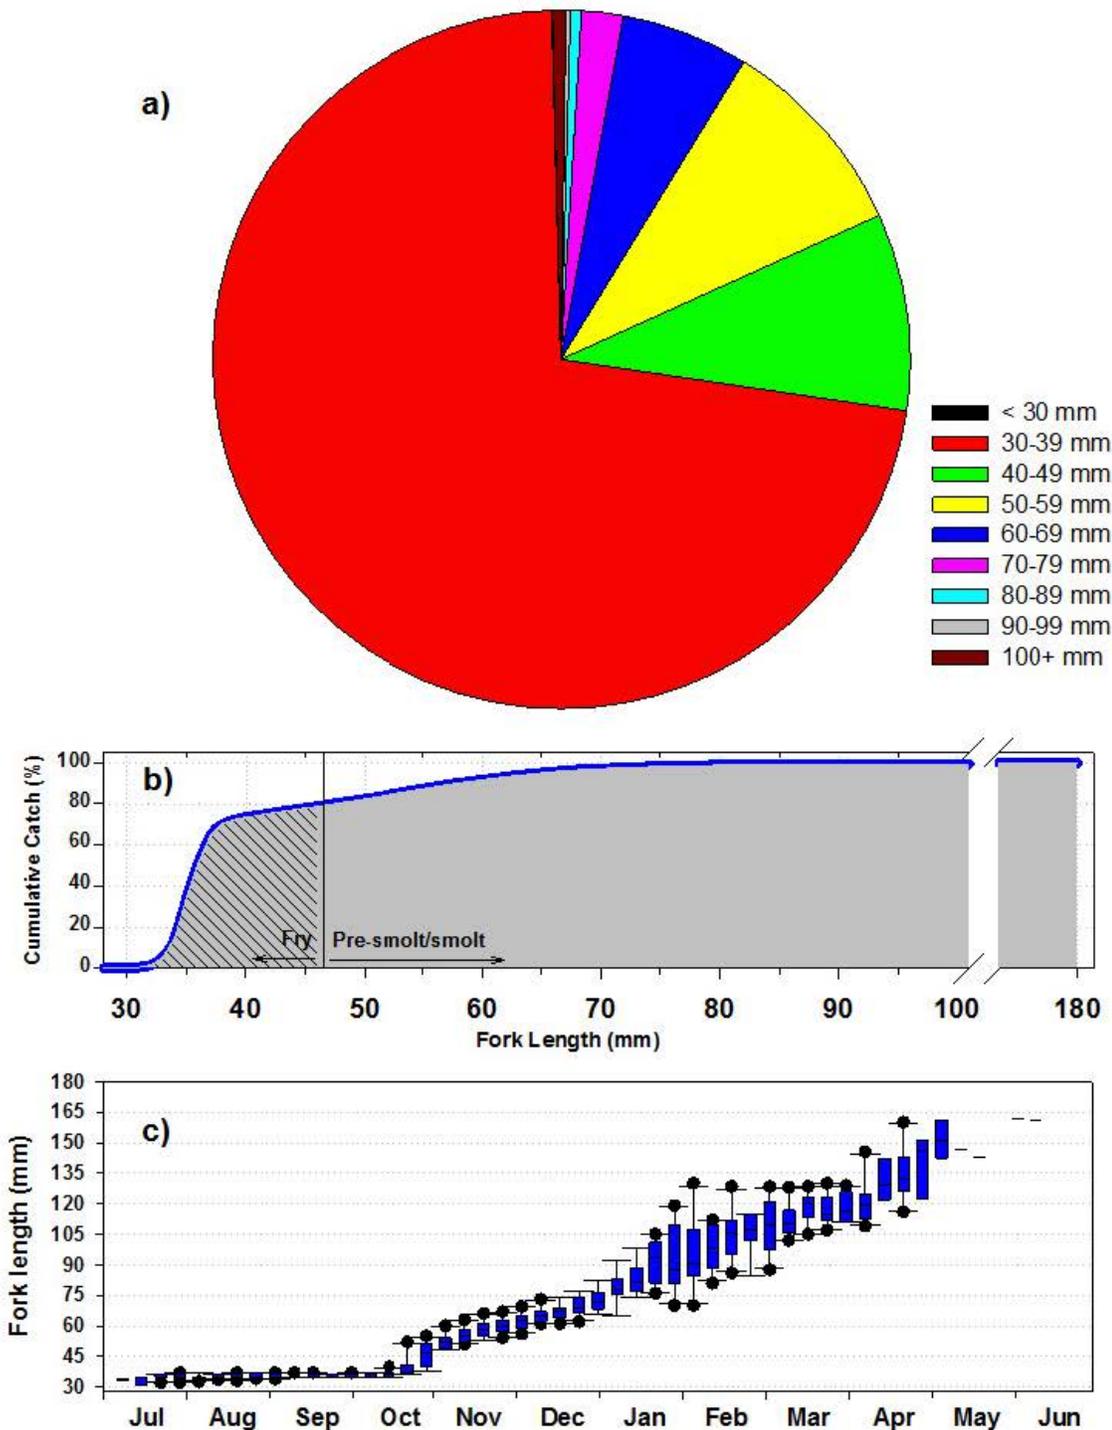

Figure 6. Winter Chinook fork length (a) capture proportions, (b) cumulative capture size curve, and (c) average weekly median boxplots for winter Chinook sampled by rotary traps at RBDD between July 2002 and June 2013.

BY 2002- 2012 Spring Chinook Capture Fork Length Summaries

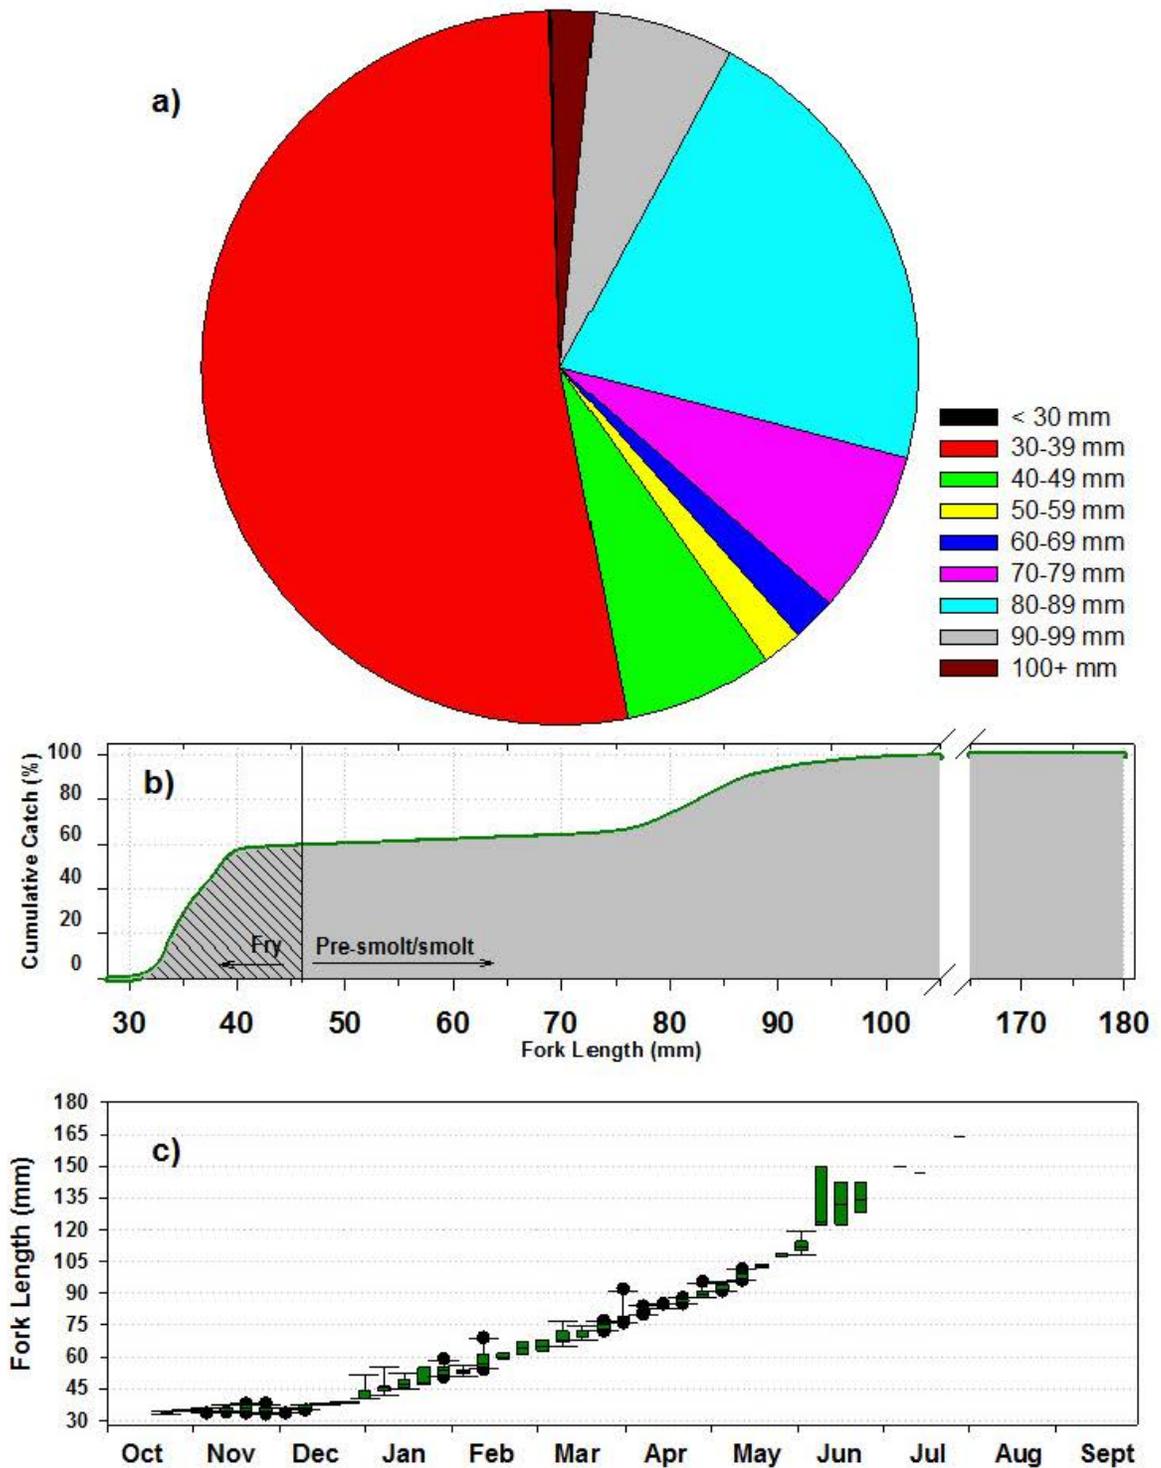

Figure 7. Spring Chinook fork length (a) capture proportions, (b) cumulative capture size curve, and (c) average weekly median boxplots for spring Chinook sampled by rotary traps at RBDD between October 2002 and September 2013.

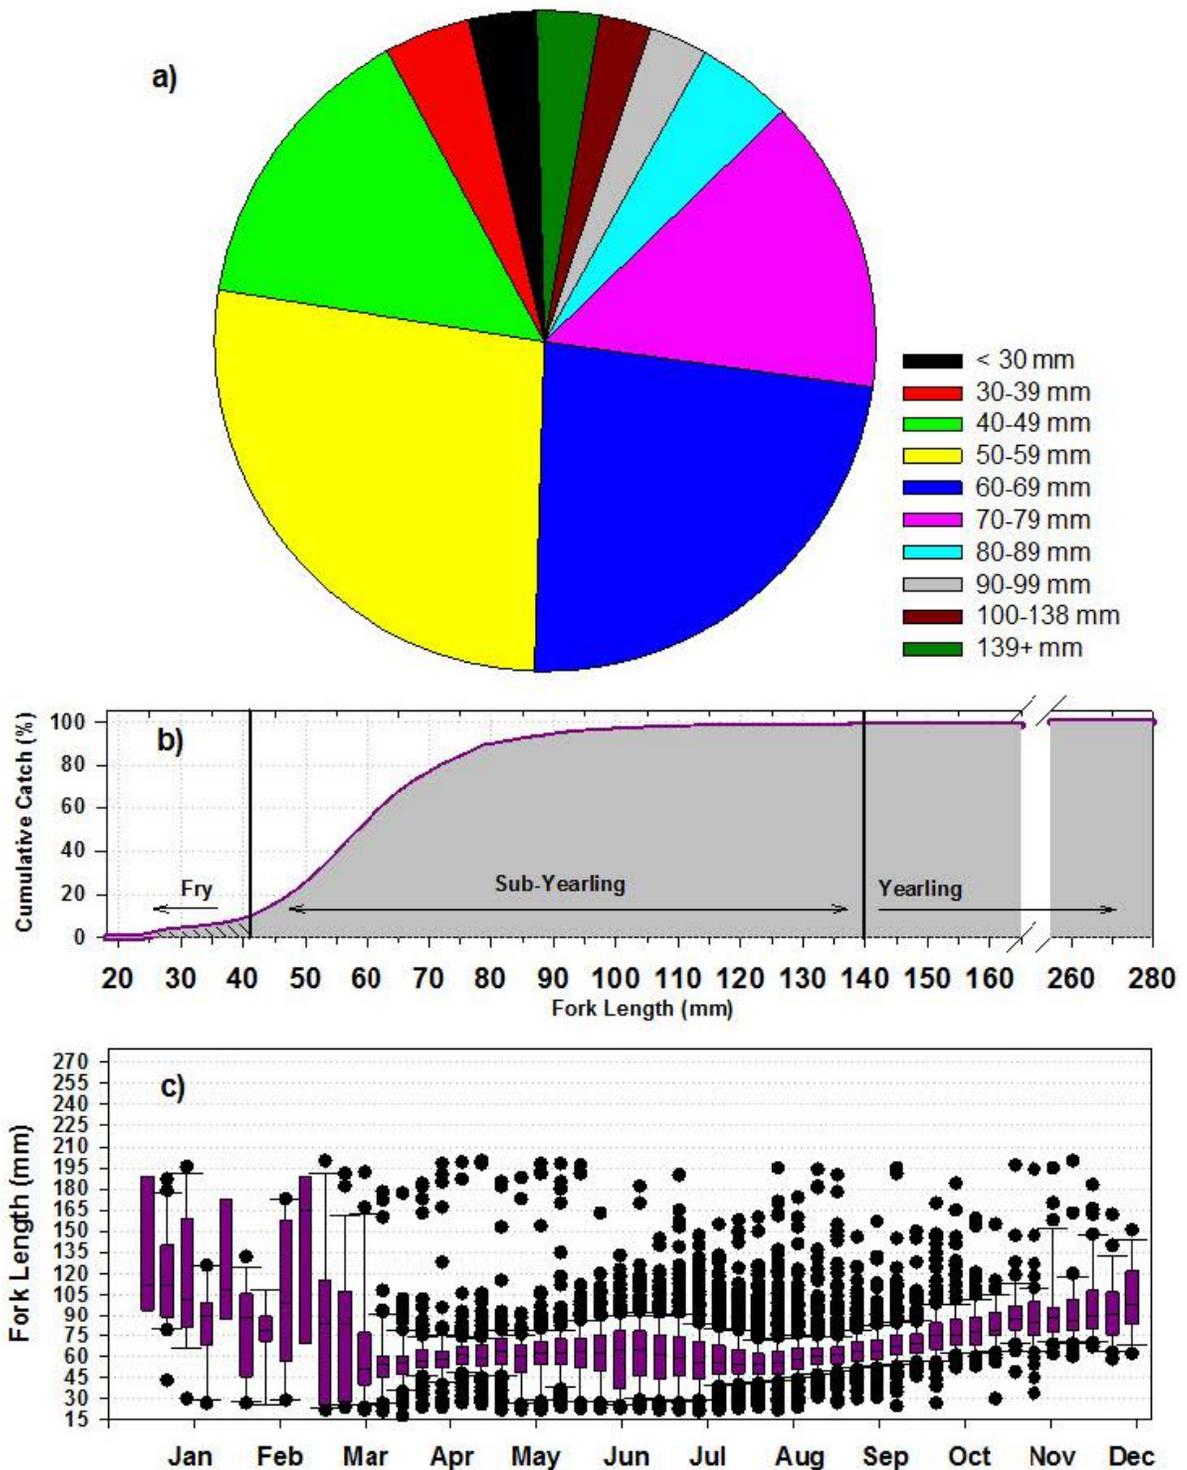

CY 2002-2012 *O. mykiss* Capture Fork Length Summaries

Figure 8. *O. mykiss* fork length (a) capture proportions, (b) cumulative capture size curve, and (c) average weekly median boxplots for *O. mykiss* sampled by rotary traps at RBDD between April 2002 and December 2012.

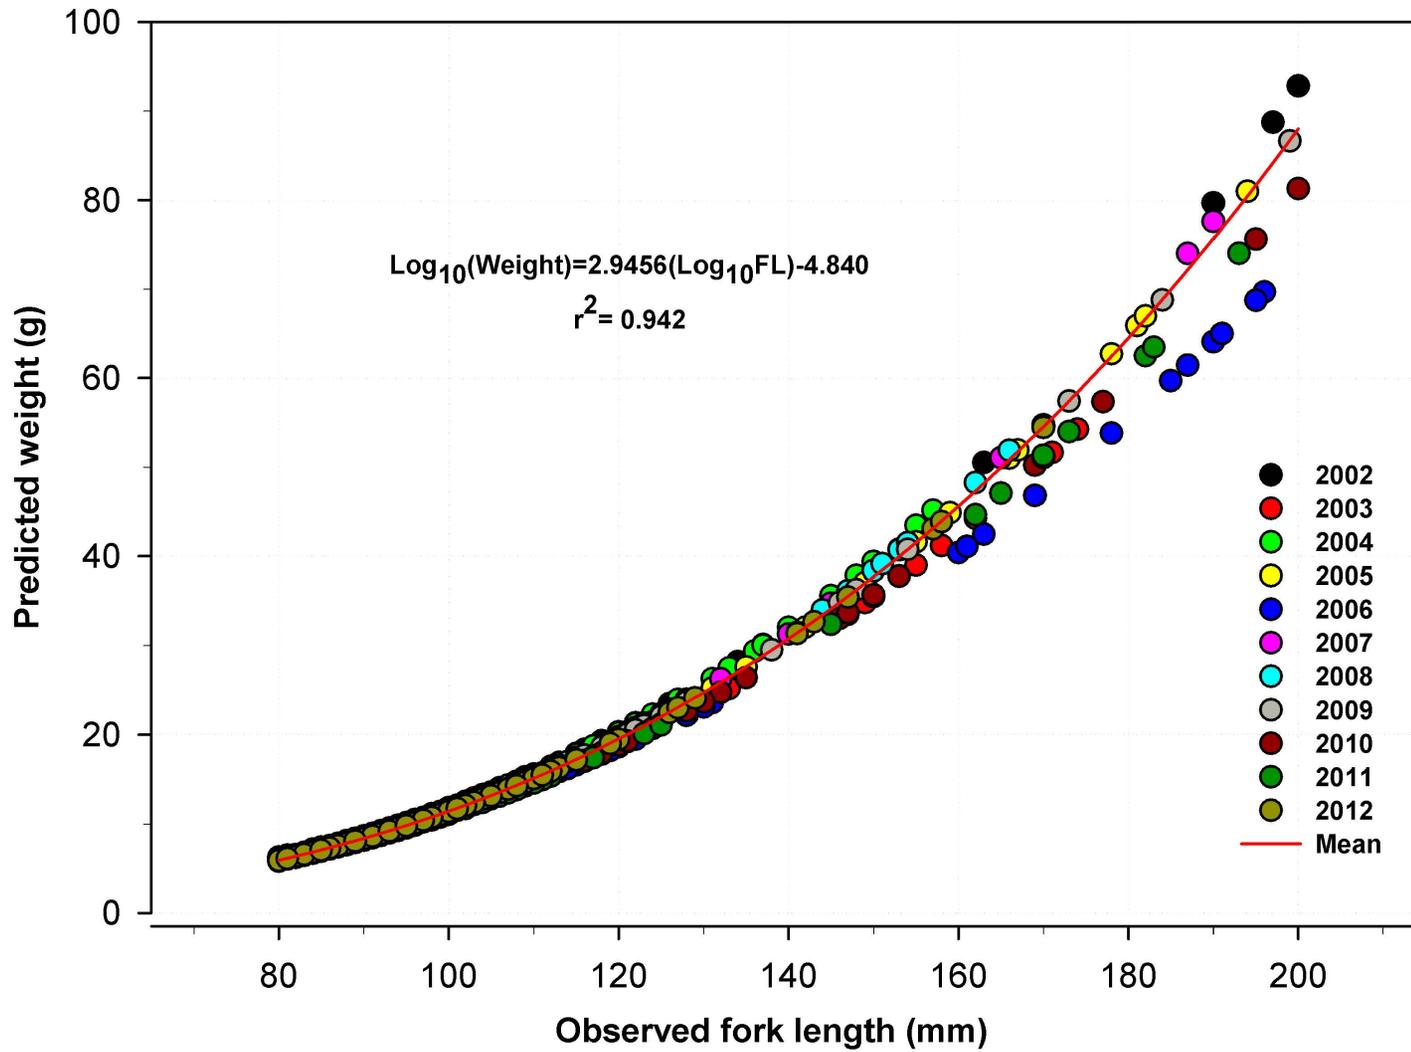

Figure 9. Predicted weight (g) for *O. mykiss* with measured fork lengths (FL) between 80 and 200 mm using annual weight-length regression equation.

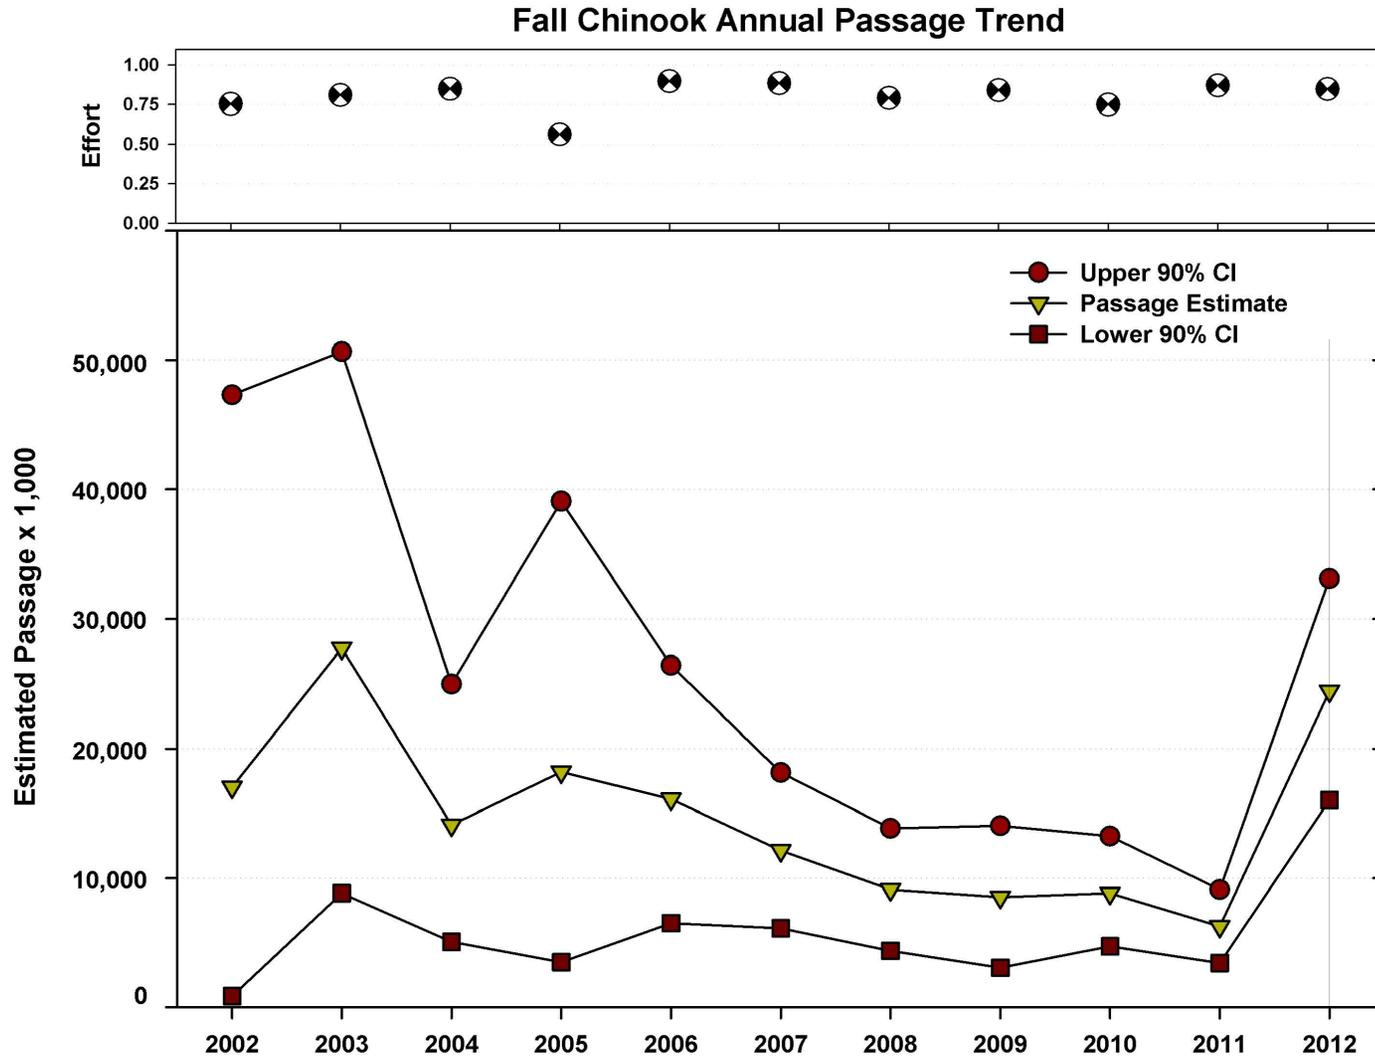

Figure 10. RBDD rotary trap fall Chinook annual sample effort and passage estimates with 90% confidence intervals (CI) for the period December 2002 through September 2013

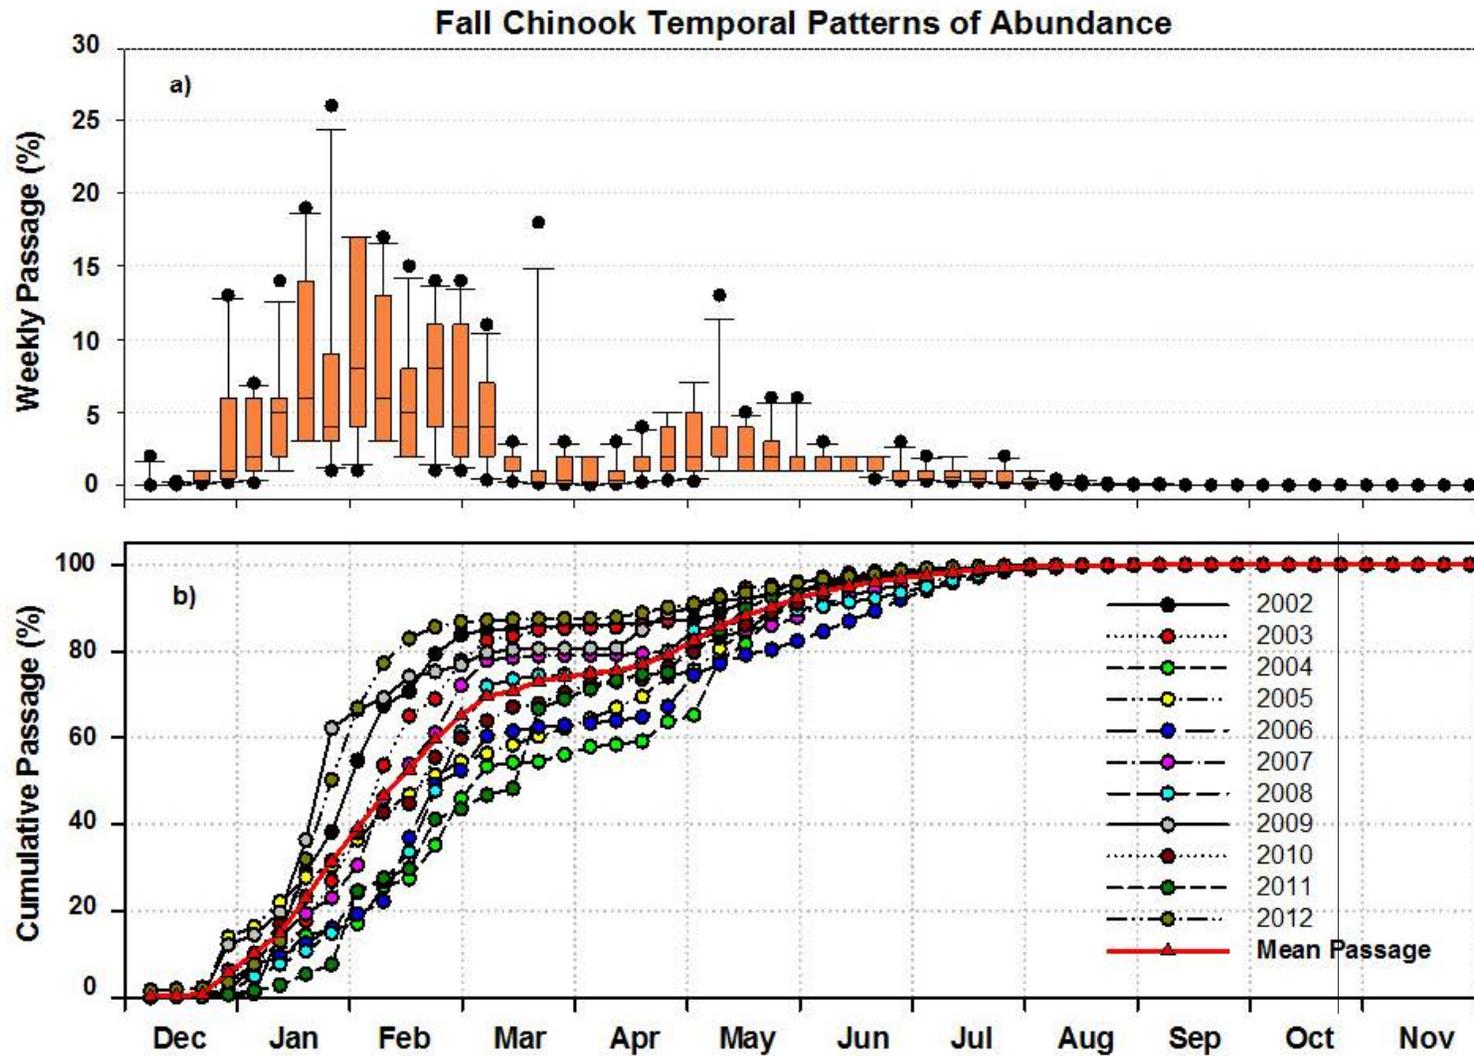

Figure 11. RBDD rotary trap fall Chinook (a) boxplots of weekly passage estimates relative to annual total passage estimates and (b) cumulative weekly passage with 11-year mean passage trend line for the period December 2002 through September 2013.

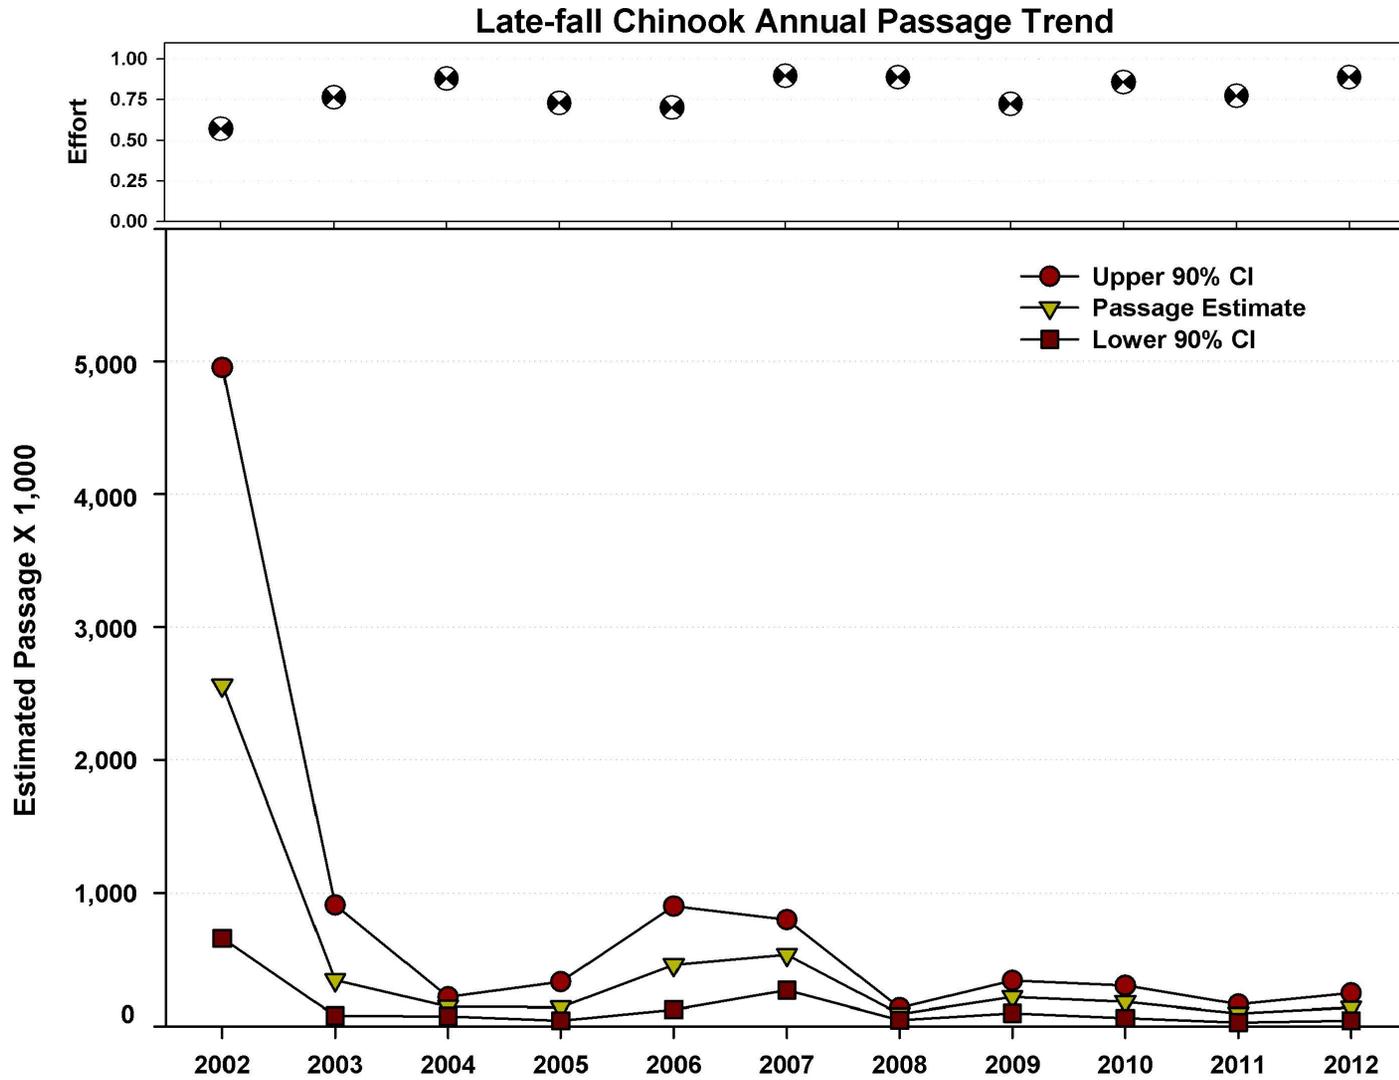

Figure 12. RBDD rotary trap late-fall Chinook annual sample effort and passage estimates with 90% confidence intervals (CI) for the period April 2002 through March 2013.

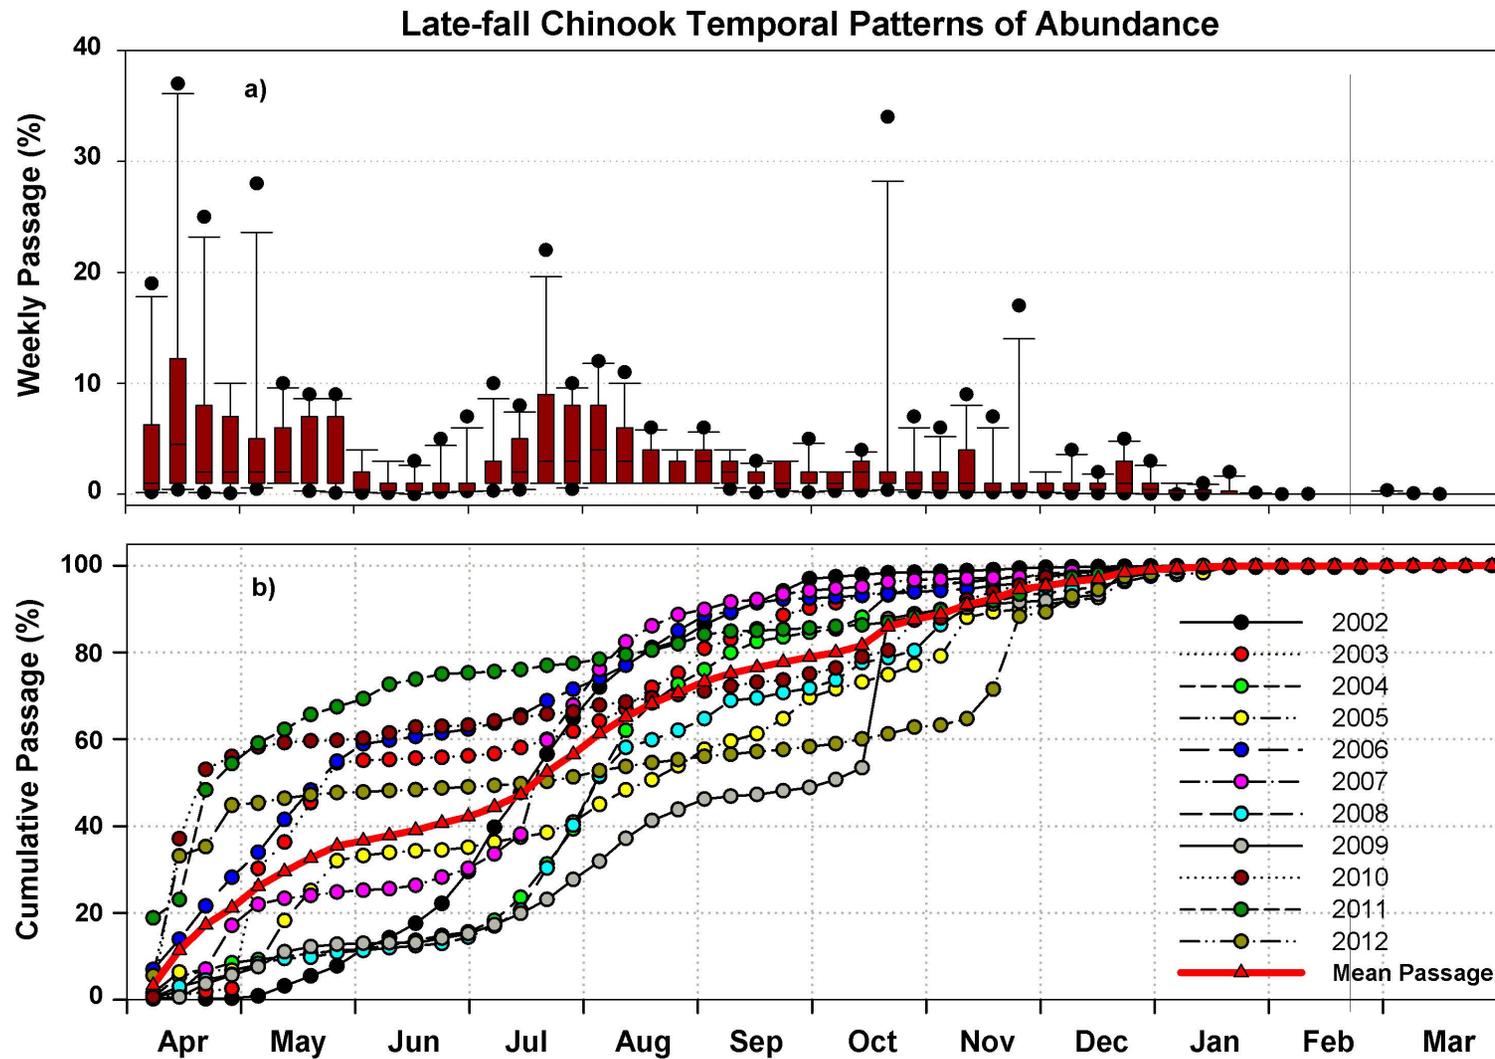

Figure 13. RBDD rotary trap late-fall Chinook (a) boxplots of weekly passage estimates relative to annual total passage estimates and (b) cumulative weekly passage with 11-year mean passage trend line for the period April 2002 through March 2013.

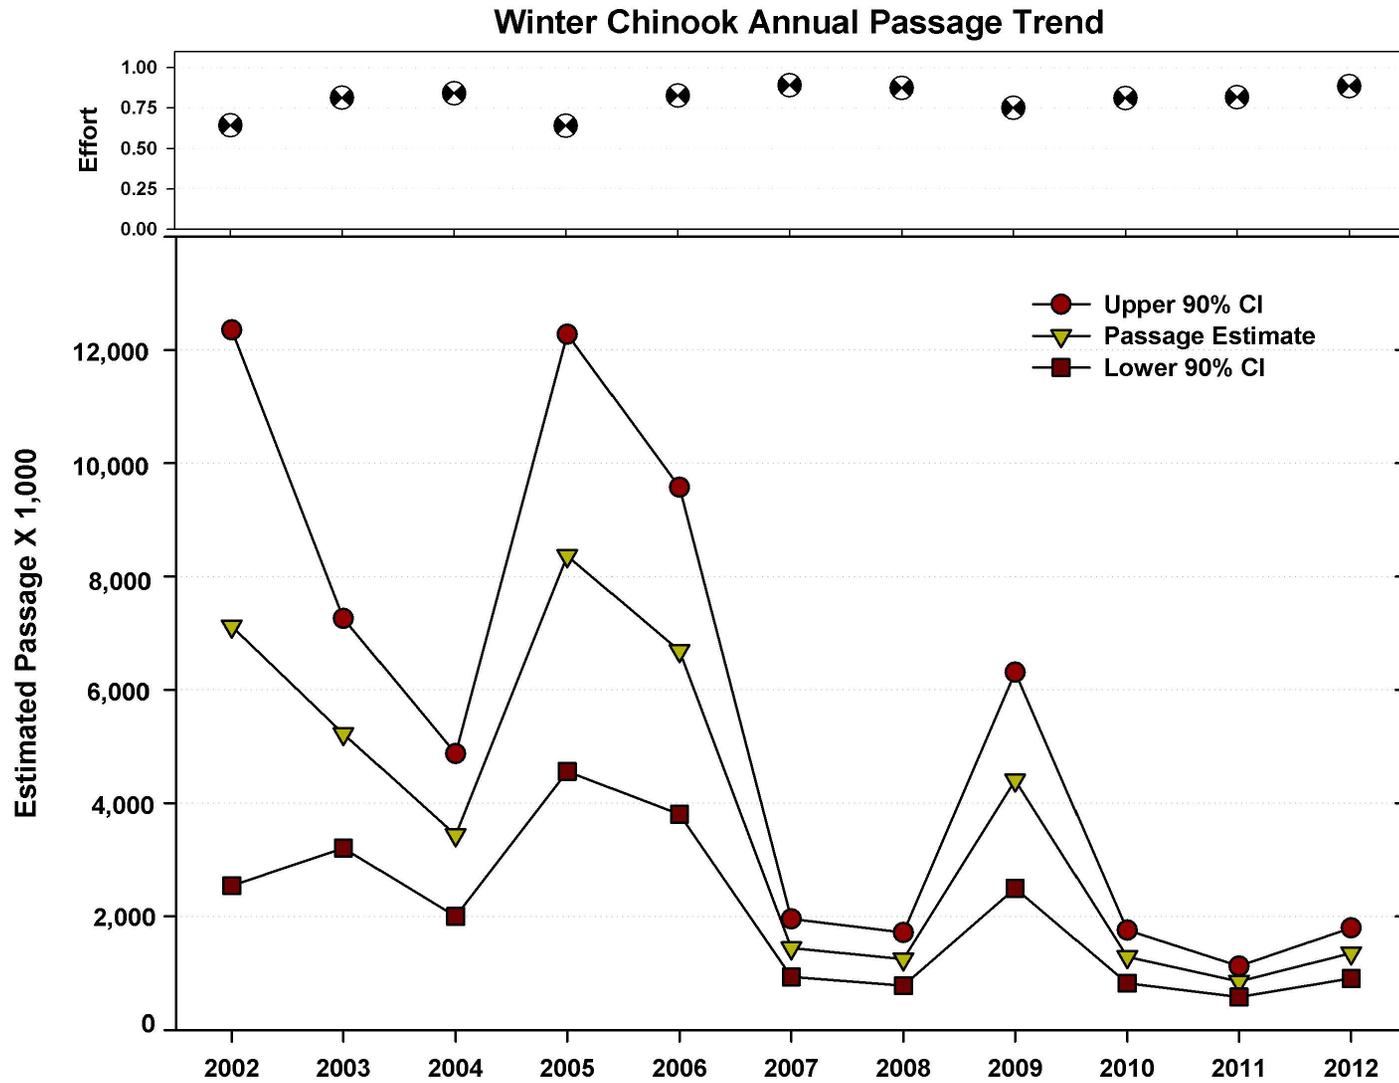

Figure 14. RBDD rotary trap winter Chinook annual sample effort and passage estimates with 90% confidence intervals (CI) for the period July 2002 through June 2013.

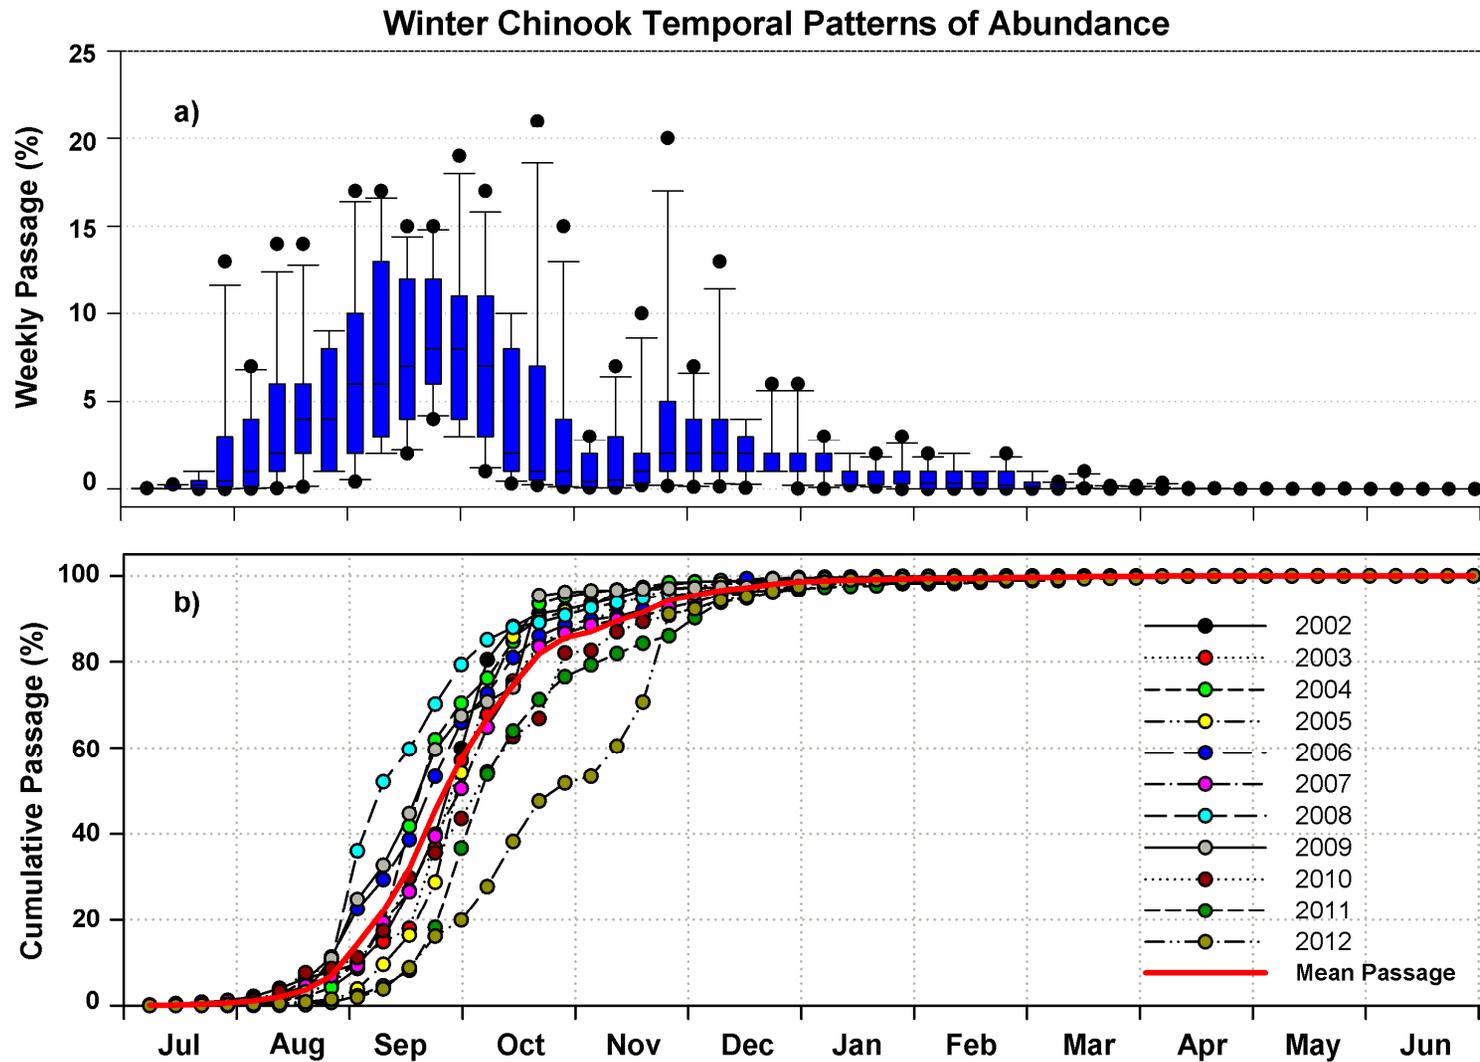

Figure 15. RBDD rotary trap winter Chinook (a) boxplots of weekly passage estimates relative to annual total passage estimates and (b) cumulative weekly passage with 11-year mean passage trend line for the period July 2002 through June 2013.

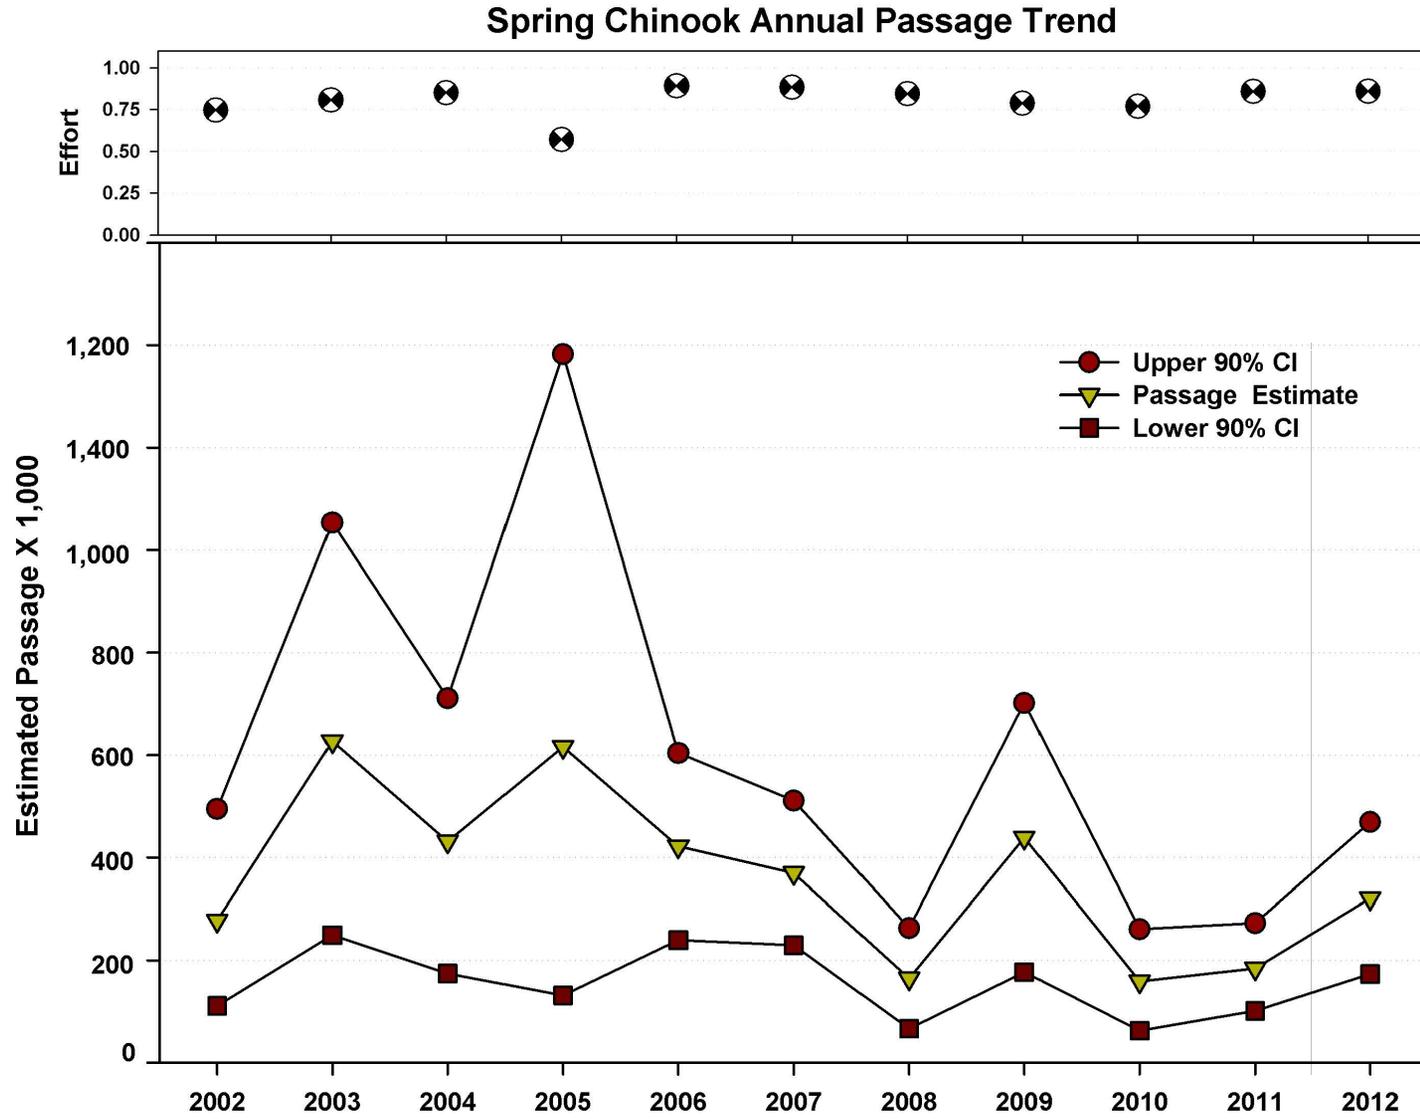

Figure 16. RBDD rotary trap spring Chinook annual sample effort and passage estimates with 90% confidence intervals (CI) for the period October 2002 through September 2013.

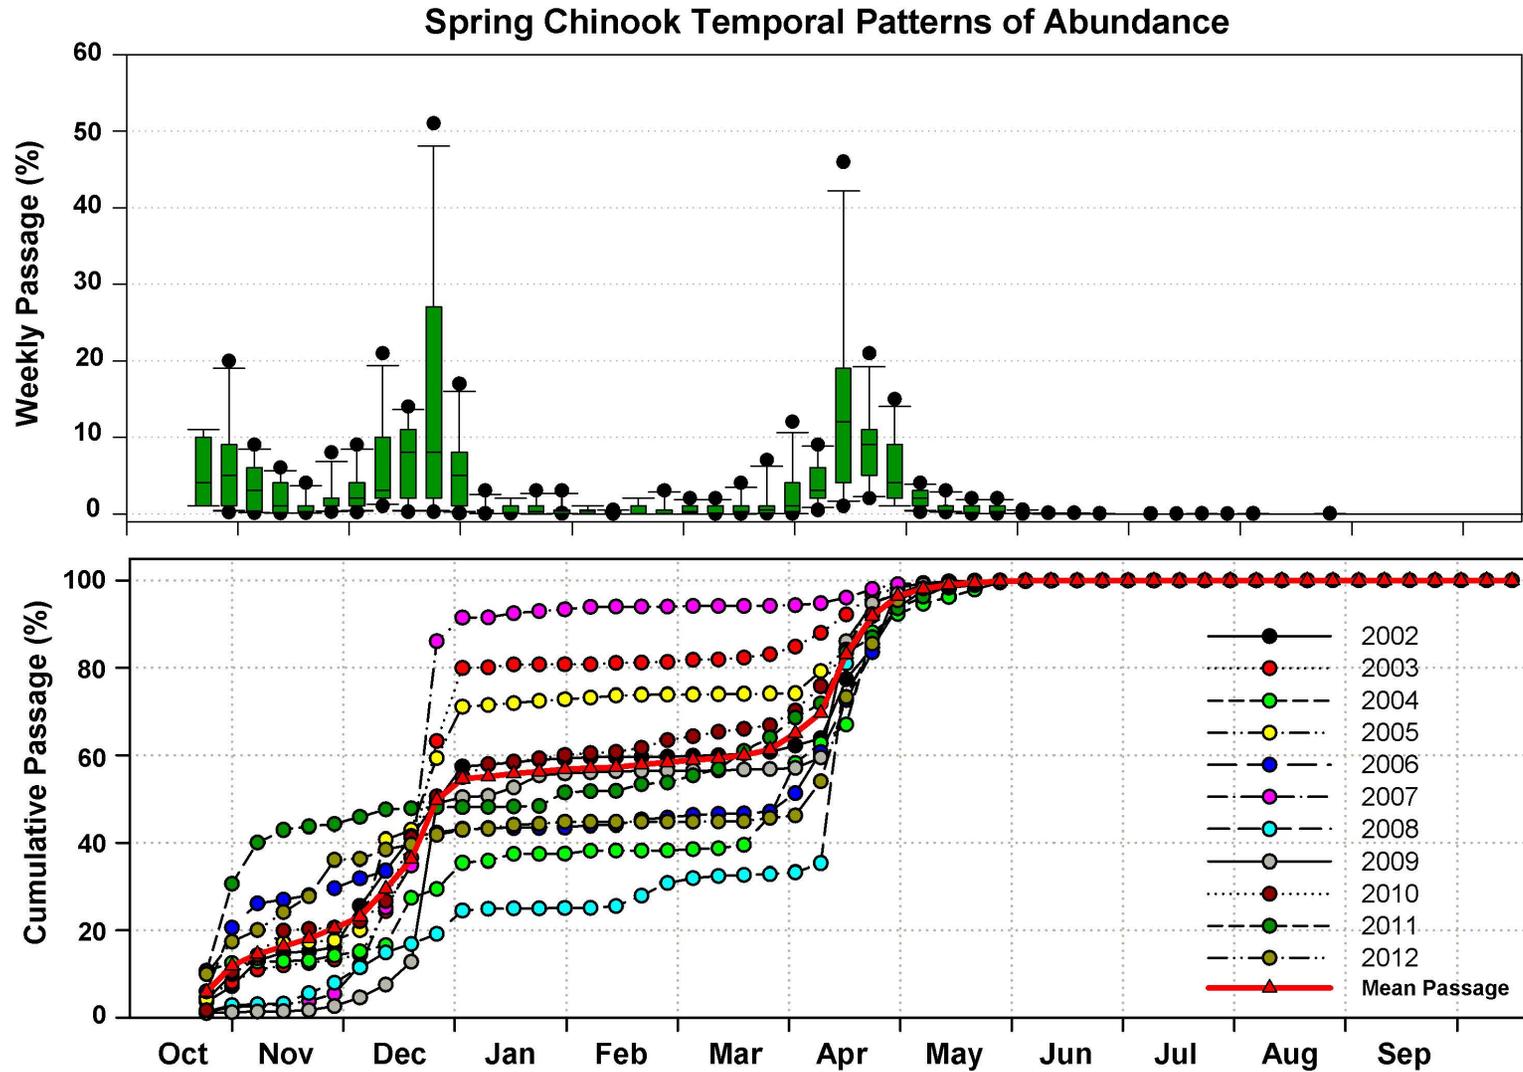

Figure 17. RBDD rotary trap spring Chinook (a) boxplots of weekly passage estimates relative to annual total passage estimates and (b) cumulative weekly passage with 11-year mean passage trend line for the period October 2002 through September 2013.

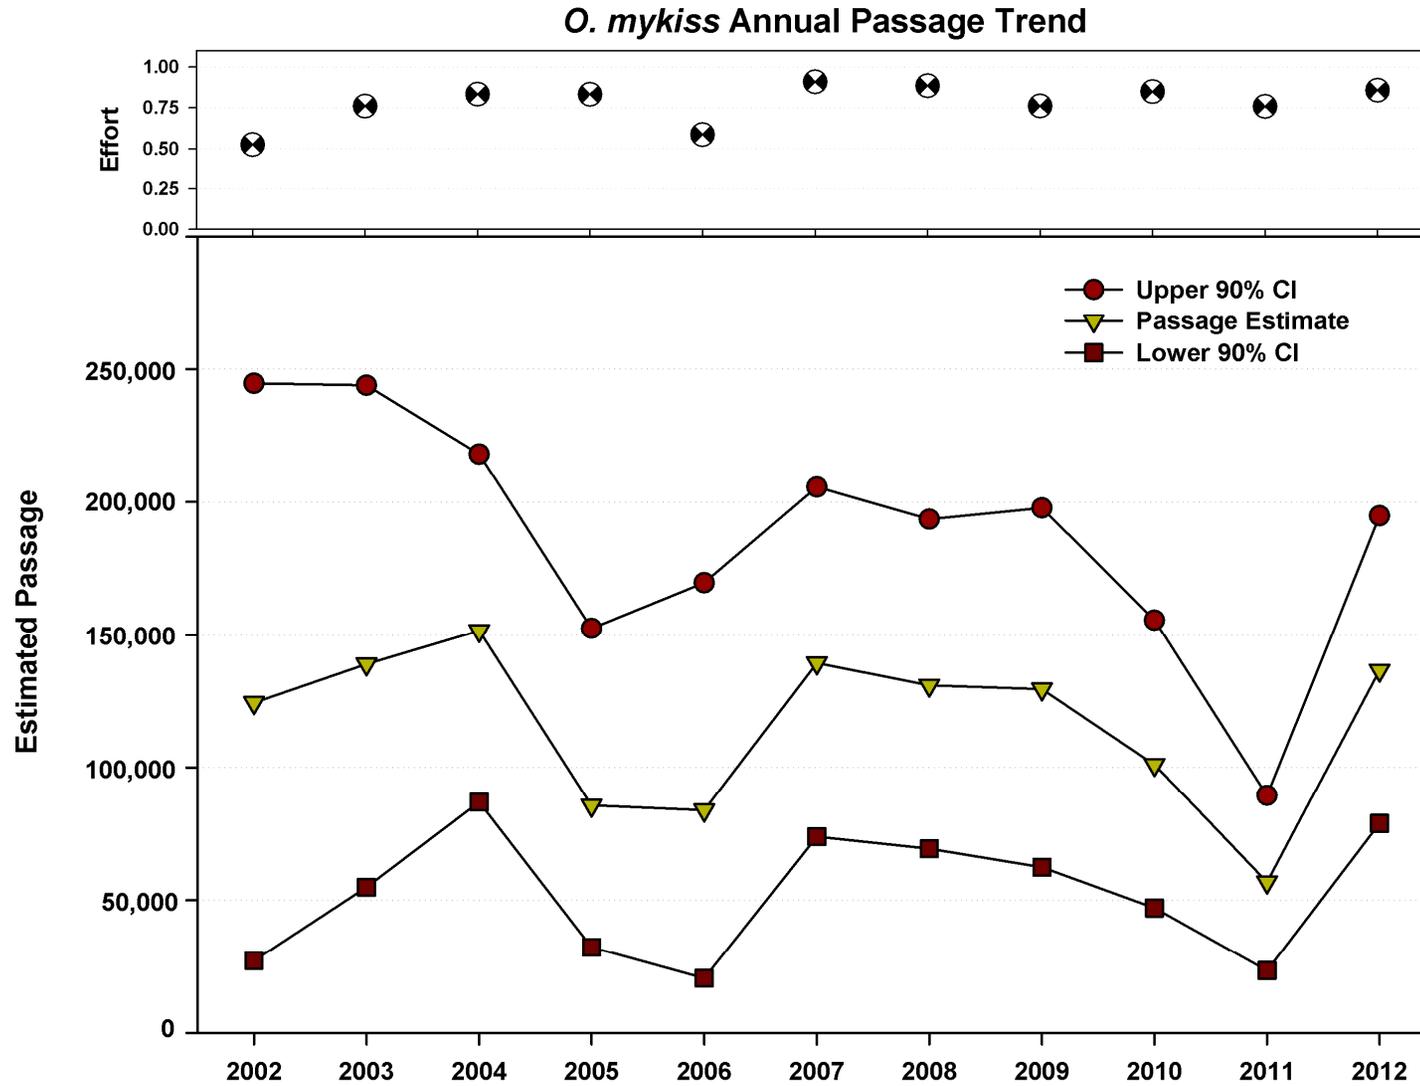

Figure 18. RBDD rotary trap *O. mykiss* annual sample effort and passage estimates with 90% confidence intervals (CI) for the period April 2002 through December 2012.

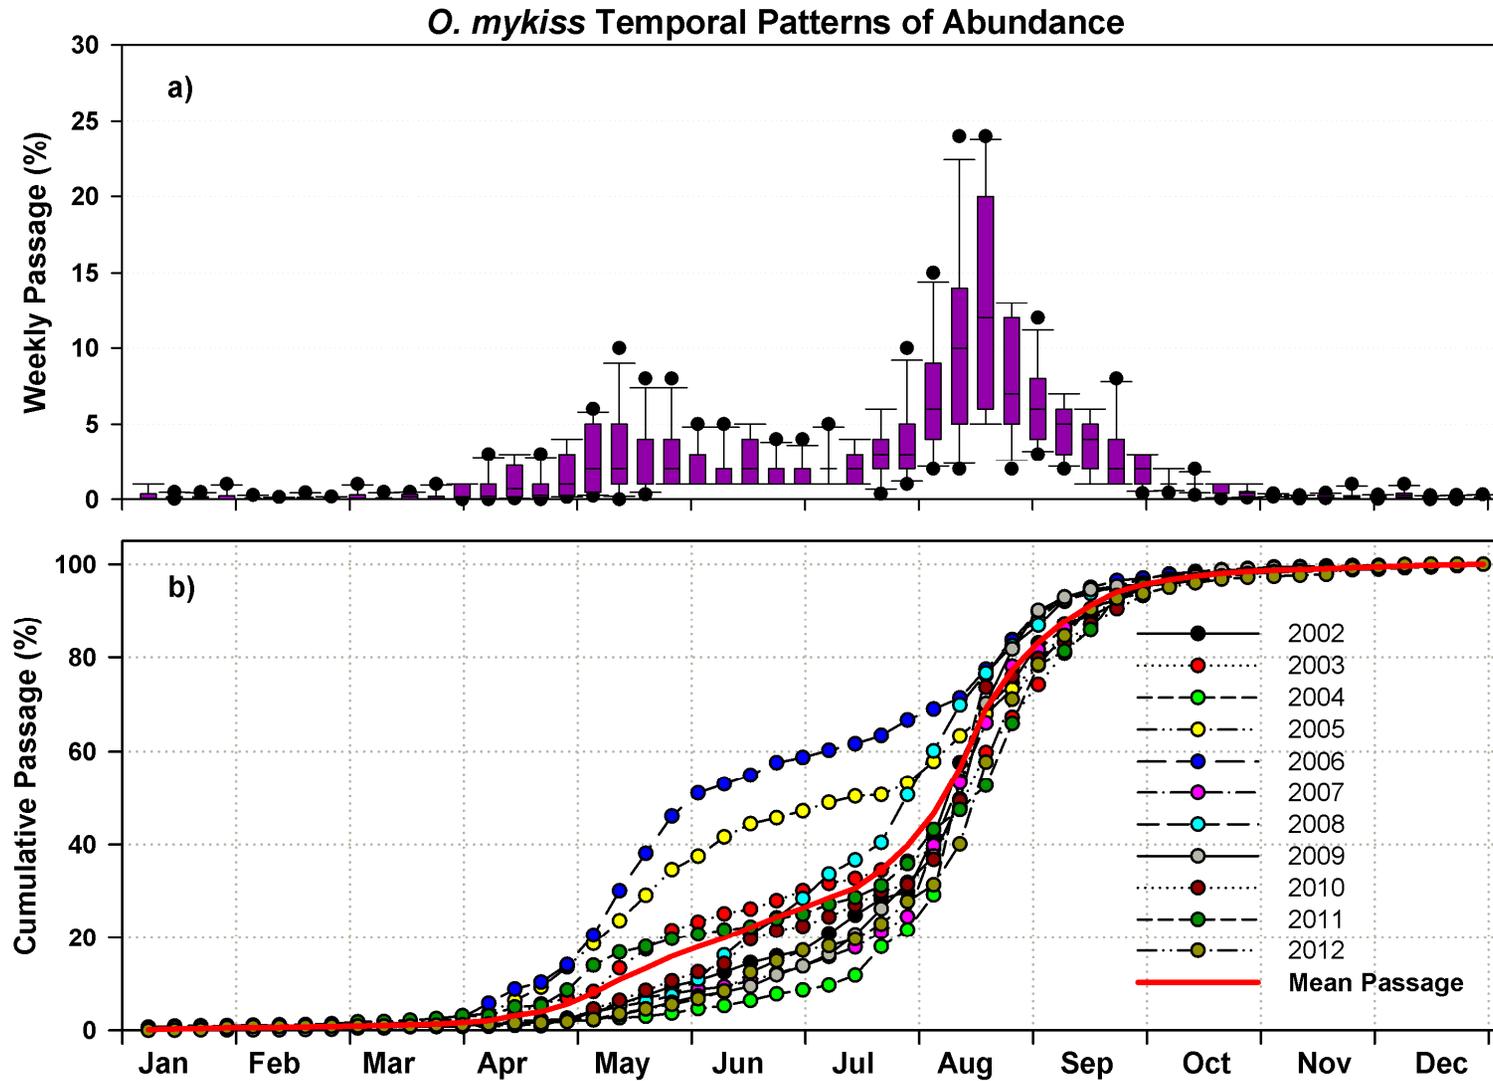

Figure 19. RBDD rotary trap *O. mykiss* (a) boxplots of weekly passage estimates relative to annual total passage estimates and (b) cumulative weekly passage with 11-year mean passage trend line for the period April 2002 through December 2012.

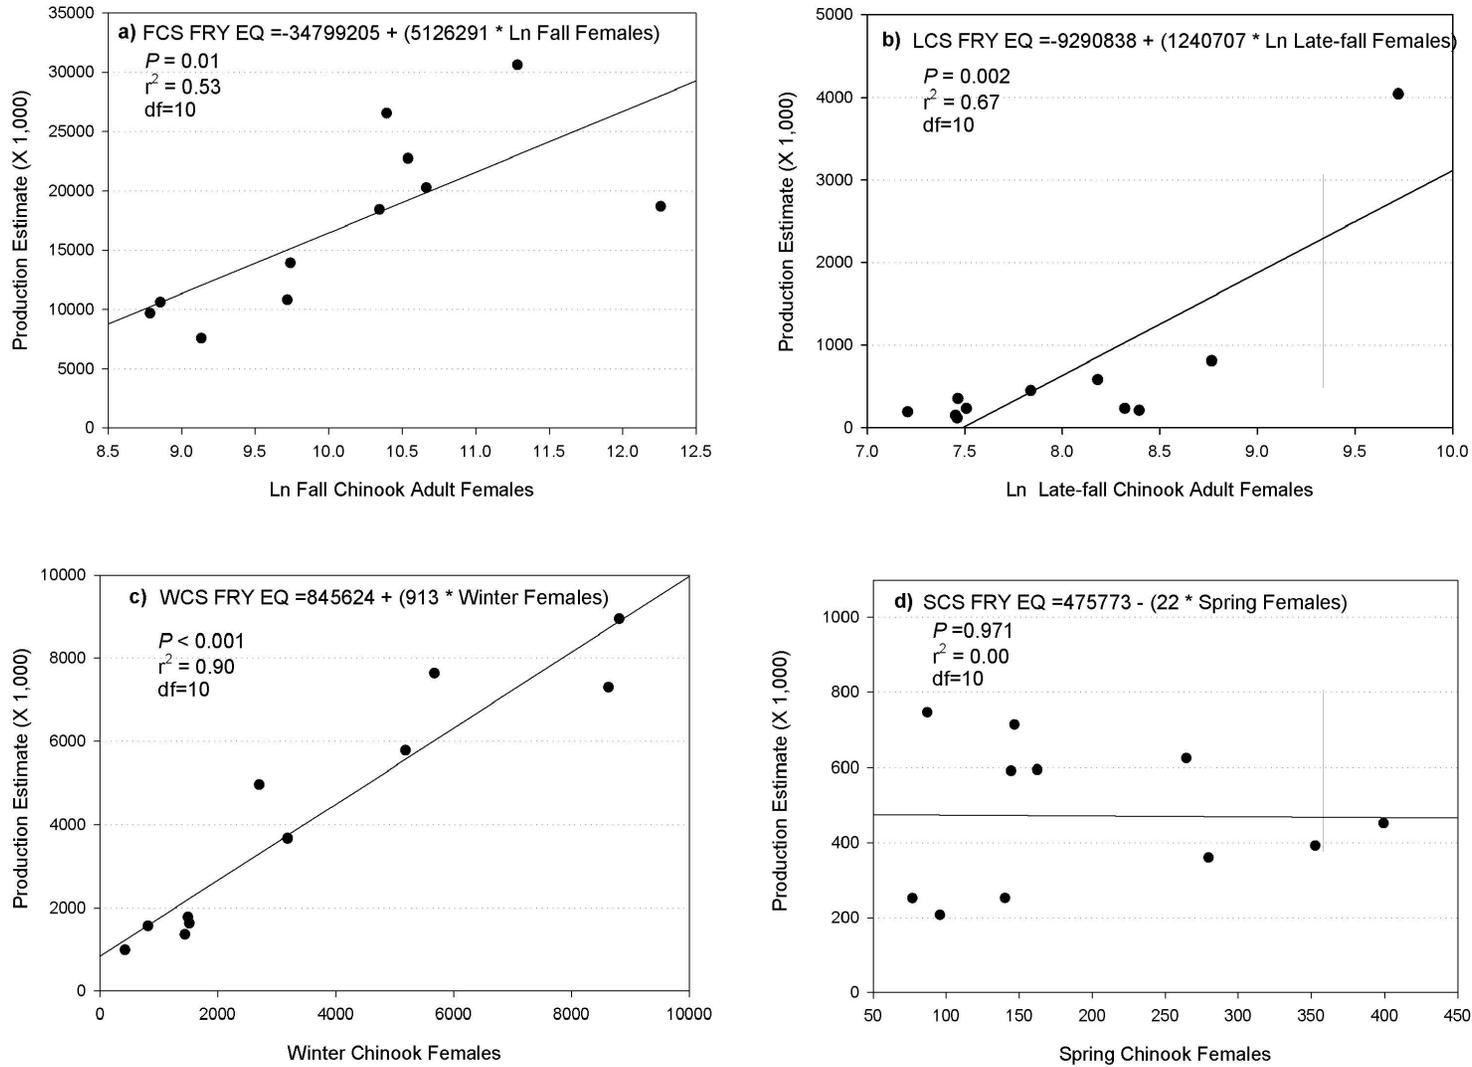

Figure 20. Relationships between a) fall, b) late-fall, c) winter, and d) spring Chinook fry-equivalent production estimates and estimated number of female adult Chinook salmon upstream of RBDD between 2002 and 2012. Note: fall and late-fall adult females were natural log transformed due to extraordinary escapement values estimated for the year 2002.

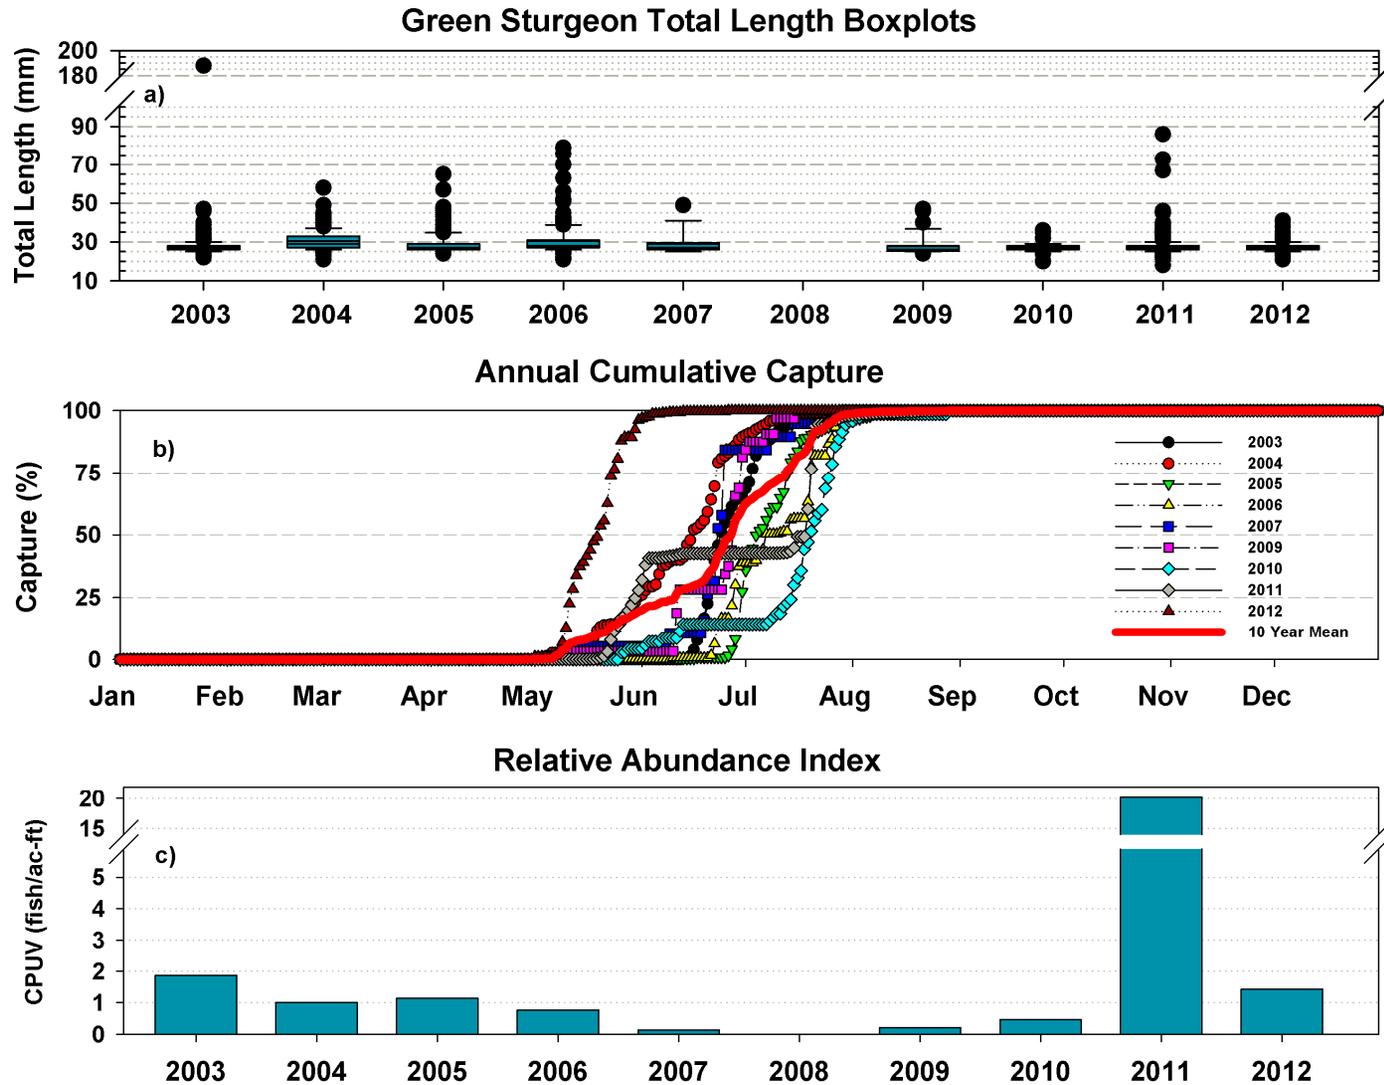

Figure 21. Green sturgeon a) annual total length capture boxplots, b) annual cumulative capture trends with 10-year mean trend line, and c) relative abundance indices. All fish captured by rotary trap at RBDD (RM 243) on the Upper Sacramento River, CA between 2003 and 2012. Data from 2002 excluded from analysis due to limited effort and USBR Crown Flow study resulting in incomparable sampling regimes and results.

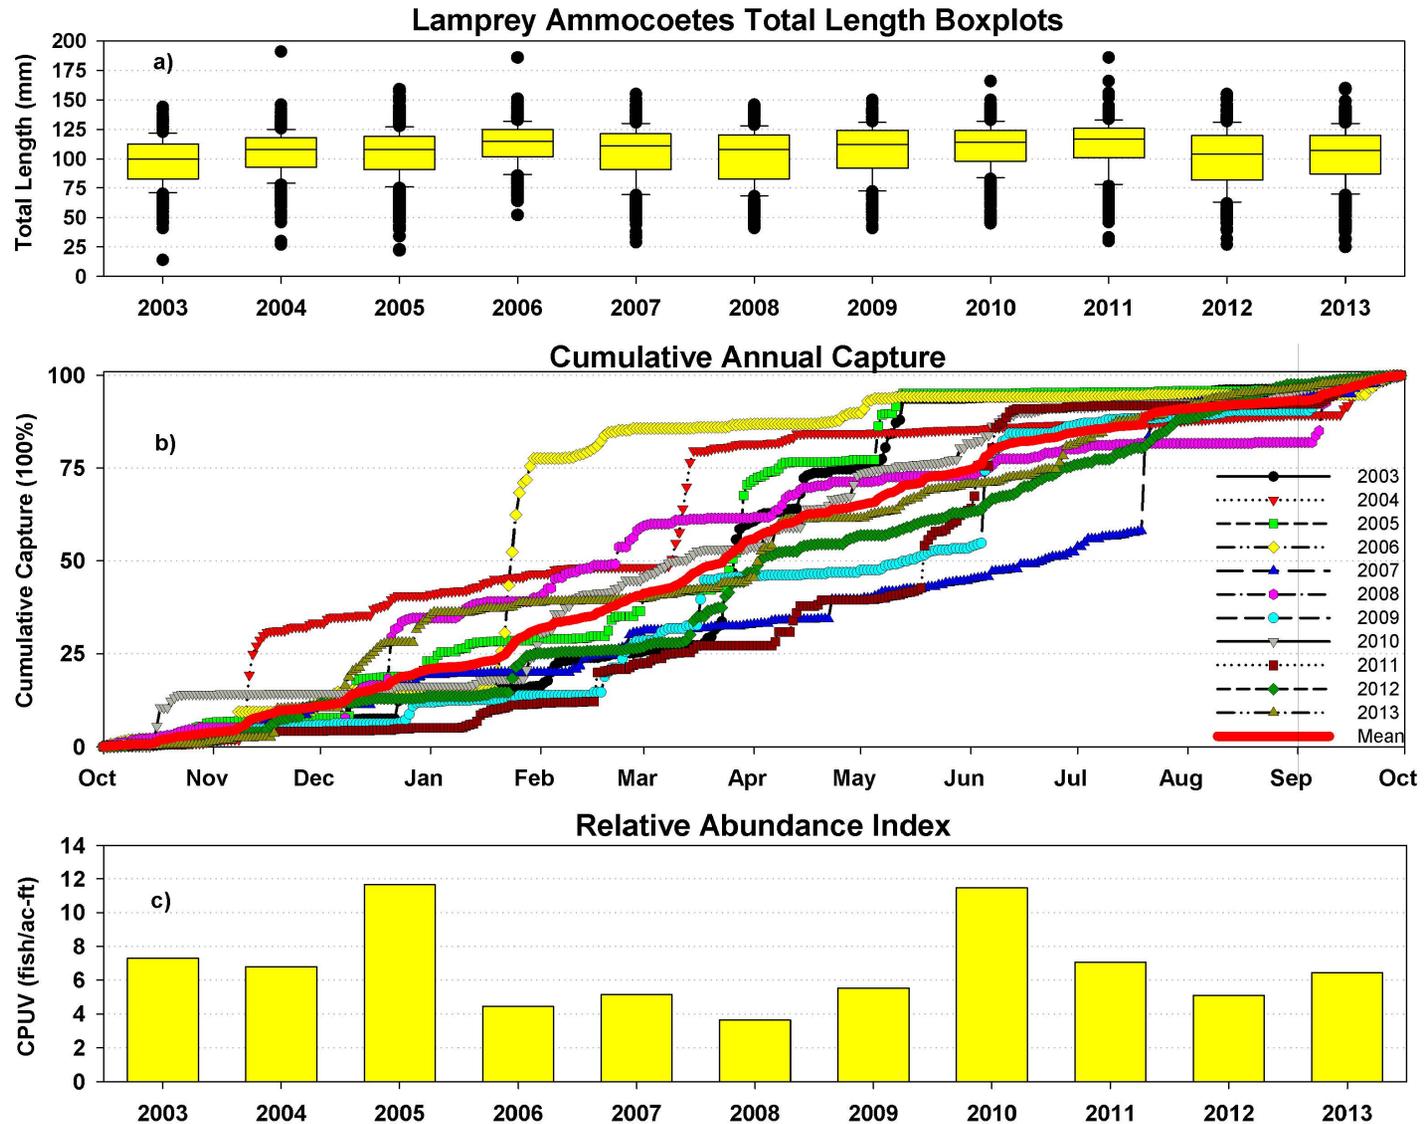

Figure 22. Unidentified lamprey ammocoetes a) total length distribution box plots, b) cumulative annual capture trends, and c) relative abundance indices from rotary trap samples collected between October 1, 2002 and September 30, 2013 by water year from the Sacramento River, CA at the RBDD (RM 243).

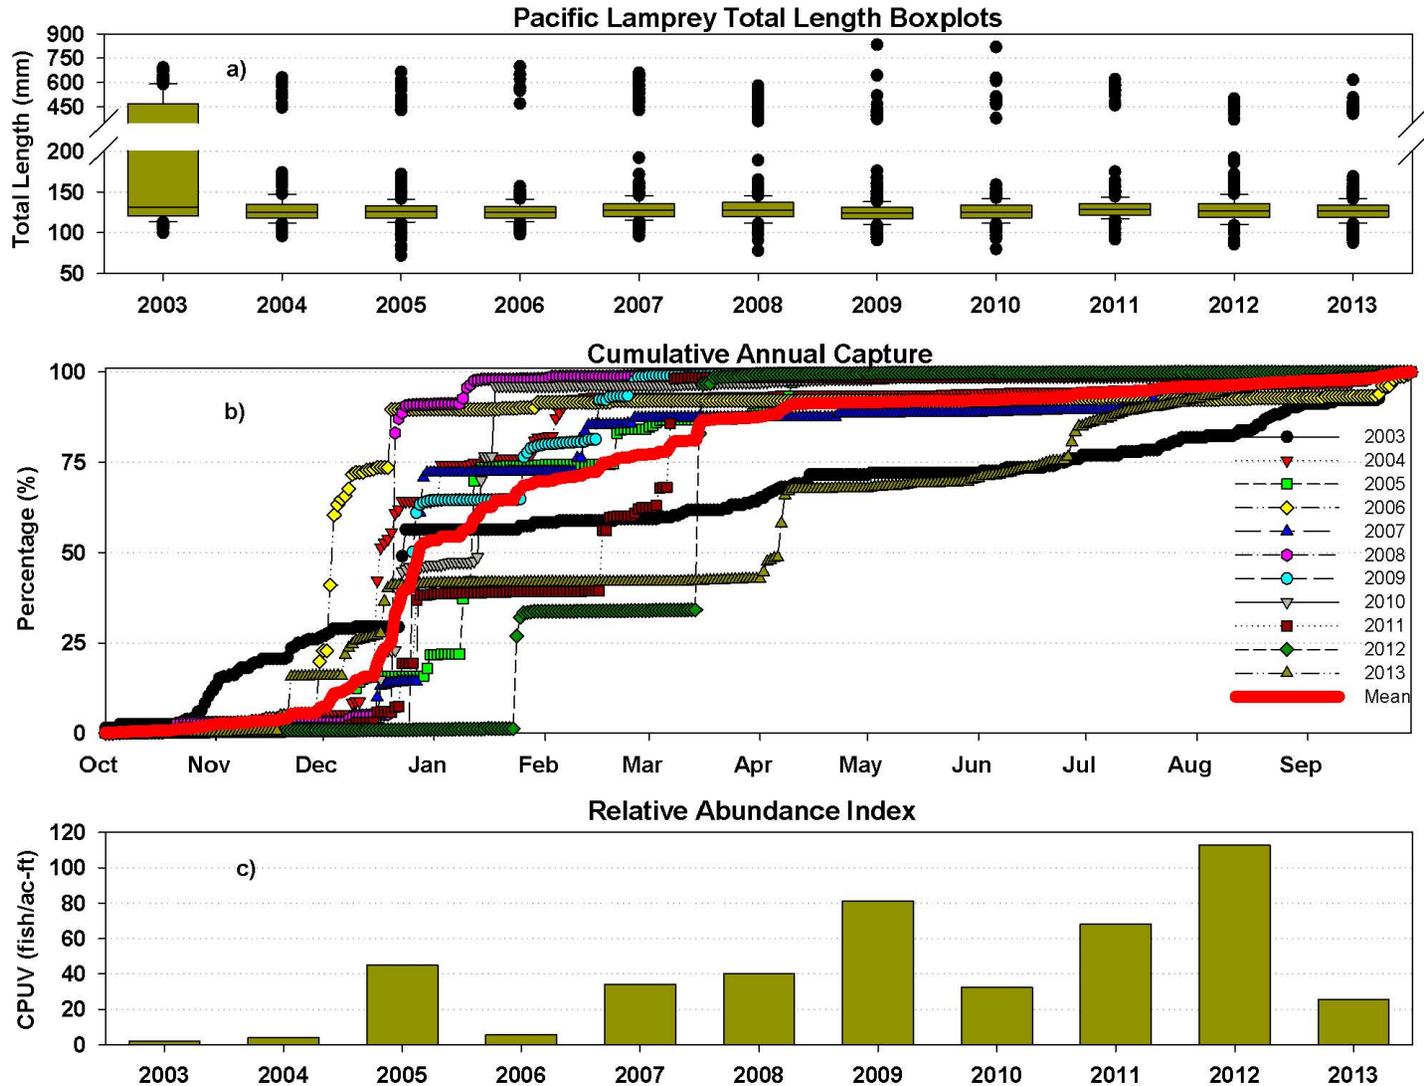

Figure 23. Pacific Lamprey (*macrophthalmia* and adults) a) total length distribution box plots, b) cumulative annual capture trends, and c) relative abundance indices from rotary trap samples collected between October 1, 2002 and September 30, 2013 by water year from the Sacramento River, CA at the RBDD (RM 243).

Green Sturgeon Relative Abundance Environmental Covariate Analyses

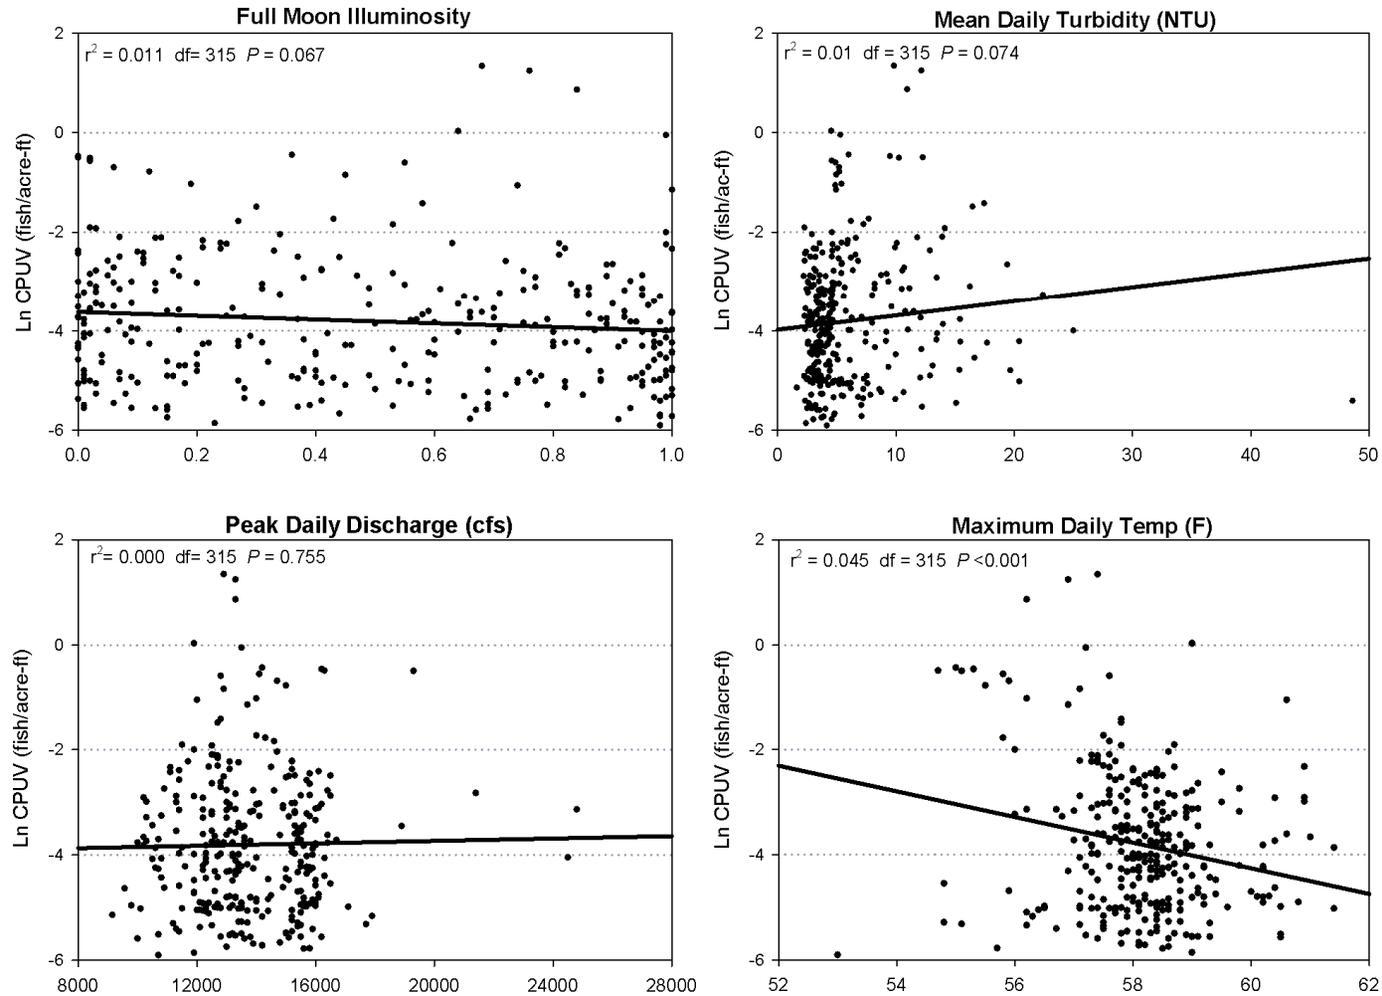

Figure 24. Regression analysis results of natural log (Ln) Green Sturgeon catch per unit volume (CPUV) and a) full moon illuminosity, b) mean daily turbidity, c) peak daily discharge and d) maximum daily temperatures at RBDD. All fish captured by rotary trap at RBDD (RM 243) on the Upper Sacramento River, CA between 2003 and 2012. Data from 2002 excluded from analysis due to limited effort and USBR Crown Flow study resulting in incomparable sampling regimes and results.

Lamprey Relative Abundance Environmental Covariate Analyses

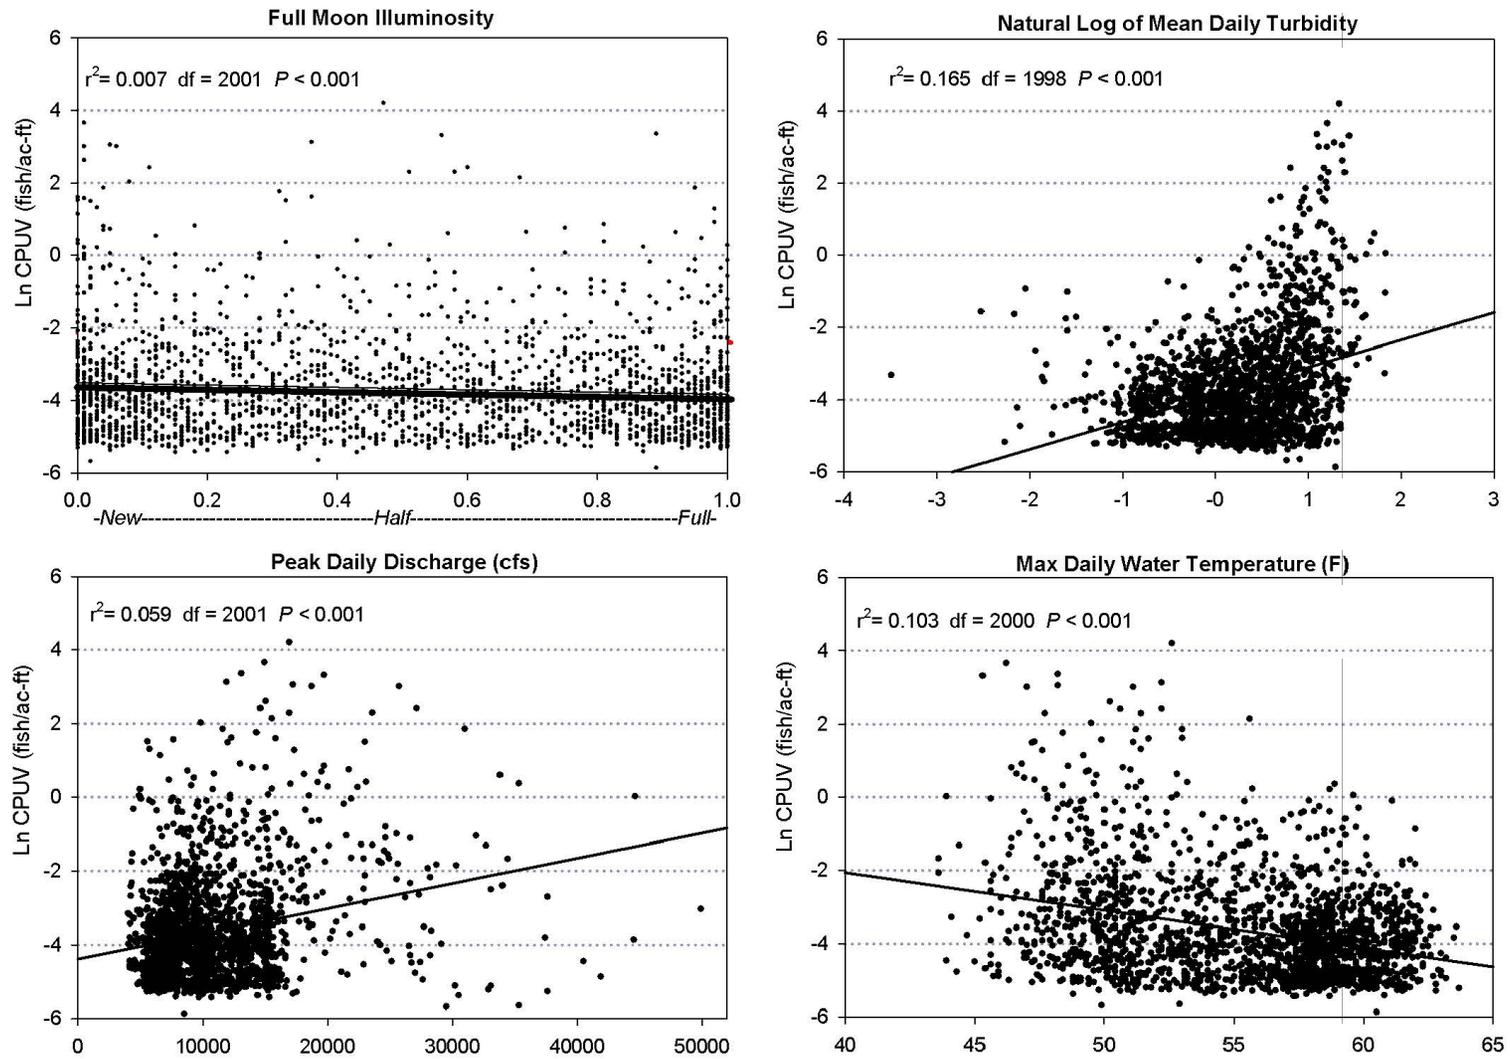

Figure 25. Regression analysis results of natural log (Ln) Lamprey *spp.* catch per unit volume (CPUV) and a) full moon illuminosity, b) Ln mean daily turbidity, c) peak daily discharge and d) maximum daily temperatures at RBDD. All fish captured by rotary trap at RBDD (RM 243) on the Upper Sacramento River, CA between water year 2003 and 2013.

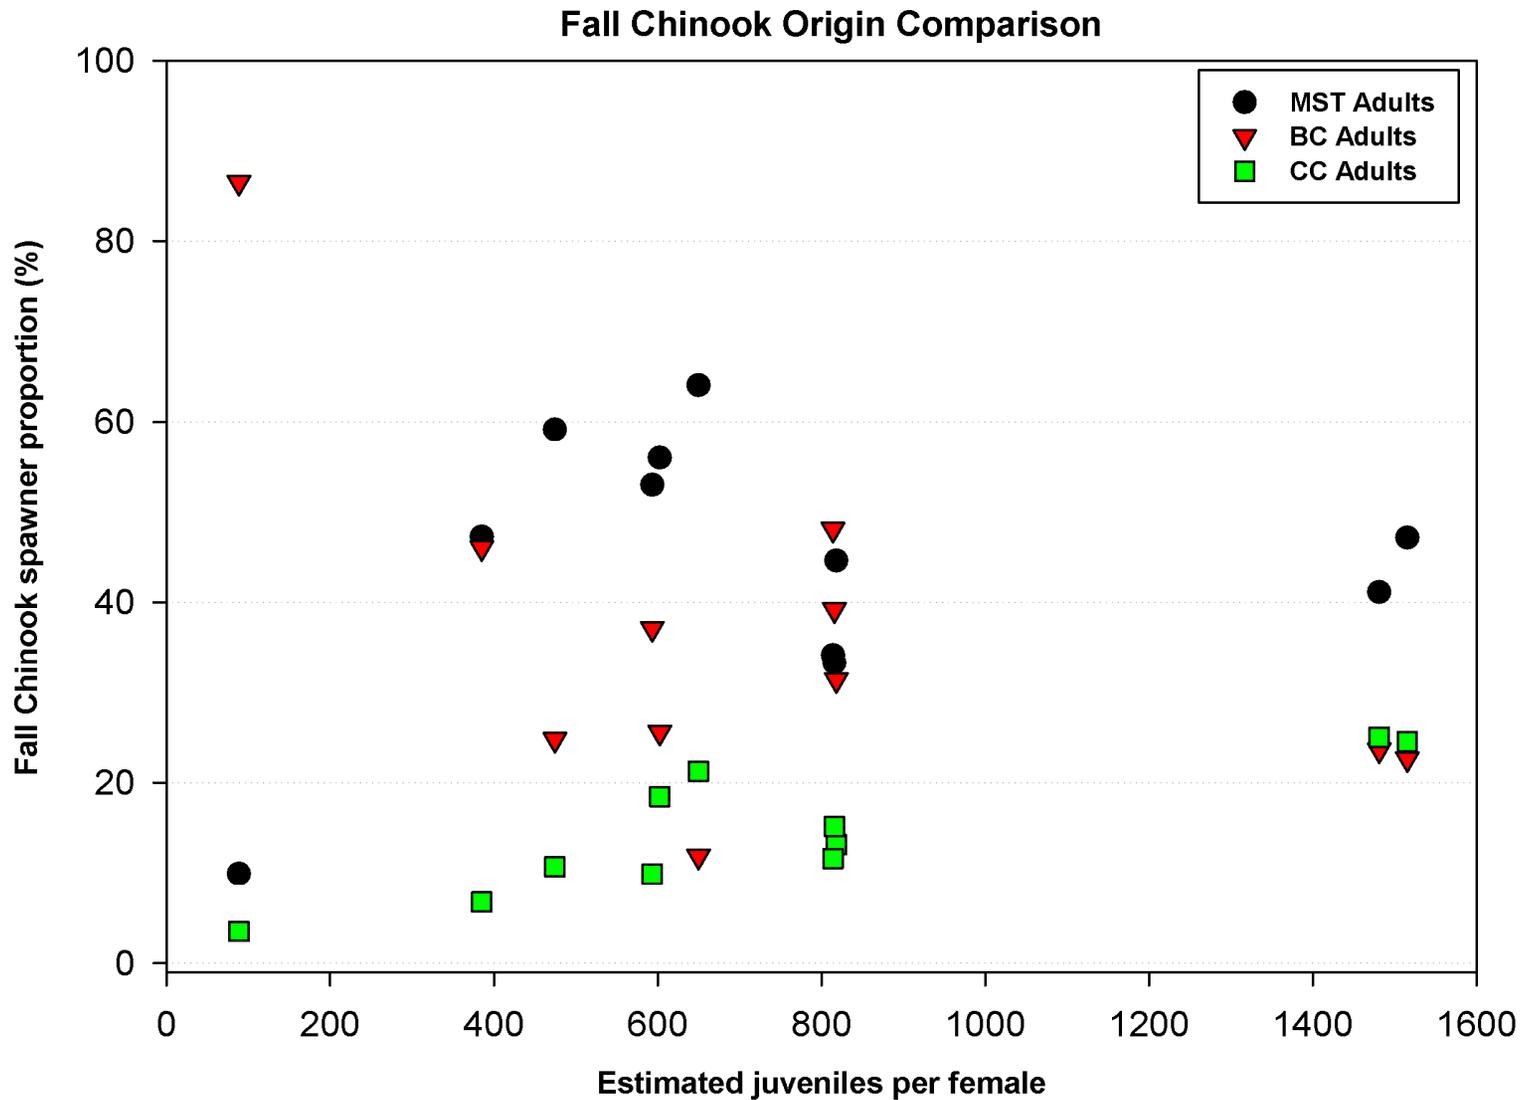

Figure 26. Comparison of estimated juveniles produced per estimated number of females in relation to distribution of fall Chinook spawners in the mainstem Sacramento River (MST), Battle Creek (BC), and Clear Creek (CC) between years 2002 and 2012.

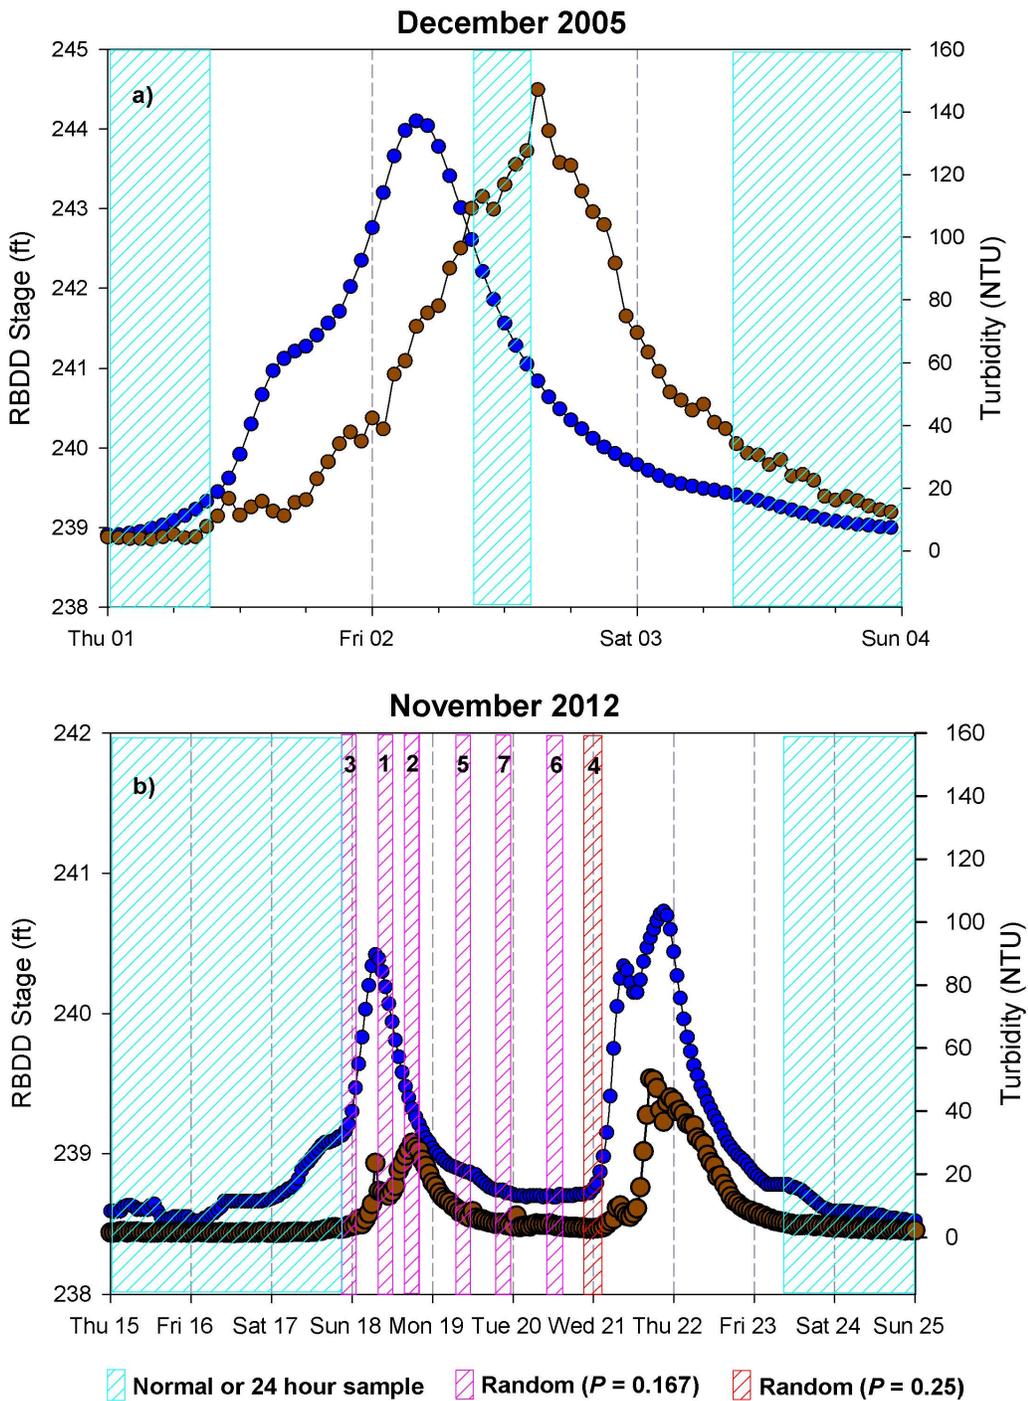

Figure 27. Timing comparison of RBDD stage (i.e., discharge level) and turbidity measurements along with sample collection times for storm events on a) December 1-4, 2005 and b) November 15-25, 2012. Numerals within sample period boxes in figure b indicate rank of standardized Chinook passage totals from greatest (1) to least (7).

APPENDIX 1

Appendix 1: List of Tables

Table	Page
A1. Summary of RBDD rotary trap annual effort, fall Chinook fry (<46 mm FL) passage estimates and lower and upper 90% confidence intervals (CI), by brood year for the period December 2002 through September 2013	108
A2. Summary of RBDD rotary trap annual effort, fall Chinook pre-smolt/smolt (>45 mm FL) passage estimates and lower and upper 90% confidence intervals (CI), by brood year for the period December 2002 through September 2013	108
A3. Summary of RBDD rotary trap annual effort, late-fall Chinook fry (<46 mm FL) passage estimates and lower and upper 90% confidence intervals (CI), by brood year for the period April 2002 through March 2013	109
A4. Summary of RBDD rotary trap annual effort, late-fall Chinook pre-smolt/smolt (>45 mm FL) passage estimates and lower and upper 90% confidence intervals (CI), by brood year for the period April 2002 through March 2013	109
A5. Summary of RBDD rotary trap annual effort, winter Chinook fry (<46 mm FL) passage estimates and lower and upper 90% confidence intervals (CI), by brood year for the period July 2002 through June 2013.....	110
A6. Summary of RBDD rotary trap annual effort, winter Chinook pre-smolt/smolt (>45 mm FL) passage estimates and lower and upper 90% confidence intervals (CI), by brood year for the period July 2002 through June 2013	110
A7. Summary of RBDD rotary trap annual effort, spring Chinook fry (<46 mm FL) passage estimates and lower and upper 90% confidence intervals (CI), by brood year for the period October 2002 through September 2013.....	111
A8. Summary of RBDD rotary trap annual effort, spring Chinook pre-smolt/smolt (>45 mm FL) passage estimates and lower and upper 90% confidence intervals (CI), by brood year for the period October 2002 through September 2013	111
A9. River Lamprey, <i>Lampetra ayresi</i> , annual capture, catch per unit volume (CPUV) and total length summaries for River Lamprey captured by RBDD rotary traps between water year (WY) 2003 and 2013	112
A10. Pacific Brook Lamprey, <i>Lampetra pacifica</i> , annual capture, catch per unit volume (CPUV) and total length summaries for Pacific Brook Lamprey captured by RBDD rotary traps between water year (WY) 2003 and 2013.....	112

Fall Chinook

Table A1. Summary of RBDD rotary trap annual effort, fall Chinook fry (<46 mm FL) passage estimates and lower and upper 90% confidence intervals (CI), by brood year for the period December 2002 through September 2013.

Brood Year	Effort	Estimated Fry		
		Passage	Low 90% CI	Up 90% CI
2002	0.76	14,687,984	348,386	42,027,818
2003	0.81	23,612,094	6,953,966	44,283,689

PREFACE

This Conceptual Model is part of a suite of conceptual models which collectively articulate the current scientific understanding of important aspects of the Sacramento-San Joaquin River Delta ecosystem. The conceptual models are designed to aid in the identification and evaluation of ecosystem restoration actions in the Delta and to structure scientific information such that it can be used to inform public policy decisions.

The DRERIP Delta Conceptual Models include both ecosystem element models (including process, habitat, and stressor models) and species life history models. The models were prepared by teams of experts using common guidance documents developed to promote consistency in the format and terminology of the models at http://www.dfg.ca.gov/ERP/conceptual_models.asp.

The DRERIP Delta Conceptual Models are qualitative models which describe current understanding of how the system works. They are designed and intended to be used by experts to identify and evaluate potential restoration actions. They are not quantitative, numeric computer models that can be “run” to determine the effects of actions. Rather they are designed to facilitate informed discussions regarding expected outcomes resulting from restoration actions and the scientific basis for those expectations. The structure of many of the DRERIP Delta Conceptual Models can serve as the basis for future development of quantitative models.

Each of the DRERIP Delta Conceptual Models has been subject to a rigorous scientific peer review process, as described on the DFG-DRERIP website and as chronicled on the title page of the model. The scientific peer review was overseen by Dr. Jim Anderson, at University of Washington for all species models and by Dr. Denise Reed, University of New Orleans, for all ecosystem models.

The DRERIP Delta Conceptual models will be updated and refined over time as new information is developed, and/or as the models are used and the need for further refinements or clarifications are identified.

I. INTRODUCTION

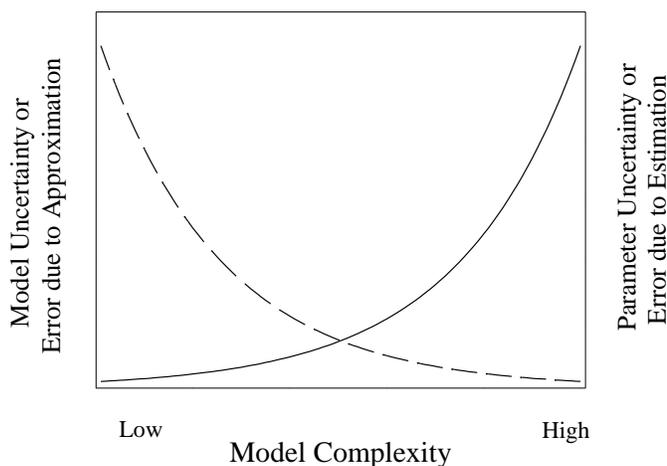

This report constitutes the conceptual model for Chinook and steelhead for the Delta Regional Ecosystem Restoration Implementation Plan (DRERIP). The report describes conceptual models, not numerical models, but several important considerations apply to both kinds, especially when they are used for management of living natural resources. First, the proper purpose of models is to help people think, not to think for them. Ignoring this can be disastrous, as exemplified by the current economic crisis. The world of credit default swaps was built on highly sophisticated models that persuaded many intelligent people that the associated risk was negligible, but they failed to recognize that a market based on houses that people could not pay for from their earnings is unsustainable.

In short, the most important “output” of a good conceptual or numerical model is clear thinking. To help people think, the model must be focused on selected features of the world that are thought to be important for the purpose at hand: in this case, management of the Delta. A model that tries to include everything will be too complex to be useful for this purpose.

Second, to be useful for management of natural living resources, numerical models must be unrealistic, because our knowledge of such resources is incomplete, and is based on data that includes measurement errors. According to Ludwig’s paradox, “Effective management models cannot be realistic” (Ludwig 1994:516), because two kinds of uncertainty must be balanced (Figure I-1; see Ch. 14 in Williams (2006) for elaboration of this point).

In our view, something similar applies to conceptual models of natural systems: to be useful, they must be simple. A schematic of the wiring in some electronic device is a conceptual model that may be useful as well as complex, but trying to develop a similar schematic of an ecosystem or part of an ecosystem is not useful, because our knowledge of such a system is much less complete than our knowledge of engineered devices, and we have only estimates of the relevant parameters.

Figure 1. Conceptual model of the trade-off between model uncertainty (dashed line) and parameter or estimation uncertainty (solid line). In a good predictive model these two types of uncertainty are balanced. Redrawn from Ludwig (1994). See Ch. 14 in Williams (2006) for more discussion of this matter.

Finally, reality is too complex to capture with a single model. Eric Lander, a noted geneticist who co-chairs President Obama’s Council of Advisors on Science and Technology,

recently remarked that “You can never capture something like an economy, a genome or an ecosystem with one model or one taxonomy – it all depends on the questions you want to ask” (NY Times, 11/11/08). Models are tools that we use to try to think, and multi-purpose tools generally do nothing well.

Therefore, although the complete life cycle of Chinook and steelhead is described here, the parts or aspects of the cycle that we think may be affected by management of the Delta are emphasized, and we try to keep it as simple as possible. More detail on most of the topics described here can be found in Quinn (2005), or in Williams (2006), from which this document draws very heavily.

A. On nomenclature:

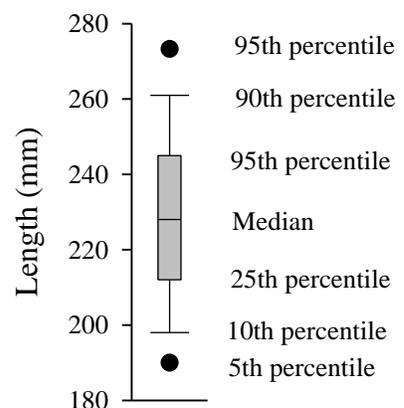

In the literature on Central Valley Chinook and steelhead, several terms are used with different meanings, which does not help an already difficult situation. For example, most people describe the area from the Golden Gate to the limit of tidal influence as the estuary, but MacFarlane and Norton (2002) apply that term only to the area influenced by the salinity of the ocean, essentially the area downstream from the Delta. This has caused many people to misunderstand their article. Similarly, the term ‘fry’ has been used to describe fish less than some length, such as 50 or 60 or 70 mm, with fish larger than that described as ‘smolts,’ although sometimes the distinction is between fry and ‘fingerlings,’ or fry and parr. Recently, CDFG has started describing fish in terms of physiological state rather than length; that is as fry, parr, silvery parr, or smolts, which is more appropriate for scientific purposes. Here, however, we often retreat to more traditional usage, and will refer to fry and fingerlings, with a division somewhere around 55 to 60 mm fork length. The term fingerling seems useful because it is a reminder that we are talking about small fish. By smolts we mean fish that are migrating rapidly and are well along in the physiological processes associated with smolting.

We use the term “salmon” to refer to both Chinook and steelhead, since both are members of the genus *Oncorhynchus*, the Pacific salmon, and steelhead were commonly called salmon in the 19th Century.

We distinguish ‘wild’ and ‘naturally produced’ fish by the extent of the hatchery influence in the population; the progeny of hatchery fish spawning in the wild are naturally produced.

All lengths given are fork lengths, unless otherwise noted.

Several of the figures in the report are “box plots,” which are conventional in science but may be unfamiliar to some readers. Box plots show distributions, as illustrated at right (with extra labeling) for the distribution of lengths of 346 unmarked juvenile steelhead captured at Chipps Island. If plots show more than two filled circles, they represent all outliers beyond the 10th and 90th percentiles.

Others of the figures show the factors influencing the probability of surviving the transition from one life stage to the next. These figures are numbered separately from the others, and follow the conventions for the DRERIP conceptual models.

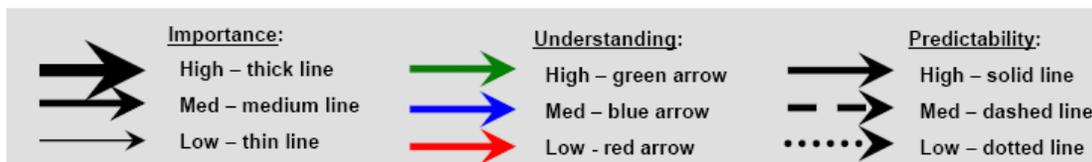

Linkages are depicted as arrows between cause (drivers) and effect (outcomes);

The **direction** of the effect is indicated by plus or minus signs;

The **importance** or magnitude of the effect is shown by line thickness;

Understanding about the relationship based on established literature knowledge is shown by line color;

The **predictability** of the effect is shown by line type.

These figures reflect the current understanding of Central Valley Chinook and steelhead, but they should be viewed with attention to the obvious limits to our understanding; for example, we did not anticipate the crash of the fall Chinook population in recent years, or do we understand why it increased before it crashed. Uncertainty does not justify inaction, but neither should it be ignored.

II. Biology

The Delta provides habitat for two species of Pacific salmon, Chinook (*Oncorhynchus tshawytscha*) and steelhead (*O. mykiss*). There are substantial differences between the species, but they are enough alike to treat them together for the conceptual models. Much less information is available on steelhead in the Central Valley than on Chinook, however. Lindley et al. (2007) commented that "... we are unable to assess the status of the Central Valley steelhead ESU with our framework because almost all of its roughly 80 populations are classified as data deficient." For the same reason, steelhead are given less attention here than they deserve.

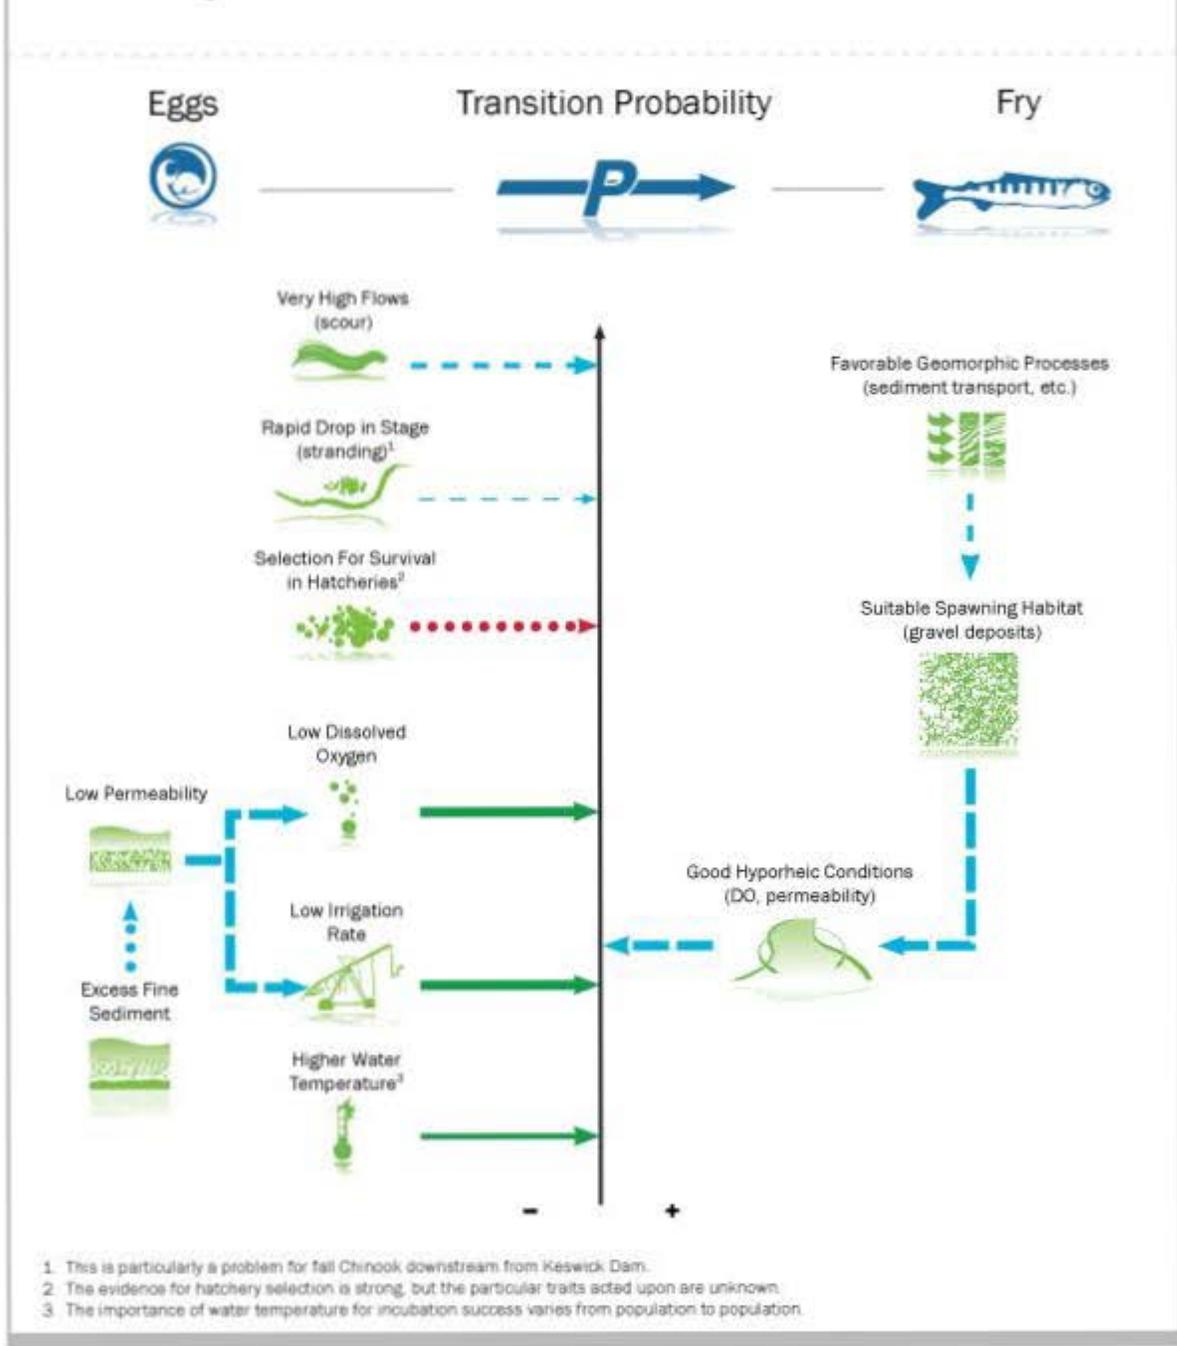

Pacific salmon typically are anadromous. That is, they reproduce in fresh water, but migrate to the ocean to gain most of their growth. There are many exceptions, however, such as rainbow trout (non-anadromous *O. mykiss*), and there is a great deal of variation in life history patterns among the anadromous fish. A conceptual model that helps explain this diversity in life histories is described in the ecology chapter, but the emphasis here is on fish that migrate through or at least to the Delta, and so are directly influenced by management of the Delta.

A. The life cycle of anadromous salmonids

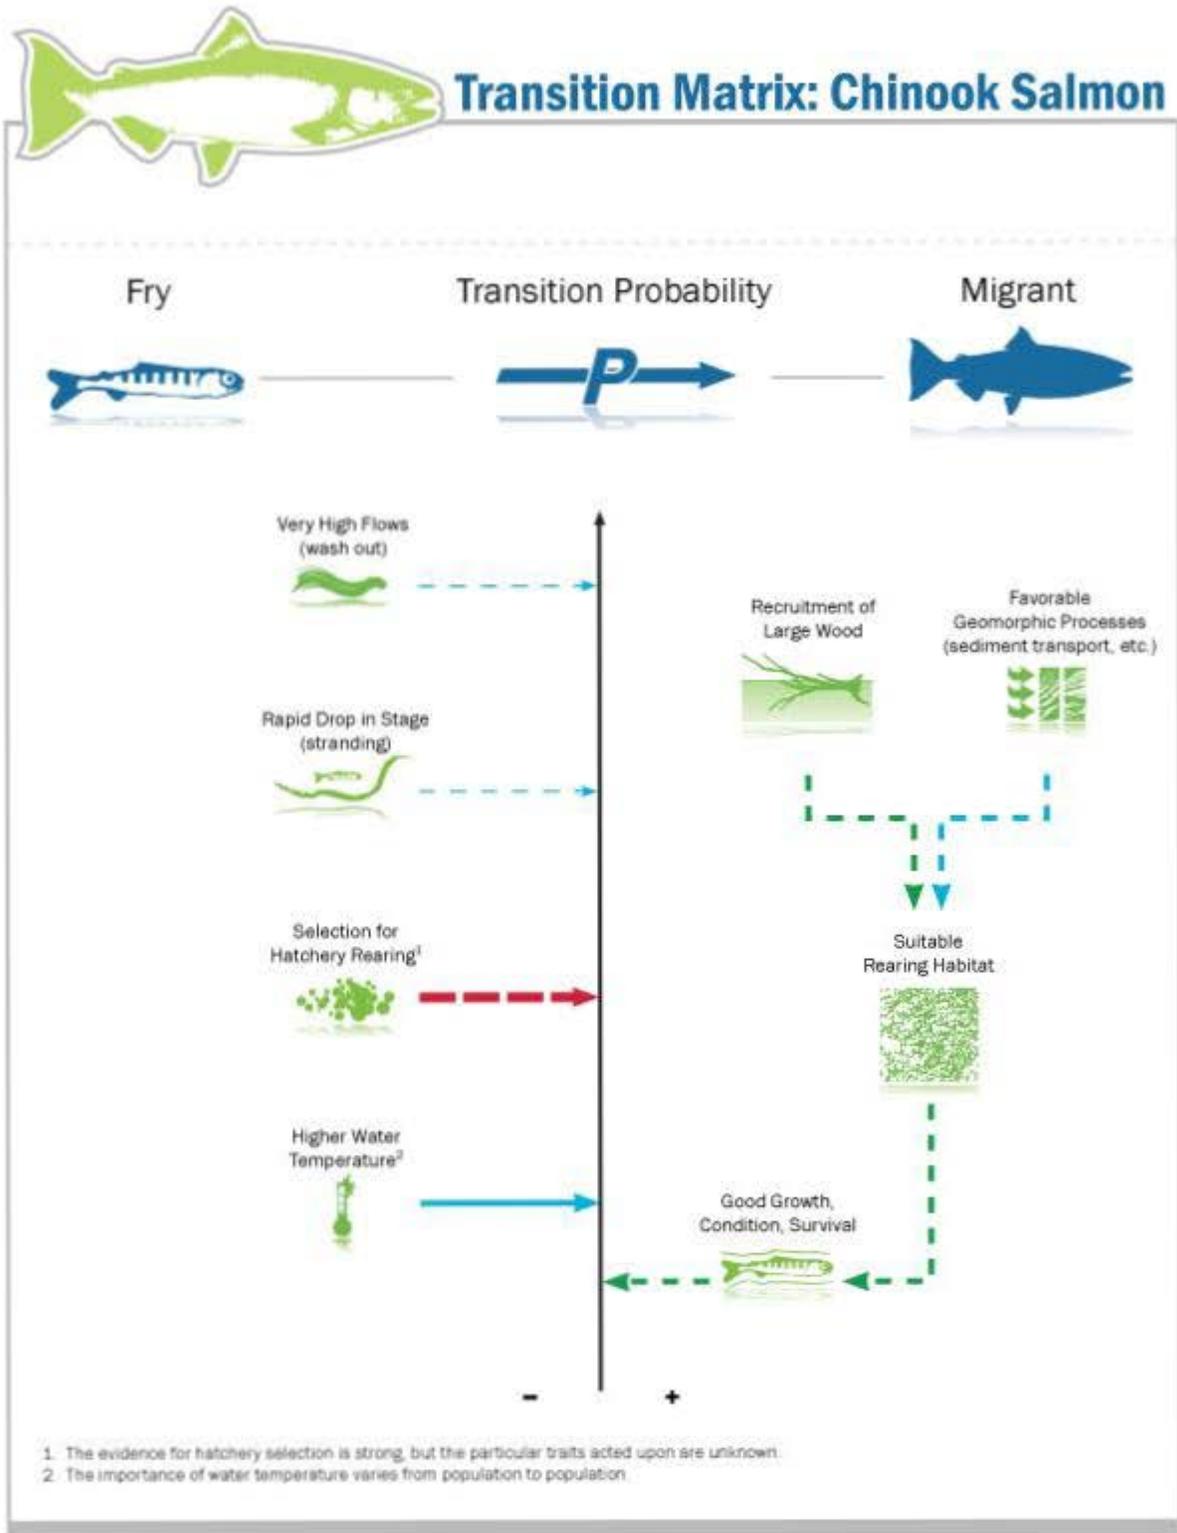

Figure 1 depicts the natural life history of anadromous salmonids. Adult females dig nests called redds in gravel-bedded streams, the eggs are fertilized by males as the female deposits them in the redd, and the female covers the eggs with gravel. Embryos develop and hatch in the gravel, and the larval fish, called alevins, remain there and grow, nourished by egg yolk attached to their bellies. Around the time the remaining yolk is enveloped by the growing fish, the fish emerge from the gravel into the overlying stream as fry, ~ 25 mm long for steelhead, and 35 mm for Chinook. Factors affecting the transition from egg to fry are depicted in Life Stage Transition Figure 1.

Although pink and chum salmon (*O. gorbuscha* and *O. keta*) migrate to sea directly after emerging, most salmon rear for months to years in fresh or brackish water before doing so. As the fish grow, they develop scales and dark vertical bands called parr marks on their sides that make the fish less visible in streams (Quinn 2005). Small parr are sometimes called fingerlings. Later, the fish go through various physiological changes that prepare them for living in salt water: externally, their shape changes, the parr marks fade, and the fish develop silvery sides and bellies that make them less visible from below. At this stage they are called smolts. Steelhead in Central Valley streams normally migrate at one or two years old. The age at which Chinook begin migrating is highly variable, however, as described in Chapter 4; the environmental factors affecting survival to the beginning of migration are depicted in Life Stage Transition Figure 2.

Transition Matrix: Chinook Salmon

Life Stage Transition 1.

Life Stage Transition 2

with a sharply different salt concentration is easier if it is done gradually, and temporary residence in an estuary allows this to occur.

For Chinook and steelhead in the Central Valley, the natural anadromous life history must be amended to include reproduction and juvenile rearing in hatcheries (Figure 2), which annually produce upwards of 30 million Chinook and 1.5 million steelhead (Williams 2006). In Central Valley rivers with hatcheries, hatchery and naturally spawning salmon are best regarded as single, integrated populations that reproduce in one of two very different habitats. Harvest is included in Figure 3, a conceptual model from Goodman (2005). Harvest is a desired outcome of management, and the rate of harvest is an important management “knob” that affects the extent of the influence of hatchery fish on the genetics of naturally reproducing fish (Goodman 2004, 2005). As this suggests, it is misleading to think of the salmonid life cycle as frozen in time. To the contrary, populations and their life histories can evolve rapidly enough that management should take evolution into account (Wilson 1997; Stearns and Hendry 2004). This is discussed below in terms of local adaptation.

Figure 2. Conceptual model combining the natural and hatchery life cycles, copied from USFWS, Warm Springs Hatchery. Note that natural reproduction seems somewhat truncated in the image.

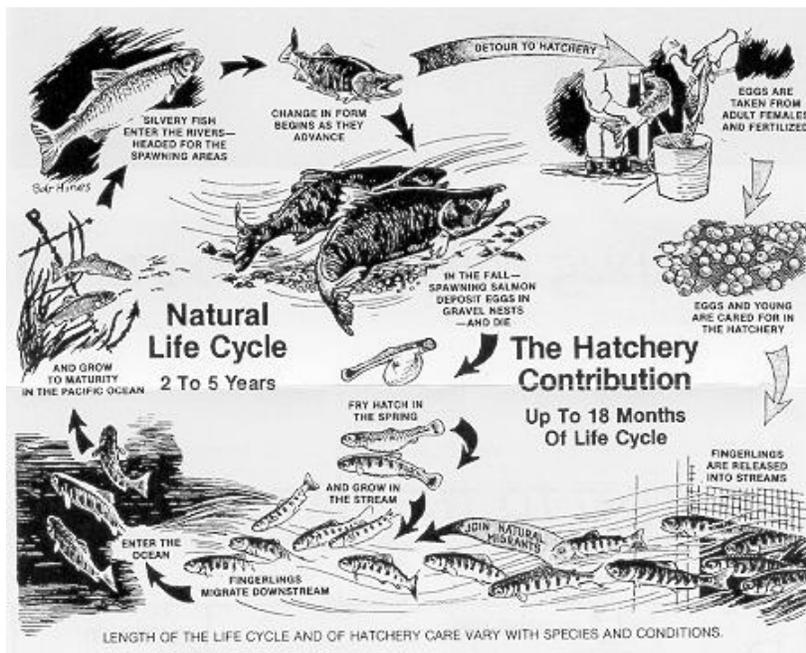

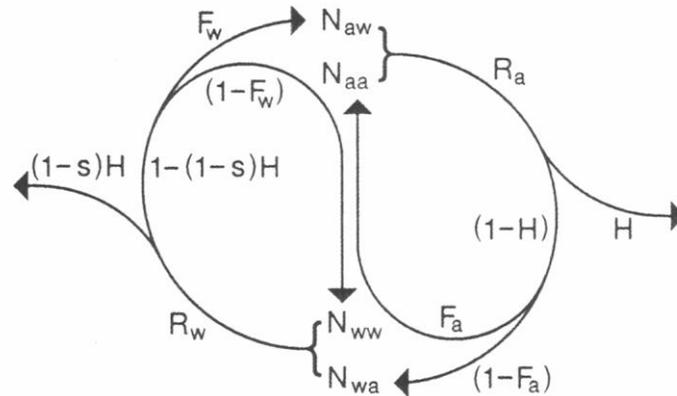

Figure 3, life cycle schematic, including hatchery production and harvest. N_{xy} is the number of spawner of origin y in habitat x , where w is natural and a is hatchery. R_y are the recruits, and F_y are the fractions of the natural and hatchery recruits taken into the hatchery. H is harvest, and s is the harvest selectivity for hatchery fish. Modified from Goodman (2004)

The juvenile life histories of Central Valley Chinook are highly variable, and the young fish enter the ocean at lengths ranging roughly from 75 to 250 mm (Williams 2006). The habitats where they gain most of this growth are also variable: at the extremes, some migrate rapidly through the Delta and grow mainly in the bays before entering the ocean, while others remain and rear in the gravel-bedded parts of the streams where they incubated and then migrate rapidly through the lower rivers, the Delta and the bays. This is discussed in more detail in the ecology chapter. Less is known about steelhead, but in the Central Valley they probably gain most of their growth in the gravel-bedded reaches. Most pass Chipps Island between ~ 215 and 245 mm in length (see the box plot in the Introduction).

B. Adult size, fecundity, and survival by life stage of Chinook and steelhead:

Chinook and steelhead have relatively few, large eggs, compared to most fishes of similar size, and average egg to fry survival is correspondingly high. However, although average egg to fry survival is high, it is also highly variable, and may be zero in many cases (Williams 2006).

Quinn (2005) compiled data from published studies on life-stage specific size and survival of wild or naturally reproducing Pacific salmon populations, and his results for Chinook and steelhead are presented in Table 1. Some studies reported survival from egg to fry or fry to smolt, and others estimated survival from egg to smolt. Quinn calculated separate estimates of adults per female using both sets of estimates, and the uncertainty in current knowledge is reflected in the different results from these two approaches. These data are from populations subject to fishing, which absorbs the surplus implied by adults per female being greater than two.

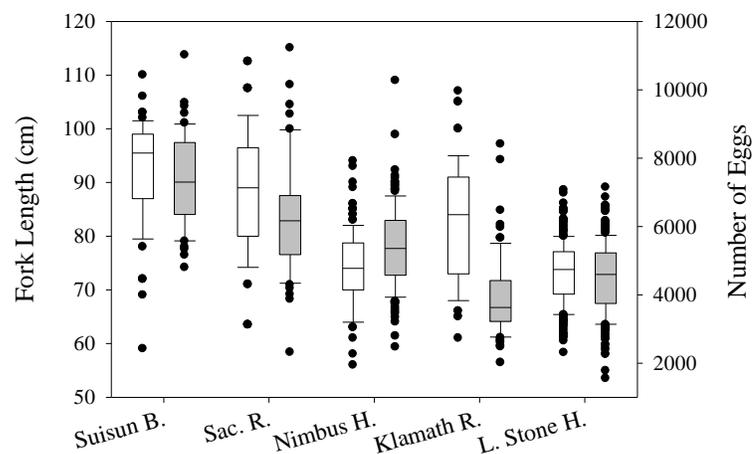

Table 1. Size, fecundity and survival estimates for Chinook and steelhead, copied from Quinn (2005).

Life History Stage	Chinook	Steelhead
Female Length (mm)	871	721
Fecundity	5401	4923
Egg size (mg)	300	150
Egg to fry survival	0.380	0.293
Fry size (mm)	35	28
Fry to smolt survival	0.101	0.135
Smolt size (mm)	60-120	200
Smolt to adult survival	0.031	0.130
Adults per female¹	6.4	25.5
Egg to smolt survival	0.104	0.014
Adults per female²	17.5	9.2

1. Calculated using egg to fry and fry to smolt survival estimates.
2. Calculated using egg to smolt survival estimates.

Historical data show that Central Valley Chinook used to be larger and more fecund than the averages given in Table 1 (Figure 4). On the other hand, Central Valley steelhead were smaller (Table 2). Current fecundity data for Central Valley Chinook are remarkably scarce, except for winter-run, but fall Chinook from a sample taken from the American River were small but fecund for their size (Figure 4). Note the lower fecundity of Klamath River Chinook for their size, which may reflect the steeper gradient and more arduous migration for fall Chinook in that river.

Figure 4. Distributions of size (open boxes) and fecundity (shaded boxes) for fall Chinook salmon collected in Suisun Bay ~ 1920, the Sacramento River ~ 1940, River Klamath River ~ 1920, and Nimbus Hatchery on the American River, 1997, and for winter Chinook from Livingston Stone Hatchery. Data from McGregor 1923b, Hanson et al. 1940, Kris Vyverberg, DFG, and John Rueth, USFWS. Copied from Williams (2006).

C. Age distribution of Chinook and steelhead.

One important aspect of life history variation among Chinook and steelhead can be summarized by tables showing the time spent in fresh and salt water. For most Chinook and steelhead, time can be specified in terms of winters in fresh water, as in Table 2, although some Chinook migrate past Chipps Island during the winter. Unfortunately, good information on the current age distributions of Chinook and steelhead in the Central Valley is only now becoming available. Table 2 gives qualitative “guesstimates” for Central Valley Chinook, based partly on data for one year in the Feather River given in Williams (2006). Table 3 gives quantitative data on four common life history patterns for Central Valley Steelhead in a somewhat different format, but the data are old and include only fish on their first spawning run, so older fish are not tabulated.

Table 2: Adult life history variation in Central Valley Chinook, based on various studies described in Williams (2006)

Winters in Fresh Water	Winters at Sea				
	1	2	3	4	5
0	Common	Common	Common	Scarce	~ nil
1	No data	Some	Some	Very scarce	~ nil

Table 3. Fork length in centimeters of Central Valley steelhead at various life stages, estimated from scale measurements of steelhead on their first spawning migration, for four life history patterns (age at return = years in freshwater/years in salt water). Data from Table 1 in Hallock et al. (1961).

Age at return	No. of fish	Length at salt water entry	Length at end of year 1	Length at end of year 2	Length at end of year 3	Length at capture
1/1	17	20.3	12.2			33.0
1/2	10	18.3	12.2	33.5		52.1
2/1	30	22.9	10.7	19.8		40.6
2/2	26	21.3	9.4	18.0	41.9	59.2

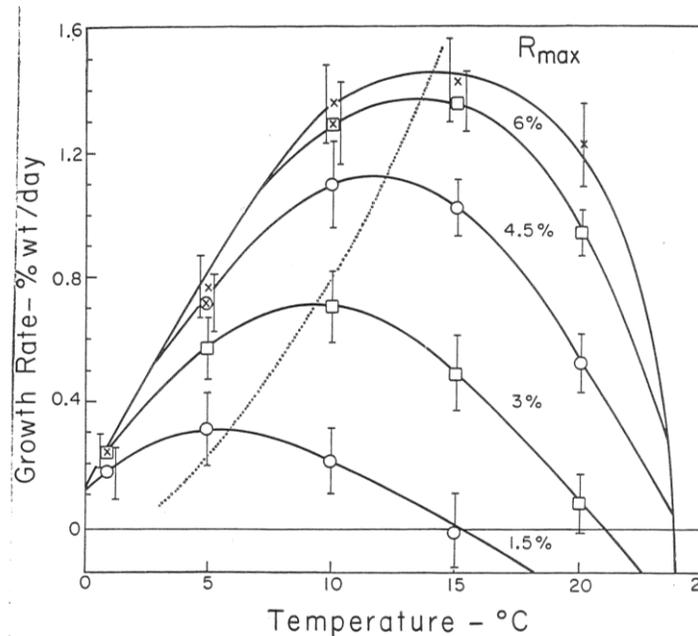

Variation in age at maturity buffers the population against environmental variation, since the consequences of reproductive failure or heavy mortality in early ocean life in any one year will be spread over several subsequent years, although the strength of this effect may be less than some suppose (Hill et al. 2003). Unfortunately, it appears that the age distribution of Central Valley Chinook has been reduced by about a year, probably by ocean harvest (Williams 2006).

Four sea-winter Chinook used to be common in the Central Valley, and there were a few five sea-winter fish, based on scale samples taken in 1919 and 1921 (Clark 1928). Only a few four sea-winter fish now occur. A rather different change has occurred with steelhead; it seems that many now forgo anadromy altogether, as discussed in the ecology chapter.

D. Juvenile Growth

The growth of juvenile salmon is strongly influenced by temperature and the amount of food available, known as “ration” in experimental studies. The best data are available for sockeye (*O. nerka*), shown in Figure 5, but the same general pattern applies to Chinook and steelhead, except that the temperature for maximum growth is higher. Based on studies of Central Valley fish, the growth of fish fed to satiety in good laboratory conditions peaks at around 19°C for Chinook and steelhead (Marine 2004, Myric and Cech 2000, 2001, 2002; 2004), although one study (Rich 1987) found maximum growth at a lower temperature; see Williams (2006) for more discussion of these studies.

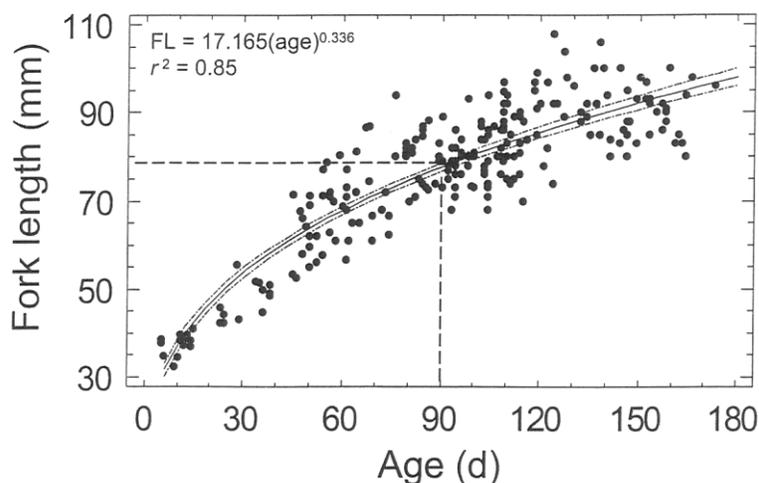

Figure 5. The relation between growth rate and temperature for different levels of ration for juvenile sockeye salmon. The dotted line connects temperature of maximum growth at each level of ration. Bars are two standard errors. Ration levels are given in percent body dry weight. Copied from Brett et al. 1969

Thus, temperature and ration are both “drivers” of juvenile growth, but other factors such as day length and the individual fish’s developmental program affect it as well, as discussed in the ecology chapter. Size and life-stage also affects growth, as growth in smaller fish is relatively more rapid, and growth (in weight) slows during smolting (Weatherby and Gill 1995). Growth also varies among individuals, even in laboratory conditions, as indicated by the error bars in Figure 9. Scofield (1920) noted regarding Klamath River Chinook that “Although from the same brood, hatchery practice and rearing pond, there was great variation in the size of the yearlings at the time of marking, the extremes in length being 1 3/16 to 5 inches ...” Data on the size at age of naturally produced Chinook in the American River and the bays show considerable variability (Titus et al. 2004; Figure 6), and a larger sample from the American River reported by

Castleberry et al. (1993) showed even more: the length of fish with ~125 otolith increments varied from about 40 to 80 mm. As another complication, fish of a given length vary in weight and in lipid content, which can be viewed as energy stored for future growth as well as future activity. In at least some populations of stream-type Chinook, day-length at emergence strongly influences juvenile growth (Clarke et al. 1992). In other words, growth is not a simple response to current environmental conditions, and fish in some sense “decide” how fast to grow. An obvious way that juvenile salmon can regulate their growth is behavioral. A fish may move up into the water column to feed, but risk being eaten itself, or it can burrow into the gravel and hide. Theory suggests that fish should adjust their behavior to minimize mortality per unit of growth, and observations support this idea (e.g., Bradford and Higgins 2001).

Figure 6. Size at age of juvenile Chinook salmon from the American River and from the San Francisco Estuary. Copied from Titus et al. (2004), courtesy of the American Fisheries Society.

Unpublished individual growth rates estimated from otolith microstructure, using the methods reported in Titus et al. (2004), vary from 0.27 mm d^{-1} to 1.05 mm d^{-1} . Interestingly, juvenile Chinook sampled in various Central Valley rivers grew faster on average than fish sampled in the Delta: 0.57 v. 0.54 mm d^{-1} (Rob Titus, DFG, pers. comm. 2008). Kjelson et al. (1982) reported that the growth of tagged fry released into the Delta mm averaged 0.86 mm d^{-1} in 1980 and 0.53 mm d^{-1} in 1981. This indicates that year to year variation in food availability in the Delta may be significant, and longer term variation may be important as well. Data on the size at date of fish collected at Chipps Island or the pumps should offer insight on this issue, as well as whether growth in the Delta is density-dependent.

Using hatchery fish in enclosures, Jeffres et al. (2008) found that juvenile Chinook grew more rapidly on the vegetated Cosumnes River floodplain when it was inundated than in the river, either within or upstream of the tidally influenced area. Food was very abundant, and the fish grew well even though the water temperature averaged 21°C for a week, with daily maxima up to 25°C . This underscores the relationship between the availability of food and temperature tolerance implied in Figure 5.

An 11 year study by NMFS found that on average juvenile fall Chinook grow slowly in length (0.33 mm d^{-1}) and hardly at all in weight during their migration through the bays, from Chipps Island to the Gulf of the Farallones, although they grow rapidly once they reach the gulf (MacFarlane and Norton 2002; MacFarlane et al. 2005, B. MacFarlane, pers. comm. 2008). Given that survival in the ocean is size-dependent, this raises the questions whether the human modification of the bays, especially loss of tidal wetlands (Nichols et al. 1986; Lotze et al. 2006), has adversely affected Chinook and steelhead, and whether naturally produced juveniles suffer from competition with hatchery fish in the bays. These questions deserve further study.

E. Temperature tolerance:

Salmon are ectotherms (cold-blooded), so their body temperatures are close to that of the water around them. Salmon do not tolerate warm water, and the Delta and lower rivers are unsuitable habitat for them in summer. However, salmon's response to temperature is affected by factors such as the availability of food, as discussed above, so, like growth, the temperature tolerance of salmon is affected by other factors in the environment.

Large embryos probably are the life stage least tolerant of warm water, because their metabolic rate increases with temperature, but they obtain oxygen and dispose of metabolic wastes only by diffusion through the egg wall. In laboratory studies with constant temperature through incubation (egg and alevin life-stages), mortality starts to increase at about 12 or 13°C, and increases sharply around 14 or 15°C (Williams 2006). In consequence, Central Valley streams are not suitable spawning habitat in summer except at high elevations, or where special circumstances such as inflows from large springs or releases from deep reservoirs keep the water cool. However, early-stage embryos seem somewhat more tolerant of warm water (Geist et al. 2006), so that Chinook spawning at 15 or 16°C in the fall may avoid harm if normal seasonal cooling occurs.

Juveniles tolerate temperatures of 20°C or even higher, provided food is abundant and the habitat is otherwise good, as in the Cosumnes River floodplain study described above. Juvenile steelhead probably are even more tolerant, as evidenced by the more southerly limit of their natural range. However, such warm temperatures do induce stress. At daily mean temperatures above 18-19°C, juvenile steelhead in the Navarro River develop elevated levels of a heat-shock protein, hsp 72 (Werner et al. 2005). At the least, this imposes a metabolic cost.

Adult Chinook can also tolerate about 20°C (Williams 2006). In Butte Creek in 2002 and 2003, adult spring Chinook suffered heavy mortality from columnaris, a bacterium, following more than a few days with mean temperatures > 21°C. There is also evidence of prespawning damage to gametes in 2002 (Williams 2006), so conditions in Butte Creek (Figure 7) probably represent the thermal limit for populations of spring Chinook, and global warming makes the prospect for the Butte Creek population dim.

Although juvenile steelhead and some juvenile Chinook stay in Butte Creek through the summer, they do not have to contend with predatory fishes there. This is not the case in the

Delta, or the larger rivers. Since the metabolic and digestive rates of predatory fishes also increase with temperature, so does the risk of predation for small salmon. Coded-wire tag studies have shown that survival in the Delta begins to decrease at temperatures that juveniles survive easily in the tributaries (Baker et al. 1995), probably because of increased predation. Whatever the cause, the lower rivers and Delta are too warm for juvenile Chinook and steelhead in the summer

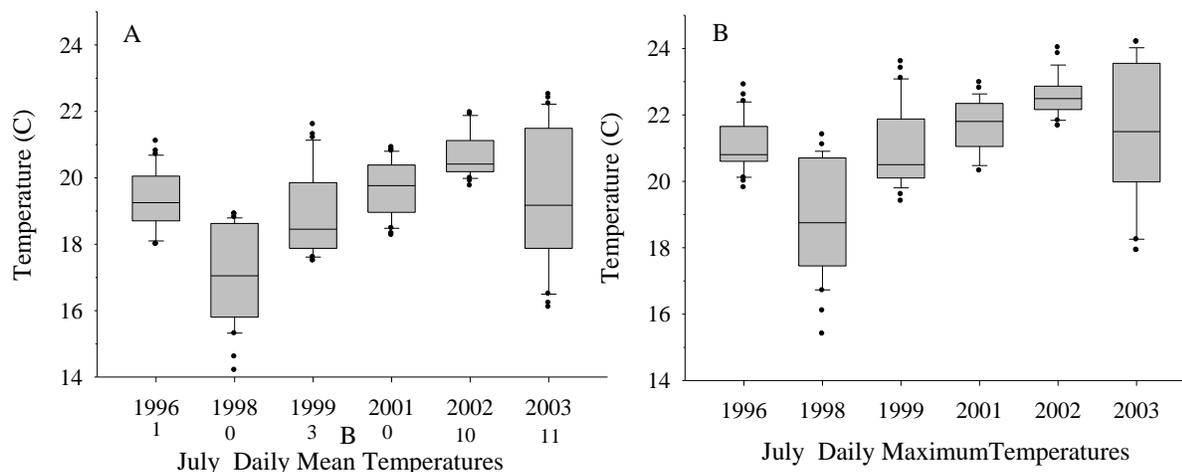

Figure 7. Daily mean (A) and daily maximum (B) water temperatures at the Pool 4 monitoring site in the reach of holding habitat on Butte Creek: The number of days with mean > 21°C in each year is shown below the date in A. July 2002 was consistently warm; July 2003 was cool early but warm later. Copied from Williams (2006); data from CDWR and CDFG.

F. Dissolved oxygen

The oxygen in water molecules is tightly bound to a carbon atom, but fish can take up dissolved oxygen through their gills. Generally, there is enough dissolved oxygen for Chinook and steelhead in flowing streams, but eggs and alevins are often under some level of oxygen stress (Williams 2006). This is particularly true for Central Valley fish, since the metabolic demands of the organism increase with temperature, the amount of dissolved oxygen that water can hold varies inversely with temperature, and fish in Central Valley streams generally incubate at relatively high temperatures. In the surface streams, dissolved oxygen is mainly an issue on the San Joaquin River near Stockton, where low flow and high biological demand in late summer and fall causes a “DO sag” (Lee and Jones-Lee 2003; Jassby and Van Nieuwenhuyse 2005). The low DO may delay migration up the San Joaquin River by adult fall Chinook, as discussed in the stressors chapter.

III. Distributions:

A. Historical distributions:

Chinook and steelhead were once widely distributed in Central Valley rivers, going just about anywhere they could swim. The past distribution of Chinook has been estimated from

historical accounts by Yoshiyama et al. (1996; 2001). Lindley et al. (2004, 2006) estimated that there were about 18 independent populations of spring Chinook, 4 independent populations of winter Chinook, and 81 independent populations of steelhead, based largely on the historical data compiled by Yoshiyama et al. (1996), and on factors such as stream gradient, basin size, and temperature. Winter Chinook inhabited streams in volcanic terrain in the upper Sacramento drainage where large springs provided substantial inflows of cool groundwater year-round: the McCloud, Little Sacramento, and Pit rivers, and Battle Creek. Spring-run probably were the most widely distributed Chinook; they ascended rivers to high enough elevations that summer temperatures remained tolerable, and because they migrated during spring snowmelt runoff, they could pass over barriers that were impassable during lower flows. Fall Chinook spawned at lower elevations than other runs, but also used accessible higher elevation habitat such as the McCloud River. However, they remained separate from other runs by spawning later in the fall than spring Chinook (Williams 2006), but earlier than late fall-run. There is little information on the natural range of late-fall Chinook (Williams 2006), but evidently they spawned at high enough elevation that the streams remained habitable for the juveniles through the summer, and spawned later than fall-run. Steelhead presumably went higher into watersheds and into smaller tributaries than Chinook, but good information on their natural range is also lacking (McEwan 2001).

Since salmon are anadromous, the distribution of any population includes habitats between the spawning grounds in gravel-bed streams and the oceans, including the Delta. Juveniles can and do swim upstream, so Chinook habitat in the Central Valley extends into small tributaries, such as Rock Creek near Chico, that are dry in the summer and do not support spawning (Maslin et al. 1999). These are relatively warm and biologically productive, and the young salmon grow rapidly there. As many as a million juveniles may still use these habitats.

Salmon habitat also extended widely across the valley floor. Historically, during the winter and spring, the rivers were not contained by their channels, and spread out over large areas, especially in the Sacramento Valley (Kelley 1989), to provide extensive floodplain habitat for juvenile salmon (Williams 2006). The overbank habitat along the lower rivers graded into the extensive tidal marsh habitat of the Delta and the bays. Although data are lacking, it seems likely that juvenile salmon historically used tidal and subtidal habitats all across the Delta. In a report on studies of Chinook in 1897 and 1898, Scofield (1899) described a few fish collected in the bays and the Delta, and observed that:

If this small number of salmon taken in salt water represents, as it unquestionably does, the first big movement of young salmon out of the river, it at first appears that more of them should have been found, but when we consider the vast expanse of territory the lower Sacramento covers with its many channels and bayous, to say nothing of San Pablo and Suisun bays, it is not so strange that so few were found—in fact, the strange part of it is that so many were found—and we can realize the vast number that must have distributed themselves in these waters.

B. Current geographical distributions:

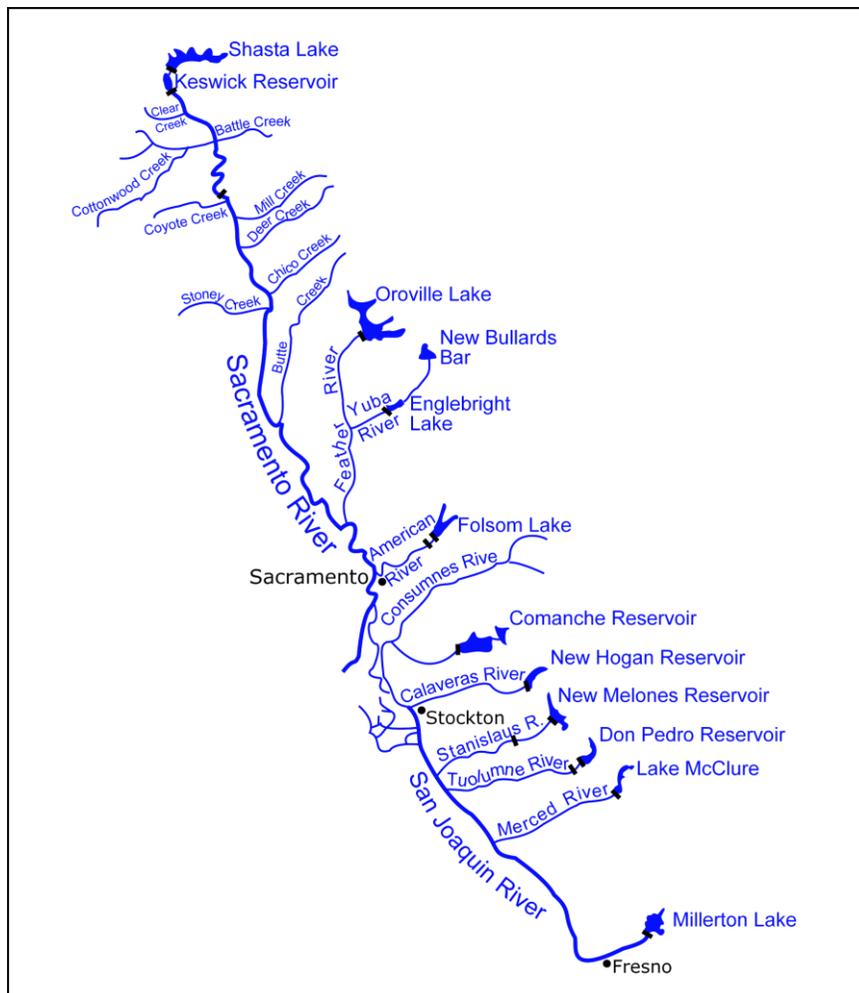

Current distributions of Chinook and steelhead are sharply constrained by impassible dams (Figure 8), or, on the San Joaquin River, by diversions. Fall Chinook, which still have access to the part of their natural range below the dams, are now most widely distributed, and are the only Chinook in the San Joaquin River and Delta tributaries. Winter Chinook persist only in the Sacramento River below Keswick Dam. Independent populations of spring Chinook remain in Mill, Deer, and Butte creeks, where migrations are not blocked by dams. Chinook enter the Feather and Yuba rivers in spring and hold over through the summer, but genetically the Feather River fish are very similar to fall-run, and the population is heavily influenced by hatchery fish; the same is probably true of the Yuba River population. Small populations of spring Chinook occur in several other Sacramento River tributaries such as Clear and Chico creeks, and a few nominal spring Chinook are reported in the mainstem. Late fall Chinook persist in the Sacramento River and apparently occur in various tributaries, but whether the tributary populations are viable is uncertain. *O. mykiss* remain widely distributed, but the number of naturally reproducing anadromous fish seems to be small, perhaps a few thousand, and there are few good data on them (Lindley et al. 2004, 2007; Williams 2006).

Along the streams and in the Delta, levees constrain the current distribution of juvenile salmon to the channels, except for the Butte Sink, the Sutter and Yolo bypasses (Figure 9), unleveed reaches of the Consumes River, and remnant tidal marshes in the Delta. Levees also block most of the tidal wetlands around the bay (Atwater et al. 1979). The loss of overbank and tidal habitat for juvenile rearing may rival the importance of the loss of upstream habitat for spawning. For example, habitat in the Butte Sinks and the Sutter Bypass probably accounts for the recent success of Butte Creek spring Chinook. The Yolo Bypass and the overbank habitat along the Consumes River provide good habitat when juvenile Chinook have access to them (Sommer et al. 2001, 2005; Jeffres et al. 2008).

Formerly an extensive tidal marsh, the Delta is now a web of constrained channels (Figure 10). The distribution of juvenile Chinook in the Delta in spring has been studied and described Erkkila et al. (1950) and by the Interagency Ecological Program (Kjelson et al. 1982; Brandes and McClain 2001). The IEP monitors the current distribution of juvenile Chinook in the Delta by seine surveys (Low 2005; Pipel 2005). Generally, density is highest along and near the Sacramento River, but juveniles occur throughout the Delta. The strong tidal flows in the Delta probably provide a sufficient explanation for the dispersal of juveniles, which preceded export pumping (Erkkila et al. 1950), but exports, active dispersal, and other factors probably affect it.

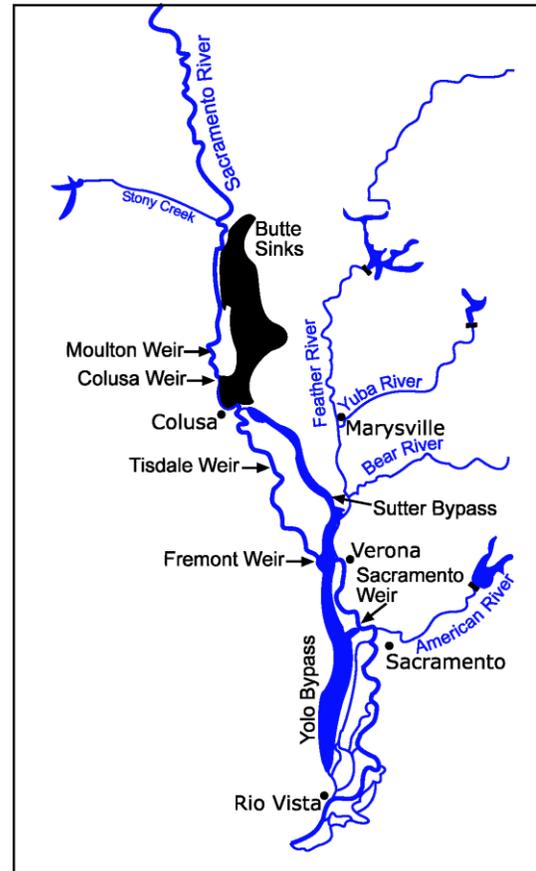

Like the juveniles, adult Chinook are widely distributed around the Delta, based on old tagging studies (Hallock et al. 1970) and the gill net fishery that existed until the 1950s. Presumably, steelhead are also distributed throughout the Delta, again with a concentration along and near the Sacramento River, but data are few.

Figure 8. Dams on Central Valley rivers. All major Central Valley rivers are blocked by large, impassable dams. Comanche Reservoir is on the Mokelumne River, and Friant Dam impounds Millerton Lake. The Red Bluff Diversion Dam is just upstream from Coyote Creek. Note that the rivers without dams are drawn ending at arbitrary points, not the upstream limit for anadromous fish. Copied from Williams (2006).

The distribution of juveniles in the bays is not well known. A few small juveniles are collected around the margins of the bays in the IEP seine surveys (SSJEFRO 2003) and in Suisun Marsh (e.g., Mattern et al. 2002). Fry use moderately saline (15-20 ppm) habitats in other estuaries (Healey 1991), so the salinity of much of the bays should not be an obstacle for them, even in dry years. NMFS has collected larger juveniles in the channels in April to June (MacFarlane and Norton 2002), but overall, data on distributions in the bay are sparse.

Figure 9. The flood bypass system along the Sacramento River. Water passes from the river through several weirs into the Butte Sinks, from which it flows into the Sutter Bypass, and then across the Sacramento River to the Yolo Bypass, which flows into the Delta. Copied from Williams (2006).

The distribution and production of hatchery salmon are summarized in Table 4. Hatchery Chinook returning as adults probably occur in all salmon streams, since hatchery fish stray more often than naturally produced fish. For example, five or six percent of the fall Chinook examined during carcass surveys on Mill and Deer creeks in 2003 and 2004 lacked adipose fins, and since only a small fraction of hatchery fall Chinook were marked at the time, a large proportion of the runs in those streams must have been straying hatchery fish (Williams 2006). The Joint Hatchery Review Committee (JHRC 2001) estimated that the straying rate of hatchery fish trucked around the Delta is over 70%, which helps explain the lack of detectable genetic variation among Central Valley populations of fall Chinook, described by Banks et al. (2000) and by Williamson and May (2005).

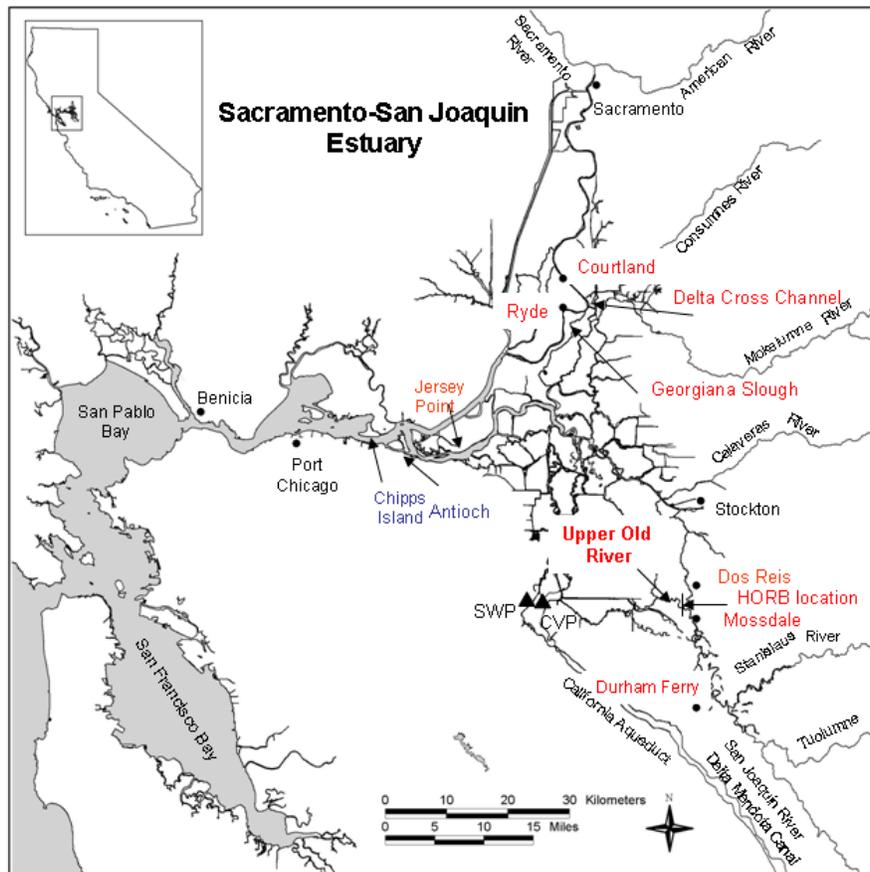

Figure 10. The Delta and bays. Locations marked in red figure importantly in IEP coded-wire tag studies. Sherwood Harbor, mentioned in the text, is not shown but is close to Sacramento. Copied from Newman (2008).

Table 4. Production and release data for salmon and steelhead in the Central Valley, data from JHRC (2001, Appendix V) and Brown et al. (2004). (JHRC) M = mitigation, E = enhancement. Coleman National Fish Hatchery is on Battle Creek, and Livingston Stone is on the Sacramento River near Keswick Dam. Fish with coded-wire tags (cwt) also are marked by removing the adipose fin.

Hatchery	Species or Run	Production Goal (millions)	Maximum Egg Take (millions)	Tag or Marks	Size and Time of Release	Release Location

C. Population Trends

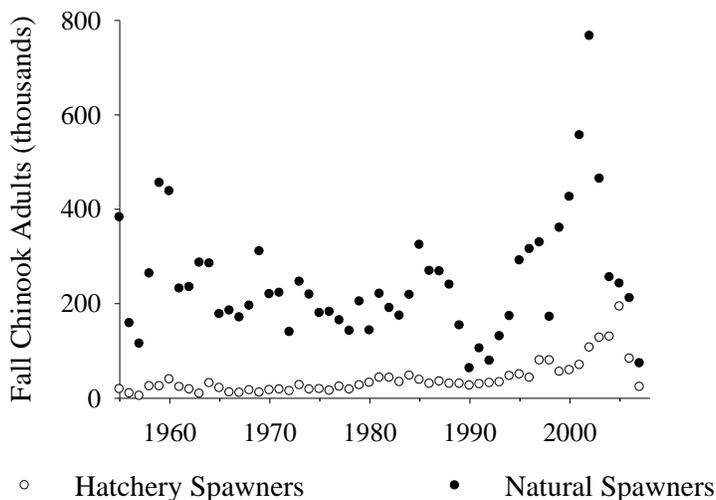

1. Fall Chinook

Returns of fall Chinook have fallen sharply from very high levels a few years ago (Figure 11). The decline is particularly striking because ocean harvest was well below normal levels for several years, and was shut down entirely in 2008. Poor ocean conditions have been identified as the proximate cause of the collapse by Lindley et al. (2009), in a report to the Pacific Fishery Management Council. However, the report also noted that “Degradation and simplification of freshwater and estuary habitats over a century and a half of development have changed the Central Valley Chinook salmon complex from a highly diverse collection of numerous wild

¹ A million fall Chinook from Coleman were trucked past the Delta in 2008.

populations to one dominated by fall Chinook from four large hatcheries.” Figure 10 understates hatchery influence, since many of the natural spawners are hatchery fish. A recent haphazard sample of about 100 from the party-boat fishery was 90% hatchery fish (Barnett-Johnson et al. 2007).

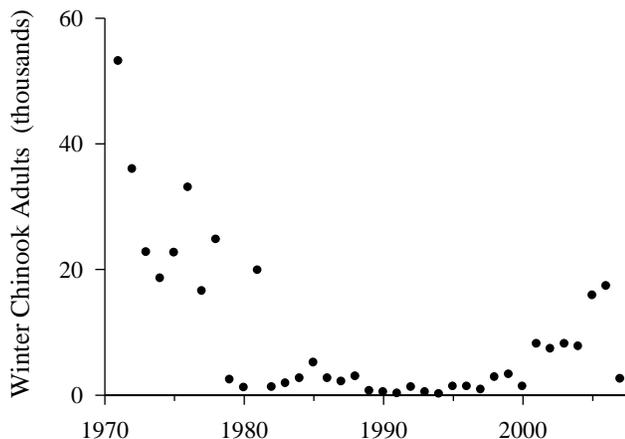

Figure 11. Returns of fall Chinook to Central Valley rivers (filled circles) and to Central Valley hatcheries (open circles). Data from CDFG. Recent years are preliminary.

2. Winter Chinook

After several years of increases, the number of winter Chinook returning to the Sacramento River declined sharply in 2007, although not as much as fall-run (Figure 12).

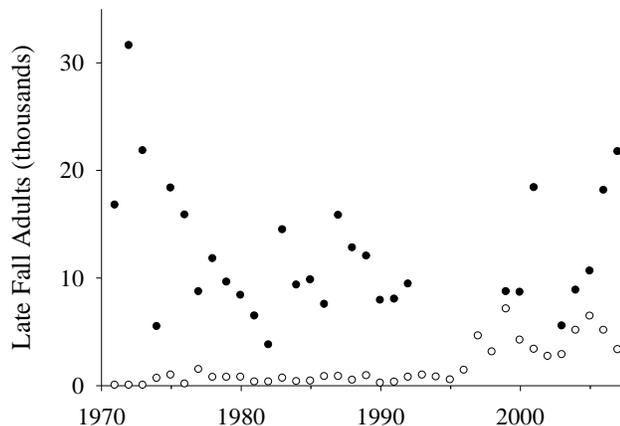

Figure 12. Returns of Winter Chinook to the Sacramento River. Data from CDFG. Recent years are preliminary.

3. Late fall Chinook

Returns of late fall Chinook have increased in recent years, in marked contrast to fall Chinook (Figure 13). As with fall Chinook, hatchery returns increased sharply after 1995. As discussed in the next chapter, late fall Chinook enter the ocean in winter, at a much larger size than fall Chinook, and this may explain why they responded differently to ocean conditions than fall Chinook.

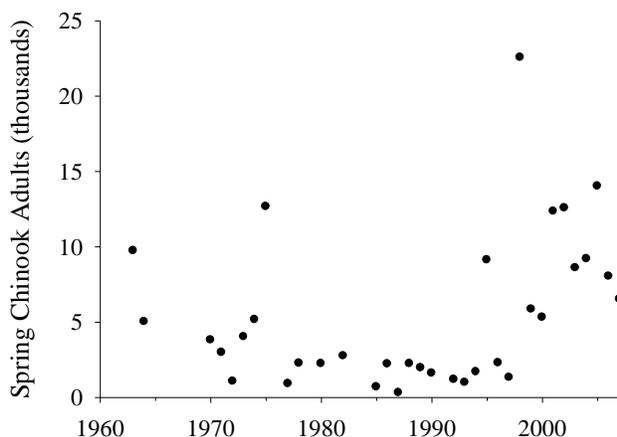

Figure 13. Returns of late fall Chinook to the upper Sacramento River (filled circles) and to Coleman Hatchery (open circles). Data from CDFG. Recent years are preliminary.

4. Spring Chinook

Spring Chinook have declined in recent years, especially in Mill and Deer creeks, but not as severely as fall Chinook (Figure 14). Spring-run from Butte Creek leave the Delta at about the same time and size as fingerling-migrant fall Chinook (see below), but for unknown reasons the spring Chinook suffered less from poor ocean conditions than did fall Chinook. There is essentially no hatchery influence on the Butte, Mill and Deer creek populations. Curiously, returns of hatchery-dominated Feather River spring Chinook were up in 2007, as were returns to the Sacramento River mainstem, which may be largely Feather River hatchery strays.

Figure 14. Returns of spring Chinook to the Mill, Deer, and Butte creeks. Data from CDFG. Recent years are preliminary.

5. Steelhead

There are few data on the abundance of wild or naturally produced adult steelhead in the Central Valley, now that they are no longer forced to pass a ladder at the Red Bluff Diversion Dam, and it is very hard to distinguish anadromous steelhead from large resident *O. mykiss* on the spawning grounds. Based on the number of unmarked juveniles captured at Chipps Island, however, the number of spawning females may average three or four thousand (Williams 2006).

IV. Ecology

A. Adult life history patterns

Chinook in the Central Valley usually are classified into four separate runs, named for the season in which adults enter fresh water: fall, late-fall, winter, and spring. Central Valley steelhead now enter fresh water mainly in fall, although a few adults of both species migrate up the Sacramento River even in the summer (Williams 2006). Winter Chinook are listed as endangered under the federal Endangered Species Act (ESA), and spring Chinook and steelhead are listed as threatened.

Fall Chinook generally enter fresh water as temperatures decline in the fall, in an advanced state of sexual maturation, and begin spawning when the water temperature declines to 15 or 16°C (Williams 2006). The timing of spawning varies somewhat from river to river and year to year (Table 5). Late-fall Chinook follow the fall-run into the rivers, but also spawn fairly soon after arriving on the spawning grounds. Winter and spring Chinook, however, typically hold in fresh water for several months to complete sexual maturation before they spawn. These different patterns are sometimes called “ocean maturing” and “stream maturing.”

Genetic evidence (Figure 15) indicates that the spring Chinook in Butte Creek are a separate lineage from those in Mill and Deer creeks, and spring Chinook in the Feather River are closely related to fall Chinook. Thus, the four named runs correspond generally but not completely with genetic lineages. Steelhead in the American and Mokelumne rivers are descended from a coastal stock brought to Nimbus Hatchery after the native run failed to thrive in hatchery culture (McEwan 2001).

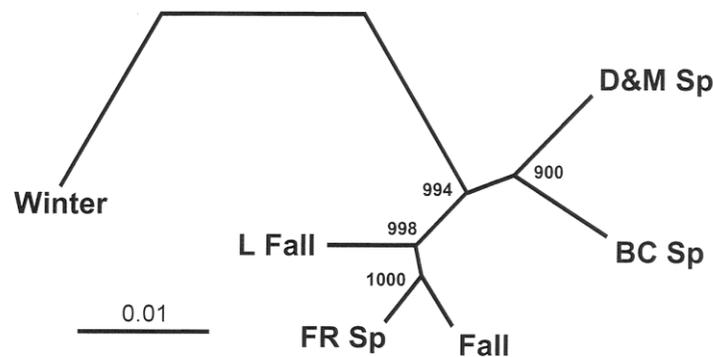

Figure 15. Genetic relationships among runs of Central Valley Chinook, based on distances (Cavalli-Sforza and Edwards) calculated from 12 microsatellite loci. The clustering analysis (UPGMA) distinguishes spring-run from Deer and Mill creeks (D&M Sp) and Butte Creek (BC Sp). Numbers next to nodes show the number of bootstrap trees, out of 1,000, showing this node. Nominal spring-run from the Feather River (FR Sp) group close to fall-run. Other genetic studies, reviewed by Hedgecock et al. (2001) have produced similar results. Copied from Hedgecock 2002.

Table 5. The estimated range in the time of spawning by Chinook salmon in various Central Valley rivers, summarized from tables 6-1 to 6-4 in Williams (2006).

Run:	5% by	Peak	95% by
Fall	mid-Sep. to late Oct.	Mid-Oct to late Nov.	early Nov. to late Dec.
Late-fall	early to late Dec.	late Dec. to late Jan.	late March to early April
Winter	early to mid-May	early June to early July	early to mid-August
Spring	late Aug. to early Sept.	Sept. to early Oct.	mid to late Oct.

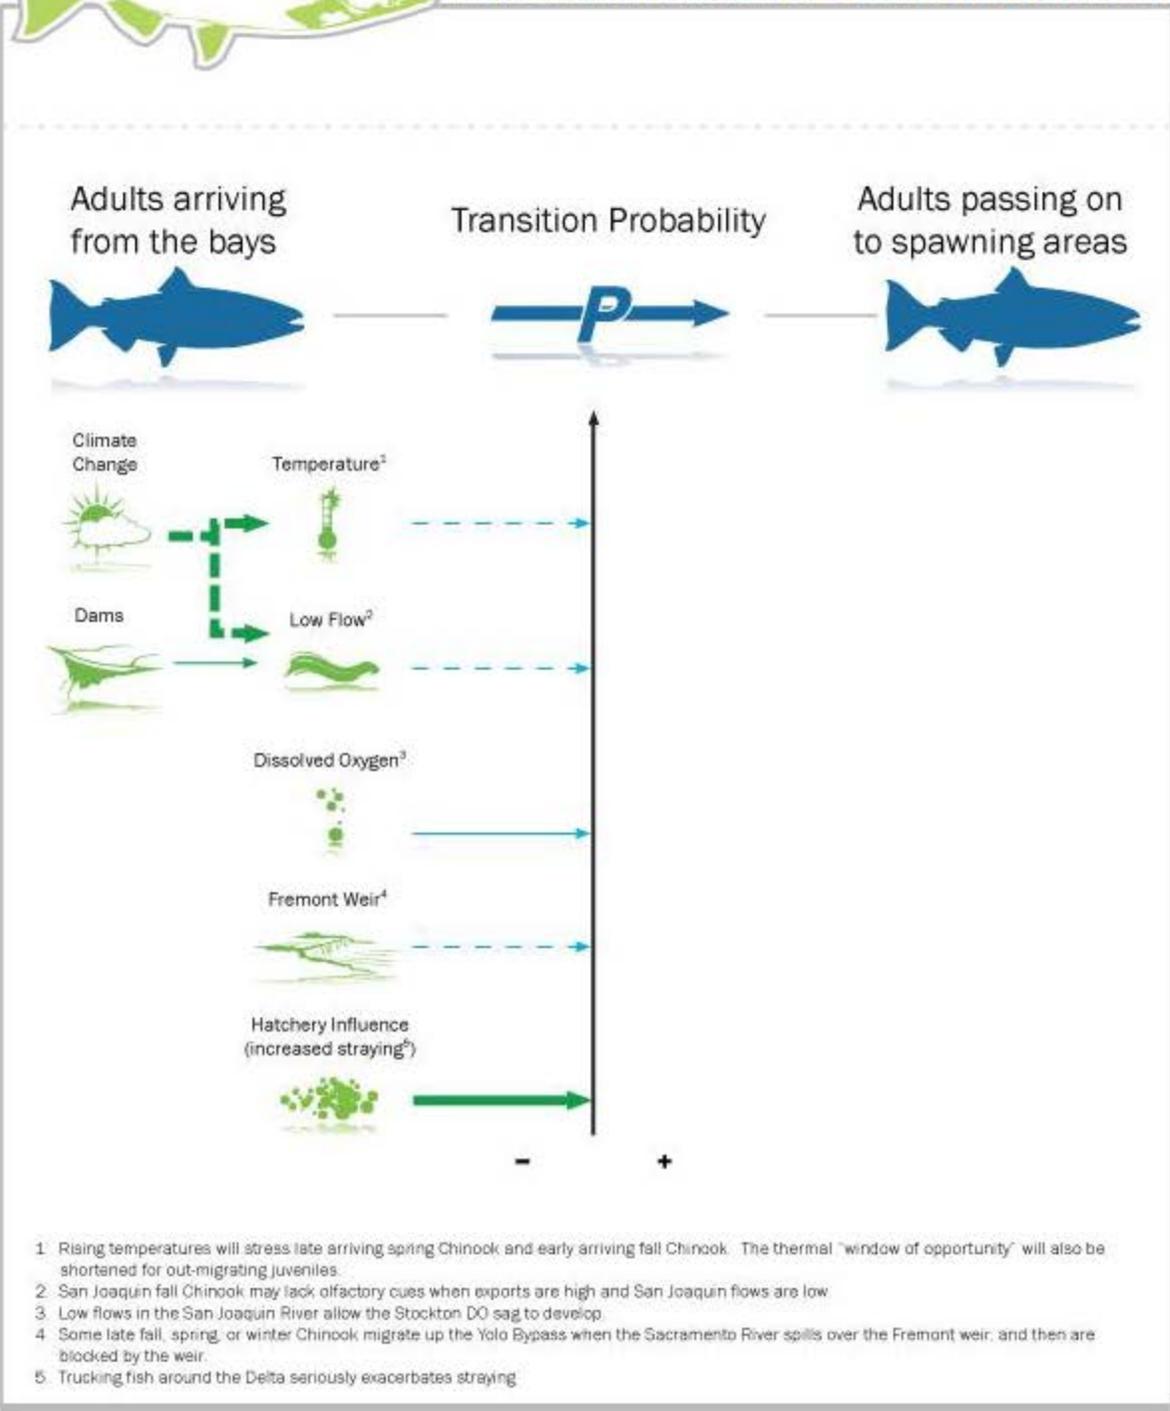

Like genetic lineages, management units of Chinook correspond generally but not exactly with the four named runs. In particular, for Endangered Species Act (ESA) purposes, fall and late fall Chinook are lumped together, as are all spring-run. Harvest is managed largely in terms of “Sacramento Fall Chinook”, which ignores fall Chinook in the San Joaquin system and in the Mokelumne and Cosumnes rivers, which flow directly to the Delta.

Steelhead migrate up the Sacramento River mainly from August through November, but some do so in all months (Hallock et al. 1961; McEwan 2001), and a summer-run may have existed historically (McEwan 2001). Although steelhead enter freshwater mainly in the fall, they are often called winter-run. The fall or winter-run steelhead spawn mainly from late December through April (Hallock et al. 1961; Hannon et al. 2003). Only few steelhead now migrate into San Joaquin River tributaries (Williams 2006).

B. Navigation by adults

Although the details remain uncertain, maturing salmon apparently find their way back to the vicinity of their natal stream using celestial and magnetic cues, and then shift mainly to their sense of smell to guide the rest of their migration (Quinn 2005). Maturing Chinook and steelhead migrating back to Central Valley rivers must pass through the Delta. Tagging studies showed that Chinook may spend weeks in the Delta (Hallock et al 1970), as they do in other estuaries (Olson and Quinn 1993), but some pass through quickly. Given the extent to which fish linger in the Delta, delays of a day or two at the Montezuma Slough gates or the Delta Cross Channel seem unlikely to be significant (Williams 2006). On the other hand, adult winter-run that try to migrate up the Yolo Bypass may find themselves trapped there. Factors reducing the survival of adults migrating through the Delta are summarized in Life Stage Transition Figure 3.

Transition Matrix: Chinook Salmon

Life Stage Transition 3

C. Juvenile life history patterns:

Early in the 20th Century, biologists recognized that some juvenile Chinook migrate to sea in the spring of their first year, while others remain in the stream through a winter and migrate the following spring. These were called “ocean-type” and “stream-type” (Gilbert 1913), but this dichotomy does not capture the actual range of juvenile life history patterns, since late fall and winter Chinook migrate downstream and into the bays during the fall and winter, and spring and fall Chinook may remain near the spawning areas for only a few days or for several months. Accordingly, juvenile Chinook of widely different sizes can be found in different Central Valley habitats (Figure 16). Although they are really points on a continuum, it seems possible to distinguish six different life history patterns for juvenile Chinook in the Central Valley, ranked below in terms of increasing amounts of time spent in fresh water. Similarly variable patterns have been described in other rivers (Burke 2004). Life history patterns can also be distinguished in terms of the habitats in which juveniles mainly rear (Figure 16).

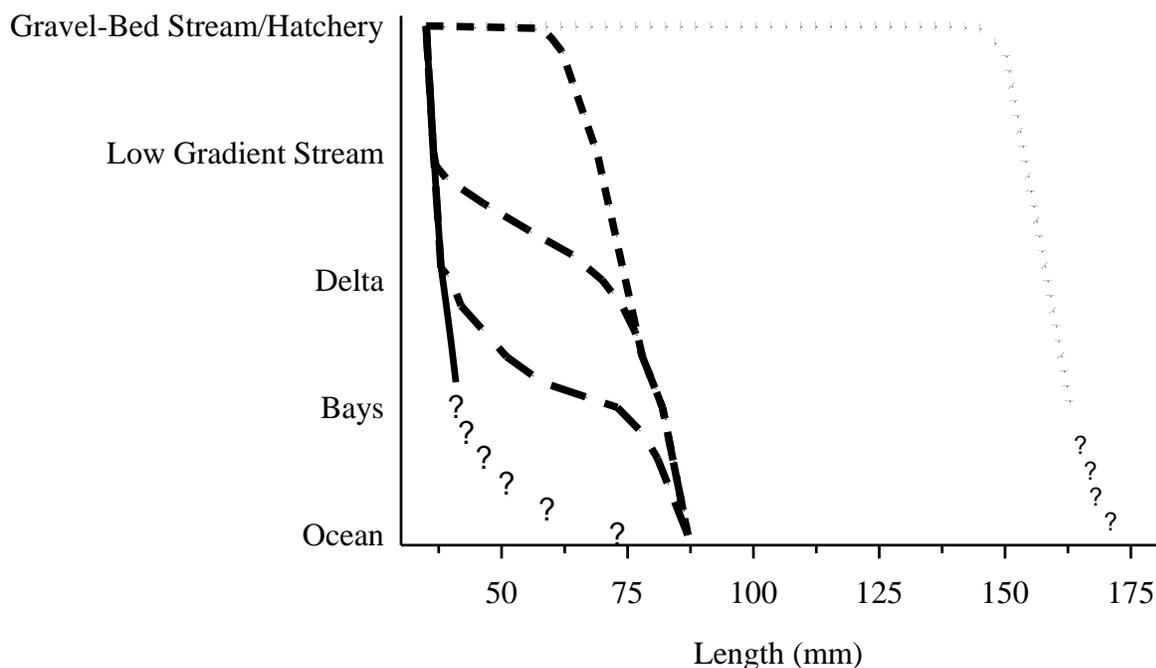

Figure 16. Conceptual “juvenile life-history space”. Lines show representative trajectories of growth and migration for juvenile Chinook. Fry emerge at ~35 mm, and may migrate directly to the bays; what they do when they get there is poorly understood. Many fish migrate directly to the Delta and rear there (long dashed line); if they survive, they migrate through the bays to ocean. Some fry migrate to the lower rivers and rear there before migrating through the Delta and bays (medium dashed line). Other fry emerge and remain in the gravel-bed reaches of the stream until they migrate, generally in spring, as fingerlings (short dashed line), while others remain in the gravel-bed stream through the summer and migrate as larger juveniles. How long they remain in the bays is unknown. Except for fry, lengths are actually highly variable, so properly the figure should show broad smears rather than discrete lines.

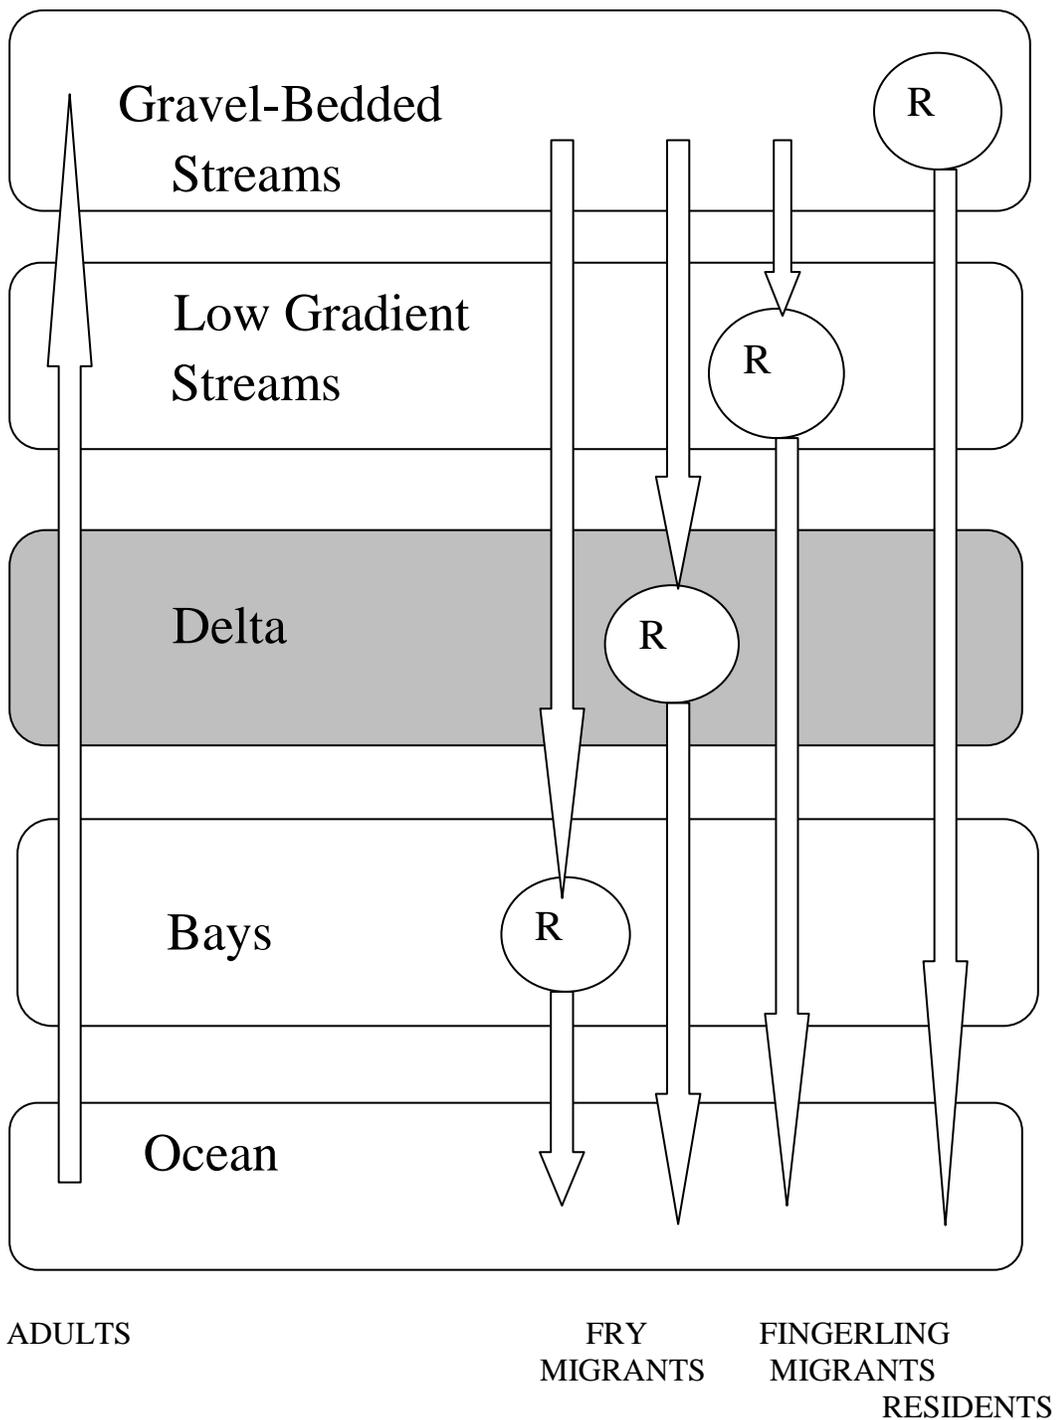

Figure 17. Schematic of the Chinook life-cycle, with arrows indicating migration and circles indicating the habitat in fish following different life-history patterns primarily rear.

Fry migrants to the bays migrate to brackish water soon after emerging from the gravel. Hatton and Clark (1942) captured significant numbers of ~40 mm juveniles at Martinez in mid-March, 1939, when flows in the rivers were low enough that these fish must have moved voluntarily through Suisun Bay. Similarly-sized fish are captured in the Chipps Island trawl, especially in wet years, although the capture efficiency of the trawl is probably low for fish of this size (Williams 2006). Modest numbers of fry were captured in seines in Suisun, San Pablo and San Francisco bays in 1980, although fewer were taken in 1981 (Kjelson et al. 1982). Only a few such fish are captured by the Interagency Ecological Program seine monitoring around the bays (SSJEFRO 2003), but this may reflect the large area over which such fish may be distributed. This life history may have been more common in the past, when more brackish tidal marsh habitat was available to them.

Fry migrants to the Delta also migrate downstream soon after emergence, but remain in the Delta and rear there before migrating into the bays. This is probably the most common life history pattern among juveniles, based on monitoring passage into the lower rivers (e.g. Figure 18), but the percentage that survive is unknown. Presumably, Chinook following this life history historically reared in the then-abundant tidal habitat in the Delta (Williams 2006).

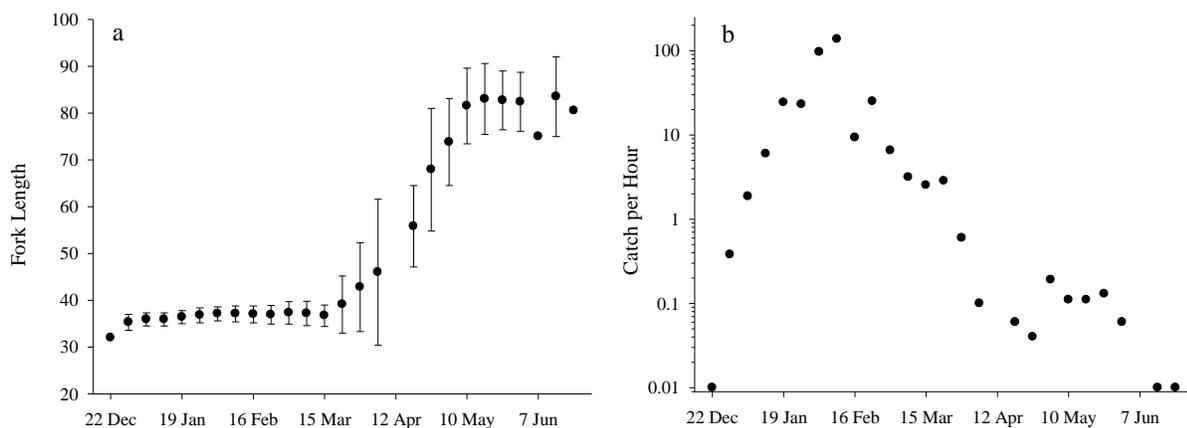

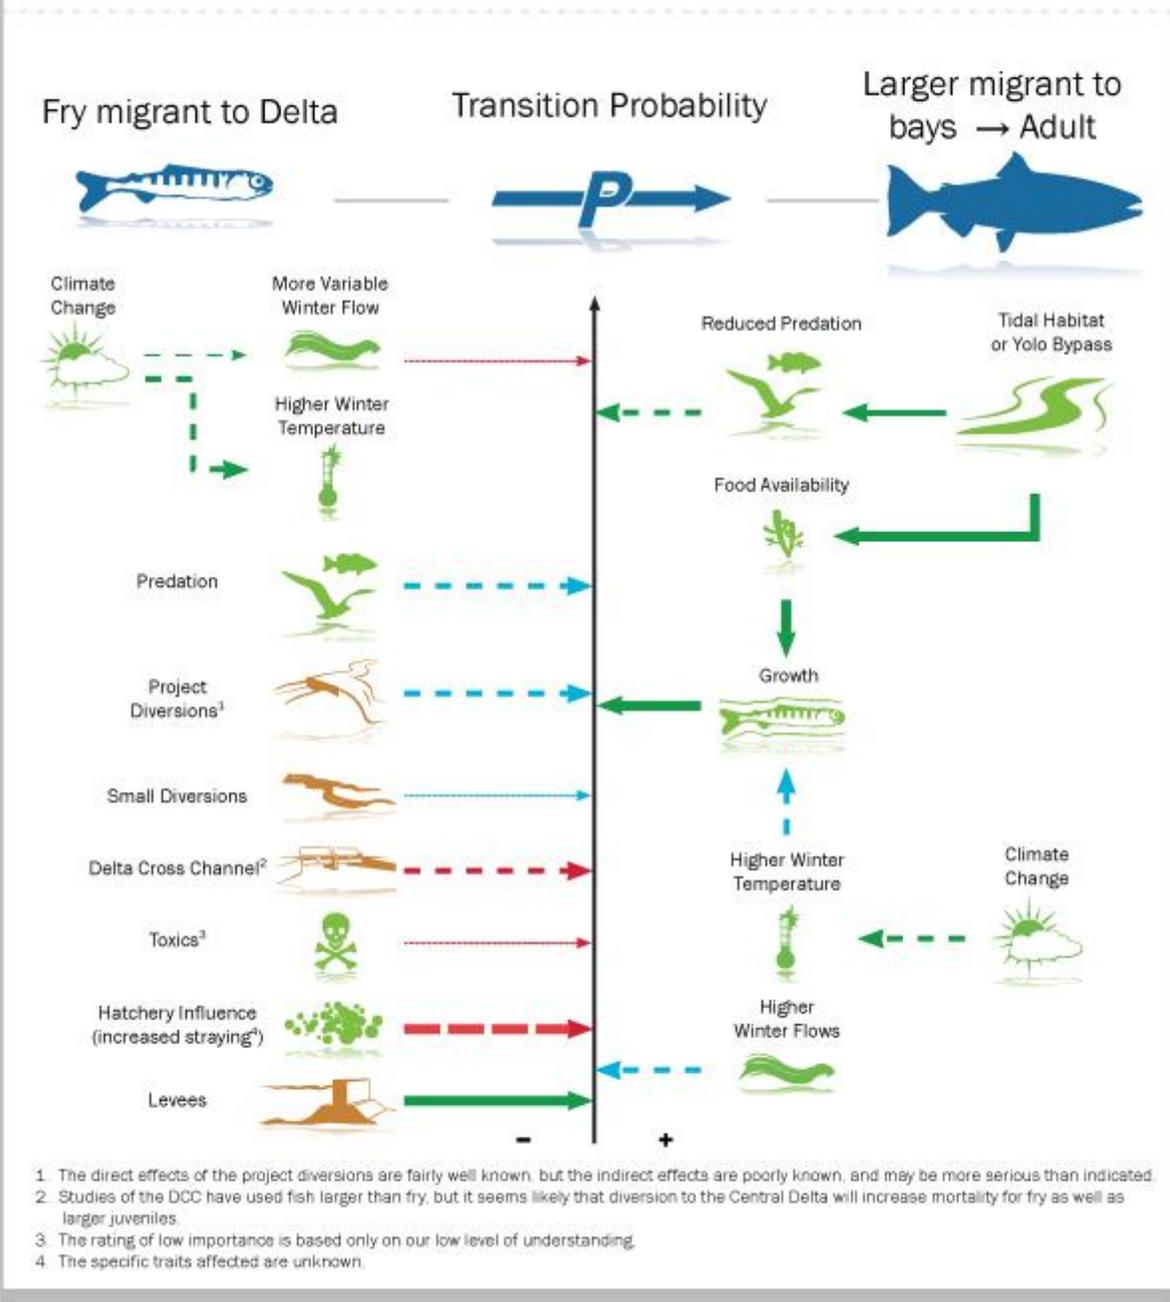

Figure 18. Mean length (a) and catch per hour (b) of juvenile fall Chinook salmon sampled in screw traps in 1999-2000 on the lower American River near the downstream limit of spawning habitat. Error bars show standard deviations. Note log scale in (b); the catch dropped sharply as size increased in March. Dates are approximately the middle of the sampling period. Data from Snider and Titus (2001); figure copied from Williams (2006).

Various factors influence the survival of fry migrants in the Delta, as summarized in the Life Stage Transition Figure 4. The negative factors (stressors) are discussed in Ch. 5; evidence for the positive effect of tidal or overbank habitat is discussed later in this chapter.

Transition Matrix: Chinook Salmon

Life Stage Transition 4

Fry migrants to low gradient streams move quickly downstream from the gravel-bed reaches where spawning occurs and rear in low gradient reaches in the valley floor before migrating rapidly through the Delta. Butte Creek spring-run exemplify this life history. Many Butte Creek spring-run fry are captured and tagged near Chico as they migrate into the Central Valley. The size of fish recaptured at Sherwood Harbor, near Sacramento, indicates that they mainly rear upstream of the Delta, presumably in the Butte Sinks or the Sutter Bypass, until they are > 70 mm; then they move rapidly through the Delta (Figure 19). The Yolo Bypass offers similar habitat to Sacramento River populations when water spills into it over the Freemont Weir, and several studies indicate that fish do well there (Sommer et al. 2001, 2005)

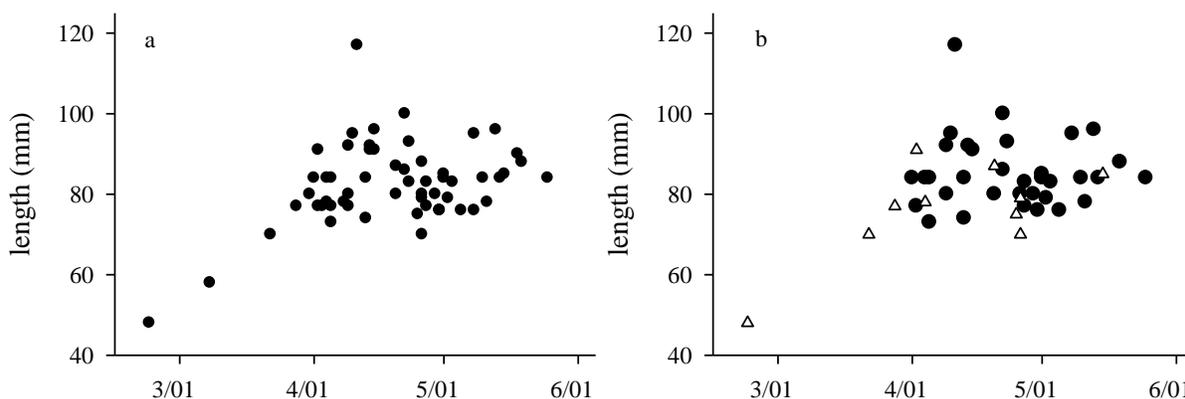

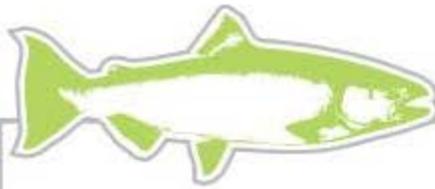

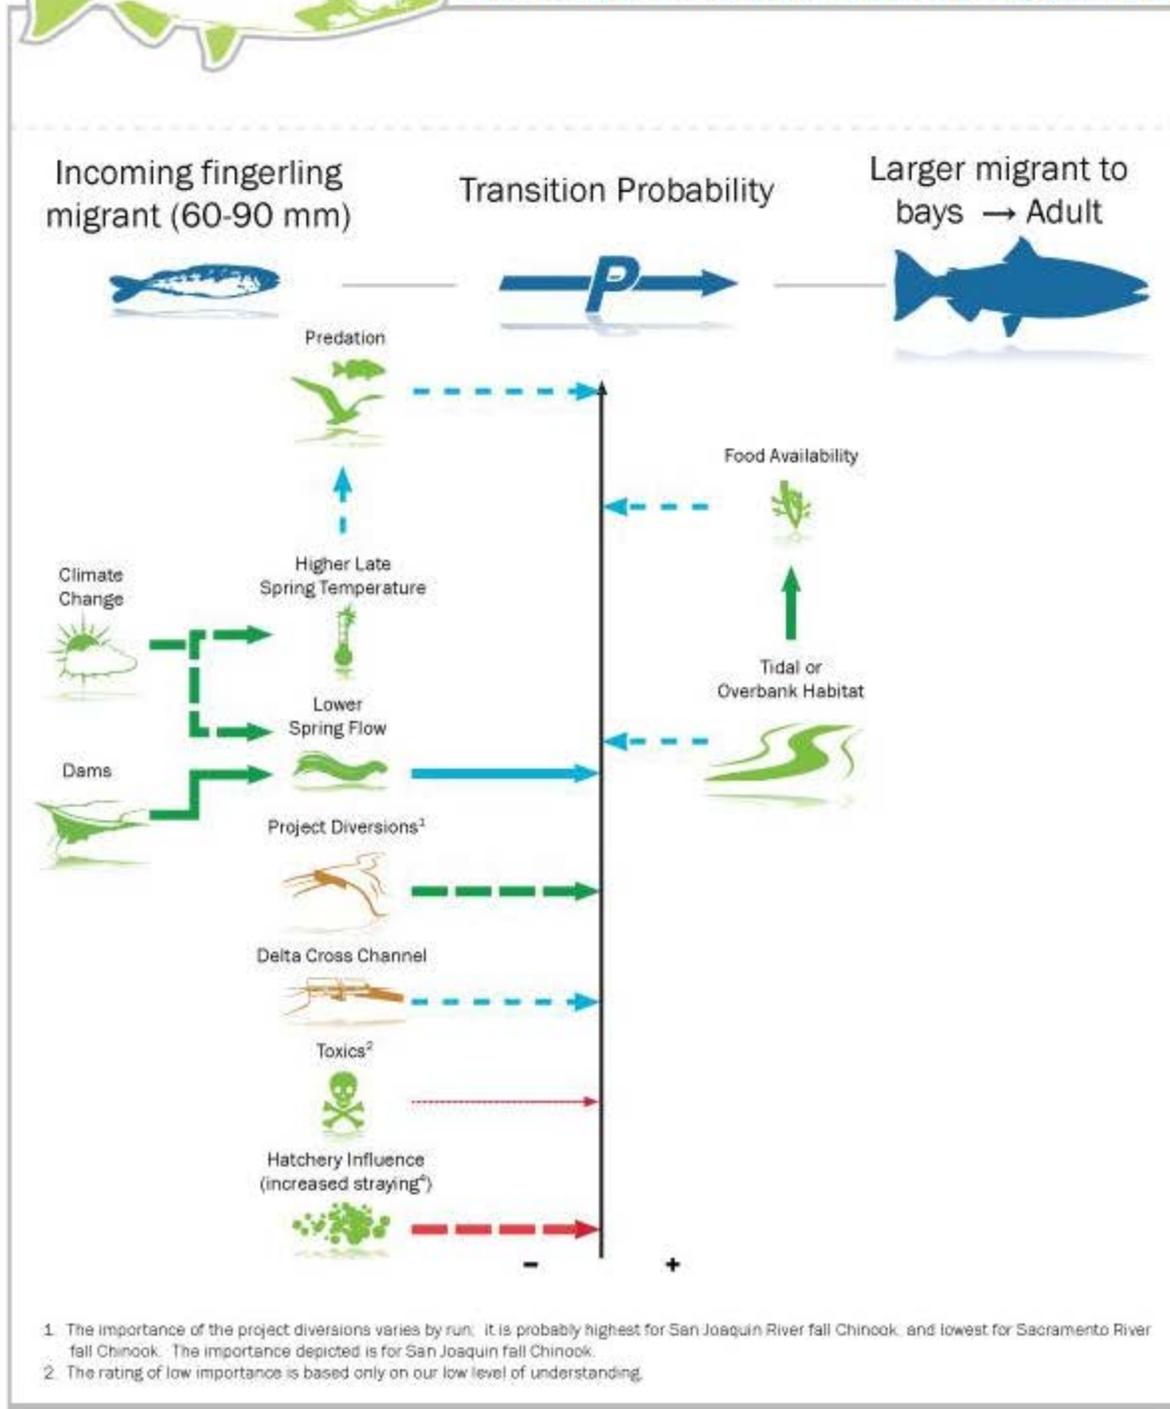

Figure 19: A. Size at date of capture of coded-wire tagged Butte Creek spring Chinook (n = 57), for all capture locations from Knights Landing to Chipps Island. B. As above, for Chipps Island (circles, n = 34) and Sherwood Island (triangles, n = 10). Data from USFWS, Stockton.

Fingerling migrants remain in gravel-bed reaches for a few months, and then migrate as larger (generally > 60 mm) parr or silvery parr, in late spring if they are fall-run. The second, smaller May mode in Figure 18b reflects this life history, which is followed by a larger proportion of the juveniles in the Mokelumne River and San Joaquin River tributaries than in the Sacramento River and tributaries, although there is considerable variation from year to year in the proportions (Williams 2006, Figure 20). The larger migrants are often called smolts, although few of them have reached this stage physiologically (e.g., Snider and Titus 2001). This life history pattern has received the most attention from managers. For example, most of the USFS coded-wire tag survival studies apply to this group. The life history of hatchery fall Chinook released into the river also approximates this pattern, since the hatchery fish are released at generally > 65 mm and most move rapidly downstream. Some move downstream very rapidly, in hatchery trucks, and are released into the bays, to avoid mortality in the Delta (Williams 2006). Factors influencing the survival of fingerling migrants to the Delta are shown in Life Stage Transition Figure 5.

Transition Matrix: Chinook Salmon

Life Stage Transition 5

Winter Chinook seem mainly to have a somewhat different juvenile life history, although the data are too sparse to support strong statements on the matter. Most of the naturally produced fish begin migrating as fry, but they seem to migrate slowly, reaching the lower Sacramento River in November (Figure 21), and generally not reaching the Delta pumps until February. More is known about the migration of hatchery winter-run, discussed below, since they are tagged, but their behavior seems to be different.

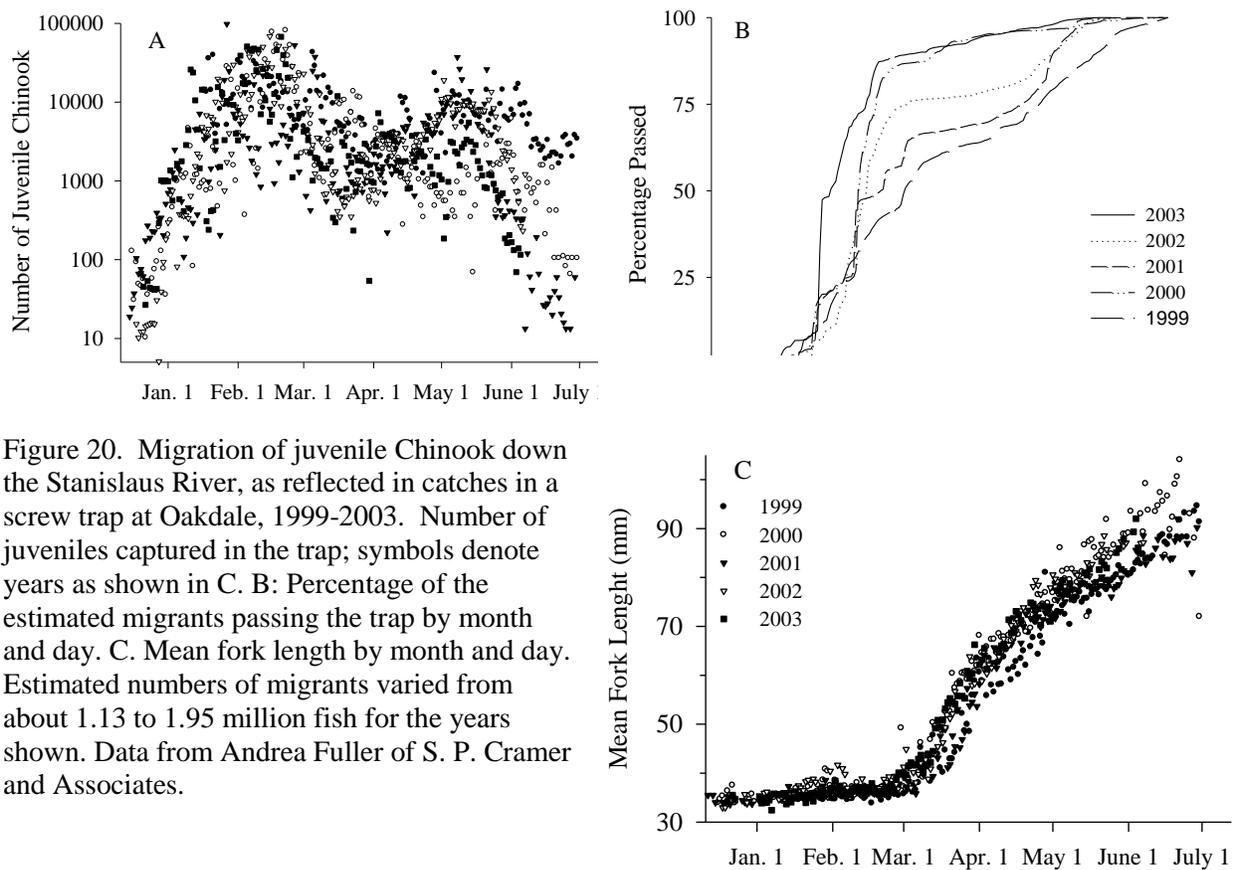

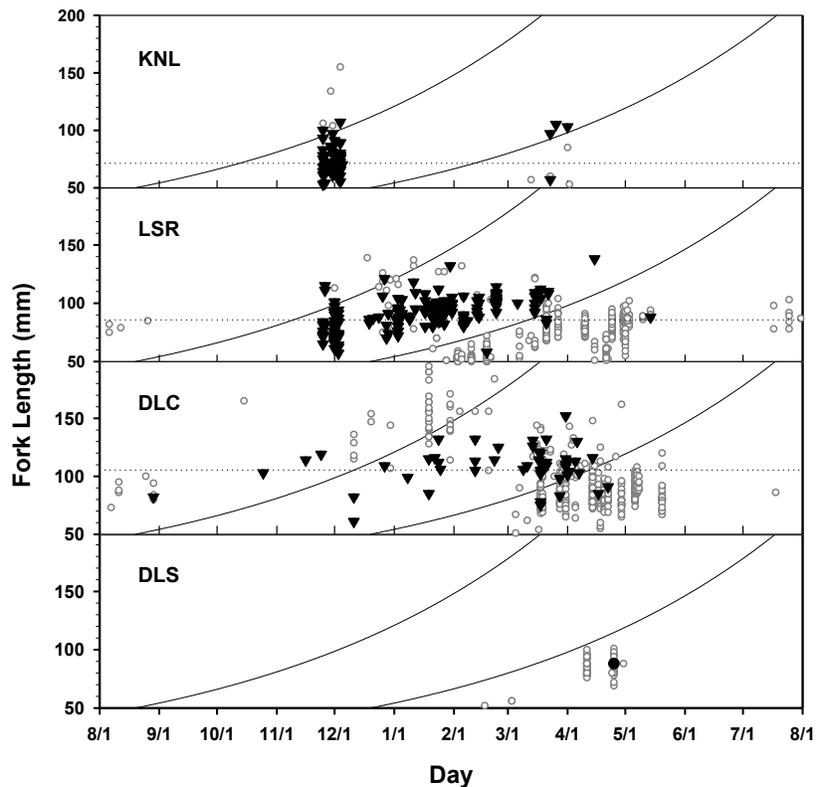

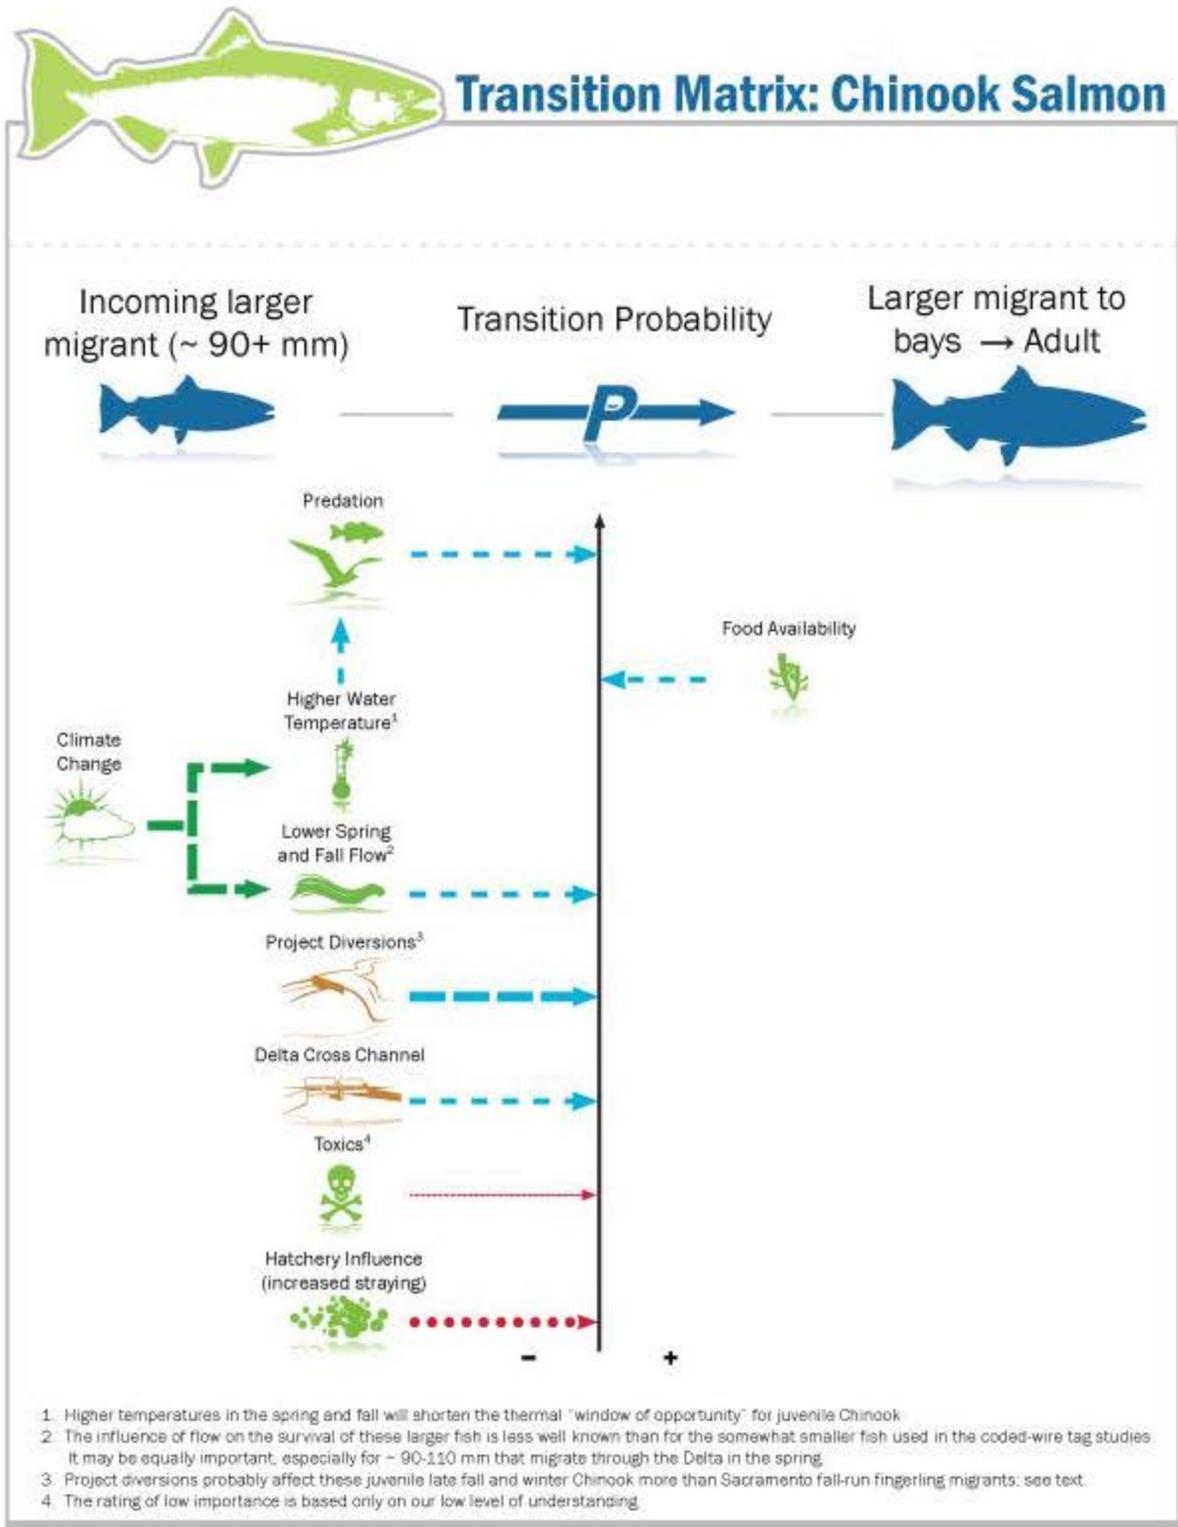

Figure 20. Migration of juvenile Chinook down the Stanislaus River, as reflected in catches in a screw trap at Oakdale, 1999-2003. Number of juveniles captured in the trap; symbols denote years as shown in C. B: Percentage of the estimated migrants passing the trap by month and day. C: Mean fork length by month and day. Estimated numbers of migrants varied from about 1.13 to 1.95 million fish for the years shown. Data from Andrea Fuller of S. P. Cramer and Associates.

Figure 21. Fork length and day of capture for juvenile Chinook assigned to runs by Hedgecock et al. (2002) for four areas from the IEP monitoring: Knights Landing (KNL), the lower Sacramento River (LSR), the central Delta (DLC), and southern Delta (DLS). Winter Chinook are shown by black triangles, other Chinook by open circles; dotted lines show mean lengths for winter-run at the site. The curved lines show length at date criteria for winter-run. Copied from Hedgecock (2002).

Fingerling residents remain in the gravel-bed reaches of the streams through the summer, and then migrate in fall or winter, generally at a length of 90 mm or more. This is probably the typical life history of late fall Chinook, and apparently it is being adopted by some fall Chinook below dams such as Keswick Dam on the Sacramento River that release cool water through the summer (Williams 2006). Many spring-run also follow this pattern; even in Mill and Deer creeks, most older juvenile spring-run migrate into the valley in November to January (Williams 2006).

Classic stream-type Chinook hatch in the spring, remain in the gravel-bed reaches of the stream through the winter, and migrate the following spring as smolts. This life history may have been more common before dams blocked most high elevation habitat, where low winter temperatures inhibit growth. Life Stage Transition Figures 6 shows the factors affecting the survival of the fingerling resident and stream-type juveniles in the Delta.

Life Stage Transition 6

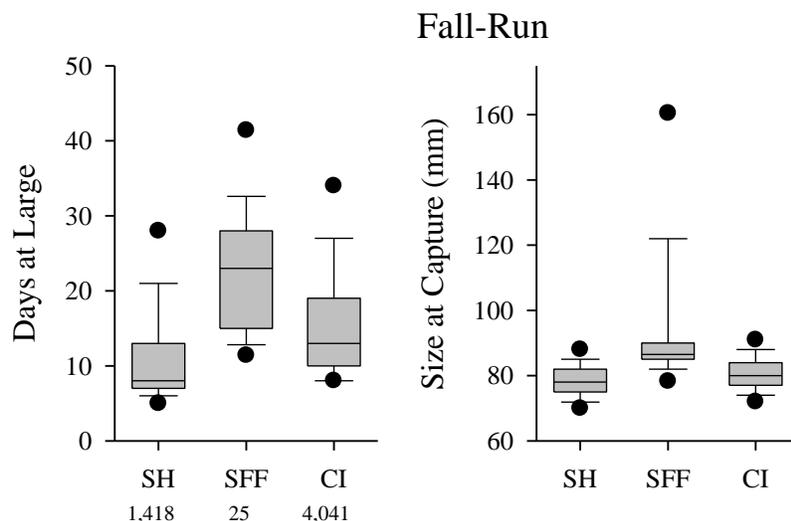

D. Juvenile migration rate

Juvenile migration is a complex matter, as suggested by the diversity of life history patterns described above, and despite many studies much about it remains unclear (Høgåsen 1998). If we take migration as a deliberate movement from one place to another, it is not even always clear whether juvenile salmon are migrating, or simply dispersing passively downstream. It is sometimes obvious that fry are being swept downstream (Williams 2006), but the downstream movement of large numbers of fry even during periods of low flows has seemed deliberate to most Central Valley biologists, starting with Rutter (1904).

The migration rates and schedules of wild and naturally produced Chinook are highly variable, as implied by the diversity of life history patterns described above. Only a few Central Valley data are available, (Williams 2006), not enough to provide good estimates, except for Butte Creek spring Chinook (Figure 19). The migration rate of tagged hatchery fish can be estimated from the number of days between the release and recapture of fish collected in monitoring programs, but hatchery fish may have different migratory behavior, so these data are most useful for comparisons among hatchery populations. All hatchery winter and late fall Chinook have been given coded-wire tags for some time, as have fall Chinook from the Merced River Hatchery, and about 8% of fall Chinook from Coleman Hatchery were tagged from 1995-2002; 25% of fall Chinook are now marked, so more data are accumulating rapidly.

Fall Chinook released from Coleman Hatchery migrate rapidly, with median travels time of 8 days to Sherwood Harbor, near Sacramento, and 13 day to Chipps Island (Figure 22). This suggests that the migration rate slows as the fish approach the Delta, since it is about 365 km from the hatchery to Sherwood Harbor, and only about 80 more to Chipps Island. The change from riverine flow to bi-directional tidal flow may account for the change in pace. Remarkably few of the fall Chinook released at Coleman have been recovered at the pumps (34 compared to 4,041 at Chipps Island), but those that do take longer to get there. Either they were larger to begin with, or they grew well ($\sim 0.8 \text{ mm d}^{-1}$) along the way.

Figure 22. Days at large, size at capture, and release date of tagged fall Chinook released at Coleman Hatchery, and recaptured at Sherwood Harbor (SH, n = 1,418) the state fish facilities (SFF, n = 25), and Chipps Island (CI, n = 4,041). Seven fish collected at the federal fish facilities and two released in January as yearlings are not shown. Sample sizes are given below X-axis labels on the left panel. Data from USFSW.

Coleman late fall Chinook do not migrate quite as rapidly to Sherwood Harbor as Coleman fall-run, despite their greater size (Figure 23). However, they appear to move more rapidly from Sacramento to Chipps Island. More Coleman late fall have been recovered at the pumps than at Chipps Island (3,898 v 3,008), very different from the fall-run. Much of this difference may be due to lower diversion rates and more intensive sampling at Chipps Island during the spring, but it seems that other factors such as migratory behavior must be involved as well.

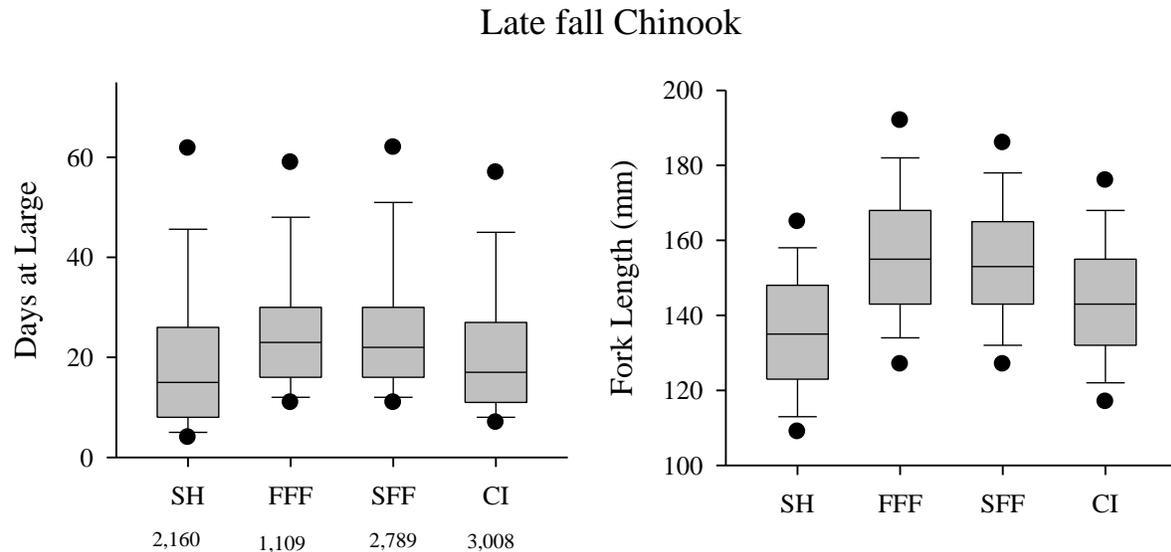

Figure 23. Days at large and size at capture of tagged late fall Chinook released at Coleman Hatchery, and recaptured at Sherwood Harbor (SH), the federal fish facilities (FFF), the state fish facilities (SFF), and Chipps Island (CI). Sample sizes are given below the labels on the X-axis, left panel. Data from USFWS.

Winter Chinook from Livingston Stone Hatchery at Keswick migrate more slowly, with median travel times of 24 days to Sherwood Harbor and 45 days to Chipps Island (Figure 24), again suggesting that migration slows approaching the Delta. Travel time to the pumps is not as long as to Chipps Island, different from the case with fall or late fall Chinook, although the hatchery winter-run collected at the pumps are larger on average than those at Chipps Island, as with fall and late fall. It seems likely that some biology that we do not understand is involved here.

L.S. Winter-Run

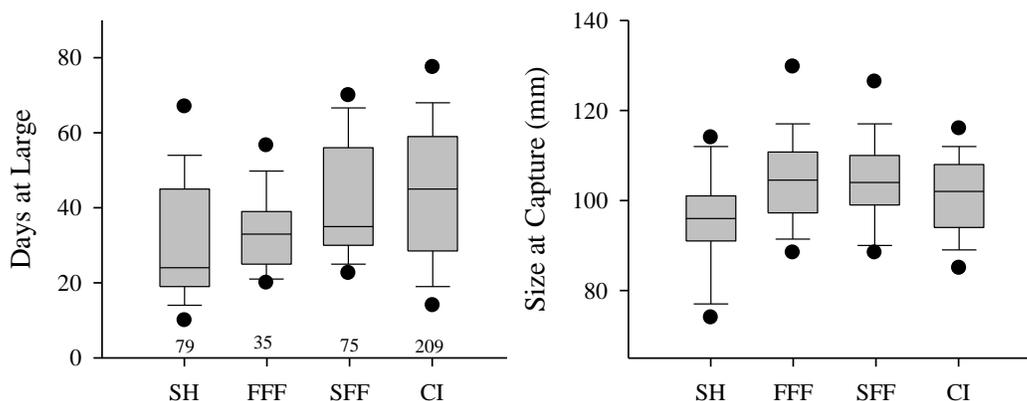

Figure 24. Days at large and size at capture of tagged winter Chinook released at Livingston Stone, and recaptured at Sherwood Harbor (SH), the federal fish facilities (FFF), the state fish facilities (SFF), and Chipps Island (CI). Sample sizes are given above the labels on the X-axis, left panel. Data from USFWS.

It is tempting to study the migratory behavior of hatchery fish because we have data with which to work, but we should remember that wild or naturally produced fish may behave differently. Hedgecock et al. (2002) analyzed tissue samples from juvenile Chinook at the pumps, and reported the length and capture date of 711 fish identified as winter-run using microsatellite DNA; they were intermediate in size between the hatchery late fall and winter Chinook, and arrived at the pumps slightly later in the year than hatchery winter-run (Figure 25), although they began migrating downstream sooner. Fortunately, it is now possible to obtain a good deal of information about the migratory history of wild and naturally produced Central Valley Chinook and steelhead by microchemical analyses of their otoliths (Barnett-Johnson et al. 2008; Phillis et al. 2008; Malamud-Roam et al. 2008). Such information is needed if we are to manage the Delta for the benefit of wild and naturally produced fish, rather than hatchery fish.

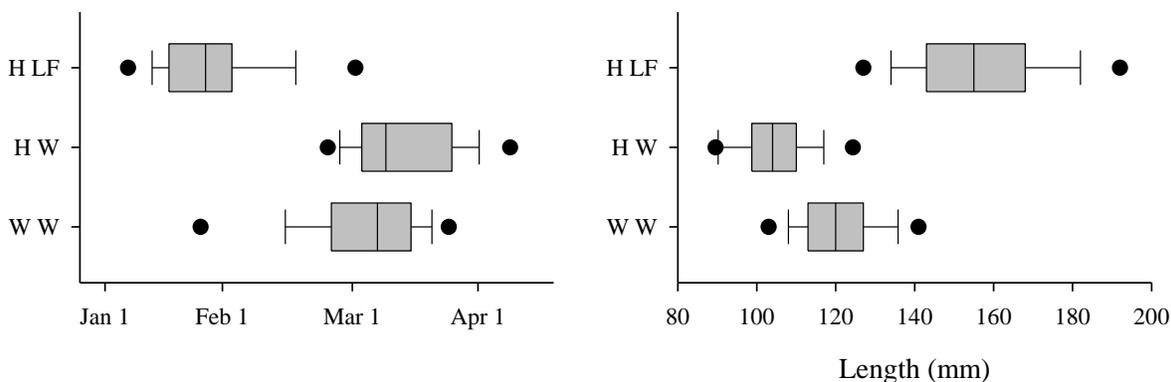

Figure 25. Distributions of dates of capture and length at capture for hatchery late fall-run (H LF), hatchery winter-run (H W), and wild winter-run (W W) at the state and federal fish facilities. Data from USFWS and Hedgecock (2002).

E. Navigation by juveniles

The sequential odor hypothesis (Harden Jones 1978) is the current working model for homing in anadromous salmon in fresh water. That is, juveniles learn a series of odors during their seaward migration, and then follow these in reverse order on their return. There is also evidence that other genetic factors may affect homing in fresh water (Quinn 2005), but these seem to be secondary. The sequential odor hypothesis implies that hatchery fish that are trucked to the bays should stray more often than fish that swim there, and this is observed (SRFCRT 1994). This raises the concern that staying hatchery fish may interbreed with locally adapted natural populations and reduce their fitness, as may have happened with fall Chinook in Mill and Deer creeks (Williams 2006).

The mechanisms by which juveniles find their way to the sea are less well known than the mechanisms by which they find their way back. In some situations, simply swimming (or drifting) downstream seems a sufficient mechanism, but in other cases, such as the complex migration of juvenile sockeye through chains of lakes (Quinn 2005), it would be hopelessly inadequate. Besides using current, juveniles can orient themselves by the position of the sun and the plane of polarization of sunlight, and by the Earth's magnetic field (Høgåsen 1998; Quinn 2005). In the Delta, tidal flows dwarf net seaward flows (Kimmerer 2004), and mechanisms besides sensing current seems necessary for navigation, especially for rapid migration through the Delta.

F. Steelhead juvenile life history patterns

The life histories of *O. mykiss* are even more variable than those of Chinook, but not much information is available on Central Valley populations; Lindley et al. (2007) described the status of populations on streams that do not have hatcheries as "data deficient." Figure 1 applies for anadromous *O. mykiss*, steelhead, but it seems that many *O. mykiss* in Central Valley streams either do not migrate, or else do not migrate beyond the large rivers or the Delta (Williams 2006). This is a recent development that may reflect evolutionary as well as environmental change. In rivers such as the Sacramento, Yuba, or Stanislaus, populations of large resident *O. mykiss* have developed where summer releases of cool water from dams provides good habitat for them.

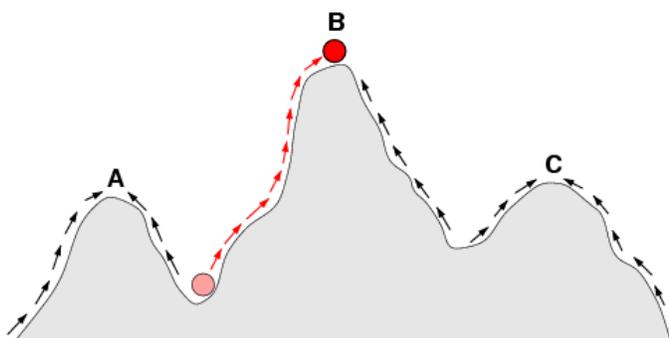

As far as is known, steelhead in the Central Valley follow a stream-type life history. Most naturally produced steelhead from the native lineage migrate to sea after two winters in fresh water, although fish from the American River grow rapidly, and migrate after one winter. Some American River fish, called "half-pounders" by anglers, may migrate only as far as the Delta or bays and then return. Hatchery steelhead also grow rapidly and migrate when released, after one winter in fresh water, but there is evidence from the sex ratios of steelhead captured at Knights Landing and Chipps Island that some hatchery males may not migrate beyond the Delta. (Rob Titus, DFG, pers. comm. 2008).

G. The adaptive landscape

Hatchery culture modifies the natural life cycle in several important ways: mates are selected by hatchery personnel rather than the fish, mortality during the egg and alevin stages are sharply reduced, and fish are canalized into a single juvenile life history pattern. There is good evidence that hatchery populations evolve to become more fit for a hatchery-based life cycle, and less fit for a natural life cycle. Older evidence is summarized in Williams (2006), but recent evidence from a study of steelhead in the Hood River, Oregon, is even stronger. By comparing the reproductive success of naturally spawning steelhead with one or two hatchery parents, Araki et al. (2007) demonstrated a rapid loss of fitness for natural reproduction.

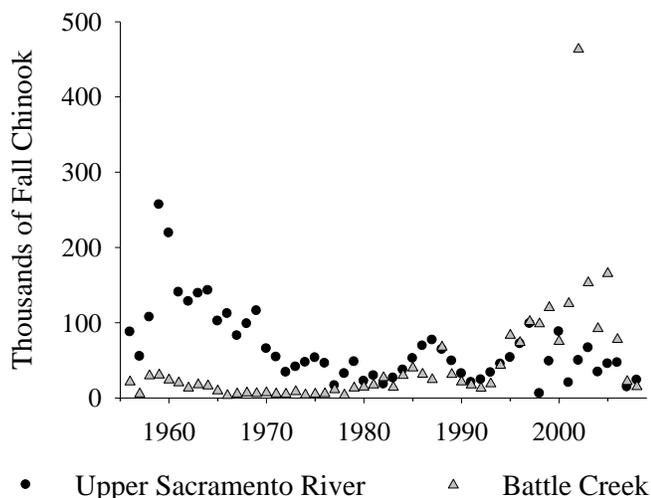

The ‘adaptive landscape’ is a conceptual model that helps explain this. For an organism in a given environment, there is a level of fitness associated with each combination of genes, or more specifically, of alleles (think of fitness as the propensity to have descendents). This can be visualized for one or two genetic dimensions, and for two dimensions looks like a topographic map, but with contours of equal fitness rather than elevation. The conceptual model can be applied to populations, except that each dimension shows the frequency of an allele in a population. Then, natural selection will tend to move the population “uphill,” toward higher fitness, although when genes interact or multiple alleles affect the trait, there may be multiple fitness peaks, some higher than others (Figure 26).

Figure 26. Cartoon of an adaptive landscape, in for one genetic dimension. The vertical distance shows fitness, and the horizontal axis shows combinations of gene frequencies. Arrows show the direction of selection, and the red ball shows a population evolving from lower to higher fitness. Copied from Wikipedia.

From this point of view, consider the situation of a population that lives in two different environments, each with its own adaptive landscape, such as a salmon population that reproduces both in a river and in a hatchery. There are two possible outcomes. Either the population will shift toward the fitness peak in one habitat or the other, or it will be caught somewhere in the middle, with intermediate fitness in both habitats. This can be modeled; Figure 3 is from a paper describing such a model, and it shows that a shift toward one peak or the other can happen suddenly. Data on fall Chinook in the upper Sacramento River suggests that such a shift may have occurred in that population, perhaps in the generations from the late 1970 to the early 1990s (Figure 27). Neither natural nor artificial selection can maximize the fitness of a population for both environments.

Figure 27. Number of adult fall Chinook returning to the upper Sacramento River (above Red Bluff) and to Battle Creek, including Coleman Hatchery. Assuming that these represent the naturally reproducing and hatchery components of the run, the run is now dominated by hatchery fish.

H. Local adaptation

Even streams in the same geographical area may provide different environmental challenges for salmon populations, and the strong tendency of salmon to return to their natal stream allows local adaptation to develop. Transplantation experiments in New Zealand, where Chinook were introduced about a century ago, show that such adaptation can develop fairly quickly. Although cases where local adaptation has been rigorously demonstrated are relatively few (Quinn 2005), there are many situations in which it seems highly likely, such as Atlantic salmon from an upper tributary of a river in Scotland that start their downstream migration sooner than salmon from a lower tributary (Stewart et al. 2006). As a local example, coded-wire tag studies suggest that juvenile Chinook from the Merced River survive better when released into the San Joaquin River than juveniles from the Feather River (Newman 2008). Traits related to juvenile migration seem a logical target for selection leading to local adaptation; for example, it seems likely that juvenile Chinook from the Sacramento River would benefit from an inherent tendency to bear to the right when they sense tidal flow reversals.

Estuaries are generally places of high biological productivity, and also provide habitat where juvenile salmon can rear and grow. For Chinook and steelhead, the importance of estuaries as juvenile rearing habitat varies inversely with the size at which the fish enter the estuaries, as indicated by the review of life history patterns above. This conceptual model is so simple that it seems unnecessary to render it in a graphic, but it is basic for assessing the importance of restoration activities in the Delta for the various runs. Spring Chinook, or at least the Butte Creek population, pass quickly through the Delta, so habitat restoration there seems unlikely to do much for them. The same is probably true for late fall Chinook, and for steelhead. Fall Chinook, however, probably would benefit strongly from tidal marsh restoration. The case for winter Chinook seems equivocal.

The life cycle of anadromous salmonids requires that the fish pass through estuaries at least twice in their lives. Navigating through a large estuary is not a simple matter, so it is important

that human activities not interfere with the navigational abilities by which salmon find their way. There is concern that various contaminants may do that, as discussed below.

I. Understanding salmonid life history diversity

There is great variability in the timing with which salmonids pass through the various stages shown in Figure 1, even within single species such as Chinook and steelhead, as discussed above. This variation is best understood for Atlantic salmon, for which a conceptual model has been developed by John Thorpe and colleagues (e.g., Thorpe et al. 1998).

The basic facts of Atlantic salmon life-history that the model seeks to explain are these. Atlantic salmon spawn in the fall, with fry emerging in the spring. The distribution of fry sizes is approximately normal at emergence, but then becomes bimodal, at least in some conditions (Thorpe 1977; Thorpe et al. 1998). In such conditions, all surviving fry feed actively early in their first summer, but the slower-growing ones restrict feeding in late summer and spend most of the winter hiding in the gravel in the streambed, while others continue actively feeding through the winter. Fish that continue feeding typically migrate in the spring, after one year in freshwater. Most of the slower-growing group then feeds actively through their second year, and then migrates to the sea, but a fraction again restricts feeding, and spends a third year in freshwater. After migrating, the fish spend a variable number of years in the ocean before returning to spawn.

The conceptual model posits a set of condition-dependent "switches" that affect or control such aspects of behavior as feeding, migration, and maturation. Individual variation in the thresholds for the switches and variation in environmental conditions can then produce the observed variation in life-history patterns. The model embodies two important generalizations about salmonid life histories: that there are photoperiodically-based "windows" of time in which life-history choices are made, and that these choices are based on the condition of the fish at some prior time, as well as on the condition of the fish shortly before the decision becomes manifest by, say, smolting or by sexual maturation (Shapovalov and Taft 1954; Thorpe 1989). Marc Mangel has developed this conceptual model into a numerical model (e.g., Mangel 1994), and with support from CALFED is currently extending and developing it for steelhead, in a form that also allows assessment of evolution in response to altered environmental conditions (Mangel and Satterthwaite 2008; Satterthwaite et al. 2009a, b). This helps explain the shift toward a resident life history in some populations of Central Valley *O. mykiss*.

The typical steelhead life-history is similar to that of Atlantic salmon, except that steelhead spawn in the late winter or spring, and some fish follow a resident life-history, especially in coastal California streams (Satterthwaite et al. 2009b). The reason this can be advantageous is sometimes obvious; for example, the Carmel River did not reach the ocean for three years during the drought of the late 1980s, and fish that probably would have been anadromous if they had had the chance were observed spawning in the upstream reaches where flow persisted. A resident life-history also seems to be developing in some Central Valley rivers where releases of cool water from reservoirs maintain good habitat for large trout through the summer (Williams

2006). However, the optimal life-history for a steelhead depends on the interactions among several environmental factors and the attributes of the particular fish (Satterthwaite et al. 2009a), so simple generalizations are hazardous.

Many Chinook salmon migrate downstream shortly after emergence, so it is clear that this model must be modified before it can be applied to them, but the fundamental insight remains that a fairly simple developmental program, together with environmental variation and genetic variation in thresholds for the switches and in the timing of the developmental windows, can account for the observed variation in life-history patterns within and among species of Pacific salmon. At least for some spring-run Chinook, a photoperiod-sensitive switch determines whether fish follow an ocean-type or stream-type juvenile life-history pattern (Clarke et al. 1992). Typically, these fish spawn at high enough altitude that winters are cold and embryos and alevins develop slowly (the incubation period is strongly temperature-dependent). Accordingly, fry emerge well after the winter solstice, and do not experience very short-day photoperiods until the following winter. This causes them to grow slowly, and as suggested by the model they do not migrate. If the fry are exposed experimentally to a short-day photoperiod, however, they will grow rapidly and adopt an ocean-type life history, migrating in their first year. This would explain why Spring Chinook in Butte Creek, which are restricted to < 350 m elevation, mostly migrate in their first spring.

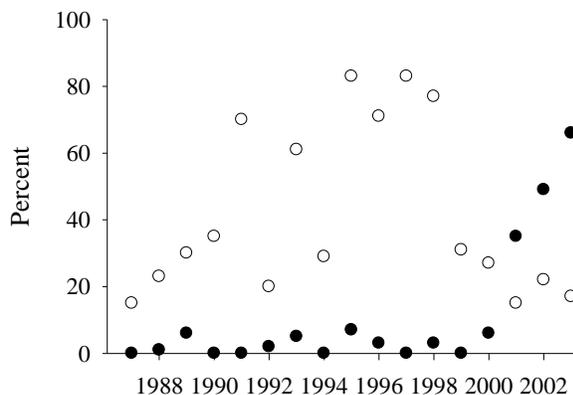

J. Use Of habitats:

1. Gravel-bed streams:

Apart from hatcheries, salmon reproduce and spend their early life in gravel-bed streams. Generally, the fish select redd sites where water flows through the gravel, such as at the tail of a pool where water downwells into the gravel, or where it upwells in the gravel bar below (Williams 2006). Water flowing through the gravel carries oxygen to the developing embryos or alevins, and carries away metabolic wastes. Some gradient in the stream is needed for suitable spawning habitat, but not much. For example, Rutter (1904) mapped fall Chinook spawning beds as far downstream as Tehama, near the Mill Creek confluence, although early commercial vessels could navigate beyond Tehama to Red Bluff.

Current distributions of spawning habitat for major Central Valley Chinook populations are well known from spawner surveys that are conducted to estimate adult returns (Low 2005; Pipel 2005), and uncertainly about most of the others is constrained by terminal dams or natural barriers. Although spawning extends well downstream, it tends to be concentrated near the barriers (Williams 2006). This is nicely illustrated by the upstream shift in the distribution of spawning by winter Chinook after passage was improved over the Anderson-Cottonwood Irrigation District (ACID) dam at Redding (Figure 28). Steelhead spawning is harder to observe, since the fish and their redds are smaller, they spawn in the winter when the water is often turbid, and it is very difficult to distinguish spawning by steelhead and similarly sized resident *O. mykiss*.

Figure 28. Percentage of winter-run redds observed above the ACID Dam (filled circles) between the dam and the Highway 44 bridge (open circles) in CDFG aerial surveys. Data from Doug Killam, CDFG, Red Bluff; copied from Williams (2006).

Redds occupy an area, and the area of suitable spawning habitat in a stream is limited. Females compete for spawning sites, and after spawning defend them for as long as they can. This limits the population that a given stream can support, and is one mechanism for the more general phenomenon of density-dependent mortality. That is, except at very low numbers, the survival or reproduction of members of a population tends to decrease as abundance increases. It is likely that density-dependent mortality among salmon occurs during other life-stages besides spawning, but not much is known about this for Central Valley populations (Williams 2006). One possibility is competition between hatchery and naturally produced Chinook in the Delta, bays, and Gulf of the Farallones. Kjelson et al. (1982:409) noted that “The problem of exceeding estuarine rearing capacity [through hatchery releases] is of some concern in the Sacramento-San Joaquin (hatchery releases total about 26 million smolts annually), but as yet has not been studied.” Many hatchery fish are now trucked around the Delta, but the point remains valid, especially for the bays.

Juvenile salmon can live at high densities if food is abundant, as demonstrated by hatcheries, but the rearing capacity of streams is more limited. Especially in smaller streams, fry tend to establish and defend territories, unless they migrate. The size of the territories increases with the size of the fish, imposing a limit on the number of fish that an area of stream can support that decreases as the fish grow. To what extent migratory fish in Central Valley are pushed out of some upstream habitat is unclear, since juveniles in larger rivers tend to form schools (Williams 2006), but density-dependent migration has been incorporated into models of salmon populations in rivers, for example Greene and Beechie (2004). It is clear, however, that a stream-type life history cannot support as large a population in a given stream as an ocean-type life history (Quinn 2005). This makes it unlikely that steelhead were ever as abundant as Chinook in the Central Valley.

2. Low gradient streams:

As juvenile Chinook or steelhead migrate downstream into the Central Valley proper, they encounter low gradient reaches with fine-grained beds. Historically, during the winter and spring, the rivers were not contained by their channels and spread out over large areas, especially in the Sacramento Valley (Kelley 1989). This graded almost imperceptibly into the Delta, so

there was not a clear distinction between the Delta and flooded overbank habitat farther upstream, especially in the Sacramento Valley (Williams 2006). The low gradient rivers now flow mostly in confined channels with steep banks, but remnants of this formerly extensive habitat remain in the Butte Sinks and the Sutter and Yolo bypasses, and along unleeved reaches of the Cosumnes River.

When the Cosumnes River spreads out over its floodplain, juvenile fall Chinook do so as well (Moyle et al. 2007). The fish grow rapidly there (Figure 29), and most move back into the river as the water level declines and floodplain drains. Similarly, juvenile salmon pass into the bypasses, and also grow well there (Sommer et al. 2001, 2005). Other fishes also use this habitat, and although many are stranded when water levels recede, these are mostly the introduced species; stranding losses of Chinook and other native species are usually modest (Sommer et al. 2005; Jeffres et al. 2008).

Figure 29. Comparison of juvenile Chinook from one enclosure on the Cosumnes River floodplain and from another in the river downstream, which is tidal in this reach and so part of the Delta. Copied from Jeffres et al. 2008.

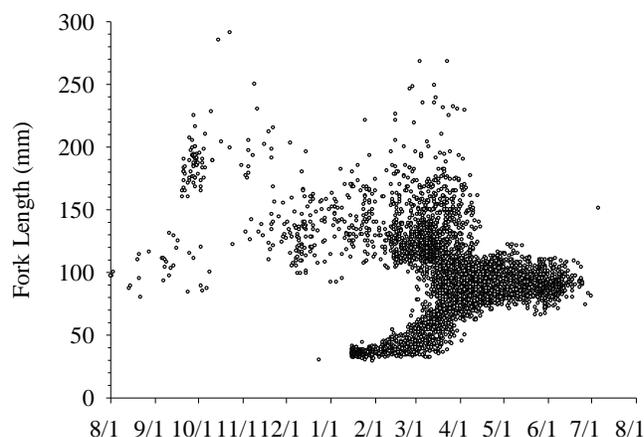

3. The Delta:

Geographical boundaries are usually more discrete on maps than on landscapes, as exemplified by the boundary of the Delta, defined here on the upstream side by the limit of tidal influence. Historically, the Delta was a vast tidal wetland (Atwater et al. 1979; TBI 1998), but most Delta channels are now confined by levees and have steep banks, like the low gradient river reaches upstream.

The diversity of juvenile Chinook in the Delta is reflected in the size at date of fish captured at the state and federal pumps (Figure 30). Larger juveniles, ~100+ mm, begin to appear at the pumps in August. The number of larger juveniles increases into March, then drops quickly in early April; it is unclear where a line should be drawn here between fingerling residents and classic stream-type. Fry migrants to the Delta, ~40 mm, begin to appear in January, and continue through most of March. Larger fry migrants, fry residents, and some fry migrants to low

gradient streams, begin to appear in March, followed by fingerling migrants and continue through June, when the Delta becomes too warm for juvenile salmon.

Figure 30. Juvenile Chinook at the Delta diversions; size at date of 6,752 juvenile Chinook sampled at the CVP and SWP diversion facilities in the Delta from August 1995 through July 2001. Data from Hedgecock (2002).

Based on studies of other estuaries, Chinook that migrate to the estuary as fry tend to rear there for some time, while Chinook that rear to fingerling size (~ 60 mm) or more somewhere upstream tend to pass through the estuary more rapidly (Healey 1991; Burke 2004). Small Chinook occupy mainly shallow water around the margins of the estuary, often moving up into tidal marsh channels on the flood tide, and retreating back to subtidal areas late on the ebb tide (e.g., Levy and Northcote 1982). The juveniles tend to move into deeper water and down the estuary as they grow (Healey 1980; 1991). Juvenile Chinook are opportunistic feeders, and reports on diet vary from study to study, but broad patterns are evident. Smaller juveniles occupying marsh channels often feed heavily on larval and pupal chironomids (e.g., Shreffler et al. 1992; Lott 2004). This has been observed in a remnant tidal marsh in the Delta (Simenstad et al. 2000), as well as in overbank habitats close to the Delta (Sommer et al. 2001, 2005; Jeffres et al. 2008). As the fish grow, larger prey become more important, and as they move farther offshore and into deeper water, their diet shifts toward prey that are available there.

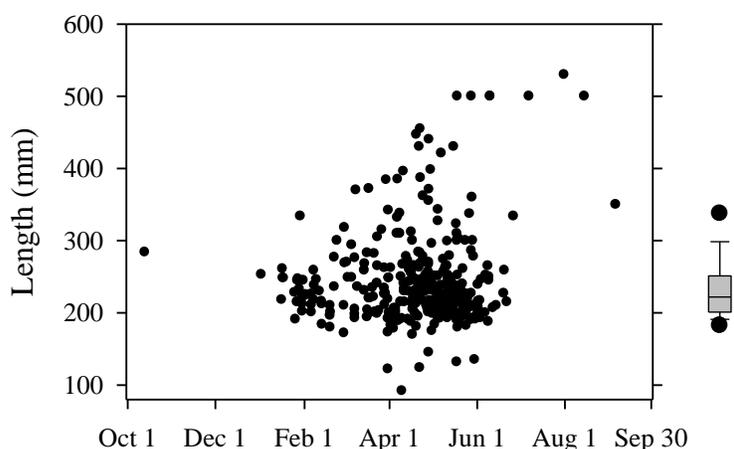

Most habitat in the Delta is now subtidal, because most channels are leveed with steep banks, and the prey available for fry reflect this. The best data are from Kjelson et al. (1982), who summarized their own and earlier studies as follows:

Crustacea and insects dominated fry stomach contents, with an increase in crustacea ingestion downstream. Cladocera and diptera were consumed frequently in the Delta, while in brackish San Pablo and San Francisco Bays, consumption of copepods, amphipods, and fish larvae increased. Similar food habits were described for older fry and smolts in Delta studies by Rutter (1904), Ganssle (1966), and Sasaki (1966).

Kjelson et al. (1982) called fish < 70 mm fry, but their samples included many fish < 50 mm. Larger juveniles sampled at Chipps Island more recently fed mainly on amphipods (*corophium*), but also postlarval crabs, flies, shrimp, and (non-fly) insects (MacFarlane and Norton 2002).

Naturally produced juvenile steelhead from the Sacramento system move past Knights Landing into the lower river in winter and spring, but mainly in April and May (Titus et al. 2004). Naturally produced juvenile steelhead are captured in the Chipps Island trawl are about the same size, mostly 200 to 250 mm long (Figure 31), suggesting a rapid migration. There are no data on the rate at which they move through the bays or how much they grow there. A few steelhead also migrate out of the Mokelumne River and San Joaquin River tributaries (Williams 2006).

Figure 31. Size and date of capture of 346 unmarked juvenile steelhead from the Chipps Island Trawl from 1999-2008. The box plot at right summarizes the size distribution. The larger fish may be kelts. Data from USFWS.

Studies on coastal streams (e.g., Bond 2006) show that lagoons can be very important habitat for juvenile steelhead. However, steelhead entering the Delta are older and much larger than the fish entering the lagoons in the coastal streams, so it is unlikely that these findings apply to the Delta.

4. The bays:

Habitat use in the bays probably is like that in the Delta, with larger juveniles mainly using deeper water farther from shore, and smaller juveniles mainly using shallower water and marsh channels around the margins. More small juveniles are captured in or entering the bays in wet years (Kjelson et al. 1982, Brandes and McLain 2001), but they have also been found there in dry years (Hatton and Clark 1942). A few are found in Suisun Marsh (e.g., Mattern et al. 2002).

Juvenile Chinook migrating through the bays from April through June were sampled in open water with trawls by NMFS, from 1995 to 2005. Most of these were fall Chinook, but some could have been ocean-type spring Chinook, which migrate at the same time (Fig. 19). On average, fish captured near the Golden Gate were 18 days older than fish captured near Chipps Island, and about 6 mm longer, but hardly any heavier (B. MacFarlane, NMFS, pers. comm.).

2008, Figure 32). The slow growth may reflect anthropogenic changes in the bays, as noted above, since early descriptions (e.g., Scofield 1913) suggest abundant food for Chinook. If so, such degradation of the bays is probably a significant problem for fall and spring Chinook, since survival in the ocean presumably increases with fish size and condition.

Figure 32 Size and condition of juvenile fall Chinook in the bays and ocean during 2005. Copied from Lindley et al. (2009). Note that “Estuary Entry” refers to Suisun Bay.

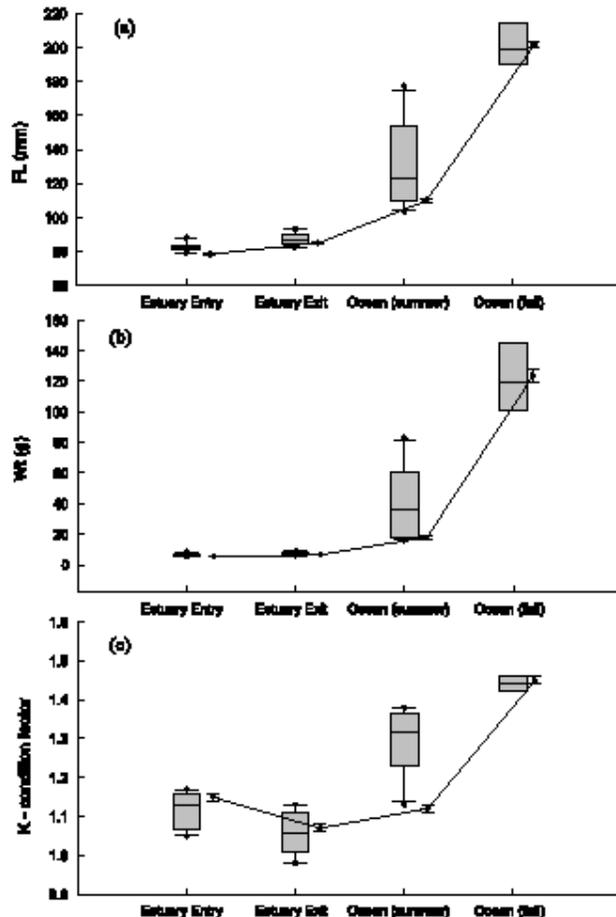

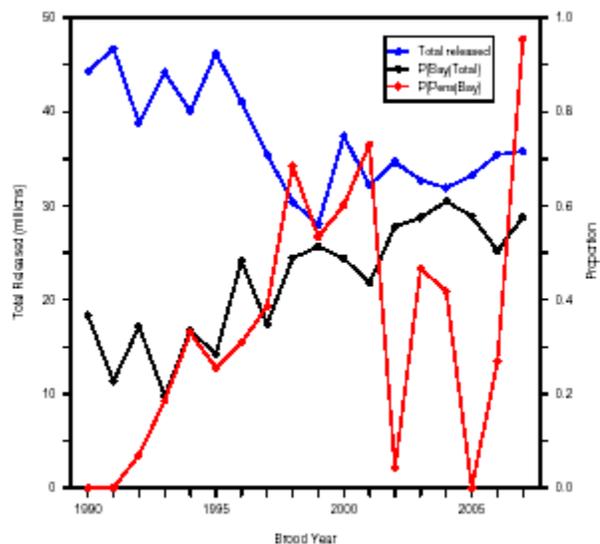

Figure 16: Changes in (a) fork length, (b) weight, and (c) condition (K) of juvenile Chinook salmon during estuarine and early ocean phases of their life cycle. Boxes and whiskers represent the mean, standard deviation and 90% central interval for fish collected in San Francisco Estuary (entry = Suisun Bay, exit = Golden Gate) during May and June and coastal ocean between 1998-2004; points connected by the solid line represent the means (± 1 SE) of fish collected in the same areas in 2005. Unpublished data of B. MacFarlane.

Poor growth in the bays also implies a strong potential for density-dependent mortality or reductions in growth, since many millions of hatchery smolts are released into the bays (Figure 33). This should be regarded as a serious problem unless new evidence suggests otherwise.

Figure 33: Total releases of hatchery fall Chinook, proportion of releases made to the bay, and the proportion of bay releases acclimatized in net pens. Unpublished data of CDFG and USFWS. Copied from Lindley et al. 2009.

5. The ocean:

Juvenile Chinook and steelhead leaving the bays enter the Gulf of the Farallones, a shallow and somewhat protected area, where they grow rapidly. From an eleven years study by NMFS, the mean and standard deviation of the length of fish entering the gulf were 87.1 and 10.4 mm; the same statistics for age (since hatching) were 153 and 22 days. Initially, the density of juveniles Chinook is highest in eddies on either side of the Golden Gate, but by September most have moved northward along the coast (B, MacFarlane, NMFS, pers. comm. 2008).

Data on the size and condition of juvenile fall Chinook in 2005 show that conditions in the ocean during the summer probably were responsible for the poor survival returns in 2007, since the size and condition of the fish were unusually small and poor (Figure 32). A statement to the contrary in Williams (2006) is mistaken. Unfortunately, such data have not been collected since 2005.

Most Central Valley Chinook, and probably steelhead as well, remain over the coastal shelf, rather than moving out into the open ocean as many salmon do at higher latitudes. Central Valley Chinook range mainly between Monterey Bay and the Columbia River, although a few go farther north or as far south as Point Conception (Williams 2006).

Juvenile steelhead from Scott Creek, on the San Mateo County coast, survive very poorly if they enter the ocean smaller than 140 mm (Bond 2006). Why smaller juvenile Chinook can successfully enter the ocean is uncertain, but higher biological productivity in summer and the protected conditions in the Gulf of the Farallones probably explain it. Conditions in the gulf can differ from conditions along the open coast farther north, which could weaken the correlation between the abundance of Chinook in the Central Valley and in coastal rivers.

K. Habitat use by run

Winter Chinook spawn in the summer, and because embryos are the most temperature sensitive life stage, winter Chinook require summer water temperatures $< \sim 14^{\circ}\text{C}$. Historically, this limited them to upper Sacramento River tributaries that drain basalt or porous lava terrain, and receive large amounts of cool water in the summer from springs (Lindley et al. 2004). Currently, winter-run spawn in the Sacramento River, downstream from Keswick Dam, where releases of water from Lake Shasta keep temperatures cool. Passage of juvenile winter-run past the Red Bluff Diversion Dam (RBDD) is well documented (Figure 34); most juveniles pass the dam as fry, in August and September. The size of the fish increases beginning in October, but the numbers drop off. The fish here are classified to runs by size and date, and so assignment involves some error, but the method is more reliable here than farther downstream, at least for smaller fish (Williams 2006).

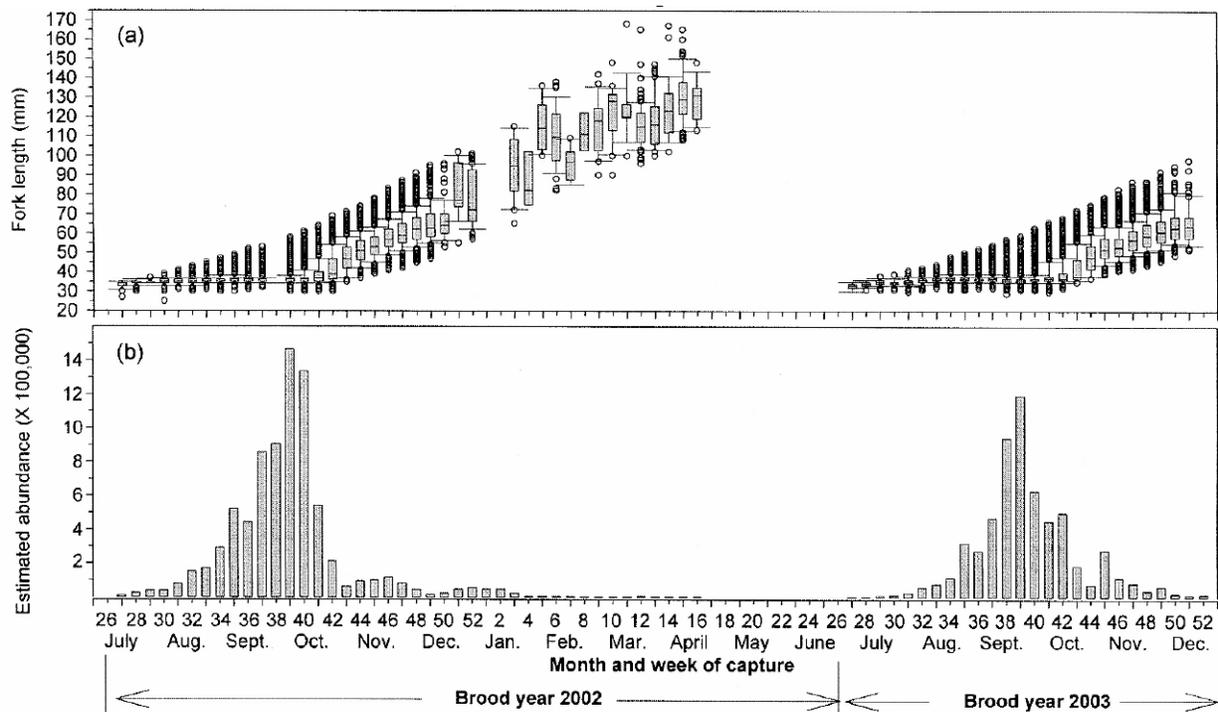

Figure 34. Size distributions (a) and numbers (b) of winter-run size juvenile Chinook salmon captured in screw traps at the RBDD in July 2002 through December 2003. Box plots in (a) show the 10th, 25th, 50th, 75, and 90th percentiles, plus outliers. Note that the outliers simply trace the size criteria when abundance is high. Classification accuracy is probably better for smaller fish. Copied from Gaines and Poytress (2004).

What juvenile winter-run do once they pass the RBDD is less well known, because the size-at-date criteria for assigning fish to runs do not work so well, and because monitoring farther downstream is less intensive. Based on a relatively small sample identified genetically, only a few winter-run reach the lower Sacramento and the Delta before late November (Figure 21). Winter-run appear at the pumps mostly in February and March, at an average length of 121 mm

(Figure 35). Generally, the data suggest a slow migration, but the relative survival of the smaller and larger migrants past the RBDD is unknown, so inferences about the migration rate and timing of the survivors are highly uncertain. Work in progress at UC Berkeley using microchemical analyses of adult otoliths (Ingram 2008) may clarify this. Tissue samples from fish captured at Chipps Island are now being analyzed to assign fish to runs, so more information should soon be available about the size and time at which winter Chinook move into the bays.

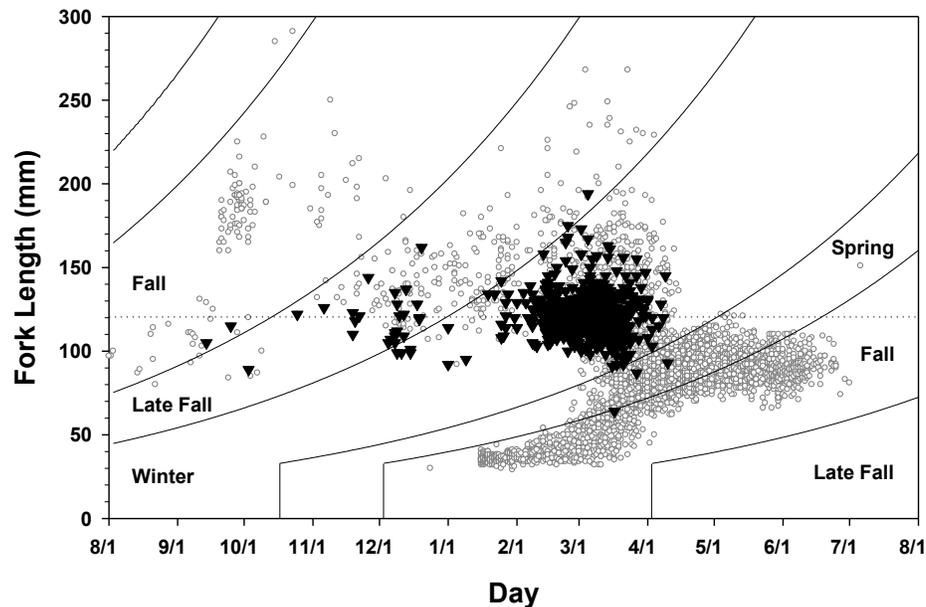

Figure 35. Distribution, by fork length and day of capture, of 6,752 juvenile Chinook salmon with assignable genotypes over a six-year period, from August 1995 through July 2001. The 711 juveniles assigned to winter-run are shown by dark inverted triangles; fish assigned to other runs are shown by open circles. Note that each symbol may represent more than one fish, and that many non-winter-run are obscured by the tight cluster of winter-run. Mean fork length of winter run juveniles (121 mm) is shown by the dotted line. The figure and most of the caption are copied from Figure 1 in Hedgecock (2002).

Adult spring Chinook hold over in streams during the summer, but do not spawn until the water temperature is declining in the fall (Table 4). They can tolerate summer water temperatures up to $\sim 20^{\circ}\text{C}$ daily average, as documented by careful monitoring in Butte Creek, although this presumably involves considerable stress. There is some evidence that gametes are less tolerant than the adults, so temperature stress may lead to reproductive failure even if spawning occurs (Williams 2006). Juveniles that remain in the stream over the summer must tolerate at least the same and perhaps higher temperatures.

Particularly in Butte Creek, most juveniles move down into the valley in spring, mainly as fry but also as larger (50 -100 mm) juveniles (Figure 36). Even larger juveniles migrate into the valley in fall, winter, and spring, but their numbers are very low by late winter. (Note that the X-

ax2s on this figure are logarithmic.) Tagging studies show that fry migrants from Butte Creek rear for some time in the Butte Sinks or Sutter Bypass before they migrate through the Delta (Figure 18). Similar information is not available for spring Chinook from Mill and Deer creeks, but it could be developed by studies of otolith microchemistry.

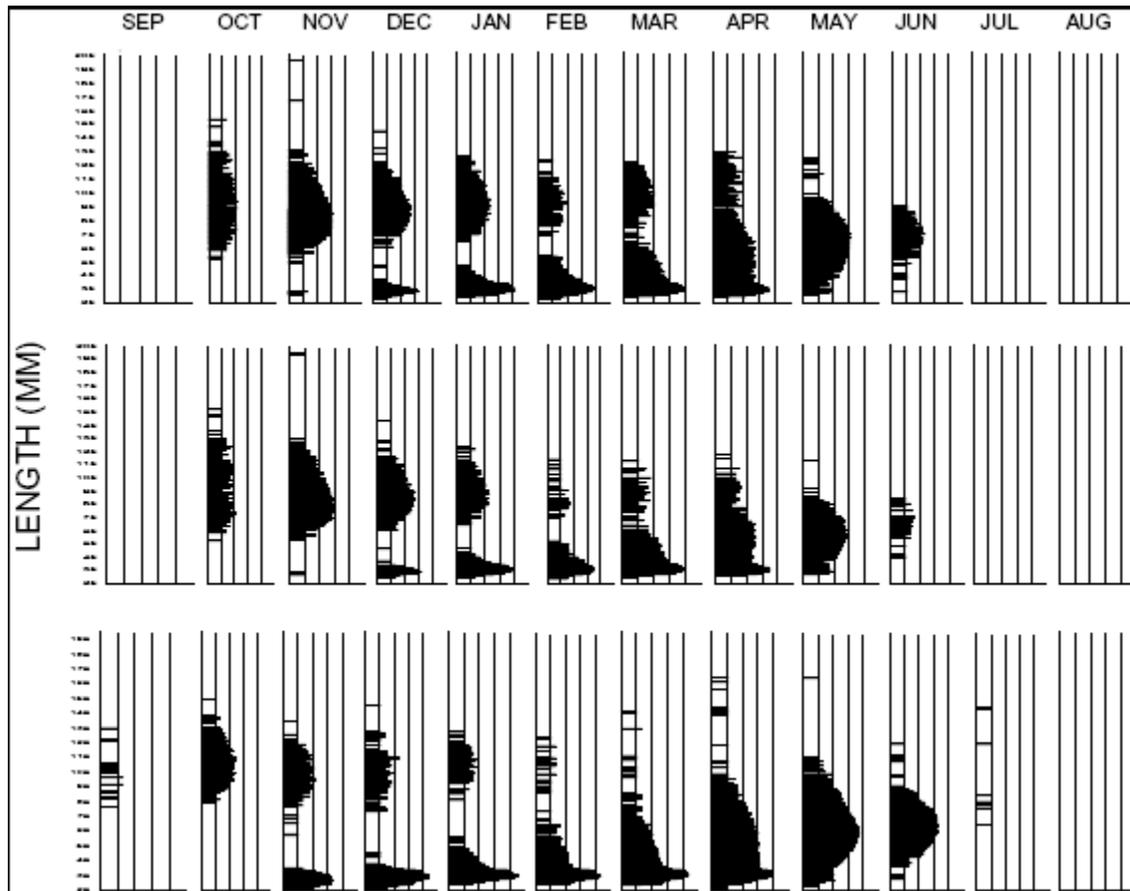

Figure 36. Length and time distribution of juvenile spring Chinook in Mill (top), Deer, and Butte (bottom) creeks. The scale of the x-axis is \log_{10} , from 1 to 10,000; the length scale is linear from 25 to 195. Copied from Lindley et al. 2004

Late-fall Chinook are present only as juveniles in the summer, and probably can tolerate about the same temperatures as the other runs. The historical distribution of their spawning habitat is not documented, but it may have been a lower elevation subset of the spring-run distribution. Naturally produced late-fall Chinook juveniles are thought to migrate to the Delta in the fall; the Chippis Island genetic sampling should clarify the timing of their migration into the bays.

Fall Chinook typically are not present during the summer, since adults normally enter fresh water as temperatures are declining, and the juveniles normally out-migrate in the spring. Some juveniles now hold over through the summer and pass through the Delta in the fall, for example

the group around 160 to 210 mm in September in Figure 30 (Williams 2006). It may be that some fall-run have always followed this life history, but summer releases of cool water from some dams make it more viable. Because fall Chinook are the most abundant run, and the only run in San Joaquin system and Delta tributaries, the traditional monitoring programs provide much more information about their behavior than about the other runs (e.g., Figure 34).

L. Environmental constraints on life history patterns:

There are at least three significant constraints on salmon life history patterns in the Central Valley. High summer water temperature is the most serious, since Chinook and steelhead one way or another must avoid thermally unsuitable habitat in the lower elevation rivers and the Delta. For example, juvenile Chinook in the Central Valley do not migrate to the Delta during the summer, although juvenile Chinook do migrate into estuaries in other rivers during that season. Similarly, as noted above, adult winter and spring Chinook are restricted to habitats that are thermally suited to spawning or holding during the summer. This constraint will become more serious as the climate warms. Butte Creek spring Chinook are most at risk; they are restricted to elevations below 350 m, and already suffer significant mortality in some years (Williams 2006).

Conditions in the ocean and probably in the bays are another constraint on juvenile life history patterns. The biological productivity of the coastal ocean and the Gulf of Farallones rises sharply in the spring when changes in the coastal winds make currents shift to predominantly southward flow, which induces upwelling of nutrient-rich water from the coastal shelf and slope (Ainley 1990; Williams 2006). The timing of this spring transition varies from year to year, and can strongly affect factors such as the nesting success of seabirds. Although direct evidence is lacking, it seems reasonable to expect that the survival rate of juvenile salmon increases with increasing biological productivity in the gulf, and Roth et al. (2007) have reported a relationship between seabird nesting success, which also depends on the productivity of the gulf, and the subsequent abundance of fall Chinook. Thus, juvenile Chinook that enter the ocean during times of lower productivity may be less likely to survive, especially if they are small. The importance of ocean conditions has been emphasized by the recent crash in the abundance of fall Chinook, for which poor ocean conditions seem the most likely proximate cause (Lindley et al. 2009).

M. Predation:

Many juvenile Chinook and steelhead are eaten in the Delta by other fishes, but high juvenile mortality is normal, so simply showing that significant predation occurs does demonstrate that something is “wrong.” Given that on average a female produces over a thousand fry (Table 1), we should expect that in natural conditions most will be eaten.

There is good evidence that predation in the Delta is significant. For example, studies of the survival of tagged hatchery fish show that fish released into Georgiana Slough survive ~45% as well as fish released into the Sacramento River nearby (Newman 2008), and acoustic tag studies indicate that increased predation there is probably the main reason for the difference, although fish released into the slough are also much more likely to be entrained at the pumps (K.

Newman, USFS, pers. comm. 2008). Similarly, Baker et al. (1995) found that the survival of tagged juvenile fall Chinook decreased as temperature rose above about 18°C. This is well within the physiological tolerance of the fish, so it seems likely that a decrease in survival results from the increased appetite of predators at temperatures that are not directly lethal for the salmon (Williams 2006). Similar increases in mortality at relatively low temperatures have been observed in the Columbia River (Anderson 2003).

The actual extent of predation remains uncertain, however, especially for smaller juveniles. The tagging studies were done with hatchery fish, and hatchery fish, especially those recently released, may be more susceptible to predation than naturally produced fish. In a modeling study, Lindley and Mohr (2003) found that the influence of striped bass predation on winter Chinook abundance probably was small, although more significant influence could not be ruled out. Nobriga et al. (2003) found relatively few Chinook in the stomachs of black and striped bass in shallow water, where small Chinook are more likely to occur, and Nobriga et al. (2006) did not find them in the stomachs of Sacramento pikeminnow.

V. ANTHROPOGENIC STRESSORS IN THE DELTA

Anthropogenic stressors in the Delta and current understanding of them are summarized in tables 7 and 8, and described below.

A. Climate Change

High water temperature is a major stressor for Chinook and steelhead in the Delta as well as in Central Valley rivers and streams. Temperature in late spring is an important predictor of the survival juvenile Chinook (Baker et al. 1995; Newman and Rice 2002; Newman 2003; Figure 32). The Delta is too warm in the summer for salmon, and Central Valley salmon have life history patterns that largely keep them out of the Delta during that season. This is a natural condition that was noted over a century ago (Rutter 1904). Water temperature in the Delta is determined primarily by atmospheric conditions, so anthropogenic climate change is already making the Delta warmer, and continued climate warming will increase the seasonal periods when the Delta is unfavorable or unsuitable for salmon.

Climate change in the Central Valley will affect different runs and life histories differently. Populations or life histories that remain in fresh water over the summer are most obviously at risk, but even ocean-type Chinook that rear upstream for some period before migrating will face a shorter period of favorable thermal conditions. Fry migrants may fare better by comparison, but may also face worsened ocean conditions. Climate change is the greatest long-term challenge facing Central Valley salmon (Williams 2006).

B. Levees

Levees impose a major stress on juvenile Chinook by blocking their access to tidal habitat (or to overbank habitat farther upstream), and confining them to habitat in the channels. This problem has been compounded in the Delta by subsidence of the Delta islands, so that in most

cases removing the levees would create subtidal ponds rather than restore the marsh habitat that used to exist there. The severity of this stress is greatest for fall Chinook, since it obstructs what was probably their predominant life history pattern. That is, the levees impose a greater stress on the fry migrant life histories that seem best able to tolerate climate change.

C. Diversions

1. Project diversions

Entrainment of juveniles in diversions at the state and federal pumps in the Delta is an obvious problem, but also a difficult one to assess. Samples of the fish that are collected for salvage are counted, providing an estimate of the total number collected, but an unknown number of fish are lost to predation near the pumps or bypass the collection facilities. Mark-recapture studies have been conducted to try to estimate mortality in the forebay at the state pumps, but these have used hatchery fish that may suffer higher mortality than naturally produced fish or hatchery fish that have been at large for some time (Williams 2006). The uncertainty in these estimates of “pre-salvage survival” compromises direct assessments of the harm done by the pumps. As a further complication, there is additional but poorly known “indirect” mortality farther from the pumps, but attributable to modification of Delta circulation patterns or other conditions associated with the pumps.

As an alternative to sampling at the pumps, the USFWS has conducted a long series of experimental releases of tagged hatchery fish that were recovered by trawling at Chipps Island or in the ocean fishery. Then, estimates were made of the effects of export pumping and other variables on the survival of the tagged fish. Two major analyses of these data have been published (Newman and Rice 2002, Newman 2003), and the results of these studies are compared in Figure 37. The magnitude of the coefficients shows the estimated strength of the influence of the associated variable, and the error bars show the associated statistical uncertainty. The effects of the exports/flow ratio is clearly strong using one analytical approach, and almost strong using the other. (See Williams 2006, Ch. 10 and Appendix B, for a more extensive comparison of these analyses).

Table 7. Summary of anthropogenic stressors in the Delta.

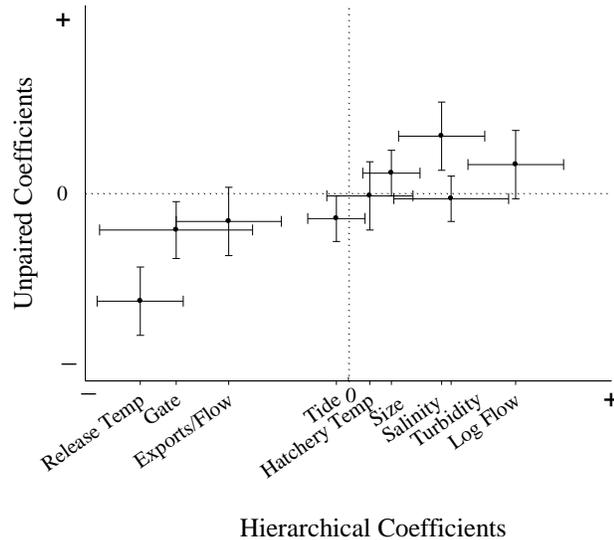

Life Stage	Stressors in the Delta						
	Levees	Water Temperature	Project Diversions	Smaller Diversions	Toxics	Hydrograph Modification	Gates and Barriers
Fry	Block access to tidal habitat	Increase predation	Entrainment, Indirect mortality	Entrainment (probably minor)	Inhibit imprinting. homing	Delay migration, change migration timing	Divert fish to Central Delta (SR fish) or South Delta (SJR fish)
Fingerlings	Block access to tidal habitat	Increase predation, physiological stress	Entrainment, Indirect mortality		Inhibit imprinting. homing	Increase late spring water temperature	Divert fish to Central Delta (SR fish) or South Delta (SJR fish)
Smolts (90+ mm)		Increase predation, physiological stress	Entrainment, Indirect mortality		Inhibit imprinting. homing	Increase late spring water temperature	Divert fish to Central Delta (SR fish) or South Delta (SJR fish)
Adults		Physiological stress	Delay migration to San Joaquin tribs		Inhibit homing?		Delay migration?

Life Stage	Stressors in the Delta		
	Hatchery Influence	Predation by introduced fishes	Dissolved Oxygen
Fry	Genetic effects from naturally spawning hatchery fish	Increases with water temperature	
Fingerlings	Genetic effects from naturally spawning hatchery fish, completion with hatchery fish	Increases with water temperature	
Smolts (90+ mm)	Genetic effects from naturally spawning hatchery fish, completion with hatchery fish	Increases with water temperature	
Adults	Genetic effects from naturally spawning hatchery fish, completion with hatchery fish, mortality from hatchery supported fishery		Low DO can delay migration of adults into the San Joaquin River.

Table 8. Summary of understanding of anthropogenic stressors in the Delta. U, I, and P are the estimated understanding, importance, and predictability of the stressors, with ranges from 1 (low) to 4 (high).

	Levees	Water Temperature	Project Diversions	Smaller Diversions	Toxics	Hydrograph Modification	Gates and Barriers	Hatchery Influence	Predation by introduced fishes	Dissolved Oxygen
Fry	U = 4 I = 4 P = 4	U = 3 I = 3 P = 3	U = 3 I = 3 P = 3	U = 3 I = 2 P = 2	U = 2 I = ? P = 1	U = 4 I = 4 P = 4	U = 2 I = 3 P = 2	U = 2 I = 4 P = 4	U = 3 I = 3 P = 3	U = 4 I = 1 P = 4
Fingerlings	U = 4 I = 3 P = 4	U = 4 I = 4 P = 4	U = 4 I = 4 P = 4	U = 3 I = 2 P = 2	U = 2 I = ? P = 1	U = 4 I = 4 P = 4	U = 3 I = 3 P = 3	U = 3 I = 4 P = 4	U = 3 I = 3 P = 3	U = 4 I = 1 P = 4
Smolts (90+ mm)	U = 3 I = 3 P = 4	U = I = P =	U = 3 I = 4 P = 3	U = I = P =	U = 2 I = ? P = 1	U = 3 I = 3 P = 4	U = 4 I = 3 P = 4	U = 3 I = 4 P = 4	U = 3 I = 3 P = 3	U = 4 I = 1 P = 4
Adults	U = 4 I = 1 P =	U = 3 I = 3 P = 3	U = I = P =	U = I = P =	U = 2 I = ? P = 1	U = I = P =	U = 4 I = 3 P = 3	U = 4 I = 4 P = 4	U = 4 I = 1 P = 4	U = 3 I = 2 P = 3

Figure 37.. Comparison of estimated coefficients plus/minus two standard errors for the unpaired analysis of Newman and Rice (2002) and the hierarchical analysis of Newman (2003) with release-specific capture probabilities. Copied from Williams 2006.

More recently, Newman (2008) has analyzed the results of several coded wire tag studies designed to address more specific questions, and summarized his results as follows:

For the most part, the substantive conclusions from the [Bayesian hierarchical model] analyses, summarized below, were consistent with previous USFWS analyses.

Delta Cross Channel: There was modest evidence, 64 to 70% probability, that survival of Courtland releases, relative to the survival of Ryde releases, increased when the gate was closed.

Interior: Survival for the interior Delta releases was estimated to be about 44% of the survival for the Sacramento River releases.

Delta Action 8: There was a negative association between export volume and relative survival, i.e., a 98% chance that as exports increased, relative survival decreased. Environmental variation in the relative survival was very large, however; e.g., for one paired release the actual relative survival at a low export level could with high probability be lower than relative survival at a high export level for another paired release.

VAMP: (a) The expected probability of surviving to Jersey Point was consistently larger for fish staying in the San Joaquin River (say passing Dos Reis) than fish entering Old River, but the magnitude of the difference varied between models somewhat; (b) thus if the HORB effectively keeps fish from entering Old River, survival of out-migrants should increase; (c) there was a positive association between flow at Dos Reis and subsequent survival from Dos Reis and Jersey Point, and if data from 2003 and later were eliminated from analysis the strength of the association increased and a positive association between flow in Old River and survival in Old River appeared; (d) associations between water export levels and survival probabilities were weak to negligible. Given complexity and number of potential models for the VAMP data, however, a more thorough model selection procedure using Reversible Jump MCMC is recommended

A shift in survival studies is underway. The studies described above used coded-wire tags, which identify batches of fish rather than individual fish, and require that fish be sacrificed for recovery of the tag. In the last few years, acoustic tags have largely replaced coded-wire tags for experimental studies, although coded-wire tags are still used to mark production releases of hatchery fish. Fish with the acoustic tags are individually marked and can be tracked remotely, which allows for addressing questions at much finer spatial and temporal scales, and for multiple detections of the same fish.

Results of acoustic tag studies in the Central Valley are beginning to appear in journals (e.g., Perry et al. In press), but have been reported mainly in talks. Unpublished work at the Delta Cross Channel indicates that the tidal and day/night cycles strongly influence the percentage of fish that pass into the central Delta through the Delta Cross Channel in the fall, which suggests that careful operation of the gate might reduce the effect of diversions through the gate on late fall and winter Chinook (Brau et al. 2007). The acoustic tag studies confirm that survival in the interior Delta is lower than in the Sacramento River. However, although visualization techniques make the data from these studies compelling, the acoustic tag studies are unlikely to be a panacea. Perry et al. (In press) and Perry and Skalski (2009) found that the survival of tagged late fall Chinook varies considerably among years and Delta channels, which suggests that considerable data will be needed before results can be relied upon, and the survival of fish with acoustic tags (e.g., those reported by Lindley et al. 2008) seems too low to be representative of a self-sustaining population. Most importantly, all studies to date have used hatchery fish, which may behave differently than naturally produced fish.

Yet another approach to analyzing the effects of the state and federal diversions uses data from the non-experimental releases of coded-wire tagged fish, usually at or near the hatchery. This approach has the advantage that fish may be exhibiting more natural migratory behavior than fish released in or near the Delta. By comparing recoveries of tagged fish at the pumps and at Chipps Island, Kimmerer (2008) estimated the percentage of fish from Coleman and Livingston Stone hatcheries leaving the Delta that are collected in the salvage facilities at the pumps, as a function of export flow (Figure 38). The analysis required some strong assumptions, so the detailed results should be regarded with due caution. One problem is that the Coleman Hatchery data include both fall and late fall Chinook, and it appears that late fall Chinook have a greater propensity to turn up at the pumps (Figure 39, Table 7). Nevertheless, the percentages of winter and especially late fall Chinook that are salvaged during periods of high exports is surely significant, especially if pre-screen mortality is high.

Figure 38. Relationship of estimated proportional salvage of tagged smolts at the fish facilities, PS, to export flow. Small symbols represent data based on six or fewer fish caught, which were not used in determining the line. Lines are from a generalized linear model with log link function and variance proportional to the mean ($p < 0.0001$, 57 df), with source of fish as a categorical variable. Thick lines are predictions for fish from each hatchery; thin lines are upper 90% confidence limits of the predicted mean values. Copied from Kimmerer 2008.

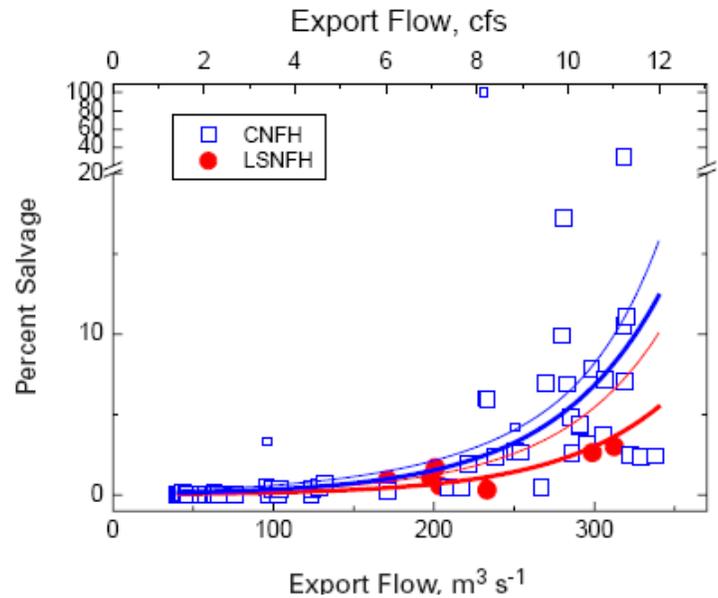

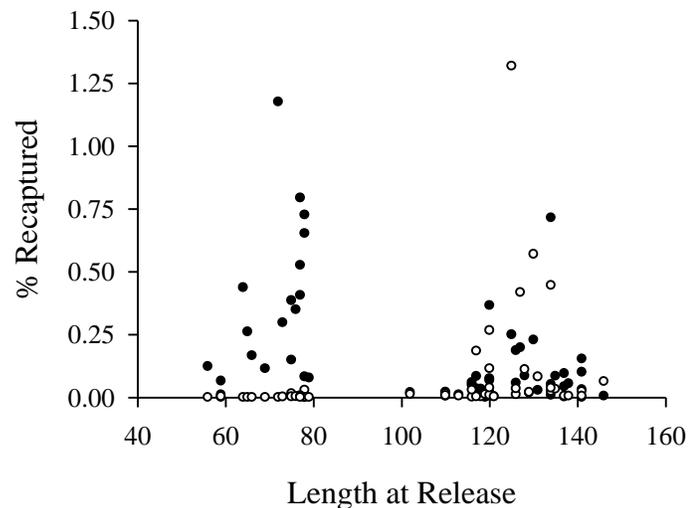

Figure 39. Recaptures of tagged juvenile fall and late fall Chinook at Chipps Island (filled circles) and the state and federal pumps (open circles). Fall Chinook (< 80 mm) are taken at the pumps much less frequently than late fall-run. Note that recaptures are not expanded to account for the limited duration of sampling, as was done for Figure 38). Data from Table 2 in Kimmerer (2008).

Based on a simple tabulation of recoveries of tagged juvenile Chinook released at the hatcheries, the state and federal pumps entrain a much higher proportion of winter-run and late fall-run migrants from the Sacramento River, and fall-run migrants from the San Joaquin River, compared with captures at Chipps Island; few Butte Creek spring-run show up at the pumps, and even fewer fall Chinook released from Coleman Hatchery do so (Table 9). Geography probably explains the much greater propensity of Merced River fall Chinook to appear at the pumps, low pumping rates during spring help explain the low number of Coleman fall-run and Butte Creek spring-run, and more frequent sampling at Chipps Island in the spring affect the numbers taken there, so the differences reflected in the table are more apparent than real. Nevertheless, the differences in the ratios of the numbers taken at the pumps and at Chipps Island are so large that it seems likely that behavioral differences among the runs are also involved. The data deserve more analysis.

Table 9: The number of marked or tagged fish recorded at the state and federal pumps and at Chipps Island: winter Chinook from Livingston Stone Hatchery, late fall Chinook from Coleman Hatchery, wild Butte Creek spring Chinook, fall Chinook from Merced River Hatchery, and steelhead from all hatcheries. Only fish released at or near the hatcheries are tallied. Data from USFWS.

	# at pumps	# at Chipps	Ratio
LS Winter	110	209	0.53
C Late Fall	3,898	3,008	1.30
BC Spring	3	34	0.09
C Fall	34	4,041	0.008
M Fall	2,570	250	10.28
Steelhead	507	177	2.86

Finally, based simply on the numbers of fish that are recovered at the pumps compared to the numbers that migrate into the Delta, the direct effects of the pumps seem not to be a major hazard for fry migrants to the Delta, at least when they are small.

2. Smaller diversions:

There are thousands of smaller diversions on Central Valley rivers and the Delta, most unscreened or poorly screened. These entrain some Chinook or steelhead, but the effects of these on salmon populations is uncertain (Moyle and Israel 2005). A recent study in the Delta by Nobriga et al. (2004) found that large numbers of larval and postlarval fishes were entrained in an unscreened diversion, but most of these were small non-native species. Generally, smaller fish are more vulnerable to entrainment than larger fish, and small Chinook are in the Delta mainly during the winter and early spring when diversion rates are low. Diversions on smaller streams may take a significant fraction of the flow, even if the absolute amount is small, and these may have a greater effect on the local populations. In light of the equivocal evidence for effects on populations, Moyle and Israel (2005) recommended that public money not be spent on screens “unless the projects have a strong evaluation component to them, including intensive before and after studies.”

D. Hatchery influence

Hatchery salmon can have negative effects on naturally reproducing salmon for various reasons, reviewed in Williams (2006). For example, hatchery Chinook presumably compete with naturally produced fish, in the Delta and especially in the bays, as noted above. Large numbers of hatchery fish may also attract predators that reduce the survival of naturally produced fish, as has occurred in streams (Nickelson 2003), and probably occurs with the ocean fishery. The presence of hatchery fish may also conceal or divert attention from the condition of wild or naturally reproducing fish. This is particularly the case when few hatchery fish are marked, as with fall Chinook until a few years ago. We will learn more about the extent of this problem this

year and next, when hatchery broods of fall Chinook with 25% marking return to spawn. In a related problem, conducting survival experiments with hatchery fish will tend to encourage management of the Delta to benefit fish that behave in the same way. If wild or naturally produced behave differently (figures 28, 29 and 36), this may be to their detriment. Similarly, attention to hatchery fish may need to neglect of fry migrants to the bays and Delta.

More serious and persistent are genetic changes, resulting from selection for a life cycle that involves reproduction in a hatchery, rather than a stream (Myers et al. 2004; Araki et al. 2007; 2008). In recognition of this, Lindley et al. (2007) included the degree of hatchery influence among criteria for viability of ESA-listed Central Valley salmon populations. Based on these criteria, Central Valley fall Chinook are at high risk of extinction.

Hatchery salmon tend to stray more than wild salmon (Williams 2006), and the practice of trucking juveniles around the Delta strongly increases straying (JHRC 2001). Straying presumably magnifies the harm from hatchery fish spawning in rivers by extending the effects of domestication selection into populations in streams that do not have hatcheries, such as fall Chinook in Mill and Deer creeks.

E. Toxics

Toxics in the Delta are a potential stressor for salmon, but the extent of the problem is unknown (I. Werner, UCD, pers. comm. 10/08). The main potential problems are ammonia, pyrethroid pesticides, and copper. Besides direct effects, ammonia reduces resistance to disease (Ackerman et al. 2006). The most likely effects from pyrethroid, organophosphate and copper pesticides are damage to the olfactory system (Schulz et al. 2000; Sandahl et al. 2004; Hecht et al. 2007) that can impair homing and predator avoidance. Past sources of acute toxicity, such as the Iron Mountain Mine, have been mostly abated.

F. Dissolved Oxygen

Dissolved oxygen concentrations on the San Joaquin River near Stockton can be low enough to block migration of adult salmon (Hallock et al. 1970; Alabaster 1989). This is a continuing problem, resulting from complex interactions among factors such as diversion of San Joaquin River water toward the Delta pumps, modifications of channel morphology to allow shipping, and wastewater discharge, that is the subject of considerable recent work (e.g., Lee and Jones-Lee 2003; Jassby and Van Nieuwenhuyse 2005) and a current test mitigation project by DWR (http://baydeltaoffice.water.ca.gov/sdb/af/index_af.cfm). Usually this problem eases in late October.

G. Water temperature

Hallock et al. (1970) reported that water warmer than 21°C blocks migration of Chinook into the San Joaquin River and water warmer than 19°C inhibits it. However, data from the new weir on the Stanislaus River indicate that in 2003 over 500 Chinook passed through water 21°C daily average, or warmer, in the lower San Joaquin River (SRFG 2004). The role of temperature in blocking migration should be clarified as data from this weir or others that may be installed on

other tributaries accumulate. Whether migration through such warm water harms gametes should also be considered.

H. Predation

Predation is natural, but human modification of the Delta can increase it, for example through increased predation associated with the pumps and the Delta Cross Channel. Striped bass and black bass, introduced species, are important predators on juvenile salmon in the Delta. Predation seems the most likely reason for the lower survival of migrating juvenile salmon in the interior Delta, discussed above. Tidal channels are thought to provide protection from predatory fishes (Lott 2004 and citations therein), so the loss of tidal habitat may increase predation. Predation by humans, harvest, is usually a serious stressor on Central Valley Chinook populations, but not in the Delta. See Chapter 13 in Williams (2006) for a discussion of ocean harvest of Central Valley Chinook.

VI. Outcomes

A logical desired outcome for Chinook and steelhead is recovery of the fish listed under the Endangered Species Act, or, more specifically, that winter and spring Chinook and steelhead should meet the viability criteria given in Lindley et al. (2007), and that the unlisted fall and late-fall Chinook should also meet these criteria. These criteria deal mainly with abundance and hatchery influence at the population level, and also with spatial diversity at the ESU or DPS level. However, for several reasons, these outcomes are only marginally useful for assessing management of the Delta. First, some of these criteria, such as the need for additional independent populations of winter Chinook, are unrelated to management of the Delta. Second, because so much of the life cycle of Chinook and steelhead occurs away from the Delta, and survival in these other habitats can be highly variable, even major improvements in Delta conditions would be unlikely to give a clear signal in abundance data until many years had passed (Bradford et al. 2005). The boom and bust of Central Valley fall Chinook over the last fifteen years illustrate the problem with using abundance alone as an indicator of success. Nevertheless, abundance and the viability criteria are surely important for assessing the overall effects of salmon and steelhead management and restoration efforts, of which Delta activities are an important part.

For assessing management of the Delta, monitoring the abundance of juveniles leaving the Delta and the bays seems more useful, but also seems very difficult to do well. Kimmerer (2008) used the Chipps Island trawl data to try to estimate the abundance of juvenile Chinook leaving the Delta, but the estimates depend on a number of strong assumptions and are of unknown accuracy and precision, and the trawl captures smaller fish less efficiently (Williams 2006). Trying to estimate the numbers coming into the Delta would face the same problems, at least downstream from the Red Bluff Diversion Dam, which presents an unusually favorable site for monitoring. Estimating the number of juveniles leaving the bays seems impossible.

Focusing on estimates of growth, growth rate and condition of juveniles rearing in and leaving the Delta should be more useful, particularly because data already exist from an 11-year NMFS program that sampled juveniles in the bays and the Gulf of the Farallones from 1995 to 2005 that provide a baseline, and allowed Lindley et al. (2009) to reach a much more robust conclusion about the collapse of the fall Chinook population than would have been possible otherwise (see Figure 32). Results from early years of the study have been published (MacFarlane and Norton 2002; MacFarlane et al. 2005), and a summary paper is in review (B. MacFarlane, pers. comm., April. 2009). There are also data on size at date from the USFWS trawling at Chipps Island. These data could be used to set quantitative targets for size at date and condition of juvenile Chinook leaving the Delta, and also to test whether there is a relationship between size at date and condition of juveniles leaving the Delta and subsequent adult returns.

Given that sublethal exposure to pesticides or other contaminants in the Delta can disrupt the olfactory system of juvenile salmon and interfere with normal imprinting, a natural rate of straying would be a desirable outcome of management of contaminants. However, straying is difficult to measure, and the natural rate of straying is not precisely known, so setting an outcome for management of toxics in terms of straying does not seem feasible. Setting targets in terms of concentrations of toxics that affect olfaction of fishes in the laboratory, or cause other harm, seems more realistic.

VII. Future Research

The suggestions below for future research try to go beyond the usual questions about the survival of tagged hatchery fish. They are based on the notion that we cannot do a good job of managing something unless we know how it works, and there are still major gaps in our understanding of how Chinook and steelhead populations work.

What are the life-history patterns followed by naturally produced juveniles from different Chinook lineages and populations? When and at what size do they enter and leave the Delta? What are the relative contributions of the different life history patterns to adult returns?

These questions can be addressed regarding lineages through genetic assignment of juveniles sampled in existing monitoring programs. This is currently underway for the sampling at Chipps Island, but it also seems important to clarify when and at what sizes the different lineages of Chinook come into the Delta, by genetic assignment of samples of fish collected in the Sherwood Harbor trawling. This seems especially important for winter Chinook, and would clarify to what extent hatchery late fall-Chinook can be used as surrogates for wild winter Chinook in survival and migration studies.

Genetic assignment should also be effective for spring Chinook, assuming that the Mill and Deer creek populations can be treated as one. It would not suffice for fall Chinook, which are too homogenous genetically to distinguish populations. However, the major populations of fall Chinook can be distinguished by microchemical analysis of otoliths (Barnett-Johnson et al. 2005; 2008), which takes advantage of geological variation along the Sierra Nevada and Cascade

Mountains. Analyses of the microstructure of otoliths collected from adults would provide information on the contributions of the different juvenile life history patterns to returns.

What determines the life-history patterns followed by Chinook and steelhead?

A modeling study to address this question for steelhead is already underway at UCSC, with funding by CALFED (Satterthwaite 2009a). However, even if the approach taken in this study is successful, much more information on the condition of juvenile steelhead and Chinook in the Central Valley will be needed to apply it fully. Fortunately, the data on growth and condition of juveniles suggested as appropriate for measuring the outcome of management of the Delta, from the point of view of salmon, will also be useful for developing the modeling approach.

How do juveniles navigate through the Delta?

Juvenile salmon may use celestial or magnetic cues to find their way through the Delta, as discussed above. Learning more about this may be useful, not from the point of view of installing giant magnets or search lights in the Delta to try to steer fish away from the pumps, but rather for understanding whether and how different groups of fish behave differently, and how hatchery practices, such as trucking fish around the Delta, might affect selection for such behavior. As a related question:

How do ATPase activity or other physiological variables correlate with or modify migratory behavior among Central Valley salmon?

There is a large and inconclusive literature on salmonids regarding this general topic, reviewed by Høgåsen (1998), but much of it is related to hatchery practices, rather than naturally produced fish, and it seems likely that the relations between physiological variables and migration will differ among different life-history types.

Ewing et al. (2001) describe migratory behavior of spring Chinook in the Rogue River, Oregon, that may be a model for the behavior of winter Chinook, although with a seasonal offset. Ewing et al. (2001) found that the migrating juveniles can be roughly divided into one group that migrates slowing down the margins of the channel and another group that migrates more rapidly down the center of the channel, with individuals shifting from the more slowly to the more rapidly migrating group over time. They also found that the status of individuals in this dichotomy can be assessed in terms of changing levels of gill Na^+/K^+ ATPase activity. If this story or some modification of it holds true for winter or late fall Chinook, this knowledge might improve monitoring and management of facilities in the Delta. It could also help answer a very applied question: can hatchery late fall Chinook be used as surrogates for wild winter Chinook?

Is migration a self-reinforcing behavior?

If migratory behavior is self-reinforcing, if the act of migration strengthens the physiological signals that promote migration, then studies of hatchery fish released into the Delta may not be representative of fish released at the hatchery, or of naturally produced fish.

What traits are involved in selection for fitness in a hatchery-based life-cycle?

It now seems settled that hatchery culture involves selection for fitness in a hatchery-based life-cycle, and against fitness in a natural life-cycle (Araki et al. 2007, 2008; Myers et al. 2004).

However, the particular traits selected for or against are not known, although it seems likely that multiple traits are involved (Araki et al. 2008). Traits affecting survival during the egg-alevin part of the cycle are good candidates, since the associated environments are radically different in hatcheries and in streams. In this regard, it is important to realize that hatchery culture does not simply relax selection for or against traits that affect survival in the wild. One reason is that hatcheries canalize fish into particular life histories, and so subject them to different conditions than they might have experienced otherwise (Goodman 2005). For example, steelhead from Coleman Hatchery smolt a year younger than most naturally produced Sacramento River steelhead. This means that Coleman steelhead will experience life in the Delta, bays and the ocean differently than naturally produced fish. Similarly, fall Chinook from Coleman are canalized into a fingerling migrant life-history, and will be subjected to different selective regimes than naturally produced fry migrants.

Does the spring transition in the Gulf of the Farallones define the beginning of a “smolt window” for Central Valley salmon?

Studies of salmon populations elsewhere have suggested that the timing of ocean entry strongly affects smolt survival, and that the timing of ocean entry has evolved in response (e.g., Tallman and Healey 1994). For Central Valley salmon, the spring transition in the Gulf of the Farallones to a regime dominated by upwelling (Ainley 1990; Williams 2006) seems a logical candidate for the beginning of such a period of higher survival. It is easy to see how the migration timing of fall Chinook or fry-migrant spring Chinook would fit such a conceptual model, but the larger juveniles that migrate down the Sacramento River during late fall and winter would seem not to fit. However, if the timing with which wild juvenile winter Chinook appear at the pumps (Figure 18) reflects the timing with which they leave the Delta, and if their migration through the bays is slow, then winter-run might indeed fit this model. This might be tested by comparing the timing of an increase in growth rate from the otolith microstructure of returning adults with the timing of ocean entry estimated from otolith microchemistry. As an alternative hypothesis, it could be that survival of winter-migrant juvenile Chinook depends on reaching a large enough size, as appears to be the case with coastal steelhead (Hayes et al. 2008).

Does food availability in the estuary limit the growth and subsequent survival of juvenile salmon? Does competition with hatchery fish adversely affect naturally produced fish in the estuary?

Recent estimates of the growth rates of juvenile Chinook in the Delta and especially in the bays seem low (Figure 32). Data on size at date from the Chipps Island trawling records and from recoveries at the state and federal pumps could be compiled to check for year to year variation and longer term trends in size at date, and data from monitoring in the rivers could be used to try to separate the effects on size of conditions in the Delta and in the rivers. Similarly, an index of food availability for juvenile salmon might be constructed from the long IEP monitoring records in the Delta. The indices of growth or of food availability might be used as covariates in statistical analyses of survival. Data on growth and condition of fish from the 1995-2005 NMFS monitoring could be used for detailed assessments for those years. The NMFS samples could also be classified as hatchery or naturally produced based on otolith microstructure, so that these groups of fish could be analyzed separately.

Abstract Fourteen years (1996–2009) of juvenile Chinook salmon, *Oncorhynchus tshawytscha* (Walbaum), migration data on the regulated Stanislaus River, California, USA were used to evaluate how survival, migration strategy and fish size respond to flow regime, temperature and spawner density. An information theoretic approach was used to select the best approximating models for each of four demographic metrics. Greater cumulative discharge and variance in discharge during the migration period resulted in higher survival indices and a larger proportion of juveniles migrating as pre-smolts. The size of pre-smolt migrants was positively associated with spawner density, whereas smolt migrant size was negatively associated with temperature and positively associated with discharge. Monte Carlo techniques indicated high certainty in relationships between flow and survival, but relationships with juvenile size were less certain and additional research is needed to elucidate causal relationships. Flow is an integral part of the habitat template many aquatic species are adapted to, and mismatches between flow and life history traits can reduce the success of migration and the diversity of migratory life history strategies. The analyses presented here can be used to assist in the development of flow schedules to support the persistence of salmon in the Stanislaus River and provide implications for populations in other regulated rivers with limited and variable water supply.

KEY WORDS: California, life history, Monte Carlo, river regulation, screw trap, survival.

Introduction

Pacific salmon, *Oncorhynchus* spp., stock abundances exhibit large temporal fluctuations that, in part, are determined by co-varying environmental parameters that characterise regional climatic conditions. This is not surprising given the profound effect freshwater flow has upon the physical, chemical and biological processes in streams, estuaries and associated coastal waters (Albright 1983; Junk *et al.* 1989; Wilcock *et al.* 1996). The freshwater hydrograph influences water temperature and quality, creation and maintenance of channel

complexity, seasonal activation of floodplain habitats, regulation of primary productivity and stimulation of migration in aquatic species (Dingle 1996; Poff *et al.* 1997; Ahearn *et al.* 2006). Particulate organic and inorganic matter, as well as juvenile salmon, are carried seaward by freshwater flow and incorporated into coastal marine food chains. In turn, conditions within coastal waters influence the health, survival and reproductive success of adult salmon returning to natal streams, causing a biological feedback on long-term health and success of salmon stocks (Mantua *et al.* 1997; Greene *et al.* 2005).

Correspondence: Steven Zeug, Cramer Fish Sciences, 13300 New Airport Road Suite 102, Auburn, CA 95602, USA (e-mail: stevez@fishsciences.net)

Salmon streams throughout the northern hemisphere have undergone dramatic and long-term anthropogenic changes including damming, mining, levee construction, hydropower generation and floodplain disconnection. Such effects have altered hydrologic, sediment and temperature regimes and impacted the native flora and fauna of these systems (Merritt & Cooper 2000; Trush *et al.* 2000; Vinson 2001). The associated decline of salmon populations that support valuable commercial and recreational fisheries has triggered efforts to design flow regimes for regulated rivers that provide conditions suitable to support self-sustaining populations. Yet, there remains a lack of information regarding the responses of different salmon life stages to specific environmental variables that can be used to inform flow strategies. Given the demands for large-scale water regulation and diversion within lotic ecosystems, effective resource management requires an understanding of how environmental conditions affect salmon (i.e. quantity, quality and migration strategy) during the freshwater portion of a given population's life cycle (Hoekstra *et al.* 2007; Nislow & Armstrong 2012).

It was hypothesised that juvenile salmon would demonstrate demographic responses to inter-annual variation in flow magnitude, flow variance and temperature. This hypothesis was tested by modeling how independent variables affected the proportion of juveniles transitioning from rearing to migration using an index of survival, the life stage when migration out of the natal stream was initiated and fish size. For this effort, 14 years of juvenile Chinook salmon migration data were collected at two locations on the Stanislaus River, California, USA, a highly regulated stream with an extant population of naturally reproducing Chinook salmon, *Oncorhynchus tshawytscha* (Walbaum). The monitoring sites included the downstream extent of identified Chinook salmon spawning habitat that was used to estimate fry abundance and the downstream extent of rearing used to estimate the abundance of Chinook salmon emigrating out of the natal stream. These analyses provide resource managers with essential information that can be used to better inform flow management for Chinook salmon in the Stanislaus River and provide implications for relationships between environmental drivers and Chinook salmon ecology in other regulated rivers.

Methods

Study site

The Stanislaus River drains approximately 2400 km² from the western slope of the central Sierra Nevada Mountains to its confluence with the San Joaquin River.

The watershed has a Mediterranean climate with dry summers, and approximately 90% of the annual precipitation occurs between November and April. Historically, relatively low-magnitude flow pulses occurred from late autumn until early spring in response to rainfall in the lower watershed followed by a snow melt-driven pulse from spring through early summer. In the 20th century, more than 40 dams were constructed on the Stanislaus River for flood protection, power generation, irrigation and municipal water supply. Collectively, these dams have the capacity to store 240% of the average annual runoff in the catchment and have reduced the amount of habitat available to Chinook salmon by 53% (Yoshiyama *et al.* 2001). Goodwin Dam (GDW), located at river kilometre (rkm) 94, is currently the upstream migration barrier to adult Chinook salmon and demarks the upstream end of the lower Stanislaus River (Fig. 1). Most fall-run Chinook salmon spawning in the lower Stanislaus River (LSR) occurs in the 29-km reach below GDW (from GDW to ~rkm 66); however, spawning has been observed as far downstream as rkm 53.1.

New Melones Dam, completed in 1979, impounds a reservoir that accounts for approximately 85% of the total storage capacity in the system and is the primary instrument of flow regulation in conjunction with GDW that serves as a re-regulating facility for the larger reservoir. In the years since New Melones Dam operation began, the LSR (below GWD) has changed from a dynamic river system, characterised by depositional and scour features, to a relatively static and entrenched system (Kondolf & Batalla 2005). Annual mean daily discharge has been reduced from 48 to 23 m³ s⁻¹ with mean 30-day maximum discharge reduced from 137 to 38 m³ s⁻¹ (Brown & Bauer 2009). Vegetation encroachment into the active channel, as well as urban and agricultural development, has altered the natural river channel-floodplain connection and has led to the coarsening of bed material, particularly within spawning habitat between Goodwin Dam and Honolulu Bar (Fig. 1).

Fall-run Chinook salmon freshwater life stages and timing

Similar to many anadromous salmonids, California Central Valley fall-run Chinook salmon exhibit distinct life stages that occur during specific time periods (Merz *et al.* 2013). In general, adults migrate from the Pacific Ocean to natal streams between August and December and spawning is initiated shortly after (peak from early October to late November). Chinook salmon require relatively cool, clear, flowing streams with appropriate substrate for successful spawning (Zeug *et al.* 2013), incubation and emergence (Tappel & Bjornn 1983).

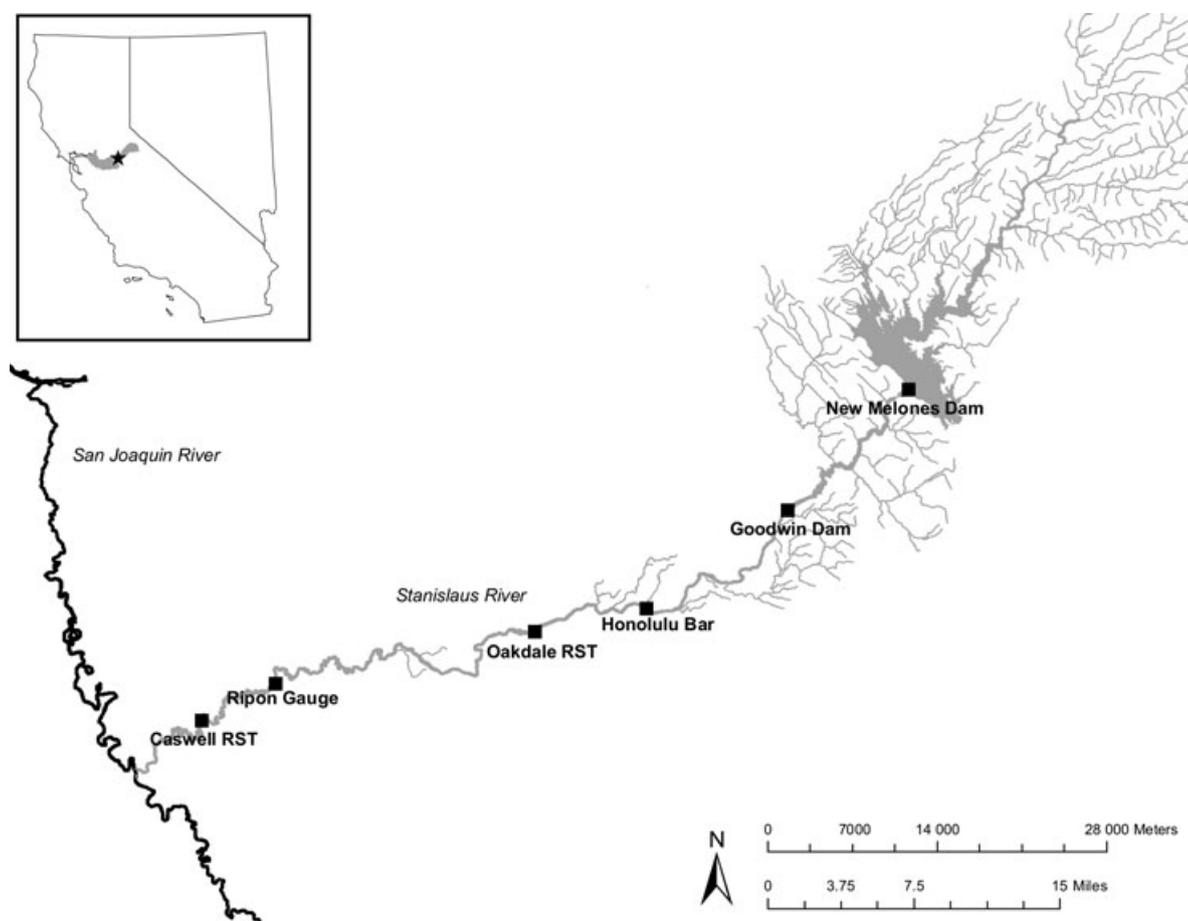

Figure 1. Location of the lower Stanislaus River, California and the location of rotary screw traps (RST) and other relevant features within the study area.

Incubation typically occurs from October through March, and emigration occurs from late December to early July.

Environmental variables

A suite of variables was measured to characterise LSR hydrologic and temperature regimes during the study period (Table 1). To facilitate comparisons of environmental conditions across years, a uniform range of days for each year was created to represent the juvenile rearing and emigration period. The beginning of the period was calculated as the day that 2.5% of cumulative juvenile Chinook salmon catch was observed for each year and averaged across years (mean = day of the year 17). The end date was calculated as the day that 97.5% of cumulative catch was observed for each year and averaged across years (mean = day of the year 147). These start and endpoints were assumed to represent conditions

the majority of juveniles experienced as they reared and migrated downstream through the LSR.

Hydrologic variables included in the analysis were cumulative discharge during the rearing period and variance in discharge during the rearing period. Mean daily flow was obtained from the United States Geological Survey stream gauge on the Stanislaus River located near Ripon, CA (Fig. 1) and converted to total daily flow ($\text{m}^3 \text{day}^{-1}$). To calculate cumulative flow, total daily flow was summed for the rearing period (130 days) each year (Table 1). Variance in flow was calculated as the sample variance of the total daily flow ($\text{m}^3 \text{day}^{-1}$) during the 130-day rearing period. Flow variation provides a mechanism for habitat creation and activation (e.g. bar formation, floodplain inundation) and has been identified as a trigger for fish migration and overall changes in metabolism (Raymond 1968; Hvidsten *et al.* 1995; Baker & Morhardt 2001).

Table 1. Environmental variables and estimates of Chinook salmon spawner abundance in the Stanislaus River during 1996–2009

Year	Cumulative discharge $\times 10^8$ (m ³)	Discharge variance $\times 10^9$ (m ³)	Degree days	Spawner abundance
1996	6.12	6.02	1602	168
1997	10.66	6.39	1838	5588
1998	8.07	5.33	1489	3087
1999	7.02	4.61	1533	4349
2000	4.78	3.75	1710	8498
2001	2.22	1.01	1767	7033
2002	2.23	0.52	1696	7787
2003	2.02	0.29	1773	5902
2004	1.68	0.41	1847	4015
2005	1.89	1.05	1849	1427
2006	11.02	8.90	1449	1923
2007	3.27	0.56	1659	443
2008	2.34	0.83	1639	865
2009	1.62	0.47	1737	595

Degree-days were used to represent the overall water temperatures that juvenile Chinook salmon were exposed to during the rearing period each year. Temperature data were obtained from the United States Geological Survey gauge on the Stanislaus River located near Ripon, CA (11303000). Degree-days were calculated by summing the mean temperature for each day during the juvenile rearing period. The use of degree-days for calculating the temperature-dependent development of poikilotherms is widely accepted as a basis for building phenology and population dynamics models (Taylor & McPhail 1985; Roltsch *et al.* 1999), and accumulated thermal units (analogous to degree-days) have been shown to initiate physiological changes linked to outmigration behavior of juvenile Chinook salmon (Sykes & Shrimpton 2010).

In addition to the three physical parameters described above, the number of adult spawners was acquired for each study year. These data were used to account for potential density-dependent effects on the demographic metrics. Spawner numbers were estimated by annual carcass surveys performed by the California Department of Fish and Wildlife and obtained from their 'Grand Tab' data base file available at <https://nrm.dfg.ca.gov/FileHandler.ashx?documentversionid=33911XXX>.

Fish sampling

Rotary screw traps (2.4-m diameter cone; manufactured by E.G. Solutions, Corvallis, OR, USA), were operated at two locations from 1996 to 2009 to index survival between the traps and estimate the size and life stage of juvenile Chinook salmon emigrating from the system. Rotary screw traps (RSTs) are commonly used in the

Pacific Northwest to monitor impacts of river management (e.g. habitat restoration, flow manipulation, dam management) on wild stocks (Volkhardt *et al.* 2007; Merz *et al.* 2013). Rotary screw traps are potentially powerful tools for validating assumptions regarding the effects of watershed restoration programs and land-use policies on fish populations (Solazzi *et al.* 2000; Johnson *et al.* 2005). These traps can also be used to assess survival between life stages, such as egg-to-smolt survival or parr-to-smolt overwinter survival (Solazzi *et al.* 2000; Johnson *et al.* 2005) and the effects of environmental parameters on migration timing and development (Sykes *et al.* 2009; Sykes & Shrimpton 2010).

The upstream RST was located at Oakdale (rkm 64.3; Fig. 1), which is immediately downstream from the majority of spawning habitat (hereafter referred to as the upstream trap). The upstream trap was assumed to provide a measure of juvenile Chinook salmon production from the spawning reach (Merz *et al.* 2013). The Caswell trap located at the lower extent of LSR rearing habitat (rkm 12.9) approximately 9 km from the San Joaquin River confluence (hereafter referred to as the downstream trap) was used to provide an estimate of out-migrating juveniles. Therefore, the lower trap provides a measure of size and survival of juvenile Chinook salmon exposed to the rearing reach just before exiting the LSR. Trap operations and configurations did not change among years at the upstream site where a single trap was operated. At the downstream site, two traps were operated in tandem for years 1996–2008; however, due to low flow and changes to site channel conditions, the trapping operation was relocated approximately 50 m downstream in 2009 to a site that would only accommodate a single trap.

Operation of LSR RSTs generally followed guidelines outlined in standard protocols [CAMP (Comprehensive Assessment & Monitoring Program) 1997; Volkhardt *et al.* 2007]. Traps were deployed each year between mid-December and mid-January, and sampling was terminated when at least seven consecutive days of trapping resulted in zero catch. This typically occurred in June or July near the end of the Central Valley fall-run Chinook salmon emigration (Williams 2006). Traps were checked daily or multiple times per day depending on debris load. Trap cones were raised on days when sampling did not occur due to excess debris or dangerous conditions.

All Chinook salmon <200 mm fork length (FL) and not demonstrating secondary sexual characteristics (e.g. releasing milt, spawning coloration) were designated as juveniles. Chinook salmon in the LSR are considered 'ocean type' because they primarily emigrate from the system prior to their first winter and typically before July

(Clarke *et al.* 1994). However, there are at least two distinct migration strategies. Juveniles may emigrate from the LSR in winter or early spring prior to smoltification (fry and parr) and rear in the estuary or possibly other non-natal waters prior to ocean entry, or they may rear in the LSR and leave as smolts later in the spring (Limm & Marchetti 2009; Merz *et al.* 2013). To examine factors influencing interannual variation in out-migration strategy, juvenile Chinook salmon were sub-classified as pre-smolt and smolt life stages. Although specific life-stage designations (i.e. fry, parr or smolt) based on morphological characteristics were made in the field, there was considerable variability in the characteristics used to differentiate the life stages, depending on the year and personnel conducting the sampling. Therefore, a piecewise linear regression model for each year of data was used to provide a more objective temporal split between pre-smolt- and smolt-dominated migration periods. These models are commonly used to identify thresholds, or 'breakpoints', where the slope of a regression line changes (Betts *et al.* 2007; Muggeo 2008). First, fish lengths were plotted by date for each year and trap location to provide a visual representation of the pattern of change in fish size. Next, the segmented statistical package in R, which uses initial estimates of breakpoint(s) to iteratively fit a standard linear model to the data, was used to generate an estimated annual breakpoint value (Muggeo 2008). This value corresponded to a day for each year and was considered the 'smolt date' whereby all fish captured up to and including the smolt date were categorized as pre-smolts and all fish captured after the smolt date were categorised as smolts, regardless of previous life stage designation.

To derive accurate abundance estimates at each trap, it was first necessary to estimate RST efficiency for each site. Mark-recapture trials with juvenile Chinook salmon were performed to estimate trap efficiency at both sites. Experimental mark-recapture groups of both hatchery and natural-origin juveniles were used to estimate trap efficiencies at the upstream ($n = 185$) and downstream ($n = 247$) traps. Release group sizes ranged from 17 to 6737 depending on the availability of fish for the trial and were performed during periods of flow change and throughout the migration period to capture the range of efficiency variability. Fish were dye-marked using a photonic marking gun (MadaJet A1000, Carlstadt, NJ, USA) with dye on the caudal or anal fin. Releases occurred approximately 430 m upstream of the traps from the north bank at a narrow, deep area of the river. Fish releases occurred approximately 1 h after dark in small groups (5–10 individuals) to encourage mixing with natural (unmarked) Chinook salmon in the river, reduce schooling and mimic pulses in natural catch during

nighttime migration. Marked fish were transported in a non-motorised boat and released across the channel at various points away from the bank. Traps were processed starting 1 h after completing release activities. Additional recaptures were recorded with the subsequent catch. To avoid pseudoreplication in efficiency analyses, data were pooled when multiple releases occurred on the same date. The maximum number of days post release that marked fish were collected ranged from 5 to 17 at the downstream trap and from 9 to 39 at the upstream trap.

Data analysis

Logistic regression was used to develop a predictive model of daily trap efficiencies. The dependent variable in these models was the binomial probability of capture. Independent variables included flow (log transformed), temperature, turbidity, fork length at release and year. A model was fit with an intercept (β_0), and then each explanatory variable was entered one at a time. The variable with the greatest explanatory power was then included in the model, and the remaining variables were again entered one at a time. The procedure was terminated when none of the remaining variables had a statistically significant effect on capture at $\alpha = 0.05$. The final model for the upstream trap included flow (negative relationship) and a year effect. The final model for the downstream trap included significant negative relationships with flow and fish fork length and a year effect.

Daily catch of migrating juvenile Chinook salmon for each trap was estimated as:

$$\hat{n} = \frac{c}{\hat{q}}$$

where c is the number of Chinook salmon captured each day and q is the estimated trap efficiency for that day from the logistic model. Error estimates for daily catch were calculated using the methods described in Appendix 1. During some years, there were periods when traps were not fished. A weighted average of all observed counts for the 5 days before and 5 days after the missing value were used to estimate a missing value of daily count (c) within a sampling period. The weights were equal to 1 through 5, where daily values that were 1 day before and after the missing day were weighted as 5, values that were two days before and after the missing day were weighted as 4, and so on. Annual catch estimates were generated by summing daily catch and error estimates (Fig. 2).

Three variables were estimated to describe the demographics of the juvenile Chinook salmon cohort in each

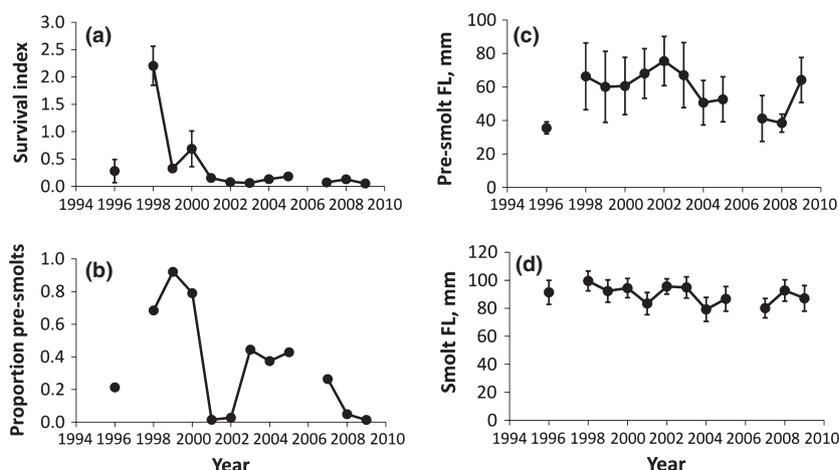

Figure 2. Demographic metrics (mean \pm SD) of the Stanislaus River juvenile Chinook salmon population during 1996–2009. (a) Survival index. (b) Proportion of migrants classified as pre-smolts. (c) Mean fork length (FL) of pre-smolt migrants. (d) Mean FL of smolt migrants.

year. First, annual catch estimates at each trap were used to index survival between the two traps:

$$S_i = \frac{\widehat{P}_D}{\widehat{P}_U}$$

where S_i is the index of survival, \widehat{P}_D is the estimated catch at the downstream trap and \widehat{P}_U is the estimated catch at the upstream trap (Fig. 2). Second, migration strategy was estimated as the proportion of all juveniles that migrated out of the system as pre-smolts in each year. Third, the fork length of juvenile emigrants was estimated in each study year. Fish length was separated by pre-smolts and smolts because portions of the population migrate at each stage. Migration strategy and fish length were modeled using only data from the downstream trap because this location captured fish that were actively migrating out of the system.

Prior to modeling the demographic metrics, a correlation analysis was performed on predictor variables to identify potential sources of multicollinearity. Correlations between all predictors were high (>0.70); thus, the full suite of predictor variables could not be included in the same statistical model without unacceptable variance inflation. Instead, four models were constructed (one for each demographic metric), and the strength of each predictor was evaluated using an information-theoretic approach.

For each of the four demographic metrics, the assumption of normality was tested with a Shapiro–Wilk test and auto correlation was tested with cross-correlation coefficients. When a parameter was identified as non-normal, an appropriate transformation was applied and the assumption of normality was retested. Four linear models were constructed for each demographic metric (16 total models) where the independent variables were: (1) cumu-

lative discharge; (2) discharge variance; (3) degree days and (4) spawner abundance. Akaike's information criterion corrected for small sample size (AIC_c) was used to evaluate the weight of evidence for each predictor. The difference in AIC_c values between each candidate model and the best model was calculated (ΔAIC_c), and models with a value <2 were considered to have similar support in the data (Burnham & Anderson 2002). Model weights ($AIC_c W$) also were calculated. These values are interpreted as the probability of each model being the 'best' of the four evaluated. The R^2 values of models with ΔAIC_c values <2 were used to evaluate overall model fit.

Finally, because estimates rather than observations were used as response variables in the linear models, Monte Carlo methods were used to reduce uncertainty in model estimates. One hundred re-samples of each response variable were performed for each year using a distribution informed by the sample mean and associated error. Abundance at each trap (used to calculate the survival index) was described by a negative binomial distribution, whereas a normal distribution was used for pre-smolt and smolt size. A predictor was considered to have good support in the data if the 95% confidence interval of its coefficient did not include zero.

Results

Survival

Indices for survival between the two traps ranged from 5% in 2009 to $>200\%$ in 1998 (Fig. 2). Fewer trap efficiency trials may have led to the survival index over 200% in 1998. As one of the survival estimates was $>100\%$, the data were scaled so that the value for 1998 was 100% and the values for all other years were

adjusted accordingly prior to use in statistical models. Following \log_{10} transformation, the data were found to be normal ($W = 0.909$, $P = 0.209$) and no autocorrelation was detected ($r = 0.36$, $P = 0.338$). Model selection based on ΔAIC_c values revealed that cumulative discharge and discharge variance had similar support for predicting survival, whereas degree days and the number of spawners were relatively poor predictors (Table 2). Both models had good overall fit to the data with R^2 values of 0.68 and 0.67 for cumulative discharge and discharge variance, respectively (Fig. 3). The coefficient in both models was positive indicating that survival increased as cumulative discharge and discharge variance increased (Table 3). The Monte Carlo exercise revealed that 94% of models that included cumulative discharge and 89% of models that included discharge variance had coefficients with confidence intervals that did not include zero suggesting low uncertainty for these relationships.

Migration strategy

The proportion of juvenile Chinook salmon that migrated as pre-smolts ranged from >0.92 in 1999 to 0.01 in 2001 and 2009 with a mean of 0.35 (SD = 0.32). Autocorrelation was not detected in the data ($r = 0.54$, $P = 0.136$), and the assumption of normality was met ($W = 0.905$, $P = 0.183$). Cumulative discharge was the best predictor of migration strategy, and discharge variance also had support in the data. However, the ΔAIC_c value of 2.11 for discharge variance was >2.00 that was the cutoff for assuming a similar level of support as the best fit model. (Table 2). Overall fit was good for models of cumulative discharge and dis-

charge variance with R^2 values of 0.43 and 0.33 respectively (Fig. 4). Similar to the survival models, the coefficients for both independent variables was positive indicating that more Chinook salmon juveniles migrated as pre-smolts when cumulative discharge and discharge variance were higher (Table 3). Monte Carlo estimates could not be generated for the migration strategy data because life stage-specific information was not consistently available from the efficiency tests to generate error estimates that could inform a distribution. All statistical analyses were performed with the program R (R Development Core Team 2012)

Pre-smolt migrant size

Juvenile Chinook salmon that emigrated as pre-smolts averaged 63.5 mm FL across all years with the smallest and largest pre-smolt emigrants observed in 1996 and 2002 (35.5 and 75.4 mm respectively). The data were normal following \log_{10} transformation ($W = 0.901$, $P = 0.163$), and autocorrelation was not significant ($r = 0.49$, $P = 0.182$). Spawner abundance was the only variable that accounted for size variation in pre-smolt migrants among years (Table 2). The R^2 value for this model was 0.51 indicating the model was a good fit to the data (Fig. 5). The size of pre-smolt migrants was greater in years with higher spawner abundance (Table 3). Models from the Monte Carlo exercise revealed only moderate certainty for the relationship with spawner density. Forty six percent of models yielded a coefficient with a confidence interval that did not include zero.

Smolt migrant size

Fork lengths of juveniles that emigrated as smolts averaged 86.8 mm across all years. The smallest smolt emigrants were observed in 2007 (80.1 mm) and the largest in 1998 (99.5 mm). Autocorrelation was not significant ($r = -0.170$, $P = 0.653$), and the logarithm-transformed data met the assumption of normality ($W = 0.933$, $P = 0.416$). Model selection indicated that three models were similarly supported predictors of smolt size (Table 2). The best model included degree days as the independent variable and competing models included cumulative discharge and discharge variance. All three competing models had moderately good fit with R^2 values of 0.31, 0.27 and 0.25 for degree days, cumulative discharge and discharge variance, respectively (Fig. 6). The coefficient for degree days was negative, whereas the coefficients for cumulative discharge and discharge variance were positive. The Monte Carlo exercise suggested high uncertainty in these relationships with $\leq 13\%$ of models for any of the three predictors having

Table 2. Results of the model selection exercise for juvenile Chinook salmon demographic metrics (response variable). Models for each response variable are listed in order from the most to least likely

Response variable	Predictor	AIC _c	ΔAIC_c	AIC _c W
Survival index	Cumulative discharge	8.75	0.00	0.58
	Discharge variance	9.42	0.67	0.41
	Degree days	17.83	9.08	<0.01
	Spawner abundance	22.32	13.57	<0.01
Proportion of pre-smolt migrants	Cumulative discharge	5.73	0.00	0.68
	Discharge variance	7.84	2.11	0.24
	Degree days	11.09	5.36	0.05

coefficients with confidence intervals that did not include zero.

Discussion

The influence of flow regimes on the health of aquatic ecosystems has been widely recognised (Poff *et al.*

1997; Bunn & Arthington 2002). However, few studies have evaluated the demographic response of fish populations to flow regimes over multiple generations (Souchon *et al.* 2008). Analysis of 14 years of RST data on the LSR indicated that hydrology was a significant driver of several demographic characteristics of a Chinook salmon population. A strong positive response in survival, the

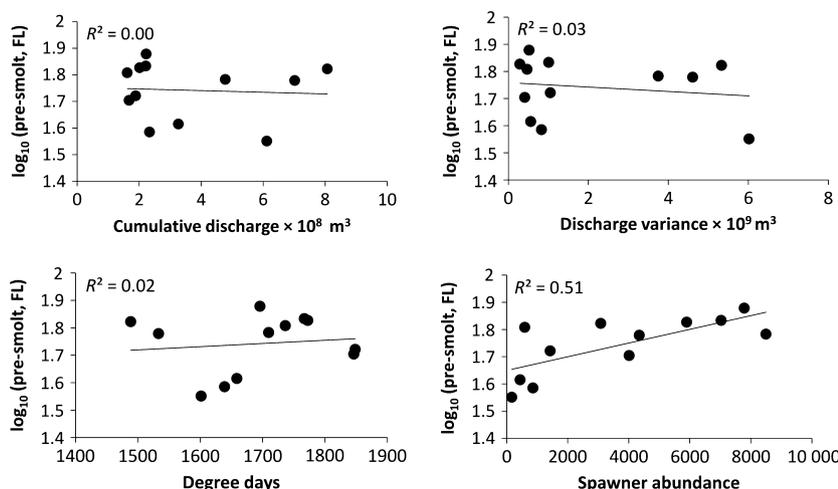

Figure 5. Relationships between the fork length (FL) of pre-smolt Chinook salmon migrants and four predictor variables.

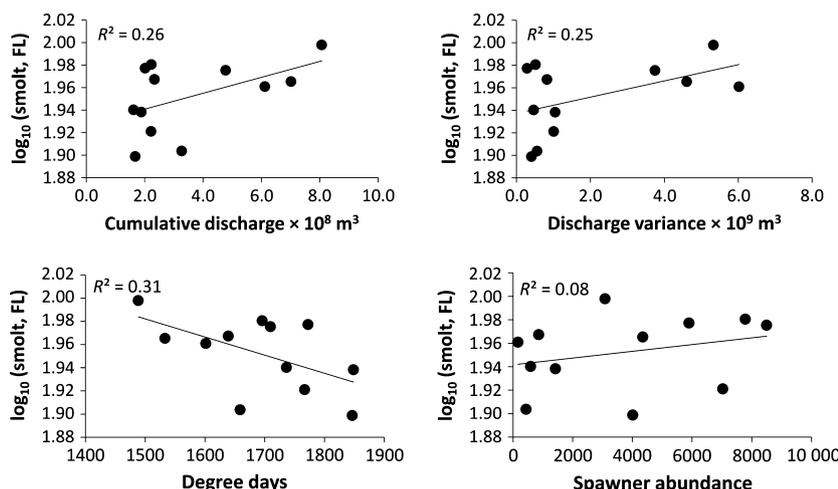

Figure 6. Relationships between the fork length (FL) of smolt Chinook salmon migrants and four predictor variables.

proportion of pre-smolt migrants and the size of smolts were observed when cumulative flow and flow variance were greater. Together, these data suggest that periods of high discharge in combination with high discharge variance are important for successful emigration as well as migrant size and the maintenance of diverse migration strategies.

Survival of migrating juveniles was higher when both cumulative discharge and discharge variance were greater. In a review of flow effects on salmonids, Nislow and Armstrong (2012) reported that reduced flow during the early emigration period was associated with lower growth and survival. Flow pulses provide fish access to seasonal habitats such as floodplains and side channels where food resources are often more abundant and predator densities lower (Junk *et al.* 1989; Bellmore *et al.* 2013). Chinook salmon rearing on California floodplains have been found to grow significantly

faster than fish in the main channel (Sommer *et al.* 2001; Jeffres *et al.* 2008). Since the construction of New Melones Dam, the LSR has become increasingly incised resulting in greater disconnection from its floodplain because greater flows are now required for floodplain inundation (Kondolf *et al.* 2001). A lack of access to off-channel habitats in years with low discharge and discharge variance may partially explain why low survival indices were observed. Higher velocities within the main channel may also reduce exposure time of migrating juveniles to predation within a specific stream reach (Cavallo *et al.* 2013). While turbidity data were not available, increased turbidity during high flow events might also influence behavior and success of emigrating juveniles (Gregory & Levings 1998), and this should be investigated further.

The proportion of Chinook salmon juveniles migrating as pre-smolts also responded positively to higher

cumulative discharge and discharge variance, supporting diversity in migration strategies (greater proportion of smolt migrants during lower discharge conditions, greater proportion of pre-smolt migrants during higher discharge conditions). It is unknown if LSR pre-smolt or smolt migrants survive better to later life stages; however, pre-smolt migrants from the Central Valley do survive and return as adults to spawn (Miller *et al.* 2010). The maintenance of multiple migration strategies can improve the persistence of salmon populations by spreading risk over space and time (Schindler *et al.* 2010). Reduction or elimination of the pre-smolt migration strategy by reducing cumulative discharge and discharge variance could have serious consequences for the LSR Chinook salmon population as risks associated with migration are increasingly concentrated into a relatively short time period (Carlson & Satterthwaite 2011).

The number of adult spawners was the only well supported predictor of pre-smolt size. Previous studies have found that marine-derived nutrients from spawner carcasses are incorporated into stream food webs that support juvenile salmon (Cederholm *et al.* 1999; Reimchen *et al.* 2002). Thus, increased spawner density may have increased productivity of invertebrate prey exploited by juvenile salmon or direct nutrient uptake from decomposing carcasses (Bilby *et al.* 1996). Alternatively, favorable ocean conditions that result in greater spawner returns may allow females to produce higher quality eggs that result in larger juveniles (Brooks *et al.* 1997; Heinimaa & Heinimaa 2004). However, caution should be used when interpreting this relationship. Negative density dependence may occur when spawner density exceeds the range observed during the years of this study. Thus, the relationship may not be linear across the range of potential spawner returns. Monte Carlo resamples of the data suggested there was only moderate certainty in this relationship. Additionally, both survival and the proportion of pre-smolt migrants could have stronger relationships with spawner density at levels above those observed during this study. The effects of quantity and quality of adult spawners on LSR juvenile offspring should also be evaluated further.

Juvenile size and water temperature at the time of Chinook salmon emigration can have a significant effect on ocean survival (Zeug & Cavallo 2013). Our results indicated that smolt size at emigration from the LSR had the strongest relationship with degree days. The Stanislaus River is located near the southern range limit of Chinook salmon spawning where temperatures can frequently exceed the optimum for the species (Myrick & Cech 2004; Williams 2006). Fish are strongly influenced by water temperature, which affects body temperature, growth rate, food consumption, food con-

version and other physiological functions (Houlihan *et al.* 1993; Azevedo *et al.* 1998). The negative relationship between smolt size and temperature suggests that temperatures may get high enough to impede growth in certain years. Monte Carlo resamples indicated high uncertainty in all relationships with smolt size. However, the negative effects of altered flow regimes can be exacerbated by temperatures outside of the optimum for juvenile salmonids (Nislow & Armstrong 2012), and further investigation of this issue in the LSR is warranted.

Despite strong relationships between hydrology and early Chinook salmon ontogeny and survival within the LSR, several considerations should be recognised when interpreting these results. Although RSTs are a tool frequently used to monitor migratory fishes (primarily salmon), they only provide indirect evidence of survival in relation to environmental conditions. More direct evidence can be obtained with techniques such as biotelemetry; however, long term data sets obtained with these technologies are not yet available for analysis, nor does such technology presently lend itself to earlier stages of salmon (i.e. fry-sized fish). Additionally, RSTs may be limited during periods of high flows when debris loads compromise trap operations and field personnel safety. This could mean that RSTs underestimate the number of juvenile salmon emigrating during these periods. It is likely that this aspect of RSTs contributed to the 1998 results when a greater number of Chinook salmon was estimated at the downstream trap. Finally, information theoretic methods can only select the best models from a candidate set. There may be predictors not examined here that better explain the data (e.g. predation rate) but were not available for analysis. If data on other potential predictors are available in the future, their fit can be evaluated against the predictors examined here. Regardless of these issues, RSTs provide robust, long-term monitoring data sets that are required to evaluate population-level responses to changes in flow regime (Souchon *et al.* 2008; Poff & Zimmerman 2010), and model selection identified several strong relationships between juvenile Chinook salmon and flow regime.

Pacific salmon life history diversity differs significantly across streams with different hydrologic regimes (Beechie *et al.* 2006). Conservation of such diversity is a critical element of recovery efforts, and preserving and restoring life history diversity depends in part on environmental factors affecting their expression (Schindler *et al.* 2010). This study found significant responses from juvenile Chinook salmon demography to variation in the LSR hydrologic regime. Although many methods have been used to establish sufficient flows for fish (Jowett 1997), strategies that mimic aspects of the natural flow regime are more likely to be successful (Richter *et al.*

1997). Flow regimes are an integral part of the habitat template to which aquatic species are adapted (Townsend & Hildrew 1994; Lytle & Poff 2004), and mismatches between flow and species life history traits (e.g. migration strategy) can create bottlenecks for population persistence (Schiemer *et al.* 2003). Reduced flow variance and cumulative flow were associated with reduced survival and the proportion of pre-smolt migrants. Although the volume of water released in regulated streams is paramount to fisheries management, stream flows during biologically important times of the year appear equally important (Kiernan *et al.* 2012). Together, these data suggest that cumulative discharge, discharge variance and water temperature are important environmental drivers, and they all should be included in the development of regulated flows to support the persistence of Chinook salmon populations and diverse life history strategies. While this study focused on a single Pacific salmon race in a highly regulated system, the analyses demonstrated here can be employed wherever migratory species and environmental parameters are adequately monitored.

Acknowledgments

The authors thank P. Bergman, B. Cavallo, R. Johnson, B. Pyper, W. Satterthwaite, A. Sturrock, D. Threlloff and M. Workman for helpful discussions on initial concepts for this manuscript. A. Gray and K. Jones provided significant input on an earlier draft. We greatly appreciate data collected by Cramer Fish Sciences, FishBio, the U.S. Bureau of Reclamation, and various entities that provided data utilized in this article. Funding for this project was provided by the U.S. Fish and Wildlife Service under contract 81332-6-G008. The findings and conclusions in this article are those of the authors and do not necessarily represent the views of the U.S. Fish and Wildlife Service. Appendix (1) The following describes the methods used to estimate the variance and confidence intervals for total annual juvenile Chinook salmon catch. It begins with a description of the variance of a given daily catch estimate (\hat{n}), and then extends the formulas to the total annual catch. As noted in the methods, daily catch was estimated by:

$$\hat{n} = \frac{c}{\hat{q}}, \quad (1)$$

where c was the observed daily count of trapped juveniles and \hat{q} was the estimated trap efficiency for that day. To simplify notation, \hat{q} is expressed in terms of the daily 'expansion factor' denoted e , where:

$$\hat{e} = \frac{1}{\hat{q}}. \quad (2)$$

Thus, the daily catch estimate (\hat{n}) can be expressed as the following product: $\hat{n} = \hat{e}c$. (3)

There are two sources of variability in \hat{n} . First, there is error associated with the estimation of trap efficiency via logistic regression, which will be expressed as error in \hat{e} . Second, there is sampling error associated with the

daily count (c), which is assumed to be a binomial variable. An estimate of the variance of \hat{n} is given by Goodman (1960):

$$\hat{\sigma}^2\{\hat{n}\} = \hat{e}^2 \cdot \hat{\sigma}^2\{c\} + c^2 \cdot \hat{\sigma}^2\{\hat{e}\} - \hat{\sigma}^2\{\hat{e}\} \cdot \hat{\sigma}^2\{c\} \quad (4)$$

To obtain a variance estimate for \hat{e} , it is first expressed in terms of the back-transformation of the logit function (see equation (4)). Substituting equation 2 into equation 4 and rearranging yields:

$$\hat{e} = 1 + \exp[-(\hat{\beta}_0 + \hat{\beta}_1 x)] = 1 + \exp(-\hat{y}), \quad (5)$$

where \hat{y} is the logit transform of the estimated trap efficiency \hat{q} (see equation (3)). Given that the distribution of \hat{y} is approximately normal, \hat{e} is assumed to be log-normally distributed with an estimator of variance given by Gelman *et al.* (1995, p. 478):

$$\hat{\sigma}^2\{\hat{e}\} = \exp(-2\hat{y}) * \exp(\hat{\sigma}^2\{\hat{y}\}) * [\exp(\hat{\sigma}^2\{\hat{y}\}) - 1] \quad (6)$$

The variance of \hat{y} , which is a prediction from a linear regression, can be expressed in matrix notation as (Neter *et al.* 1990, p. 215):

$$\hat{\sigma}^2\{\hat{y}\} = \mathbf{X}'\mathbf{s}^2\{\mathbf{b}\}\mathbf{X}, \quad (7)$$

where \mathbf{X} is a vector containing the daily values of the explanatory variables, \mathbf{X}' denotes the transpose of \mathbf{X} , and $\mathbf{s}^2\{\mathbf{b}\}$ denotes the scaled estimate of the variance-covariance matrix for the logistic regression coefficients ($\hat{\beta}$). Specifically,

$$\mathbf{X} = \begin{bmatrix} 1 \\ x \end{bmatrix}, \mathbf{X}' = [1 \quad x], \mathbf{s}^2\{\mathbf{b}\} = \hat{\phi} \begin{bmatrix} \hat{\sigma}^2\{\hat{\beta}_0\} & \hat{\sigma}\{\hat{\beta}_0, \hat{\beta}_1\} \\ \hat{\sigma}\{\hat{\beta}_0, \hat{\beta}_1\} & \hat{\sigma}^2\{\hat{\beta}_1\} \end{bmatrix}. \quad (8)$$

Here, x is the daily value of $\log(\text{flow})$. Note that the variance-covariance matrix for the logistic regression coefficients is multiplied (i.e. scaled) by the estimated dispersion parameter ($\hat{\phi}$) to account for extra-binomial variation. Equation 6 through equation 8 define the variance estimate for \hat{e} required in equation 4. Also required in equation 4 is the variance of c , the observed daily count of trapped juveniles. Assuming that c follows a binomial distribution conditional on daily catch (n) and trap efficiency (q) (i.e. $c \sim \text{Bin}(n, q)$), the theoretical variance for c would equal $nq(1-q)$. However, a more reasonable and conservative approach is to assume that c is subject to the same extra-binomial variation estimated for the trap-efficiency tests. Extra-binomial variation

would be expected due to unaccounted for factors affecting trap efficiency or characteristics of fish behavior, such as schooling. Thus, the variance of c is estimated as:

$$\hat{\sigma}^2 c = \hat{\phi} \hat{n} \hat{q} (1 - \hat{q}) \quad (9)$$

Equations A4 through A9 define the variance estimate for a given daily catch estimate (\hat{n}) given the estimated trap efficiency (\hat{q}) and trap count (c) for that day. The estimated total catch (N) of juveniles across days ($i = 1, 2, 3, \dots, k$) of the sampling season is the sum:

$$\hat{N} = \sum_{i=1}^k \hat{n}_i, \quad (10)$$

with associated variance (Mood *et al.* 1974, p. 179)

$$\hat{\sigma}^2\{\hat{N}\} = \sum_{i=1}^k \hat{\sigma}^2\{\hat{n}_i\} + 2 \sum_{i=1}^{k-1} \sum_{j>i}^k \hat{\sigma}\{\hat{n}_i, \hat{n}_j\}. \quad (11)$$

The left side of equation 11 is sum of the variances of the daily catch estimates as defined by equation 4. The right side denotes the sum of the covariances among all pairs of daily catch estimates. These covariances arise from the fact that all daily catch estimates are based on predictions of q derived from the same logistic regression. Following from equations 3 and 5, the covariance of any two catch estimates can be approximated as follows:

$$\hat{\sigma}\{\hat{n}_i, \hat{n}_j\} = (c_i \hat{e}_i) * (c_j \hat{e}_j) * (\mathbf{X}'\mathbf{s}^2\{\mathbf{b}\}\mathbf{X}), \quad (12)$$

where

$$\mathbf{X} = \begin{bmatrix} 1 & x_i \\ 1 & x_j \end{bmatrix}, \mathbf{X}' = \begin{bmatrix} 1 & 1 \\ x_i & x_j \end{bmatrix}. \quad (13)$$

Again, $\mathbf{s}^2\{\mathbf{b}\}$ denotes the scaled variance-covariance matrix for the logistic coefficients as in equation 8.

Approximate 95% confidence intervals for \hat{N} assuming log normally distributed error is given by:

$$95\%LCI\{\hat{N}\} = \frac{\hat{N}}{c}, \text{ and } 95\%UCI\{\hat{N}\} = \hat{N} * c, \quad (14)$$

where

$$c = \exp(Z_{\alpha/2}) * \sqrt{\log_e(1 + (\hat{\sigma}\{\hat{N}\}/\hat{N})^2)} \quad (15)$$
